Preface

The synthesis of the totality of evidence in kidney disease was the original challenge we undertook when we conceived of the first edition of this evidence-based nephrology (EBN) textbook, thereby providing students of nephrology and practicing clinicians with a single convenient source of clinical evidence that had been passed through an evidence-based filter. More than 12 years have passed since the first edition, and so it is timely to revisit the challenge in the form of a second edition. The reasons for a second edition are principally three: the scale of new available data is substantial, newer methods of research synthesis have been developed, and there is a renewed focus on consumer engagement in general, including in the evaluation and management of kidney disease.

Scale of new data

Compared to the time of the first edition, the amount of new data is impressive. There are today more than 15 000 randomized controlled trials in nephrology published in approximately 30 000 reports, 11 300 more than in 2009, resulting in more confidence and precision around the estimates of intervention effects and new evidence in areas that were previously mostly evidence-free. These trials have also been summarized in systematic reviews, with over 6500 additional reviews in Medline since the first edition. Much of this new evidence is incorporated in three new sections of this textbook and multiple either new or entirely updated chapters.

Novel methods

Methods to assess the methodological quality of both systematic reviews and other study designs, including nonrandomized (case-control or cohort studies) and diagnostic test studies, have developed since the first edition. In addition, the number of syntheses of cohort studies has increased and the technique of network meta-analysis for comparing more than two interventions both directly (head to head) and indirectly (via a common comparator) has become more developed and is commonly encountered. These methods assist the summarizing and interpreting of evidence in key areas of decision-making, which is useful to patients, healthcare providers, and policy-makers.

Using these methods, organizations including the Cochrane Kidney and Transplant group and several guideline agencies have committed on a large scale to summarize the evidence and provide timely updates of established and emerging new evidence, making research findings more manageable and reliable for end users. Much of this work has been included in this edition of the textbook. We hope this will allow the end-user to both access best evidence from this diversity of resources as summarized by chapter authors and to become more familiar with how the newer techniques and resources contribute to a practice that is informed by best evidence.

Consumer engagement

Recently, there has been increasing recognition of the critical importance of engaging the end-users in research to ensure relevance and uptake. In particular there have been large-scale efforts to engage patients in all stages of research, including the evidence synthesis process and the dissemination of findings. For example, the Cochrane Kidney and Transplant group now has a patient editor, whose role includes translating scientific outputs into plain language summaries to simplify the "medical jargon" and make evidence easily accessible to people without a medical background, as well as prioritizing review topics. The Standardized Outcomes in Nephrology (SONG) initiative was launched in 2014 to establish the core outcomes to be reported in all trials in chronic kidney disease, based on a consensus among patients, caregivers, health professionals, and policy-makers. This initiative has emphasized patient-centered research and improved clinical outcomes in nephrology, ensuring that the outcomes measured and reported in clinical trials and other forms of research are relevant and meaningful to patients and increase the acceptability, transparency, and generalizability of the results in this population. New studies assessing these

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. outcomes are now being developed, with advancement of knowledge which could be incorporated into this edition of the textbook.

In short, compared to the previous version published in 2009, this updated textbook includes 20 new chapters and three new sections, covering supportive care and patient-centered care and outcomes. In addition, every chapter that was in the first edition has been extensively updated. Specifically, the new textbook covers epidemiology, acute kidney injury, primary diseases of the kidney, secondary diseases of the kidney, chronic kidney disease and complications, hemodialysis, chronic kidney disease stage 5, peritoneal dialysis, supportive care, transplantation, electrolytes and acid-base disorders, and patient-centered care and outcomes for both adult and pediatric patients. This effort was undertaken by existing and new authors and section editors, whom we would like to thank for their extensive work.

Giovanni Strippoli has joined as the third co-editor of *Evidence-based Nephrology*. Altogether, we hope that we have produced an even better evidence-based nephrology tool, where each chapter provides a clear foundation of the topic that is supported by the best current evidence.

We believe that this updated textbook more broadly covers available evidence and addresses crucial clinical questions regarding the treatment and care of people with all stages of chronic kidney disease, including people undergoing any form of dialysis (hemodialysis or peritoneal dialysis), those requiring kidney transplantation, and pediatric patients.

Inherently a textbook of this nature will always manifest potential limitations. We acknowledge that a textbook is unable to collect all new evidence in real time, and, like all of healthcare internationally, the COVID-19 pandemic did impact this book, specifically the publication timelines as contributors had to contend with major challenges. The inclusion of nonrandomized studies to maximize relevance and comprehensiveness has added complexity in the methods and may lead to residual uncertainty in the estimate of intervention effects. Finally, we focused on empiric evidence for management decisions and so pathophysiological mechanisms of chronic kidney disease and its treatment were not considered in detail. We have attempted to include economic evaluations where particularly relevant for national and international management guidelines.

In the true spirit of evidence-based medicine, we hope that this edition of *Evidence-based Nephrology* will continue to push the specialty toward greater reliance on the totality of evidence and the generation and utilization of evidence that is the least biased and the most precise to inform clinical decision making. To the material detailed in all the chapters we would expect that our readers will add, through their own judicious application of evidence-based medicine principles, their local context, and incorporate their patients values and preferences, given that objective evidence is rightly only one consideration in the delivery of true patient-centered care. Additionally, a textbook like this can at best be only one of several resources for the evidence-based medicine practitioner, and should be supplemented with current methodologically rigorous and transparent clinical practice guidelines. We hope this effort will provide a core resource for the evidence-based nephrology practitioner who is otherwise limited by time constraints from researching every question that may arise daily in the care of patients.

We certainly wish that students and evidence-based nephrology practitioners will benefit from this updated edition in the search for answers to questions that arise in daily care and their ambition to deliver the best care possible.

An Introduction to the Epidemiology of Chronic Kidney Disease

Mark Canney and Adeera Levin

Division of Nephrology, University of British Columbia, Vancouver, BC, Canada

Introduction

The purpose of this part of the book is to describe the epidemiology of chronic kidney disease (CKD) across the spectrum of disease, from early detection through to major complications and end-stage kidney disease (ESKD). Fundamental to this is an understanding of what defines CKD. We will therefore begin this chapter by revisiting the 2002 National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF/DOQI) guideline, which first proposed a harmonized definition of CKD based on simple laboratory markers. A tremendous amount of data has been accrued since that seminal publication, data which informed the updated CKD classification system by Kidney Disease Improving Global Outcomes (KDIGO) in 2012.

The definition and staging of CKD has generated debate and controversy among the nephrology community. There is confusion surrounding the definition and the classification system. The former is an important, inclusive, and objective definition to describe the state of kidney function and structure which is associated with disease. The latter describes the severity of disease and risk associated with two parameters: level of estimated glomerular filtration rate (GFR) and degree of albuminuria. The classification of CKD is underpinned by the risk of a series of clinical outcomes. The key outcomes in this context are progression to ESKD, cardiovascular, and all-cause mortality. Other outcomes include acute kidney injury (AKI), hospitalization, cardiovascular events, and infections. This chapter provides an overview of the risk relationships between CKD and these first three well-studied outcomes. We also highlight some of the more controversial aspects of the CKD paradigm: the definition of CKD in older individuals, and strengths and limitations of different filtration markers and GFR estimating equations. These important issues continue to be discussed and debated within the nephrology community. However, it should be acknowledged that patients with kidney disease are looked after by other healthcare providers, including primary care physicians, cardiologists, and gerontologists. Thus, the framework for diagnosis, staging, and risk stratification of patients with kidney disease must be clear and well-communicated to all stakeholders. This is especially pertinent in developing countries, where our understanding of the epidemiology of kidney disease and its risk factors is more limited.

The subsequent chapters in this part expand on these concepts and provide the reader with an up-to-date review of the state of knowledge of the epidemiology of kidney disease. Chapter 2 describes the variety of surveillance mechanisms currently utilized for CKD and ESKD, along with the challenges of obtaining accurate data from around the world. The importance of early detection of CKD and the evidence for population-level screening is discussed in Chapter 4. Chapters 3 and 5 provide an evidence-based approach to prognostication for progression of CKD and the risk of important clinical outcomes such as cardiovascular disease and mortality. Finally, the emerging literature regarding the burden of CKD in disadvantaged populations is described in Chapter 6. Throughout these chapters, a standardized nomenclature for CKD is used to frame the discussions. Hence, that is where we begin this introduction.

Evidence-Based Nephrology, Second Edition. Edited by Jonathan C. Craig, Donald A. Molony, and Giovanni F.M. Strippoli.

Definition of CKD

In 2002 NKF-KDOQI published a guideline proposing a new paradigm for the classification and evaluation of kidney disease [1, 2]. This conceptual framework (Figure 1.1) addressed an unmet need in nephrology: the early identification of patients at risk of either developing kidney disease or progressing to more advanced stages of disease. The NKF-KDOQI working group suggested a new classification system that could categorize the severity of an individual's kidney disease, irrespective of etiology, using simple laboratory parameters. One of the most significant contributions of this work was the harmonization of nomenclature for kidney disease [3]. The term "chronic kidney disease" and its stages would supplant ambiguous terminology such as "azotemia," "predialysis," or "renal insufficiency" [4]. The original guideline has had a major impact over the last 15 years or so by facilitating collaborative research endeavors, standardizing clinical and laboratory practices, and informing health policy.

The definition of CKD was further refined by the KDIGO working group in the 2012 guidelines, and is the one used in contemporary clinical practice. KDIGO defines CKD as abnormalities of kidney structure or function, present for at least 3 months, with implications for health [5]. CKD can thus be defined by markers of kidney damage and/or markers of reduced kidney function. GFR is considered the best metric of kidney function and is estimated from the serum concentration of a circulating filtration marker such as creatinine or cystatin C. CKD can be diagnosed by GFR criteria alone if an individual has at least two estimates of GFR below 60 ml/min/1.73 m^2 at least 3 months apart. Even in the presence of "preserved" kidney function (GFR ≥ 60 ml/min/1.73 m^2), CKD can be diagnosed in the presence of persistent urinary abnormalities such as albuminuria, hematuria, or evidence of tubular dysfunction. In the absence of any of these factors, an individual can be diagnosed as having CKD if they have a structural abnormality identified on imaging tests, for example polycystic kidney disease, or a histopathological abnormality such as tubulointerstitial disease.

KDIGO proposed a standardized approach to the classification of CKD based on the cause of disease (C), level of GFR (G), and amount of albuminuria (A), the CGA system. The classification and staging of CKD can be done independent of cause, but the guidelines clearly recognized the importance of attempting to ascertain the etiology of CKD. Statements within the guidelines acknowledge the importance of interpreting the GFR and albuminuria results in the context of an underlying cause, as the specific cause may influence the risk or anticipated rate of disease progression. In many cases, however, the cause is unknown or can only be speculated upon based on the presence or absence of key risk factors such as diabetes or hypertension. For many patients a kidney biopsy remains the only means of establishing a firm diagnosis, although recent advances in molecular diagnostics have the potential to overcome this barrier [6]. The clinical focus on GFR and albuminuria for CKD staging is based on iterative studies demonstrating that both parameters are powerful predictors of clinical outcomes. The cross-classification of GFR and albuminuria stages provides a categorization of an individual's risk status (Figure 1.2). The synergistic effect of both risk markers is reflected in the fact that individuals with a combination of reduced GFR and a high degree of albuminuria are at greatest risk for ESKD. It is also evident from this risk classification that the presence of albuminuria is a strong risk factor for ESKD even if the GFR is normal. The thresholds of GFR and urinary albumin to creatinine ratio (ACR) that are used to establish the stage of CKD are based on large population-based studies examining the association between both markers and hard clinical endpoints.

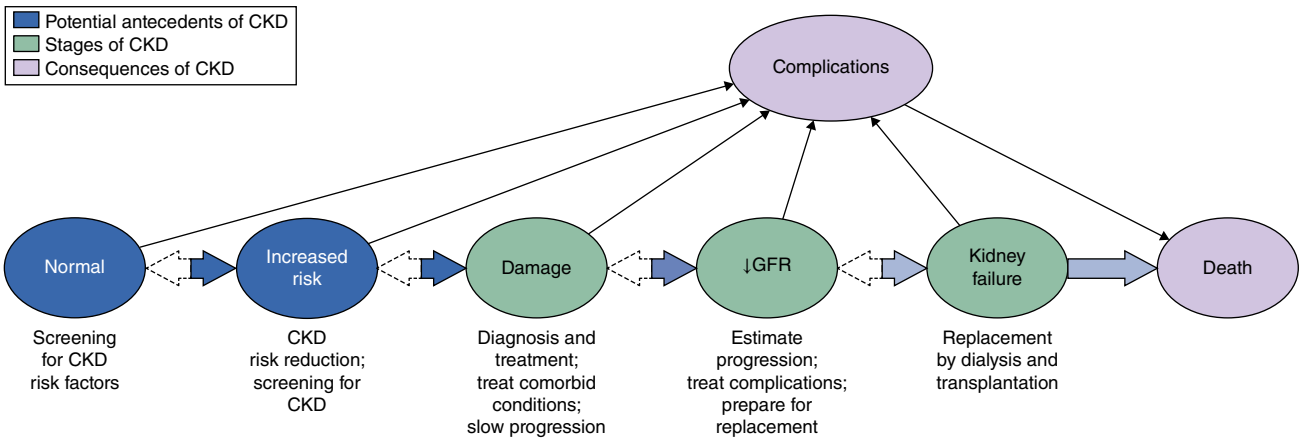

Figure 1.1 Conceptual paradigm for chronic kidney disease. CKD, chronic kidney disease; GFR, glomerular filtration rate.

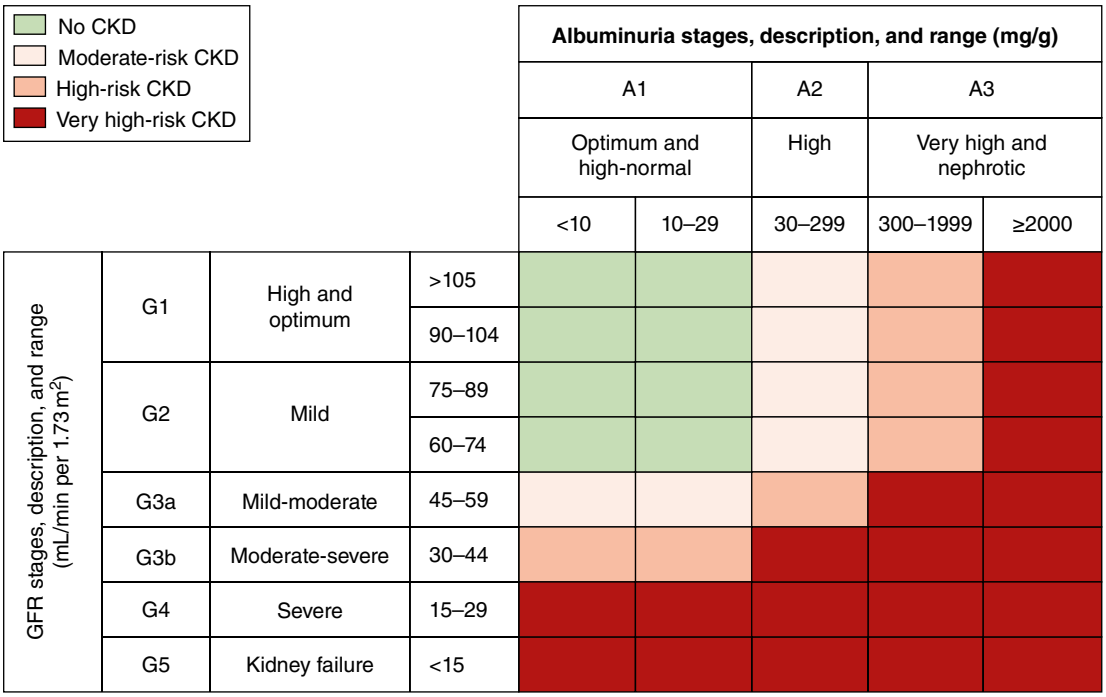

Figure 1.2 Cross-classification of glomerular filtration rate and albumin to creatinine ratio stages with respect to risk of clinical outcomes. CKD, chronic kidney disease; GFR, glomerular filtration rate.

CKD and Outcomes

Contemporary data pertaining to CKD and risk of clinical outcomes come predominantly from the CKD Prognosis Consortium (CKD-PC), an international team of investigators from over 70 cohorts worldwide [7]. These cohorts represent individuals from the general population, those at high risk of vascular disease, as well as individuals with established kidney disease. CKD-PC investigators have consistently demonstrated higher risk of adverse outcomes associated with reduced eGFR and/or increased ACR, independent of demographic and clinical characteristics.

All-Cause Mortality

In general population cohorts, both a reduced eGFR and an elevated ACR have been associated with higher risk of all-cause mortality [8]. The risk relationship between eGFR and mortality tends to be J-shaped, in that individuals with "high" eGFR (>95 ml/min/1.73 m^2) also appear to have an increased mortality risk. This is most likely explained by malnutrition or low muscle mass (and therefore lower creatinine generation) in the setting of severe illness. The association between albuminuria and mortality tends to be broadly linear. In one large meta-analysis, risk of death was increased by 20%, 63%, and 122% for ACR values of 10, 30, and 300 mg/mg compared to an ACR of 5 mg/mg [9]. CKD, whether defined by eGFR or ACR criteria, is associated with substantial reductions in life expectancy [10, 11].

Cardiovascular Events

CKD has been identified as a risk factor for several cardiovascular outcomes, including coronary events, heart failure, stroke, peripheral arterial disease, and cardiovascular mortality [12–14]. The risk of myocardial infarction associated with CKD may be at least as high as the risk associated with diabetes [15]. The presence of CKD is also a risk factor for recurrent coronary events, with a magnitude of risk that is higher than traditional cardiovascular risk factors such as smoking [16]. These findings suggest that CKD should be regarded as a coronary heart disease risk equivalent [17]. Data from CKD-PC quantified the risk of cardiovascular mortality for eGFR and ACR categories in 266 975 individuals with known cardiovascular risk factors [18]. An increased risk of mortality was evident below a threshold eGFR of 45 ml/min/1.73 m^2. Even small increases in albuminuria were associated with higher cardiovascular risk. Individuals with CKD often have other comorbidities such as hypertension and diabetes, both of which are also highly prevalent in the general population. The risk of cardiovascular disease associated with CKD may be attributable to shared risk factors in people with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

these conditions. This specific question was addressed in two large meta-analyses which demonstrated that the higher observed risk of cardiovascular mortality in individuals with reduced eGFR and/or increased ACR was evident in those with and without diabetes and hypertension [19, 20]. The underlying mechanism driving poor cardiovascular outcomes in people with CKD is multifactorial and continues to be an area of intensive research efforts. Despite consistent evidence of higher cardiovascular risk, patients with CKD are often underinvestigated and undertreated. One of the reasons for this is the under-representation of patients with kidney disease, particularly advanced disease, in clinical trials. It is not known if interventions which have been shown to improve outcomes in people without kidney disease will have the same benefits and adverse effect profiles in people with CKD. This knowledge gap needs to be urgently addressed. The strength of evidence for cardiovascular risk prediction is expanded upon in Chapter 5.

Progression to ESKD

The risk of ESKD is dramatically increased in the setting of reduced eGFR and/or high-grade albuminuria. In the general population, this increased risk becomes apparent below an eGFR of 75 ml/min/1.73 m^2 and increases in exponential fashion at the lower end of eGFR [21]. In CKD cohorts, each 15 ml/min/1.73 m^2 reduction in eGFR below 45 ml/min/1.73 m^2 confers an approximate sixfold higher risk of ESKD [22]. Similar to cardiovascular and mortality outcomes, the risk relationship between albuminuria and ESKD appears to be more linear. The consistency of the associations between eGFR, ACR, and ESKD risk facilitated the creation of the Kidney Failure Risk Equation, which calculates the probability of progressing to ESKD at specific time points based on an individual's age, sex, eGFR, and ACR [23]. Risk prediction models and risk factors for disease progression are comprehensively evaluated in Chapter 5.

GFR Estimating Equations and Risk

Indirect quantification of GFR, via clearance of an exogenous filtration marker, is the gold standard for measurement of GFR but is rarely performed in practice outside of specific clinical indications. The large-scale population studies described above would not have been feasible without a method for calculating an estimate of GFR. A number of GFR estimating equations have been developed and validated for use in clinical and research settings. In contemporary practice, the most widely used is the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) equation [24]. CKD-EPI has a number of advantages over its predecessor, the Modification of Diet in Renal Disease (MDRD) equation [25, 26]. These include a more diverse derivation cohort which included people with and without kidney disease, less bias in the upper range of GFR (≥60 ml/min/1.73 m^2), and superior risk discrimination for hard outcomes [27]. A significant limitation of the CKD-EPI cohort was the under-representation of individuals over the age of 70 years. An alternative GFR estimating equation for this demographic was developed by the Berlin Initiative Study (BIS) investigators [28].

There is a trade-off in the use of any GFR estimating equation: the widespread ease of their use versus the uncertainty in estimation. Some of this uncertainty is due to inherent variability in the regression models that generated the estimates, most notably at the higher range of GFR where the models tend to perform less well. More importantly, creatinine generation can vary widely between individuals due to differences in muscle mass and dietary protein intake [29]. Several alternative filtration markers have been studied, but none have managed to replace creatinine as the marker of choice in routine clinical practice. One such alternative is cystatin C, a 13 kDa protein that is produced by all nucleated cells and freely filtered at the glomerulus. Although cystatin C is a better predictor of measured GFR than creatinine [30], the adjustment of creatinine for body composition using the variables age, sex, and race largely overcomes this deficit [31]. Where the two markers differ is with respect to risk stratification. GFR estimated from cystatin C is a stronger and more consistent predictor of clinical outcomes compared to GFR estimated from creatinine [32]. It should be noted that cystatin C also has "non-GFR" determinants, including adiposity and inflammation, themselves recognized as risk factors for adverse clinical outcomes such as cardiovascular disease [33, 34].

Risk Factors for CKD

Hypertension

Hypertension is estimated to affect 1.13 billion adults globally, with an age-standardized prevalence of 24.1% in men and 20.1% in women [35]. Hypertension is highly prevalent among individuals with CKD, especially in more advanced stages of disease. The kidney is a vulnerable organ to the effects of sustained elevations in blood pressure (BP), and hypertension is a risk factor for both incident CKD and progression to ESKD [36, 37]. In the CKD population, the relationship between BP and cardiovascular outcomes and mortality tends to be J-shaped, suggesting higher risk of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. adverse outcomes with high and low BP [38–40]. This finding could be explained by underlying cardiac disease in individuals with low BP, which may be subclinical and not optimally captured in studies [41]. Blood pressure is a dynamic measure of health, and what we consider as the mean or "usual" BP may not be telling the whole story [42]. Variability in ambulatory BP recordings is a strong predictor of major cardiovascular events such as stroke, independent of the mean BP [43]. Similarly, large variability in visit-to-visit BP has been identified as a risk factor for adverse CKD outcomes [44]. Impaired stabilization of BP during postural change has recently been highlighted as a potential contributor to adverse outcomes [45, 46] and is also associated with CKD [47, 48]. These studies illustrate the complexity of the relationship between changes in blood pressure and their effects on the kidney. Our understanding of hypertension in CKD is further hampered by the under-representation of CKD patients in large clinical trials, such that optimal management of hypertension in patients with kidney disease continues to be debated.

Diabetes Mellitus

Diabetes continues to be a major contributor to CKD and associated outcomes. While the rates of diabetes-related complications including ESKD have reduced over time in relative terms, the prevalence of diabetes has continued to increase such that the absolute rates of complications are expected to continue to rise [49, 50]. The risk of kidney disease attributable to diabetes in large population studies is subject to misclassification. Individuals with diabetes tend to have a higher prevalence of other CKD risk factors such as obesity and hypertension. As such, in the absence of a tissue diagnosis the cause of their kidney disease cannot be definitively ascribed to diabetes. This limitation has historically hampered efforts to understand mechanisms in diabetic kidney disease and has motivated initiatives like the Kidney Precision Medicine Project [51]. The landscape of diabetic kidney disease could change dramatically with the advent of sodium-glucose cotransporter type 2 (SGLT2) inhibition as a therapeutic target. Clinical trials of SGLT2 inhibitors have demonstrated improvements not only in glycemic control, but also in cardiovascular and renal endpoints [52, 53]. These effects may be mediated through beneficial changes in blood pressure, glomerular hemodynamics, body weight, and uric acid [54].

Acute Kidney Injury

AKI may be defined as a transient reduction in kidney function, detected clinically by a change in creatinine or a decrease in urine output over a specified time interval [55]. AKI is associated with increased risk of morbidity and mortality, particularly from cardiovascular disease [56, 57]. Severe AKI necessitating temporary dialysis is a risk factor for long-term development of ESKD [58]. On the other end of the spectrum, apparently "mild" injury has been associated with increased risk of developing CKD, especially if recovery is slow and even if kidney function ultimately returns to its baseline value after the event [59, 60]. In some patients the relationship between AKI and CKD is bidirectional [61]. A diminished GFR and albuminuria are cardinal risk factors for AKI [62–64], which in turn may contribute to progression of underlying CKD [65]. The importance of AKI as a risk factor for CKD progression, and methods to identify those at risk of progression after an AKI event, are discussed in detail in Chapter 3.

Prevalence of CKD

Several studies have provided estimates of CKD prevalence from different jurisdictions around the world, with estimates between 8% and 16% [66]. In the United States, prevalence data come from a series of national surveys called the National Health and Nutrition Examination Survey (NHANES), a stratified cluster probability sample of US adults. The application of survey weights provides representative estimates of disease prevalence. Data from NHANES suggest an overall prevalence of CKD in the United States of 13%, with the majority of individuals with CKD having mild to moderate reductions in eGFR (30–59 ml/min/1.73 m^2) and less than 1% having more severe disease [67]. European prevalence data from various cohorts were recently published from the European CKD Burden Consortium [68]. In keeping with US data, the investigators documented an overall high prevalence of CKD. This group also found substantial heterogeneity in the methodology of included studies, for example different definitions of CKD using eGFR, ACR, or both, varying sample response rates, use or nonuse of a sampling frame, and lack of standardization of assays for creatinine [69]. This heterogeneity poses a significant challenge when seeking to understand the true prevalence of CKD and is discussed further in Chapter 2.

An important, but perhaps under-appreciated, source of bias in prevalence studies is misclassification of CKD stage based on a single measurement of eGFR or ACR. While it is understandable from a feasibility perspective that large population studies would not perform a second test of eGFR and ACR after 3 months to fulfill the chronicity criterion of the KDIGO definition, recent studies have demonstrated the potentially large degree of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

misclassification that can arise from a single test [70]. The same is true of prognostic studies, yet the implication of misclassification in that context is unclear. The amount of albumin excretion can vary significantly within an individual [71], while eGFR can be affected by a host of factors related to creatinine generation such as changes in diet and body composition [72].

CKD in the Developing World

The bulk of our knowledge of CKD epidemiology comes from studies undertaken in high income countries with sufficient data infrastructure to reliably estimate prevalence and incidence rates. The majority of the world's population lives in middle-income and low-income countries, where our understanding of the burden of kidney disease is sorely lacking. What is evident from the available data is that this burden is expected to increase dramatically in the coming decades due in large part to growing rates of diabetes, obesity, and hypertension in the developing world [73]. Infection continues to be a major driver of CKD in these countries, including the many and varied renal manifestations of infection with human immunodeficiency virus [74, 75]. A current area of intensive research efforts is chronic kidney disease of unknown etiology (CKDu), a condition highly prevalent among young and middle-aged male agricultural and plantation workers. Affected individuals lack traditional risk factors for kidney disease, and a number of pathogenic factors have been hypothesized including heat stress, dehydration, and exposure to heavy metals [76]. The final common pathway appears to be interstitial inflammation and fibrosis, as suggested in a biopsy series from Central America [77]. Similarly, in a large series from Sri Lanka, half of patients who underwent kidney biopsy had evidence of a primary tubulointerstitial kidney disease [78]. Our knowledge of kidney disease epidemiology and appreciation of underlying mechanisms in developing countries is in its infancy. The multiple and diverse challenges that need to be overcome in order for us to enhance our understanding of, and effect meaningful change in, kidney disease burden among disadvantaged populations are discussed in detail in Chapter 6.

Kidney Disease as a Global Public Health Priority

The importance of understanding the epidemiology of CKD is underscored by the impact of CKD on health at a population level around the world [79]. The magnitude of this impact, and how CKD compares to other chronic conditions, has been quantified by the Global Burden of Disease (GBD) studies. Since 1992, the GBD investigators have ranked individual diseases based on the number of global deaths and disability-adjusted life years (DALY) attributable to each disease [80]. DALY is a time-based measure that combines years of life lost due to morbidity and premature mortality, and was developed with the aim of informing cost-effective analysis and public health policy. The scope of the GBD study continues to expand since its first report in 1990. The 2015 iteration reported data for 300 diseases in 195 countries [81]. Those 25 years have witnessed an ominous trend for CKD, which is now the 12th leading cause of death worldwide compared to a ranking of 27th in 1990 [82]. Mortality attributable to CKD is an estimated 1.2 million deaths, representing a rate of 19.2 per 100 000 persons per year. Cardiovascular disease is the biggest contributor to that mortality rate [83]. Worryingly, this mortality rate may be an underestimate, given that CKD is not always listed as a cause of death, for example in the setting of diabetes [84]. In keeping with mortality data, CKD is also a major contributor to DALYs. In some parts of the world, including Latin America and South-East Asia, CKD is currently ranked in the top 10 for DALYs [81, 82]. It is evident, therefore, that the impact of CKD on population health is considerable, and growing.

CKD in Specific Subgroups

Older Adults

The diagnosis of CKD in older adults has been one of the more controversial aspects of the CKD classification system. Measurement studies from decades ago demonstrated an age-related decline in GFR. Similar findings have been shown in contemporary large population studies using estimated GFR. For example, in a cross-sectional study from the Netherlands, the expected decline in eGFR was 0.4 ml/min/1.73 m^2 per year of age among apparently healthy adults with no renal or cardiovascular risk factors [85]. The current eGFR diagnostic threshold of 60 ml/min/1.73 m^2, without albuminuria or other evidence of kidney damage, captures a substantial proportion of older community-dwelling adults as having CKD. Among individuals over 70 years of age, prevalence estimates have been as high as 40% [67, 68]. The majority of older adults with CKD have relatively modest reductions in eGFR (45–59 ml/min/1.73 m^2). It has been argued that the threshold to define CKD in otherwise healthy adults over the age of 60 years should be lowered to an eGFR < 45 ml/min/1.73 m^2 to avoid overdiagnosis and disease-labeling in this subpopulation [86]. Central to this viewpoint is the recognition of a mismatch between a seemingly high prevalence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

disease and low incidence of organ failure, partly explained by competing mortality from other age-related comorbidities [87]. On the other side of the debate, investigators point to the risks associated with CKD in older people [88]. A large meta-analysis leveraging data from over 1 million participants from 33 general population and high-risk (of vascular disease) cohorts specifically addressed this question by examining the interaction of age and kidney parameters for the risk of ESKD and mortality [89]. This study demonstrated that, while the relationship between eGFR/ACR and outcomes varied by age, a reduced eGFR or increased ACR was associated with increased risk of ESKD and mortality across all age categories. In addition to hard outcomes, older adults with CKD are also at higher risk of more proximal outcomes. Several studies have identified CKD as an independent risk factor for reduced physical performance, frailty, and cognitive impairment [90–92]. Thus, the notion of changing the threshold for the definition of CKD based on age alone is not substantiated with data; and would be analogous to changing thresholds for other diseases such as diabetes or hypertension based on age. The implications of a diagnosis of CKD, potential interventions, and targets of therapy may differ between older and younger individuals, but the actual definition of CKD is not age-dependent.

Sex Differences in Kidney Health and Outcomes

The prevalence of CKD appears to be higher in women compared to men, estimated at 16.5% and 13%, respectively, in the United States [93]. Possible reasons for this discrepancy include a shorter life expectancy in men and potential misclassification of CKD using GFR estimating equations in the general population [94]. On the other hand, proportionately more men start renal replacement therapy owing, at least in part, to faster decline in kidney function compared to women. The association between eGFR and albuminuria and hard outcomes is consistent in both sexes, although the slope of the relationship with mortality may be steeper in women [95]. While understudied, women also have unique risk factors for kidney disease, including pregnancy complications and higher incidence of systemic autoimmune disease [96].

Race/Ethnicity

The impact of race on the incidence and severity of kidney disease has been most comprehensively studied in the United States. It has long been recognized that African American patients with kidney disease have a higher-risk profile, evidenced by a substantially increased prevalence of ESKD compared to other racial groups. Recent landmark genetic studies have shed light on this phenomenon. Mutations in the apolipoprotein L1 (APOL-1) gene, found exclusively in individuals of recent African descent and protective against trypanosomal infection, are strongly associated with nondiabetic kidney disease, including that attributed to idiopathic focal segmental glomerulosclerosis and hypertension [97, 98]. APOL-1 variants have also been shown to confer a higher likelihood of CKD progression [99]. The potential influence of race and ethnicity on kidney outcomes around the world is not well understood due to a lack of data infrastructure and high-quality studies (see Chapter 2). While prevalence rates of CKD vary by race, data from the CKD-PC suggest that the risk relationships between reduced eGFR, albuminuria, and clinical outcomes are consistent across racial groups [100]. On a broader level, the use of race in medicine has come under increasing scrutiny, particularly the inclusion of race in diagnostic and treatment algorithms [101]. From a nephrology perspective, there is a growing concern that the inclusion of a race coefficient in GFR estimation and in the evaluation of organ donors is disadvantaging Black patients [102]. In 2021, a task force jointly created by the National Kidney Foundation and American Society of Nephrology recommended the implementation of a new race-free GFR estimating equation published by the CKD-EPI investigators [103, 104]. The implications of this for clinical decision-making and health policy are currently being evaluated, but it is hoped that this change will go some way towards achieving equity for all patients with kidney disease.

Knowledge Gaps and Future Directions

Our knowledge and understanding of kidney disease epidemiology has grown exponentially over the last 15 years, which is testament to the intensive and rigorous research efforts of the international nephrology community. Inevitably, as more data accrue more questions will arise. The CKD classification system provided a common platform from which to start from. There is now a need for improved understanding of variability in outcomes on the individual patient level to inform shared decision-making based on individualized risk-stratification. Integral to this is accurate definition of the disease phenotype, moving from assumptive to definitive diagnosis through molecular diagnostics or by lowering the threshold for kidney biopsy in "common" disorders. The data that currently inform clinical practice have been almost exclusively acquired from studies

in developed countries with an appropriate data infrastructure and access to nephrology care, including renal replacement therapy. This data cannot be extrapolated to the majority of the world's population in developing countries where susceptibility to kidney disease, access to care, and choice of therapies are fundamentally different. The subsequent chapters in this part expand on these and other important issues, as we strive to meet the current and future challenges of kidney disease around the globe.

The Surveillance and Burden of Chronic Kidney Disease

Chaisiri Angkurawaranon[1], Dorothea Nitsch[2], and Ben Caplin[3]

[1] *Department of Family Medicine, Faculty of Medicine, Chiang Mai University, Chiang Mai, Thailand*

Surveillance of CKD

The World Health Organization defines surveillance as the "continuous, systematic collection, analysis and interpretation of health-related data for the planning, implementation and evaluation of public health practices." In terms of chronic kidney disease (CKD), surveillance refers to activities aimed at providing key information on the burden of, and risk factors for, CKD with a view to reducing variation in, and improving the quality of, care processes and health outcomes associated with the condition [1]. Information from CKD surveillance can potentially be used to guide resource planning and implementation of medical and public health measures along with informing health policy. Optimization in the management of CKD could prevent progression to kidney failure and the need for dialysis and transplantation [2] as well as potentially reducing the burden of hospitalization from nonrenal complications (e.g. cardiovascular disease) [3].

Potential Benefits of CKD Surveillance

While there is insufficient evidence to support the efficacy of screening for CKD among the general population [4–6], consistent evidence suggests that presence of proteinuria or reduced estimated glomerular filtration rate (eGFR) is strongly associated with end-stage renal disease (ESRD), cardiovascular, and all-cause mortality in population-based studies [7–10]. Equations that predict progression of CKD have been validated in high-income settings [11, 12]. The absolute numbers reaching ESRD are small, but those who do go onto need renal replacement therapy (RRT) benefit from early referral to specialist services [13]. However, the best approaches to identify this group remain the subject of ongoing research [14–16]. Combining testing for CKD with screening for other noncommunicable diseases or risk factors means that surveillance for CKD in high-risk populations may be the most efficient and effective approach [1, 17]. These targeted populations include those with hypertension, diabetes, and cardiovascular disease [18–21]. Aside from benefits at the patient level, estimates of the projected incidence of ESRD and dialysis needs in a local population are key for health services planning. Furthermore, understanding prevalence of CKD in a population may have broader implications given the relationship between CKD and hospitalizations from multiple causes such as cardiovascular events, acute kidney injury (AKI), and infections [3].

For patients with ESRD (sometimes also including those with the advanced stages of CKD), many countries have registries where treatments and outcomes are monitored [22]. As well as providing data on the incidence of RRT in a particular population, these registries aim to guide management and improve care processes toward better health outcomes [23, 24].

Types of CKD Surveillance

Surveillance systems are generally divided into passive and active approaches. A passive surveillance system relies on data routinely collected in current practice. These include death registries, hospital records, and primary care records (Table 2.1). These types of routine data sources are efficient and powerful tools in CKD surveillance, particularly where

Table 2.1 Types of passive surveillance for CKD.

Passive surveillance	Potential indicators	Numerator	Denominator	Generalizability	Potential strengths	Potential limitations	Potential biases
Death registries	Mortality rate Age- and sex-specific mortality rate SMR	Deaths attributed to CKD/ESRD	Population covered by death registration	Local and national level International comparisons (SMRs)	Resource efficient Explore geographical variations	Attributing deaths to CKD/ESRD Disaggregation by area/populations	Coverage and validity of death certificates
Dialysis registries and transplant registries	Incidence of ESRD Age-specific incidence of ESRD Standardized incidence of ESRD	Patients with ESRD starting RRT because of ESRD (requiring dialysis for 90 days or more)	Population with access to dialysis and transplantation	Patients with coverage for ESRD	Resource efficient Explore geographical variations	Not representative of burden of CKD (untreated ESRD) Obtaining patient-level data Limited data on treatment and patient outcomes	Coverage of RRT Access to care Competing mortality
Hospital records (admissions data)	Prevalence of CKD and/or ESRD	Patients diagnosed with CKD and/or ESRD	Patients who are in hospital care	Patients who seek or are referred to hospital care	Availability of kidney (bio) markers Availability of treatment and patient outcome data	Not representative of true population prevalence/incidence of CKD Completeness of information	Classification based on eGFR and/or ICD 10 Influence of AKI on results Creatinine calibration and method used Referral patterns from primary care Competing mortality
Primary care records	Incidence and prevalence of CKD and/or ESRD	Patients diagnosed with CKD (from kidney function measures)	Patients in outpatient/primary care	People who are screened/attend checkups or present for outpatient care	Detection of early stages of CKD	Not representation of true population prevalence/incidence of CKD (rather among those who regularly get renal function tests) Completeness of information	selection bias due to self-presentation or volunteer of community population Classification based on eGFR and ICD 10 Single measurement or multiple measure for diagnosis of CKD Influence of AKI on results Laboratory calibration issues

AKI, acute kidney injury; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; ICD 10, International Classification of Diseases-10; RRT, renal replacement therapy; SMR, standardized mortality rate.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. laboratory test results are available in parallel to clinical data. Outputs such as attributable deaths from CKD, and prevalence or incidence of CKD can be derived. However, there are important limitations to these datasets which mostly surround data quality, coverage, and comprehensiveness. These limitations will vary substantially both between different types of electronic health records and between different health systems. Specifically, variation in access to healthcare in some settings may lead to major issues with the representativeness of any estimates of disease burden, therefore the interpretation and generalizability of the conclusions derived from these data sets requires a clear understanding of the context and ascertainment methods within each system.

Active surveillance systems, such as national surveys or outreach testing in high-risk populations, are often more resource intensive than passive surveillance systems. With an active system the accuracy of the diagnosis of CKD may be improved and a wider range of patient factors, treatment, and health outcomes may potentially be explored. However, with the exception of population-based surveys, these data will not provide a measure of the population prevalence of CKD (Table 2.2).

In reality, most comprehensive health systems will undertake a variety of surveillance approaches using different data sources. Typically these might include death certification data, a dialysis and transplant registry, electronic health record-based surveillance and targeted outreach in high-risk groups. Indeed unexpected differences in estimates of disease burden or outcomes from these different sources may in turn provide key information about population coverage and patient care pathways within or between regions.

Challenges of Surveillance for CKD

Surveillance approaches have different challenges and limitations. Understanding these is key to the interpretation of surveillance outputs as well as finding methods to mitigate these problems. Any form of CKD surveillance should provide meaningful data as to whether burden of disease is increasing, decreasing, or stable in a population and many outputs can also be used to detect differences between populations.

Cross-sectional Surveys of eGFR

Even an imperfect surveillance method, which misclassifies an individual as to whether they have CKD, might still be useful to detect meaningful differences in CKD prevalence between populations or changes of CKD prevalence over time within a population. This is the basis of a number of single time point, or snapshot, approaches quantifying the prevalence of reduced eGFR to monitor CKD at population level, examples include the National Health and Nutrition Examination Survey (NHANES) [25] and the Health Survey for England [26]. Although the single time point measurement in a survey participant does not meet criteria for CKD per se, as chronicity is not demonstrated, conclusions can still be drawn about CKD prevalence, assuming the methods used (at different points or in different regions if comparing populations) remain the same and survey nonresponse is appropriately dealt with.

Registries of Patients Receiving RRT

Many health systems will use incidence of RRT as a measure of CKD burden. However, there are two important limitations in using this measure. First, it is based on the assumption that all patients with ESRD can access dialysis or transplantation. Across the world there are inequalities in accessing care [27] and even in Europe substantial variations exists [28]. Furthermore, health system incentives may influence the numbers starting RRT. Second, in an attempt to capture those receiving RRT due to CKD rather than AKI many registries only collect data on patients who have received dialysis for a minimum duration, for example 90 days. This means that all those patients who started dialysis because of ESRD but died within a 90-day window are not included in these estimates, potentially leading to an underestimate of disease burden.

CKD Outreach Screening

Although the use of outreach approaches to detect CKD in populations has the advantage that it can be combined with initiatives to improve the awareness of CKD, estimates of disease burden from this type of work will be critically dependent on who presents for testing and hence potentially misleading. This bias may drive estimates higher or lower, for example it may be that the more health-conscious members of the population are captured ("the worried well"), who are less likely to have kidney problems. Alternatively, those who have risk factors for, or family members with, CKD, might seek the opportunity for kidney function testing that may otherwise be difficult to access. Hence, any estimate of disease burden that does not include a representative sample of the source population of interest (best ensured by random sampling) needs to be treated with caution and may not provide useful insight into the true prevalence of CKD or trends over time in disease burden.

Routine Health Records

Passive systems utilizing available data can have many of similar problems to active approaches, in that the interpretation of the data is dependent on the source population,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 2.2 Types of active surveillance for CKD.

Active surveillance	Potential indicators	Numerator	Denominator	Generalizability	Potential strengths	Potential limitations	Potential biases
National surveys (population-based studies)	Prevalence of CKD and/or ESRD	Participants diagnosed with CKD (from kidney function measures)	Random/ stratified sample of population targeted by survey	Population targeted by survey	Representative of true population incidence and prevalence of CKD in population targeted by survey	Requires sampling frame, or enumeration of population Obtaining resources and Implementation of fieldwork	Nonresponse bias
Clinic/hospital-based surveys (testing of patients not routinely tested)	Prevalence of CKD and/or ESRD	Participants diagnosed with CKD (from kidney function measures)	Hospital/clinic population attending clinic	Self-presenting or population eligible for attending hospital clinic	Completeness of kidney (bio)markers Completeness of treatment and patient outcomes data	Not representation of true population prevalence/incidence of CKD	Selection bias due to self-presentation or healthcare access Nonresponse bias
Outreach testing	Prevalence of CKD and/or ESRD	Participants diagnosed with CKD (from kidney function measures)	Selected reporting populations, often volunteers	Prevalence of CKD in selected populations	Completeness of kidney (bio)markers Completeness of treatment and patient outcomes data	Not representation of true population prevalence/incidence of CKD	Selection bias due to self-presentation or volunteer of community population
Occupational or workplace-based surveys	Prevalence of CKD and/or ESRD	Participants diagnosed with CKD (from kidney function measures)	Random sample/stratifies or whole workforce	Generalization within population of survey	Less prone to nonresponse bias	Identifying appropriate comparator population	Selection bias restricts generalizability, especially if particular occupational groups do not attend

CKD, chronic kidney disease; ESRD, end-stage renal disease.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

i.e. in these cases the population that attended the respective clinical service. In the context of CKD there is also the issue that diagnosis is often based on blood and urine tests which the treating clinician must actively order, and there may be reasons why certain groups of people are more/less often tested. For example, a particular group of patients may have differing access to care, e.g. because of lack of insurance or because they are too unwell to attend routine appointments. Furthermore, a patient may receive a kidney function test as the clinician worries about the potential of AKI as the patient is acutely unwell, when a kidney function test may not otherwise be done, a situation that would lead to an underestimate of kidney function in the tested population. Therefore, surveillance for CKD using hospital or primary care records should use results from steady state routine testing, i.e. when the patient was not acutely unwell. Furthermore, any changes in prevalence or incidence over time may be driven by differences in the way people were tested and/or managed rather than changes in disease burden. For example, changes in patient pathway may explain apparent changes in prevalence, e.g. a particular group of patients may now be referred to secondary care when they were previously managed elsewhere or vice versa.

Measurement Error

With all approaches based on the testing of renal biomarkers, it is also important to consider the issues surrounding laboratory calibration and external quality assurance which can be the source of substantial measurement error. Compounding the problem with biomarker measurement error is the fact that the various estimating equations for the eGFR have generally been validated in US and European populations and whether the same relationship between serum creatinine (or cystatin C) and kidney function exists in all populations and in other settings remains unclear. For example, although there is a correction factor for African-Americans in both the Modification of Diet in Renal Disease (MDRD) and CKD-Epi eGFR formulae, evidence suggests these correction factors cannot be applied with certainty to Sub-Saharan African populations [29]. Finally, although again less important if examining CKD within a region, when attempting to compare the burden of CKD between different areas it should be recognized that the distribution of healthy kidney function in many populations remains unknown. Therefore, whether the threshold GFR of 60 ml/min/1.73 m^2 as an indicator of future adverse renal (and cardiovascular) outcomes is appropriate in non-European/North American settings is not established, i.e. is there a role for different GFR thresholds for CKD in different populations?

Outputs from Estimates of CKD Burden from Around the World

As discussed above, the population burden of CKD can be estimated using a range of approaches. The corresponding range of estimates will be of more or less valuable depending on the purpose for which the data are sought (provision of basic medical services, RRT planning, etiological insight, or an understanding of secular or regional trends) as well as the access the population has to specific healthcare resources.

RRT Registries

RRT incidence and prevalence are widely reported as part of nephrology society or health service-led registry initiatives and the number of registries capturing these data worldwide is steadily increasing. Most of these registries were initially developed to describe variation in provision and outcomes of dialysis but the same datasets can provide a surrogate for the incidence of treated stage 5 CKD in some populations, specifically in those countries where RRT is freely available.

Although RRT prevalence is a widely cited figure for health service planning and resource calculations, this figure reflects not only CKD burden but is also a function of the survival of those undergoing dialysis or receiving kidney transplantation (a key metric, but one which varies substantially between different regions of the world). Where available, RRT incidence is likely a more useful estimate of the burden of ESRD in a population. However, individuals receiving of conservative care for kidney failure, an increasing number of the elderly in high income countries, and of course those who have no prospect of receiving any kind of RRT, i.e. the majority of the ESRD population in lower-income countries, will inevitably be excluded from such estimates.

Figure 2.1 summarizes reported RRT incidence from a number of international registries. The highest numbers of patients starting RRT per million population are in the Americas (Mexico and the United States) and East Asia (Taiwan, Thailand, and Japan). Importantly although numbers appear to be stabilizing in a number of high-income settings there continue to be dramatic year-on-year increases in numbers starting RRT in middle-income settings such as Mexico and Thailand. These numbers may represent improved ascertainment, true increases in incidence, or both, but of note, Thailand recently introduced an insurance system by which free peritoneal dialysis is made available to those who require it.

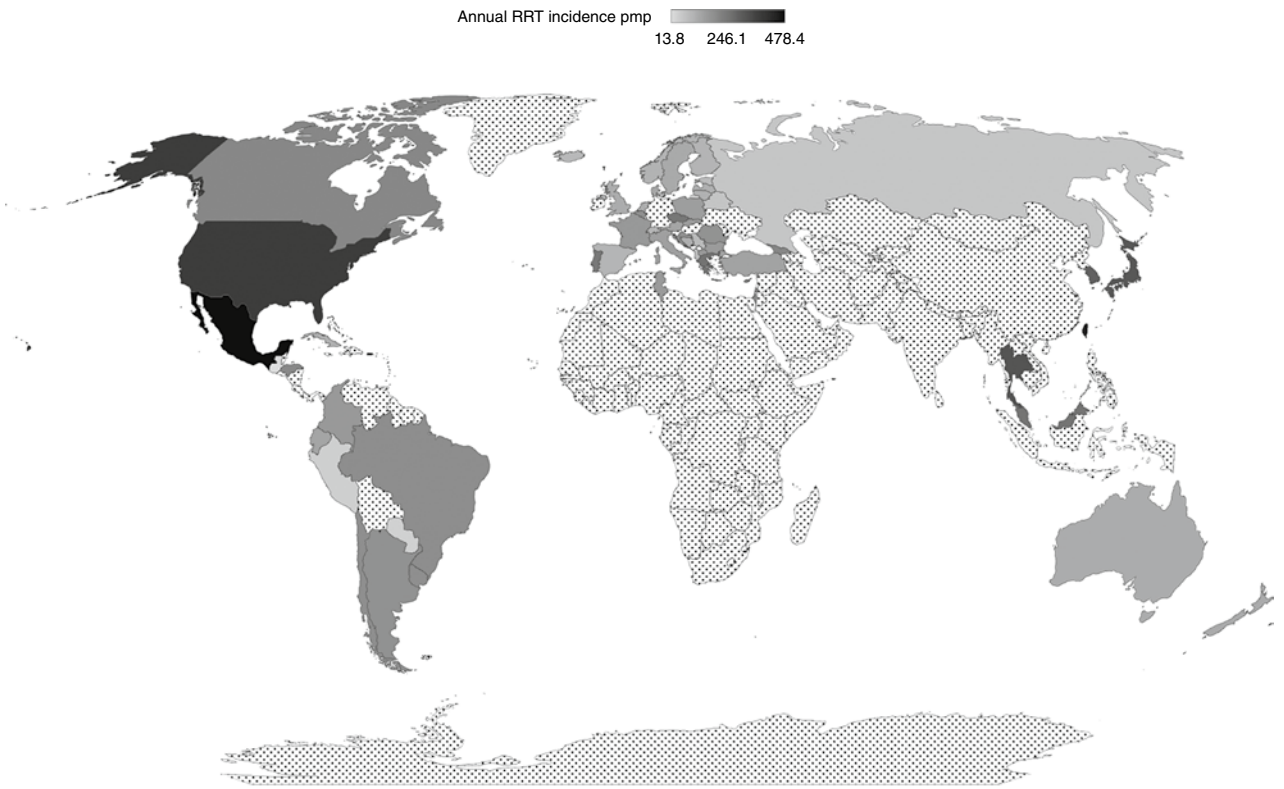

Figure 2.1 Global incidence of renal replacement therapy. Most recent data from publicly available renal registries [30–41], various years. Crude rates per million population. See text for limitations.

Testing of High-Risk Populations

Evidence from high-income countries suggests that most people with CKD can be identified by testing those with risk factors, specifically diabetes, hypertension, those with a family history and older age groups. For example, in the Norwegian population almost 60% of those with an eGFR < 60 ml/min/1.73 m^2 can be captured by testing those with diabetes, hypertension, or a family history of these conditions [17] and this proportion increases to around 90% if everyone in older age groups is also tested.

A number of initiatives aimed at quantifying the burden of CKD have used a similar risk stratification approach to invite individuals for testing (Table 2.3).

Although these approaches are efficient at identification of those with low eGFR and established risk factors such as diabetes, the utility of this approach has not been validated in all populations. For example, those with nonproteinuric CKD living in agricultural communities in low- and middle-income countries would typically not be identified using this type of screening.

Health Systems Data

Health systems that utilize electronic health records have access to a useful source of data on the burden of CKD in the primary care population, for example when used as part of audit and/or quality improvement programs. There is evidence that these programs can in turn lead to improved care processes [44]. Although electronic diagnostic coding of CKD is generally poor in health systems where it is not incentivized (see reference [45] vs. reference [46]), estimates of the burden of CKD can also be obtained by interrogating laboratory records. Coverage is often high, particularly among high-risk groups, because kidney function testing is required for appropriate treatment in those at risk (e.g. hypertension drug management, choice of diabetes drug) and care (many older people receive multiple renal function tests as part of other investigations), hence a high proportion of patients with reduced eGFR are detected. Furthermore, this type of data is useful for demonstrating the chronicity of impaired eGFR or proteinuria. Some examples are shown in Table 2.4.

Population Representative Data

Population-based surveys provide the gold-standard for assessing the prevalence of CKD. Although often challenging to conduct, studies of representative samples with high response rates will provide the best estimates of the burden of disease.

Table 2.3 Examples of risk-stratification for CKD testing.

Study	Countries	Risk group included	eGFR < 60	Albuminuria	Notes	Reference
KEEP	USA	18 years + First-degree relative with diabetes, hypertension, or kidney disease Personal history of hypertension or diabetes	17%	29% (urinalysis)	Over 90% of those with eGFR < 60 were unaware that they might have abnormal kidney function	[25]
KEEP Mexico	Mexico	18 years + First-degree relative with diabetes, hypertension, or kidney disease Personal history of hypertension or diabetes	Mexico City 7% Jalisco State 10%	Mexico City 19% (ACR > 30 mg/g) Jalisco State 31% (urinalysis)		[42]
Hiperdia Programme	Brazil	Diabetes and hypertension	24.6%	36.6%		[43]

ACR, albumin creatinine ratio; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate.

Table 2.4 Studies using electronic health records to estimate CKD burden.

Country	Coverage	Reference
Australia	Melbourne	[47]
Canada	Alberta	[48]
Singapore	Singhealth system	[49]
UK	National (~9% of English and Welsh population)	[46]
	Grampian, Scotland	[50]
United States	Ohio (Cleveland clinic)	[45]
	National (Veterans Affairs Administration)	[51]

CKD, chronic kidney disease.

Population-based surveys have been conducted around the world in attempts to establish the national or regional prevalence of eGFR < 60 ml/min/1.73 m^2, with or without also testing for urinary albumin. Often cross-sectional in nature and nested within epidemiological studies of other noncommunicable diseases, a key issue when interpreting these studies is whether chronicity (i.e. kidney abnormalities present for more than 3 months) has been established. This is important as evidence suggests that between a quarter and one-third of those with a single measure of eGFR < 60 ml/min/1.73 m^2 (albeit those with values only just below the threshold) will have a value above this threshold on retesting [52, 53]. Similarly, variation in the underlying age structure of the population between studies will mean data are not easily comparable across regions without standardization to a reference population.

As discussed above, there are a number of other challenges that arise when comparing these data, including laboratory biomarker quality assurance, validation of GFR estimating equations in different groups as well as a poor understanding of the population distribution of healthy GFR across different regions and ethnicities. Despite these shortcomings this type of cross-sectional survey probably provides the greatest insight into the burden of CKD, particularly in lower-income settings where access to health services, routine laboratory testing, and especially RRT is incomplete. There have recently been international initiatives aimed at conducting simplified population-based studies using standardized protocols with adequately refenced laboratory procedures [54]. It is only using this type of population-representative epidemiological approach that the burden of impaired kidney function (as well as information on specific causes of CKD) can be robustly captured and compared between regions and internationally. Furthermore, these types of study are likely to be key to understanding changes in the burden of kidney disease over time as well as providing the potential to gain insight into previously unappreciated risk-factors for disease.

Examples of population-based studies examining the prevalence of low eGFR (as a surrogate for CKD) are illustrated in Figure 2.2. The highest population prevalence of an eGFR < 60 ml/min/1.73 m^2 has been reported in studies conducted in Cameroon, Iran, Japan, and the countries of Central America. Whether these high rates reflect the age structure of the population, the burden of known CKD risk factors such as diabetes or HIV infection, or reflect specific regional endemic nephropathies is often

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Figure 2.2 Crude prevalence of eGFR < 60 ml/min/1.7 m^2 reported from a range of studies around the world since the year 2000. Includes representative population-based studies aimed at capturing prevalence of CKD across the age range (includes studies that included minimum age as high as 40 years old). eGFR calculated from the CKD-Epi (or MDRD equation where CKD-Epi not provided, and with local correction factors in some cases). Studies only included where external creatinine validation was reported (e.g. IDMS referenced standards) and prevalence standardized to the local age structure where reported. Estimates based on a single measure of eGFR only (see text). *Source:* [26, 52, 55–85].

not fully characterized. However, it is also important to recognize that even country-level figures can often obscure important regional/local differences in CKD prevalence. For example, in Nicaragua age-standardized rates of eGFR < 60 ml/min/1.73 m^2 reach 18% amongst rural males but are less than half that in urban centers in the same region [55].

As might be expected given the issues discussed in this chapter prevalence of impaired kidney function at a population level will not necessarily be reflected in high rates of RRT. However, substantively different RRT rates are reported in settings with similar CKD prevalence even where there is unrestricted access to RRT [56], suggesting there are important modifiable factors in the natural history of disease.

Combined Estimates of CKD Burden: The Global Burden of Disease Project

As none of the above approaches to determining CKD burden can be easily applied to all regions of the world, summary approaches using a composite of all the above approaches may be useful. The Global Burden of Disease project combines data from a huge range of data sources. There are a number of challenges when undertaking this kind of quantification but nonetheless the results are informative. Estimates from this work report a global prevalence of CKD of 3.7% (ranging from 3.4% in low-income regions to 5.3% in high-income regions) [86]. More concerning perhaps is the increase in burden of kidney disease over the last 25 years. Much of this increase originates from aging but increasing rates of diabetes and other causes of CKD are also a substantial contributor in a number of low- and middle-income settings. Globally, CKD now ranks 22nd (from 30th in 1990) of all diseases and accounts for 1.5% (from 0.9% in 1990) of all disability adjusted life years lost.

Summary and Conclusions

No single approach to CKD surveillance will capture all aspects of the burden of CKD comprehensively and data reported from most approaches need to be considered

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. alongside any limitations and the health systems context. However, understanding the burden of CKD has an important role in health service planning as well as in quantifying benefits from the introduction of care pathways or interventions by characterizing changes over time. Furthermore, inter-regional comparisons may provide insight into important health inequalities along with the risk-factors and causes of some kidney diseases.

Introduction

Chronic kidney disease (CKD) is associated with significant risks of several adverse outcomes, including progression to kidney failure, cardiovascular events, and mortality [1–4]. Assessment of CKD progression is a chief focus of CKD care and a central target of interventions to prevent the development of kidney failure, an important patient-centered outcome. Kidney failure may be variably defined as initiation of kidney replacement therapy (KRT, including dialysis or kidney transplantation), death attributed to kidney disease, or sustained levels of estimated glomerular filtration rate (eGFR) below a threshold of 15 ml/min/1.73 m^2, which can influence estimates of disease incidence and prevalence [5]. Regardless of definition, there remains significant variability in the risk of progression to kidney failure among patients with CKD. Reliable approaches to risk stratification are important in order to identify high-risk patients who may require specialized care, need closer follow-up or derive greater benefit from certain interventions, and to provide timely psychological or educational preparation and planning for initiation of KRT or a conservative approach to care.

Several prognostic factors for CKD progression have been evaluated in large cohort studies that have characterized associations between clinical and laboratory measurements and risk of kidney failure. Much of this work has been synthesized by the Chronic Kidney Disease Prognosis Consortium (CKD-PC), in a series of patient-level meta-analyses of prognostic factors, usually in relation to eGFR and albuminuria [6]. More recently, prediction model studies have combined prognostic factors to derive and validate multivariable models for kidney failure, which can be used to provide patients and their care providers with individualized estimates of their future risk of kidney failure.

This chapter provides an evidence-based approach to risk stratification for the progression of CKD. A summary of evidence is provided for (i) individual prognostic factors of CKD progression to kidney failure, (ii) validated multivariable clinical risk prediction models for progression to kidney failure, and (iii) the clinical impact of these existing risk prediction models. Where possible, evidence for each prognostic factor is provided from pooled meta-analyses of multiple, high-quality cohort studies, many reported by the CKD-PC. For multivariable risk prediction models, those that have been derived, internally validated, and externally validated in one or more cohorts have been included. Because clinical impact analysis is part of the full evidence base for risk prediction models prior to widespread acceptance and adoption, studies on clinical application and impact are also discussed.

The certainty of evidence was assessed using the Grading of Recommendations Assessment, Development and Evaluation (GRADE) framework for prognosis studies [7]. Because no GRADE criteria are currently available for prediction model studies, their quality has been described according to the extent of external validation and the consistency and generalizability of model performance.

Epidemiology of CKD and Kidney Failure

CKD is common, affecting up to 15% of the population worldwide [8]. In the United States, the reported prevalence of CKD ranges from 7% to 15%, depending whether it is

defined using eGFR criteria alone or also by the presence of albuminuria [9, 10]. The majority of patients with CKD have earlier stages of disease, with a much lower prevalence of kidney failure reported in the adult population. Among older individuals, in whom multimorbidity can be common, the reported prevalence of CKD is as high as 40% worldwide (approximately 25% in the United States), the majority of whom would be classified as having stage G3a CKD by eGFR criteria (i.e. 45–59 ml/min/1.73 m^2) [11]. The aging population and increased prevalence of cardiovascular disease, diabetes, and other noncommunicable diseases are anticipated to further increase the global burden of CKD and its associated morbidity and mortality [8]. Primary and secondary prevention approaches are desirable so that modifiable risk factors can be addressed to delay development or progression to kidney failure, and to prevent associated complications such as cardiovascular events.

There is substantial variability across the stages of CKD in risk of progression to kidney failure, and a significant amount of research has aimed to characterize the factors that contribute to this risk. The current international CKD staging system [5] categorizes patients according to both eGFR and albuminuria thresholds based on risk relationships, although some have suggested that age- and gender-specific eGFR criteria may be more appropriate, particularly when compared to eGFR alone [12]. Albuminuria was added to the previously accepted eGFR-based classification system following studies demonstrating its association with increased risk of CKD progression and mortality independent of eGFR [13]. Kidney Disease Improving Global Outcomes (KDIGO) has developed a visual "heat map" to identify patients at progressively increased risk for kidney failure at different levels of eGFR and albuminuria (Figure 3.1) [5]. Declining eGFR in combination with increasing albuminuria may better predict progression to kidney failure than either one alone [14]. However, while CKD staging can identify patients at increased risk of progressing to kidney failure, risk for progression on an individual level can vary greatly even within these CKD stages. This suggests that other factors beyond eGFR and albuminuria contribute to the risk of kidney failure, and identification of variables that provide incremental prognostic value could lead to improved risk stratification approaches.

Kidney failure (ESRD)

Figure 3.1 Kidney Disease Improving Global Outcomes (KDIGO) CKD Clinical Practice Guideline heat map for risk of kidney failure. eGFR is reported in units of ml/min/1.73 m^2 and ACR in mg/g (multiply by 0.113 to convert to mg/mmol). Values in the cells represent adjusted relative risks. ACR, albumin-to-creatinine ratio; ESRD, end-stage renal disease; eGFR, estimated glomerular filtration rate. *Source:* Levey et al. [13]. © 2011 Elsevier.

Pathophysiology of CKD Progression

Although CKD may result from a wide variety of causes, once it is established, common pathological findings of vascular injury, glomerulosclerosis, and tubulointerstitial fibrosis have been described, regardless of the inciting cause [15]. These maladaptive changes are believed to contribute to a final common pathway of scarring, further nephron loss, and progressive kidney damage that can ultimately lead to kidney failure [16]. Hemodynamic factors, activation of the renin–angiotensin–aldosterone system, and inflammatory responses leading to tubulointerstitial fibrosis are major pathophysiological mechanisms that have been identified in this process.

Both systemic and glomerular hypertension have been identified as common mediators of CKD progression. The afferent and efferent arterioles can moderate glomerular perfusion and pressure independently from systemic blood pressure. However, in the remnant kidney model in rats, reduced nephron mass results in progressive hyperperfusion, glomerular hypertrophy, and glomerulosclerosis [17]. Micropuncture studies suggest that single nephron hyperfiltration in response to renal ablation leads to glomerulosclerosis [18], and animal and human studies suggest that interventions such as renin-angiotensin system inhibitors that decrease glomerular pressure can ameliorate sclerosis, reduce albuminuria, and slow progression of CKD [19].

Tubulointerstitial fibrosis is a second common pathophysiological process associated with CKD progression [20, 21]. While it has been traditionally viewed as a consequence of

nephron ischemia in CKD [15], more recent mechanistic studies suggest that inflammatory stimuli in response to injury may play an important effect in fibrotic processes in the kidney, moderated via macrophage signaling, cytokines, eicosanoids, and anti-angiogenic factors [22]. These factors may lead to decreased peritubular capillary density and phenotypic transition of interstitial and parenchymal epithelial cells into myofibroblasts, which in turn leads to interstitial fibrosis and glomerulosclerosis, and progressive loss of kidney function [23].

Prognostic Factors for Progression to Kidney Failure

Several commonly ascertained measures have been identified as risk factors or risk modifiers of progression of CKD to kidney failure. The evidence for these laboratory (eGFR and albuminuria), demographic (age, sex, and race), and clinical variables (acute kidney injury, blood pressure, diabetes mellitus, and cardiovascular disease) is reviewed here and summarized in Table 3.1.

eGFR

There is high certainty evidence that reduced eGFR is associated with kidney failure in people with an established diagnosis of CKD, as well as in the general population and those with cardiovascular disease and a high risk of CKD. This finding has been demonstrated when serum creatinine values, standardized to isotope dilution mass spectrometry-traceable methods, are used to estimate glomerular filtration rate (GFR) using either the Modification of Diet in Renal Disease (MDRD) study equation or the CKD Epidemiology Collaboration (CKD-EPI) equation. The first phase of collaborative meta-analysis published by the CKD-PC [4] examined the risk of kidney failure in a total of 21 688 patients from 14 cohorts with CKD, in which the incidence rate of kidney failure varied markedly from 13.6 to 115.3 per 1000 person-years. In adjusted analyses, each decrease in MDRD eGFR by 15 ml/min/1.73 m^2 below a threshold of 45 ml/min/1.73 m^2 was associated with a sixfold increase in hazard of kidney failure. In meta-analysis of cohorts drawn from the general population, with a higher mean eGFR (range 72–144 ml/min/1.73 m^2) and the absolute risk for end-stage kidney disease (ESKD) of 0.31 events per 1000 person-years, the risk of kidney failure was not related to MDRD eGFR at values between 75 and 105 ml/min/1.73 m^2, but was exponentially higher at lower levels of eGFR. At MDRD eGFRs averaging 60, 45, and 15 ml/min/1.73 m^2, and adjusted hazard ratios for kidney failure were 4, 29, and 454, respectively, compared with an eGFR of 95 ml/min/1.73 m^2 [2].

The CKD-EPI equation has been shown to more accurately estimate GFR than the MDRD study equation, especially at higher GFR. A meta-analysis of data from 1.1 million adults from 21 general population, high-risk, and CKD cohorts demonstrated that although the general pattern of the eGFR and kidney failure risk relationship was similar for both equations, eGFR computed by the CKD-EPI equation predicted risk of kidney failure more accurately than the MDRD study equation when eGFR was used for classification into six categories (90, 60–89, 45–59, 30–44, 15–29, and 15 ml/min/1.73 m^2) [24] by both equations. In the general population cohorts, 25.0% of patients were reclassified by the CKD-EPI equation, mostly to a higher eGFR category, with overall reclassification leading to lower risks of kidney failure in patients reclassified into higher eGFR categories and higher risks of kidney failure in patients reclassified into lower eGFR categories. The exception was the MDRD eGFR category of 15–19 ml/min/1.73 m^2, where no significant difference in risk was observed between patients reclassified into the higher eGFR category using CKD-EPI and those not reclassified.

Change in eGFR

A progressive decline in GFR can be viewed as an intermediary on the pathway to kidney failure, and existing evidence suggests with high certainty that a patient's past trajectory of decline in eGFR provides additional prognostic information about the risk of kidney failure, over and above the most recent eGFR available. In a meta-analysis of 232 250 patients from 11 CKD cohorts, where the risk of kidney failure over 2 years of follow-up was 1.4%, a decline in eGFR of 6 ml/min/1.73 m^2 per year over the previous 3 years (i.e. a decline of 18 ml/min/1.73 m^2 versus no decline) was associated with approximately double the adjusted relative risk of kidney failure compared to no decline, whereas a current eGFR of 30 versus 50 ml/min/1.73 m^2 (i.e. a difference of 20 ml/min/1.73 m^2) was associated with 20-fold higher relative risk of kidney failure [33]. These findings thus demonstrate that despite the prognostic value of a change in eGFR, current eGFR is associated more strongly with future risk of kidney failure than the magnitude of past eGFR decline, especially when eGFR falls below 30 ml/min/1.73 m^2.

Albuminuria

Proteinuria can be measured in several ways, including urinary dipstick, albumin-to-creatinine ratio (ACR) or protein-to-creatinine ratio (PCR) on a spot urine sample, or quantification from a 24-hour urine collection. Regardless of the method of assessment, there is high certainty evidence that increasing proteinuria confers a higher risk

Table 3.1 Summary of findings: individual prognostic factors for kidney failure.

Prognostic factors	Definition of prognostic factor	Evidence source	Summary of findings[a]	Certainty of evidence (GRADE)[b]
eGFR [4]	MDRD eGFR categorized as 30–44, 15–29, and <15 ml/min/1.73 m^2, compared to a reference group with eGFR = 45–74 ml/min/1.73 m^2	CKD prognosis consortium meta-analysis including 14 CKD cohorts, with 21 688 patients	**Absolute risk:** Incidence rate of kidney failure varied between cohorts from 13.6 to 115.3 per 1000 person-years. **Relative risk:** Each decrease in MDRD eGFR by 15 ml/min below a threshold of 45 ml/min/1.73 m^2 was associated with a HR 6.24 (95% CI 4.84–8.05), (I^2 = 87.9%, P < 0.001) eGFR 30–44: HR 2.72 (95% CI 1.29–3.37) eGFR 15–29: HR 10.21 (95% CI 8.36–12.46) eGFR <15: HR 51.48 (95% 31.95–82.97)	**High** ●●●●
CKD-EPI versus MDRD study eGFR [24]	Estimated GFR classified into six categories (90, 60–89, 45–59, 30–44, 15–29, and 15 ml/min/1.73 m^2) by MDRD study and CKD-EPI equations.	CKD prognosis consortium meta-analysis including 1.1 million adults from 21 general population, high-risk, and CKD cohorts	**Absolute risk:** eGFR computed by the CKD-EPI equation predicted risk of ESKD more accurately than the MDRD Study equation; 35% of patients with eGFR 45–59 ml/min/1.73 m^2 by the MDRD study equation reclassified to eGFR of 60–89 ml/min/1.73 m^2 by the CKD-EPI equation and had a lower incidence rate of kidney failure compared with those not reclassified (0.5 vs. 0.8 per 1000-person years). Net reclassification improvement (NRI) significantly favored the CKD-EPI equation for predicting kidney failure; NRI 0.06 (95% CI, 0.02–0.10).	
Change in eGFR [25]	Three-year eGFR slope evaluation	11 CKD cohorts (232 250 patients)	**Absolute risk:** Absolute risk of kidney failure over a mean follow-up of 2 years by eGFR slope; 4.7% for eGFR slope <−5 ml/min/1.73 m^2/year, 1% for eGFR slope ≥−5 to ≤5 ml/min/1.73 m^2/year, 0.1% for eGFR slope ≥5 ml/min/1.73 m^2/year. **Relative risk:** Adjusted hazard ratios of kidney failure, compared to eGFR slope of 0 ml/min/1.73 m^2/year; eGFR slope of −3 ml/min/1.73 m^2/year over preceding 3 years had a HR 1.73 (95% 1.50–2.00), I^2 = 0, eGFR slope of −6 ml/min/1.73 m^2/year over 3 years had a HR 2.28 (95% CI 1.88–2.76), I^2 = 34.3%. No evidence of effect modification of the relative risk of kidney failure associated with eGFR slope according to level of last eGFR (P value for interaction 0.26).	**High** ●●●●
Proteinuria [4]	Proteinuria was categorically defined as follows[c]: ACR (mg/g; multiple by 1.113 to convert to mg/mmol): <30, 30–299, 300–999, and ≥1000 Dipstick proteinuria: −/±, +, ++, +++	Collaborative meta-analysis of 13 CKD cohort studies, including 21 688 patients with follow-up of 1.9–7.5 years	**Absolute risk:** Unadjusted absolute risk kidney failure by ACR category (range of incidence rates per 1000 person-years of follow-up)[d]: ACR <30 mg/g: 2.8–13.8 ACR 30–299 mg/g: 2.8–90.1 ACR 300–999 mg/g: 16.4–141.5 ACR ≥1000 mg/g: 50.2–247.4 Unadjusted absolute risk of kidney failure by dipstick category (incidence rate per 1000 person-years of follow-up)[d]:	**High** ●●●●

Table 3.1 (Continued)

Prognostic factors	Definition of prognostic factor	Evidence source	Summary of findings[a]	Certainty of evidence (GRADE)[b]
Cardiovascular disease [32]	Previous diagnosis of myocardial infarction, percutaneous coronary intervention, bypass grafting, heart failure, or stroke	28 cohorts including 185 024 participants from 30 different countries, greater than 18 years of age, with eGFR ≤30 ml/min/1.73 m^2	**Absolute risk:** Unadjusted absolute risk of kidney failure in all cohorts[f]: 22 301 (12.1%) kidney failure overall among the 185 024 patients. Absolute risk not stratified by those with versus without history of CVD. **Relative risk:** HR for history of CVD = 0.91 (0.82–1.02) in the 19 cohorts with outcome information on kidney failure, CVD events, and death. HR for time-varying CVD = 2.28 (2.02–2.57) in the 19 cohorts with outcome information on KRT, CVD events, and death.	**Low** ●●○○

ACR, albumin-to-creatinine ratio; AKI, acute kidney injury; BP, blood pressure; CI, confidence interval; CKD, chronic kidney disease; CKD-EPI, CKD Epidemiology Collaboration; CVD, cardiovascular disease; eGFR, estimated glomerular filtration rate; HR, hazard ratio; KRT, kidney replacement therapy; MDRD, Modification of Diet in Renal Disease.

[a] The majority of the CKD-PC studies defined kidney failure as initiation of kidney replacement therapy (dialysis or kidney transplantation) or death due to kidney disease other than acute kidney injury [4, 24, 25, 27–31], whereas two studies defined kidney failure as initiation of kidney replacement therapy alone [26, 32].

[b] GRADE assessment of the certainty of evidence: High: We are very confident that the true prognosis (probability of future events) lies close to that of the estimate. Moderate: We are moderately confident that the true prognosis (probability of future events) is likely close to that of the estimate, but there is a possibility that it is substantially different. Low: Our confidence in the estimate is limited: the true prognosis (probability of future events) may be substantially different from the estimate. Very low: We have very little confidence in the estimate: the true prognosis (probability of future events) is likely to be substantially different from the estimate.

[c] PCR was not reported in this table as the results were similar to ACR.

[d] Values that were only provided in figures and were approximated using graph digitizing software.

[e] Results are from a single study, Kaiser Permanente Northwest.

[f] CKD-PC includes three cohort types based on source population, general population cohorts, high-risk cohorts selecting subjects at high cardiovascular risk (such as hypertension or diabetes), and CKD cohorts specifically enrolling subjects with CKD. Where not otherwise specified results refer to overall estimates within all three of these cohorts.

of developing kidney failure independently of eGFR and other clinical variables. In a collaborative meta-analysis that included 12 CKD cohorts and 21 321 patients reporting on ESKD outcomes, more severe proteinuria when measured by dipstick, ACR, or PCR was independently associated with an increased risk of kidney failure [4]. Among included studies, the unadjusted incidence rate for kidney failure was as high as 200 events per 1000 person-years in those with greatest degree of albuminuria, compared to rates of less than 10 per 1000 person-years for those with no albuminuria [4]. Similarly, the pooled relative risk of developing kidney failure increased significantly with higher categories of albuminuria, even after adjusting for age, comorbidities, and eGFR. Although there was significant heterogeneity between studies, the point estimates of association did not vary significantly between studies with the exception of one outlier that demonstrated a more strongly positive association between increasing ACR and kidney failure [33].

In the meta-analysis by Astor et al., both lower eGFR and higher albuminuria were independently associated with an increased risk of kidney failure and mortality in CKD cohorts [4]. In one cohort study that stratified by eGFR, patients with heavier albuminuria within each eGFR category had significantly increased adjusted rates of both kidney failure and mortality compared to those with lesser or no albuminuria [34]. In fact, those with heavy albuminuria but without overtly abnormal eGFR appeared to have worse clinical outcomes than those with moderately reduced eGFR and no albuminuria. Increasing severity of albuminuria may predict a more rapid rate of decline in kidney function, regardless of baseline eGFR [35].

These findings highlight the importance of considering the influence of albuminuria in addition to other clinical factors, such as eGFR, when assessing risk of CKD progression, and have contributed to interest in using albuminuria as a surrogate for progression to kidney failure [36, 37]. The most recent international clinical practice guidelines for CKD management acknowledge albuminuria as a valid and important independent predictor of kidney, cardiovascular, and mortality outcomes, resulting in a modification

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of the previous eGFR-based CKD staging system to a risk-based one that considers both severity of eGFR decline and albuminuria [5]. These guidelines refer specifically to use of albuminuria (i.e. ACR) rather than the proteinuria, as albumin is the primary component of urinary protein in most conditions, and the epidemiologic data supporting the association between proteinuria and outcomes is strongest for urinary albumin quantification.

Acute Kidney Injury

Acute kidney injury (AKI) is a potentially avoidable complication that may occur in hospital or the community. There is moderate certainty evidence that patients who have survived AKI have an increased adjusted risk of subsequent progression of CKD and kidney failure compared to those without an episode of AKI [34]. In a large cohort study of nearly one million individuals from Canada, an episode of AKI was associated with higher risk of long-term sustained doubling of serum creatinine or ESKD, with the largest increases in risk seen in individuals with higher eGFR and lesser degrees of proteinuria at baseline [38]. This illustrated that an episode of AKI provides extra prognostic information for progression of CKD in addition to that provided by eGFR and proteinuria. Pathophysiologic processes that are believed to contribute to the transition from acute injury to chronic damage include a failure of differentiation and persistently high signaling activity of regenerating cells in the tubulointerstitium, with inflammation, capillary rarefaction, and fibroblast proliferation ultimately contributing to progression of CKD [39].

In a systematic review and meta-analysis of 13 cohort studies, including over one million patients with follow-up ranging from 6 to 75 months, the pooled incidence of kidney failure was 8.6 events per 100 person-years, and was threefold higher for those with AKI than without AKI. The magnitude of the association between AKI and kidney failure varied substantially between the studies included in this systematic review; however, the definitions for AKI were heterogeneous between studies and all studies reported higher risks among patients with AKI. Furthermore, the risk of kidney failure increased in a graded manner with greater severity of AKI. More recently AKI has also been associated with a later risk of developing CKD even in patients with recovery of kidney function to normal levels [40], and a longer duration of AKI has also been associated with a higher risk of developing CKD [41].

Among patients who have had an episode of AKI, cohort studies have identified several factors that are associated with high risks of developing advanced CKD (eGFR $<30\,ml/min/1.73\,m^2$), including older age, lower baseline eGFR, more severe AKI, and incomplete recovery of kidney function [42, 43]. A multivariable model developed with 9973 participants with AKI and externally validated in a cohort with 2761 participants from Canada included age, sex, AKI stage, prehospitalization serum creatinine level, albuminuria, and discharge serum creatinine in the final risk index [44]. This model achieved a c-statistic of 0.81 and was well calibrated for predicting advanced CKD after hospital discharge. However, the clinical impact of using this model to guide care remains to be evaluated. Whether interventions to prevent AKI or enhance recovery from AKI reduce the risk of progressive CKD and ESKD remains uncertain.

Age

Age does not appear to uniformly influence the risk of developing kidney failure independent of the effect of baseline kidney function and albuminuria. In an individual-level meta-analysis of 46 cohorts and approximately two million patients, the adjusted incidence rate of kidney failure at a given level of eGFR was lowest for persons over age 75 years compared with those in younger age categories (e.g. 9.8 vs. 28.2 per 1000 person-years for ages >75 years and 55–64 years, respectively, at an eGFR of $45\,ml/min/1.73\,m^2$) [27]. However, once eGFR declined to $15\,ml/min/1.73\,m^2$, the adjusted risk of kidney failure was similar across age categories. Among the 13 CKD cohorts in this meta-analysis, similar findings of lower adjusted incidence rates of kidney failure among the oldest age group were reported, although the absolute risk of kidney failure appeared to increase steeply for individuals' ≥75 years of age with an eGFR below $25\,ml/min/1.73\,m^2$ to reach risk estimates comparable to other age groups. Overall, a trend toward lower risk of kidney failure was identified among older individuals, although the absolute and relative risks were not significantly different across age categories.

Kidney function generally declines with advancing age, the significance of which (and the extent to which it is considered pathological) has been debated [45]. In the meta-analysis described above, low eGFR was independently associated with mortality regardless of age, although the relative mortality risk was attenuated with increasing age [27]. Findings from previous studies suggest that elderly individuals are less likely to progress to kidney failure than they are to die from other causes [46], although these risks may vary depending on how kidney failure is defined, an individuals' baseline kidney function, and whether the kidney failure is treated with KRT. In the systematic review by Hallan et al., kidney failure was defined as initiation of dialysis, transplantation, or death as a result of kidney disease. However, this definition may fail to identify those whose who do not start dialysis for kidney failure

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and those who die from a nonkidney-related cause. One large cohort study suggested that whereas the absolute and relative risks of "treated" kidney failure (i.e. receipt of dialysis or kidney transplantation) are higher in younger compared to older people at a given eGFR, the rates of "untreated" kidney failure (progression to eGFR <15 ml/min/1.73 m^2 without renal replacement therapy) were significantly higher in older individuals [47]. This suggests that kidney disease does progress in older adults and that the incidence of kidney failure in this population may be higher than what has been assumed when kidney failure is defined only by receipt of KRT. These findings have implications for clinical practice and decision making for adults of all ages with CKD, including perception and communication of risk, and evaluation of treatment options.

Sex

Although females have a higher prevalence of CKD than males, observational studies from the United Kingdom and North America suggest that females have a lower risk of kidney failure than males [48]. Moderate certainty evidence from a meta-analysis of 13 CKD cohorts from Europe, North and South America, Asia, and Australasia, including 38 612 patients, have confirmed this finding, and also found no differences by sex in the relative risk of kidney failure associated with a greater degree of albuminuria or reduced eGFR [28, 49]. It is not yet clear the extent to which biological differences related to sex versus societal and social norms related to gender influence the higher incidence of KRT in men than in women.

Race

Moderate certainty evidence suggests that a patient's race does not independently influence his or her relative risk of developing kidney failure for a given eGFR, despite variations in baseline risk across racial groups. Pooled data from a meta-analysis of 45 cohorts indicate that the relative risk of kidney failure and mortality increases similarly among the three studied races (i.e. Asian, Black, and White) across a range of eGFR and/or albuminuria, with greatest risk at low eGFR and high albuminuria [29]. The majority of cohorts in this meta-analysis were from the general population, although a similar relationship was observed among the 13 CKD cohorts ($n = 36\,295$, 3% of the study population). For example, compared to a reference eGFR of 50 ml/min/1.73 m^2, Asian, White, and Black patients at an eGFR of 30 ml/min/1.73 m^2 had an approximately 2.5- to 3.5-times increased risk of developing kidney failure after adjusting for measured confounders. This is despite differences in clinical and demographic characteristics and absolute risk of kidney failure among the cohorts and racial groups. It is worth noting that in this study, most Black patients were from US cohorts, most Asian patients were from East Asian cohorts, and few cohorts included multiple racial groups.

The absolute risk of kidney failure appeared to be highest among Black patients in the general population cohorts of this meta-analysis (adjusted incidence rate 2.36 vs. 0.46 in White patients and 0.27 in Asians, per 1000 person-years) [29]. Unadjusted incidence rates in the CKD cohorts were similar. Genetic factors, including apolipoprotein L1 (*APOL1)* gene polymorphisms, contribute in large part to the significantly increased rates of kidney failure among Black patients; *APOL1* mutations, found exclusively in individuals of African descent, have been associated with earlier onset of CKD, increased albuminuria, and a more rapid decline in eGFR [50–52]. Whereas findings from other studies support differences in rates of kidney outcomes across racial groups and nationalities [53–56], race may also predict rate of eGFR decline and development of CKD in persons without known kidney disease. In one US population-based study, Black Americans and Hispanics with normal kidney function experienced more rapid rates of eGFR decline than White Americans and had higher rates of incident CKD [57]. Consistent findings of a relationship between eGFR and renal outcomes regardless of race support the use of internationally adopted practice guidelines that stage CKD according to eGFR and albuminuria without defining specific thresholds for racial groups [5]. However, to address modifiable risk factors and impact care delivery across populations with variable risk, it is important to consider the reasons for such baseline differences, including contributions of socio-cultural, environmental, and genetic influences [58].

Hypertension

As a cause and consequence of CKD [59], hypertension is a target of treatment in CKD, and there is moderate quality evidence that patients with CKD and hypertension have a higher incidence of progression to kidney failure and death. A large cohort study of 300 000 adults within the general population found that there were graded increases in the risk of kidney failure with increasing blood pressure and this relationship was independent of existing kidney disease [60]. These results are further supported by a large US cohort study of 332 544 men that found increasing risk of developing kidney failure with increasing severity of hypertension, with up to a 20 times greater risk among men with stage 4 hypertension in comparison to those with optimal blood pressure [60, 61]. Similarly, an increased risk of kidney failure has also been associated with hypertension in women [62].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Among patients with CKD, the relationship between hypertension and kidney failure is not uniform and varies based on eGFR and ACR levels. A meta-analysis of 13 CKD cohorts, comprising 21 072 patients with hypertension and 17 088 without hypertension, found an incidence of 19.5% (3327 kidney failure events) among those with hypertension and 12.3% (2597 kidney failure events) in the nonhypertensive patients [30]. Hypertensive patients, characterized by systolic blood pressure ≥140 mmHg and diastolic blood pressure ≥90 mmHg, had a higher risk of kidney failure at an eGFR of 50 ml/min/1.73 m^2 and ACR of 100 mg/g. However, the effect of hypertensive status was attenuated at lower eGFR and higher ACR levels, such that lower eGFR and increasing ACR levels corresponded with increasing risk of developing kidney failure [30] among patients both with and without hypertension. No significant interaction was found when antihypertensive medication use was incorporated into the analysis.

However, there is evidence for a protective effect on progression to kidney failure based on the type of antihypertensive treatment regimen. An individual patient-level meta-analysis of 11 randomized controlled trials (1946 patients) compared antihypertensive treatments with or without angiotensin converting enzyme (ACE) inhibitors and showed that patients with CKD who had proteinuria and were treated with ACE inhibitors were at significantly decreased risk of developing kidney failure (7.4%) in comparison to patients who received other antihypertensive regimens (11.6%) [63].

Taken together, this evidence suggests that hypertension increases the risk of kidney failure in the general population and CKD patients, but the relative prognostic importance of hypertension for progression to kidney failure tends to diminish at later stages of CKD.

Diabetes Mellitus

Diabetes is a common cause of CKD, and individuals with diabetes are at greater risk of kidney failure and mortality [64, 65]. Evidence from a large meta-analysis of over 100 000 patients reported that patients with advanced (i.e. stage G4) CKD and diabetes mellitus had a 30% higher event rate of kidney failure compared to those with advanced (i.e. stage G4) CKD without diabetes [32].

A second meta-analysis including 38 612 patients from 13 CKD cohorts investigated the association of diabetes (defined as fasting glucose of at least 7.0 mmol/l, nonfasting glucose of at least 11.1 mmol/l or HbA1c of at least 6.5%, use of glucose-lowering drugs, or self-reported) with risks of developing kidney failure [31]. These analyses were adjusted for other cardiovascular risk factors, including blood pressure, total cholesterol, body mass index, and history of cardiovascular disease. Findings indicated that diabetic patients had a higher relative risk of kidney failure when the references were set to an eGFR of 50 ml/min/1.73 m^2 and an ACR of 20 mg/g in nondiabetic patients. However, this relationship did not extend across low eGFR and high ACR levels, with no significant difference in the relative risk of kidney failure by diabetes status across the full range of eGFR values (hazard ratio [HR] 0.79, 95% confidence interval [CI] 0.56–1.13, *P* value 0.19) and ACR values (HR 1.08, 95% CI 0.95–1.23, *P* value 0.22). There is low certainty in this evidence due to the variability observed between studies.

While the aforementioned reviews did not specifically compare treated versus untreated diabetes, there is also evidence that patients with poor glycemic control are at greater risk of progression to kidney failure. A Canadian population-based cohort study found that among patients with diabetes and an eGFR of 30–59 ml/min/1.73 m^2, the risk of progression to kidney failure increased with increasing HbA1c [66]. Such patients with an HbA1c between 7% to 9% and higher than 9% had increased relative risks of 22% and 152%, respectively, of developing kidney failure compared to those with an HbA1c level <7%. This risk of kidney failure with increasing HbA1C diminished at eGFR levels of 15–29 ml/min/1.73 m^2.

Overall, individuals with diabetes and CKD have a higher risk of kidney failure in comparison to those without diabetes at normal eGFR and ACR levels, and this risk is heightened among patients with poor glycemic control. However, diabetic status provides less additional prognostic value for kidney failure at lower eGFR and higher ACR levels.

Cardiovascular Disease

Many studies have shown that CKD is associated with the development of cardiovascular disease, and traditional cardiovascular risk factors are also highly prevalent in patients with CKD [3, 67]. Some studies have shown that the risk of cardiovascular events and mortality is a prominent competing event in CKD and may exceed the risk of kidney failure in many patients. A meta-analysis of 28 cohorts across 30 countries included 185 024 patients with advanced CKD (i.e. CKD G4+) and found an overall incidence of 12.1% (22 301 events) for kidney failure requiring KRT [32]. Adjusted meta-analyses suggested no increased risk of kidney failure requiring KRT among those with a history of cardiovascular disease at cohort entry (defined by previous diagnosis of myocardial infarction, percutaneous coronary intervention, bypass grafting, heart failure, or stroke). However, when time-varying cardiovascular events were added to the model, they were significantly associated with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

increased risk of both progression to kidney failure (HR 2.28, 95% CI 2.02–2.57) and mortality (HR 2.87, 95% CI 2.57–3.20). The certainty of this evidence is low due to heterogeneity between the study cohorts and imprecision of pooled estimates.

Risk Prediction Models for Kidney Failure

The best ways to assess patient prognosis use prediction models that combine multiple risk factors to provide estimates of a patient's absolute risk of an outcome. Risk prediction models have been developed and tested in other clinical settings to inform clinical decision making. To be certain that a risk prediction model provides reliable prognostic information, it should undergo validation, ideally in a separate group of patients from those in whom the models were derived, to demonstrate the model's ability to discriminate between patients who will have an event and those who will not. Furthermore, the model should deliver predictions of absolute risk that are well calibrated to observed risks [68]. Three multivariable risk prediction models to predict progression to kidney failure have been developed and externally validated in cohorts with CKD (Table 3.2) [49, 69, 70].

In 2011 Tangri et al. reported the derivation and performance of kidney failure risk equations (KFREs) to estimate 2- and 5-year absolute risks of treated kidney failure, defined by the need for dialysis or a pre-emptive kidney transplant [49]. The models were derived in a cohort of over 3000 patients with CKD (eGFR <60 ml/min/1.73 m^2) cared for by nephrologists in Toronto, Canada, and externally validated in a separate cohort of almost 5000 patients receiving similar care in nephrology clinics in British Columbia, Canada. The most accurate model included eight variables (age, sex, eGFR, albuminuria, serum calcium, serum phosphate, serum bicarbonate, and serum albumin) and achieved a c-statistic of 0.92 in the development cohort and 0.84 in the validation cohort. Prediction model discrimination and calibration was also very good for a simpler, four-variable model including age, sex, eGFR, and albuminuria (Table 3.2). The generalizability of predictions based on the KFREs have since been demonstrated through external validation of the original four- and eight-variable equations in 31 cohorts from North America, Europe, Asia, and Oceania [71], including cohorts with patients not under the care of a nephrologist. The four-variable risk equation maintained very good discrimination and calibration in North American cohorts, although recalibration was required among non-North American cohorts to account for the lower incidence of kidney failure in these geographic regions. These findings provide strong evidence that estimates of the absolute risk of kidney failure can be achieved with a level of accuracy considered helpful for use in clinical decision-making, using demographic and commonly ordered laboratory tests for patients with a broad range of CKD stages.

Shroeder et al. have also developed and externally validated a pragmatic prediction model for the 5-year risk of progression to KRT among patients with stage G3 or G4 CKD [69]. The development and validation cohorts were composed of patients with CKD from two geographically distinct cohorts of patients from a large health maintenance organization in the United States. The final model included eight predictors: age, sex, eGFR, hemoglobin, proteinuria/albuminuria, systolic blood pressure, antihypertensive medication use, and diabetes and its complications. This multivariable model had excellent discrimination, with a c-statistic of 0.95, and maintained very good calibration in the external validation cohort, with the exception of slightly lower observed than predicted risk in the highest-risk quintile. These findings provide further evidence that a combination of demographic, clinical, and laboratory variables that are routinely collected in primary care can provide accurate estimates of the risk of kidney failure for patients across a broad range of stages of CKD.

Multivariable models have also been developed using data from over 260 000 individuals with eGFR <30 ml/min/1.73 m^2 from 30 countries included in the CKD-PC [70]. These models included nine prognostic factors (age, sex, race, eGFR, ACR, systolic blood pressure, smoking status, diabetes mellitus, and history of cardiovascular disease) and were developed to predict 2- and 4-year risks of competing outcomes of CKD, including kidney failure requiring KRT, a nonfatal cardiovascular event, and death. Discrimination of the model for risk of kidney failure at 2 years was very good, and when compared to the original four-variable KFRE developed by Tangri et al. showed similar discrimination (c-statistic 0.81 vs. 0.82), with good calibration when used for risk stratification into risk categories of <20%, 20–40%, and >40% predicted risk of kidney failure. These findings provide evidence that multivariable risk models can also aid with risk stratification for kidney failure in patients with advanced (G4) stage CKD and can be used to provide estimates of this risk in relation to competing risks of other relevant clinical outcomes of cardiovascular events and mortality before or after initiation of KRT.

Since publication of the original KFRE, several studies have examined strategies for model updating, with the addition of new or repeated measures in attempts to improve risk prediction for kidney failure. Tangri et al.

Table 3.2 Summary of findings: validated multivariable risk prediction models for kidney failure.

Model (author)	Cohort descriptions	Prognostic variables	Predictive performance	Tools for use
Kidney failure risk equations (Tangri et al.) [49]	Derivation cohort of 3 449 patients with CKD stages 3–5 from 2001 to 2008 at Sunnybrook Hospital, University of Toronto Health network, Toronto Canada. 11% developed kidney failure over 5 years Validation cohort of 4 942 patients with CKD stages 3–5 from 2001 to 2008 from the British Columbia CKD Registry. 24% developed kidney failure over 5 years	Eight-variable model; age, sex, eGFR, albuminuria, age, sex, eGFR, albuminuria, serum calcium, serum phosphate, serum bicarbonate, and serum albumin Four-variable model; age, sex, eGFR, albuminuria	Eight-variable model; c-statistic 0.92; (95% CI 0.90–0.93) in the derivation cohort and 0.84 (95% CI, 0.82–0.86) in the validation cohort. Four-variable model; c-statistic 0.91 (95% CI 0.89–0.93) in derivation cohort and 0.85, 0.83, and 0.83 at 1, 3, and 5 years, respectively, in the external validation cohort	A risk calculator is available online at www.kidneyfailurerisk.com, for use with an app for handheld electronic devices at https://qxmd.com/calculate/calculator, and as excel risk calculator provided in the supplementary material of the original publication
Kaiser Permanente risk of renal replacement therapy (RRT) model (Schroeder et al.) [69]	Derivation cohort of 22 460 patients in the Kaiser Permanente Northwest health maintenance organization with stage G3 or G4 CKD from 2002 to 2008. 4.7% developed kidney failure over 5 years Validation cohort of 16 553 patients in Kaiser Permanent Colorado from 2006 to 2008. 2.6% developed kidney failure over 5 years.	Age, sex, eGFR, proteinuria or albuminuria, hemoglobin, diabetes, systolic blood pressure, anti-hypertensive medication, and diabetes with number of complications	Derivation cohort: c-statistic 0.96 (0.95–0.97), $R^2 = 79.7\%$ (78.6–80.8) at 5 years Validation cohort: c-statistic 0.95 (0.94–0.97), $R^2 = 81.2\%$ (79.6–82.6)	An integer-based risk score is available in the original publication
CKD Prognosis Consortium models (Grams et al.) [70]	264 296 patients with eGFR <30 ml/min/1.73 m^2 from 29 cohorts and 30 countries included in the CKD Prognosis Consortium. 4-year risk of kidney failure ranged from <0.5% to 28% across cohorts.	Age, sex, race, eGFR, systolic blood pressure, history of cardiovascular disease, diabetes, albuminuria, smoking history.	c-statistic 0.814 (within cohort range in c-static of 0.680–0.972).	A risk calculator is available online through KDIGO at https://kdigo.org/equation

CI, confidence interval; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate.
Note: In all risk prediction models, kidney failure is defined as initiation of dialysis or kidney transplantation.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. assessed a dynamic risk prediction strategy using time-varying laboratory data in a cohort study of patients with CKD [72]. A latest-available-measurement predictive model with eGFR as a time-dependent predictor incrementally improved risk prediction for kidney failure compared to a static measurement model with only a single eGFR (integrated discrimination improvement 0.73%, 95% CI 0.56–0.90%), providing evidence that incorporating additional eGFR measurements over time can improve risk prediction. There is no good evidence that addition of other biomarkers can significantly improve upon the existing KFREs for predicting risk of kidney failure in CKD populations. In one cohort study of patients with CKD who underwent duplex ultrasonography testing, adding renal resistive indices did not improve risk prediction for kidney failure beyond the four- and eight-variable KFRE [73] models. In another cohort study of patients with CKD who had undergone a kidney biopsy confirming diabetic nephropathy, the addition of a score based on pathological biopsy features (the Diabetic Nephropathy Classification Score of the Renal Pathology Society) to the KFRE did not significantly improve risk prediction of kidney failure [74].

Clinical Application and Impact of Kidney Failure Risk Prediction Models

Several potential clinical uses for prognostic information on kidney failure risk have been proposed, which may include the use of this information by patients and family members, primary care clinicians, specialists, health system payers and policy makers. However, there is little evidence guiding their application and assessing their impact in the clinical setting. Three studies have reported on patient or provider perspectives and experiences on the potential impact of implementation of kidney failure risk prediction models in clinical care (Table 3.3) [75–77].

Table 3.3 Summary of findings: clinical implementation and impact of risk prediction models for kidney failure.

Study	Design	Population	Objective and model implementation	Findings
Chiu 2015 [75]	Quantitative (surveys)	111 nephrologists across Canada	To determine perspectives on the importance of predicting kidney failure, risk thresholds that would influence CKD treatment plans, and experiences using existing risk prediction tools.	80% of respondents were not satisfied with their current ability to predict kidney failure, cardiovascular outcomes, and death, and most indicated that they would use validated risk scores to predict clinical outcomes. Risk prediction over a 1- to 5-year time frame was felt to be important for clinical decision making, such as guiding referral for arteriovenous fistula creation.
Hingwala 2017 [76]	Quantitative (quasi-experimental)	Patients referred for nephrology assessment in Manitoba, Canada from 1 January 2013 to 31 December 2013	To describe the incorporation of the KFRE in a triage system for general nephrology referrals. Patients with a 5-year kidney failure risk of ≥3% were booked with nephrology either urgently (risk ≥10%) or nonurgently (risk 3–10%); those with a risk of <3% were referred back to their family physician.	34% of referrals were classified as low risk and referred back to their family physician. The median wait time for nephrology consultation improved from 230 days to 58 days post triage.
Smekal 2018 [77]	Qualitative (focus groups, interviews, open-ended survey responses)	Adult patients with non-dialysis CKD and their family members ($n = 12$ across two focus groups), and healthcare providers (nurses, nephrologists [$n = 16$ interviews; $n = 40$ survey respondents]) from a multidisciplinary CKD clinic in Alberta, Canada	To explore perceived benefits and challenges of implementing a KFRE-based approach to determine eligibility for multidisciplinary CKD care.	Perceived challenges to implementing a risk-based CKD care approach included lack of capacity to manage low-risk patients outside of the CKD clinic setting and more fragmented care. Perceived benefits included targeted care for CKD patients at highest risk of progression and improved program efficiency.

CKD, chronic kidney disease; KFRE, Kidney Failure Risk Equation.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Chiu et al. surveyed 111 Canadian nephrologists about their views on and experiences with CKD risk prediction tools [75]. Approximately 80% were dissatisfied with their current ability to predict risk of kidney failure, cardiovascular events, and death among CKD patients, and the majority indicated that they would use validated risk scores if such tools accurately predicted risk and influenced their management to improve clinical outcomes. Furthermore, this survey was able to characterize nephrologist consensus on risk thresholds at which treatment decisions should be made, such as arteriovenous fistula planning when a patient's 1-year predicted kidney failure risk exceeded 30–50%.

Two studies have evaluated the impact of the KFRE in clinical nephrology practice, including in the triage of nephrology CKD referrals [76] and determining eligibility for multidisciplinary CKD clinic care [77]. Hingwala et al. applied a KFRE-based threshold of 3% kidney failure risk over 5 years to triage referrals to specialist nephrology assessment. Approximately one-third of referrals were considered low risk and consequently were referred back to their family doctor with CKD care recommendations provided in a standard "low risk letter." In the post-triage period, the median wait time for nephrology assessment decreased from 230 to 58 days, suggesting that this approach may help improve access to nephrology care for patients at highest risk of progression to kidney failure. Smekal et al. sought the perspectives of patients with CKD, their families, and nephrology healthcare providers on the use of the KFRE to determine patient eligibility for multidisciplinary CKD clinic care (2-year kidney failure risk ≥10%) or general nephrology care (2-year kidney failure risk <10%). In focus groups, interviews, and open-ended survey responses, participants expressed concern about the lack of capacity to manage lower risk CKD patients in the community and loss of services for patients previously followed in the multidisciplinary setting. However, they also recognized the potential efficiency gains and focused allocation of resources in providing targeted CKD care for those at highest risk of kidney failure.

These studies have primarily examined perceptions and experiences surrounding implementation of the KFRE to inform risk-informed nephrology care in the Canadian context. However, the broader clinical impact of using risk prediction models in practice remains uncertain. Although the use of kidney failure risk estimates have been proposed to inform several clinical decisions in CKD management [78], successful strategies for their implementation in clinical practice, utility in clinical decision making, and subsequent impact on patient-, provider-, and system-level outcomes [79, 80] has yet to be comprehensively evaluated. Such data will contribute to the generation of an important evidence base for the effectiveness of kidney failure risk prediction models in the care of people with CKD.

Conclusions

High-quality evidence has established substantial variability in the risk of progression of CKD, and that demographic, clinical, and laboratory variables can provide independent prognostic value for the prediction of kidney failure. eGFR and albuminuria are well characterized, strong risk factors for progression of CKD to kidney failure, with high certainty evidence supporting the use of these variables in combination to assess CKD prognosis. Validated multivariable models that incorporate these and other readily available demographic and clinical risk factors are now available for use as kidney failure risk stratification tools in clinical practice (Figure 3.2). Whether implementation of these risk prediction models in clinical care improves patient outcomes and experiences in CKD care remains uncertain, and further research in the area of clinical application and impact is needed.

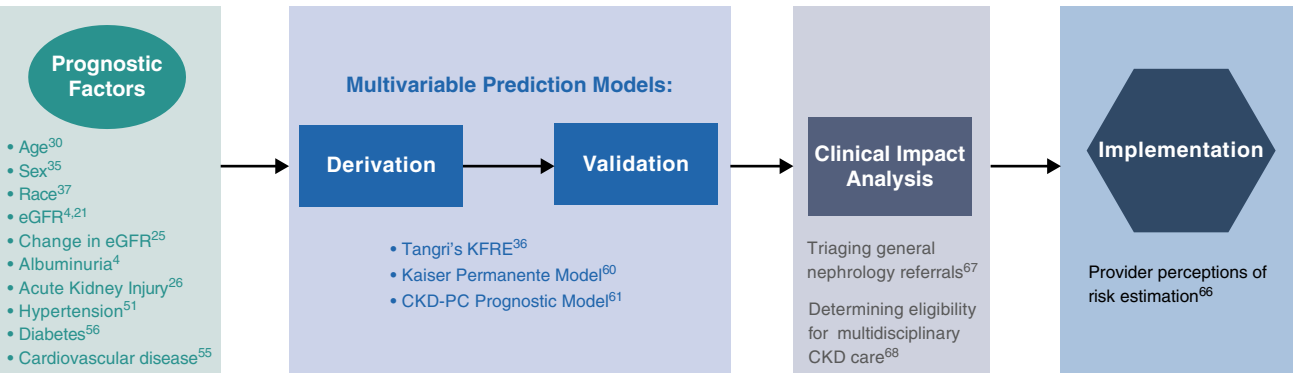

Figure 3.2 Phases in evidence generation to establish risk prediction models for CKD progression in clinical practice. CKD, chronic kidney disease; CKD-PC, Chronic Kidney Disease Prognosis Consortium; eGFR, estimated glomerular filtration rate; KFRE, kidney failure risk equation.

List of Abbreviations

ACR	albumin-to-creatinine ratio
AKI	acute kidney injury
BP	blood pressure
CI	confidence interval
CKD	chronic kidney disease
CKD-EPI	CKD Epidemiology Collaboration
CKD-PC	Chronic Kidney Disease Prognosis Consortium
eGFR	estimated glomerular filtration rate
ESKD	end-stage kidney disease
GFR	glomerular filtration rate
GRADE	Grading of Recommendations Assessment, Development and Evaluation
HbA1C	hemoglobin A1C
HR	hazard ratio
KFRE	kidney failure risk equation(s)
KRT	kidney replacement therapy
MDRD	Modification of Diet in Renal Disease
PCR	protein-to-creatinine ratio
U.S.	United States

An ounce of prevention is worth a pound of cure.
Benjamin Franklin

Introduction

Screening is performed to differentiate healthy people from those in the early stages of disease who are not experiencing symptoms or exhibiting signs of illness. This might be justified when effective early interventions are available that lead to better outcomes, for example screening for motor neuron disease would do more harm than good, given the lack of effective interventions and risk of overdiagnosis, false-positive results, and associated anxiety [1]. This chapter aims to discuss the utility of a screening program for chronic kidney disease (CKD) with regard to associated outcomes and costs.

CKD is highly prevalent in many countries and access to treatment is often limited [2, 3]. CKD tends to be an asymptomatic condition that goes undetected until its later stages when most kidney function has been lost [4]. The asymptomatic nature of kidney disease is one of the main reasons why several patients in developing countries often present late for kidney care when dialysis is urgently needed [5]. Late presentation, which is associated with increased mortality, [6] may be due to late referral; however, a lack of access to healthcare plays a major role in many low-income countries. Screening for CKD and early detection to slow disease progression is thus important in these settings, given the high costs associated with treatment. The findings of one study that assessed the cost utility of one-off, point-of-care screening and treatment for CKD among a rural adult Canadian indigenous population revealed an incremental cost-effectiveness ratio (ICER) of $23 700 per quality-adjusted life-year (QALY) compared to usual care [7]. Findings from a systematic review show the cost-effectiveness ratios for proteinuria screening to be $14 063–$160 018 QALY for the general population, $5298–$54 943 QALY for diabetics, and $23 028–$73 939 QALY for hypertensives [8]. However, the cost-benefit ratios of screening have not been adequately studied in developing countries where such assessments are largely needed.

Who Should be Screened for CKD?

Most countries do not have a coordinated approach to CKD screening, leading to so-called "opportunistic screening." Several researchers have used World Kidney Day as a platform to increase awareness of the importance of CKD screening [9–12]. Because screening techniques are not standardized, data on CKD prevalence often are unreliable, even within a single country or region [10, 13]. Even in countries with national programs for early detection of CKD, treatment plans often are unclear and access to healthcare resources may be limited [14]. Large-scale, population-based screening programs should include follow-up protocols and successful care referrals for individuals who test positive to ensure appropriate diagnosis, treatment, and counseling.

A major problem with screening for CKD revolves around who to screen: the general population or only at-risk populations such as those with diabetes, hypertension, family history of CKD, and other patient groups at

increased risk for CKD, such as those with HIV. This conundrum has generated much debate [15]. Those in favor of general population screening argue that early identification is clinically and scientifically relevant to reduce the burden of CKD [16, 17], while others use the same argument to support screening among at-risk populations only [4, 8, 18–21]. In a population-based study of dipstick screening, Boulware et al. [22] reported an unfavorable ICER for screening individuals with neither hypertension nor diabetes ($282 818 QALY), but more favorable ratios for screening individuals age 60 and older ($53 372 QALY) and those with hypertension ($18 621 QALY). The authors concluded that routine proteinuria screening is only cost-effective for high-risk populations or when performed very infrequently (i.e. every 10 years) [22]. Those supporting targeted screening even suggest that harms may be associated with mass screening due to false-positive results and unnecessary testing and treatment. Overall, there is insufficient evidence that providing early treatment for patients without risk factors who are identified via screening yields benefits [19]. The American College of Physicians (ACP) recommends against screening for asymptomatic adults without risk factors for CKD, as well as adults who are receiving renin-angiotensin-aldosterone system (RAAS) blockade therapy due to low-quality evidence [23]. Due to insufficient evidence, Kidney Disease – Improving Global Outcomes (KDIGO) did not comment on the benefit of screening for early detection of disease versus the harm of "disease labeling" [24]. As one analysis suggested, screening for CKD may be cost-effective for at-risk patients (i.e. individuals with diabetes and hypertension) and populations with higher incidences of CKD and rapid rates of progression (e.g. HIV-positive patients and relatives of CKD patients) [8, 25].

Methods of CKD Screening and Characteristics of Screening Tests

Ideally, we would like to have a test with very high sensitivity and specificity. However, there is usually a trade off between these two properties of the test. Imagine we want to decide on a cut-off value for estimated glomerular filtration rate (eGFR) to define CKD. The lower the cut-off value, the lower the likelihood of mislabeling a healthy person with CKD, but the higher the likelihood of missing some patients with CKD [26]. Any screening program is associated with costs and potential harms (i.e. false-positive results causing unnecessary anxiety, overdiagnosis, and overtreatment). As the frequency of screening increases the marginal benefit will plateau, and cost and harm will increase disproportionately. Therefore, it is important to choose the right frequency for any screening program [27].

A successful detection method is a test with high validity (i.e. specificity and sensitivity). Such a test should also be highly reliable (i.e. consistently yield the same results when repeated under the same conditions) [28]. Albuminuria is an early and sensitive marker of CKD, whether it is estimated via a 24-hour measurement (gold standard) or dipstick assessment of spot urine. Screening for CKD relies on quick and simple methods to assess kidney function, such as testing urine for protein (albumin) and/or measuring serum creatinine. Although a CKD diagnosis is confirmed based on two abnormal results with a repeat test conducted after a 3-month period [29], for the purpose of screening and early disease detection, one abnormal result is considered a positive test. The CKD prevalence rates reported from screening tests thus depend on the assessment methods utilized, with a potential to under-report or over-report identified cases of CKD [16, 30, 31]. For instance, in a large study in Japan, Uchida et al. [32] showed that a significant proportion of CKD might be under-reported if only dipstick proteinuria is used to assess kidney function, and strongly recommended that both urinalysis and serum creatinine measurement be used in CKD screening. Among 538 846 people, 14.4% had an eGFR below 60 ml/min/1.73 m^2, 5.2% had proteinuria, and 18.1% had CKD, 71.4% of whom had nonproteinuric CKD (47.9% had diabetes mellitus and 66.8% had hypertension). In contrast, a single assessment of serum creatinine level in the third National Health and Nutrition Examination Survey (NHANES III) was reported as misleading due to age, gender, and ethnic variability [33].

Existing CKD Early Detection and Prevention Programs

CKD diagnosis requires detecting persistent structural (albuminuria) or functional (low eGFR) abnormalities of the kidney through laboratory measurements [29]. Collectively, the factors described above make CKD well-suited for population-based screening for early detection and treatment. Wilson and Jungner's first screening principle is the importance of the condition based on its prevalence [34]. Therefore, in this section we examine CKD prevalence data and summarize relevant population-based studies of CKD epidemiology in various parts of the world, and report on recent findings that reveal national capacities for CKD screening and detection with the following objectives:

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. - To perform a review of the literature of the population-based epidemiology of CKD.
- To describe such studies in terms of design, scope, population, CKD outcomes, and relevant findings.
- To identify areas for further work.

We conducted an extensive literature review by performing a broad and intensive search for population-based studies of CKD published between 2000 and 2018. We searched several databases (i.e. PubMed, Cinahl, Embase, and Cochrane) using the following keywords: population-based, community, screening, chronic kidney disease, CKD, chronic kidney failure, CKF, end-stage renal disease, ESRD, end-stage kidney disease, ESKD, early detection, prevention, management, risk factors, epidemiology, albuminuria, microalbuminuria, and proteinuria. Only studies that examined CKD and/or albuminuria in a community setting and were published in English were retrieved. To be included, a study had to:

- include a measure of prevalence for CKD and/or albuminuria in a general population
- be based on data collected from adults aged 18 years and older who were recruited from a community-based population sample
- present sufficient detailed methodology and results, as well as ethical approval from the relevant authorities
- be the original and/or most recent publication if multiple studies based on data from the same population exist

To inform efforts for the prevention, detection, and treatment of CKD, it is vital to have high-quality evidence that yields accurate estimates of the disease burden in the population. The most recent systematic review and meta-analysis estimate the global prevalence (44 countries) of CKD to be 13.4% (95% confidence interval [CI] 11.7–15.1%) [35]. Another systematic review and meta-analysis estimates worldwide CKD prevalence to be 10.4% among men (95% CI 9.3–11.9%) and 11.8% among women (95% CI 11.2–12.6%) [36]. These estimates of global CKD burden in the low double-digits were calculated by combining CKD prevalence data published in the literature. There are several methods to obtain population-level epidemiological data on CKD burden, and each has its benefits and drawbacks. The most commonly used are health examination surveys [37]. When coupled with a representative random sample of the national population, these cross-sectional studies can provide insights into the true prevalence of disease and associated risk factors. Moreover, periodic health examination surveys can be used as surveillance tools to monitor disease trends over time. For example, the NHANES, one of the earliest attempts to quantify CKD burden since the introduction of the CKD staging system, has been instrumental in estimating the scale of CKD prevalence in the United States at 13.1% (95% CI 12.0–14.1%) [37]. If well executed, surveys can provide precise data for estimating CKD prevalence. However, they can be associated with limitations related to (i) cross-sectional data collection, which typically entails a single measurement of kidney function instead of repeat testing to establish CKD diagnosis, (ii) the vast financial and human resources required to perform large scale surveys [38], and/or (iii) the methods used to estimate CKD, such as eGFR equations, calibrations, and standardized assays of serum creatinine and albuminuria [39].

Another approach to quantifying CKD burden is to analyze data stored in administrative databases, which often hold records on a large number of individuals that cannot easily be surveyed. These databases often can be repurposed to provide information on CKD burden in the population. For instance, Go and colleagues used data from the Kaiser Permanente renal registry, a sizeable health plan laboratory database in the United States, to estimate the morbidity (cardiovascular events, hospitalization) and mortality associated with CKD [40]. They reported an inverse and graded relationship between a decrease in kidney function and increased risk of death, cardiovascular events, and hospitalization using large population data [40]. This technique has the advantage of obtaining data on a large segment of the population over long periods of time while requiring relatively fewer resources than prospective studies. However, some known disadvantages of this approach are (i) the accuracy of the data, since they typically are collected for purposes other than research, (ii) the representativeness of the target population, because most data in administrative databases are from people with access to healthcare, making generalizability to the whole population challenging, (iii) the lack of well-established health systems that collect data using rigorous methods in many parts of the world, and (iv) the observational nature of these study designs and the potential for biases. Of note, data obtained from surveys can be stored and later linked to other databases or analyzed in retrospective studies to answer different research questions.

The Global Burden of Disease (GBD) studies have revealed additional insights about the burden of CKD. The GBD studies are systematic, scientific efforts using Bayesian inferences and sophisticated statistical modeling to quantify the burden of all major diseases, including CKD [41, 42]. The GBD studies involve more than 3000 collaborators and cover more than 195 countries from 1990 to date. In the GBD studies, CKD's ranking among the hierarchical causes of disability-adjusted life years (DALYs) rose from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

30 to 22 between 1990 and 2016 [43]. In addition, the GBD studies predicted an estimated 28.8% increase in CKD prevalence from 2006 to 2016; importantly, more than half of the increase was attributed to diabetes (+30.1%) and hypertension (+34.7%) [44]. Although GBD studies are currently at the forefront of global efforts to estimate disease burden, they have several limitations, including coding practices, sampling measurement, and case definition errors involved in obtaining and merging this voluminous data from a wide array of sources [41, 42]. Finally, prospective registries that collect data for surveillance and monitoring purposes are important sources for estimating CKD burden. Although end-stage kidney disease (ESKD) registries on disease incidence and prevalence are well established in many developing countries, predialysis CKD registries are almost nonexistent. In the Global Kidney Health Atlas (GKHA) survey, only nine out of 125 countries surveyed reported viable CKD registries [45].

National Capacity for CKD Screening

The GKHA project evaluated national capacities to detect CKD in both primary and secondary care settings (Figure 4.1), including several CKD screening-related anthropometric and laboratory measurements that are necessary to identify CKD risk factors or kidney damage. Interestingly, less than half of low-income countries did not have the capacity to routinely test for serum glucose, serum creatinine urinalysis (qualitative and quantitative), and urine portions in primary care settings. Moreover, none of the low-income countries reported the capacity to automatically report eGFR or test for urine proteins in primary care settings. Similarly, lower-middle income countries reported limited capacity to measure HbA1c and serum creatinine with and without eGFR, and to perform urinalysis (qualitative and quantitative) and measure urine proteins. While less than half of upper-middle income countries had these capacities, the majority of high-income countries reported the availability of these services (Figure 4.1). As expected, CKD-related health services were more available in secondary care settings; however, capacities for automated eGFR reporting and proteinuria assessment were limited compared to the other services, especially in low income countries.

CKD Testing for High-risk Populations

The GKHA evaluated routine testing for CKD among several high-risk populations (Figure 4.2). Across countries in all income groups, CKD testing was almost universal for patients with hypertension and diabetes (94–100%), but minimal for high-risk ethnic populations (<30%). More than 50% of countries tested for CKD in patients with cardiovascular disease who were taking chronic nephrotoxic medications and with a family history of CKD. Elderly populations (age ≥65 years) also were tested for CKD in more than half of the countries in the high and upper-middle income groups, but not in the lower-middle (47%) and low (41%) income groups. Overall, CKD testing rates followed the economic development classification, with the highest rates in higher income countries and lowest rates in low-income countries (Figure 4.2).

CKD Detection Program

The GKHA also evaluated the presence of an active CKD detection program based on national policies and/or guidelines. Overall, less than a third of countries reported having a CKD detection program. Most of the programs were in high-income countries (32%), followed by upper-middle (27%) and lower-middle (22%) income countries. Among the responding low-income countries, only one reported an active CKD detection program (Figure 4.3). The majority of countries with CKD detection programs implemented them through active screening during routine health encounters (68%) or through specific screening processes (57%), while 54% reported a reactive approach in their program implementation (Figure 4.3). These findings indicate that there is no single program implementation approach. Moreover, many countries reported more than a single method in their program implementation.

From what has been presented so far, it can be inferred that many studies have been performed worldwide on the prevalence of CKD at both the national and community levels. Many of these studies are based on the initial observation by the NHANES III that up to 11% of the US population may have CKD. Prevalence of albuminuria/proteinuria in the results ranges from 0.6% to 29.7% in general population studies, and from 2.7% to 45.4% in studies of high-risk individuals. Overall, there is a graded effect in terms of the number and size of the studies observed, from high-income countries to low-income countries. These significant variations may undermine developing countries' abilities to develop screening programs tailored to their contexts. Recent findings from the GKHA that many countries have insufficient capacity for detecting and monitoring CKD in both primary and secondary care settings is concerning. Any discussion of CKD screening programs implies resource availability and testing capabilities. Currently, the two pillars of CKD detection are estimated GFR from serum creatinine and urine proteins, and capacities to perform these measurements are significantly limited in many parts of the world.

Review of Current Guideline Recommendations for CKD Screening

In 2012, the US Preventive Services Task Force (USPSTF) reviewed evidence related to screening for CKD in asymptomatic adults and concluded that it is insufficient to assess the balance of benefits and harms of routine testing. Thus, they did not provide any recommendations in their report, even for people with diabetes and hypertension [47]. Likewise, the ACP did not find any randomized control trials evaluating the benefits or harms of screening for CKD stages 1–3 among the general population. They pointed out potential harms of universal screening, including disease labeling, adverse effects of testing and treatment, and financial consequences. Thus, they recommended against screening for CKD in asymptomatic adults without risk factors for CKD (grade: weak recommendation, low-quality evidence). They also recommended against testing for proteinuria in adults with or without diabetes who are currently taking an angiotensin-converting enzyme inhibitor (ACEi) or an angiotensin II–receptor blocker (grade: weak recommendation, low-quality evidence). The ACP also found the current evidence insufficient to evaluate the benefits and harms of screening for CKD in asymptomatic adults with CKD risk factors [23]. These recommendations were endorsed by the American Academy of Family Physicians

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. (AAFP) in a guideline statement published in 2014 [48]. In the UK, the National Institute of Health and Care Excellence (NICE) made several recommendations regarding CKD screening for at-risk populations [49]. NICE did not make any explicit recommendation for asymptomatic people without known risk factors for CKD, and strongly recommended against using age, gender, ethnicity, obesity in the absence of a metabolic syndrome, diabetes, or hypertension as risk factors. For people with risk factors for CKD, they recommended offering CKD screening tests, and for patients with nephrotoxic drug prescriptions, they strongly suggested annual screening for CKD.

Although the American Society of Nephrology does not have a guideline, it issued a press release in response to the ACP guidelines in which they strongly suggested screening for CKD among general populations, regardless of risk factors [50]. In 2013, KDIGO published one of the most comprehensive guideline recommendations for management of CKD; however, these guidelines do not explicitly include screening recommendations [29]. In 2002, the National Kidney Foundation (NKF) and the Kidney Disease Outcome Quality Initiative (KDOQI) had recommended screening at-risk individuals for CKD [51]. In a 2014 commentary on the 2012 KDIGO guidelines, they highlighted KDIGO's lack of specific recommendations for CKD screening and endorsed their previous recommendation to screen individuals at high risk for developing CKD [52]. They disagreed with the ACP's recommendation not to screen patients who take ACEi or angiotensin receptor blocker (ARB) medications.

Other renal organizations around the world have published their own commentaries or recommendations, with a common theme of screening individuals at high risk for CKD. In its commentary on the KDIGO guidelines, the Canadian Society of Nephrology outlined consensus statements. They did not recommend screening individuals for CKD, but recommended that practitioners continue to use case findings as a means to identify patients with CKD in high-risk populations [53]. The Kidney Health Australia – Caring for Australasians with Renal Impairment (KHA-CARI) guidelines strongly recommend screening people at higher risk of CKD due to diabetes, hypertension or established cardiovascular disease (1B), or additional risk factors such as obesity, a history of smoking, Aboriginal and Torres Strait Islander heritage, family history of stage 5 CKD or hereditary kidney disease in a first- or second-degree relative, or severe socioeconomic disadvantage (1D) [54]. Similarly, the UK Renal Association strongly recommends screening patients at higher risk of CKD (1B) [55]. These recommendations are summarized in Table 4.1.

Effectiveness of Screening for CKD in Terms of Costs and Consequences

Given its silent nature and associated negative consequences, early detection and treatment of CKD must be emphasized. One way to achieve these goals is to perform primary screening for CKD using blood or urine tests; however, it is important to understand the cost-effectiveness of doing so prior to adopting such an approach [8, 56–59]. In healthcare settings, decisions typically are made with consideration to benefits, risks, and costs, yet the economic component of any program arguably is the key determinant. Economic analyses are decision tools based on formal quantitative methods to investigate and compare program adoption to the usual care and/or no care while taking into account the costs of diverting resources from competing priorities, otherwise known as opportunity costs. The most widely used economic measurement to compare and evaluate programs with different costs and outcomes is ICER. ICER is the ratio of the difference in costs to the difference in benefits of the program or intervention. Costs typically are represented in monetary terms, while benefits are expressed in clinical terms such as life-years gained (LYG) or lost, or QALYs gained or lost. QALY is a bi-dimensional composite measurement of length of life and quality of life expressed in a single number. ICER is a way to ascertain both the effectiveness and cost of an intervention compared to another, hence the name cost-effectiveness. Additionally, interpreting ICER requires a value judgment to be placed on the opportunity cost of QALY or LYG. Since data on opportunity costs are limited, determining this threshold can be challenging and tends to be based either on historical funding decisions (e.g. $50 000 per QALY from dialysis) or consensus agreements (e.g. $80 000 per QALY).

Several studies have looked into the cost-effectiveness of screening for CKD using eGFR and/or proteinuria [59–70]. These studies (chapters 17, 22,59 and 62–67) are nicely summarized in a recent systematic review on the cost-effectiveness of CKD screening studies from 1992 to 2012 (Table 4.2) [8]. In this section, we use these systematic review studies as a framework to evaluate the cost-effectiveness criteria for CKD screening.

None of the included studies were randomized control trials, and all were based on Markov simulation models. Seven of the studies evaluated proteinuria, one study evaluated eGFR, and another study evaluated both proteinuria and eGFR as CKD screening methods. The comparator to screening was usual care in four studies, no screening in three studies, and both in two studies. As cost-effectiveness modeling assumptions depend on high-quality evidence, all of the included cost-effectiveness studies were based on

Table 4.1 Screening recommendations by the professional medical and nephrology societies.

Organization	Nature of organization	Date	Population	Recommendation statement	Strength and evidence of recommendation
US Preventive Services Task Force	Government/ Generalist	2012	Asymptomatic adults without diagnosed CKD	No recommendation	Grade I (insufficient evidence): The evidence is insufficient to assess the balance of benefits and harms of routine screening for CKD in asymptomatic adults. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.
American College of Physicians	Generalist	2013	Asymptomatic adults without risk factors for CKD	ACP recommends against screening for chronic kidney disease in asymptomatic adults without risk factors for chronic kidney disease	Grade: Weak recommendation, low-quality evidence
American Academy of Family Physicians	Generalist	2014		Endorsed recommendation made by the American College of Physicians	
National Institute of Health and Care Excellence (NICE), UK	Generalist	2014; updated 2015	People prescribed nephrotoxic drugs	1.1.27 Monitor eGFR at least annually for people prescribed drugs known to be nephrotoxic, such as calcineurin inhibitors (for example, cyclosporin, or tacrolimus), lithium and non-steroidal anti-inflammatory drugs (NSAIDs) (2008, amended 2014)	Strong
			People with risk factors for CKD	1.1.28 Offer testing for CKD using eGFR creatinine and ACR to people with any of the following risk factors: diabetes, hypertension, acute kidney injury, cardiovascular disease (ischemic heart disease, chronic heart failure, peripheral vascular disease, or cerebral vascular disease), structural renal tract disease, recurrent renal calculi or prostatic hypertrophy, and multisystem diseases with potential kidney involvement, e.g. systemic lupus erythematosus, family history of end-stage kidney disease (GFR category G5), or hereditary kidney disease, opportunistic detection of hematuria	Strong
			Asymptomatic adults	1.1.29 Do not use age, gender or ethnicity as risk markers to test people for CKD. In the absence of metabolic syndrome, diabetes, or hypertension, do not use obesity alone as a risk marker to test people for CKD [2008, amended 2014].	Strong

Table 4.1 (Continued)

Organization	Nature of organization	Date	Population	Recommendation statement	Strength and evidence of recommendation
American Society of Nephrology	Renal organization	2013	Asymptomatic adults	Strongly recommends regular screening for kidney disease, regardless of an individual's risk factors	
National Kidney Foundation/Kidney Disease Outcomes Quality Initiative	Renal organization	2002	Individuals at risk for CKD	Guideline 3: Individuals at increased risk of CKD: Some individuals without kidney damage and with normal or elevated GFR are at increased risk for development of CKD. All individuals should be assessed, as part of routine health encounters, to determine whether they are at increased risk of developing chronic kidney disease, based on clinical and sociodemographic factors. Individuals at increased risk of developing CKD should undergo testing for markers of kidney damage and to estimate the level of GFR. Individuals found to have CKD should be evaluated and treated as specified in Guideline 2. Individuals at increased risk but found not to have CKD should be advised to follow a program of risk factor reduction, if appropriate, and undergo repeat periodic evaluation.	Opinion
		2013	Individuals at risk for CKD	The commentary work group endorses the recommendations from the original guideline for screening among individuals at high risk for CKD despite the absence of this specific recommendation in the KDIGO guideline, and as such is in agreement with the recommendation of the ACP to screen asymptomatic adults only if they are at high risk for CKD.	Opinion
Kidney Disease Improving Global Outcomes	Renal organization	2013		Screening of CKD was beyond the scope of the CKD Work Group and no specific recommendations were made.	
Canadian Society of Nephrology	Renal organization	2015	Asymptomatic individuals	No screening	Consensus

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

			At risk of CKD	Practitioners should continue to use case findings in keeping with usual clinical practice: in people with new onset or long-standing hypertension or diabetes, people with vascular disease, people who are to undergo major surgery or be exposed to other potential causes of acute kidney injury, people with multisystem or generalized symptoms, people who are being considered for nephrotoxic medications or medications that require dose adjustment for renal function, people with a family history of polycystic kidney disease or hereditary nephritis, and people from First Nations populations or other ethnic groups known to be at increased risk.	Consensus
KHA-CARI Guidelines	Renal organization	2013	Diabetes, hypertension, or established cardiovascular disease.	We recommend that screening for CKD be targeted and performed in individuals at increased risk of developing CKD, including those with diabetes mellitus, hypertension, and established CVD	1B
			Additional risk factors such as: obesity, cigarette smoking; Aboriginal and Torres Strait Islander peoples; family history of stage 5 CKD or hereditary kidney disease in a first- or second-degree relative; and severe socioeconomic disadvantage.	We recommend screening in those with additional CKD risk factors identified in Guideline 2a (obesity, cigarette smoking, Aboriginal and Torres Strait Islander peoples, family history of stage 5 CKD, or hereditary kidney disease in a first- or second- degree relative and severe socioeconomic disadvantage) (1D)	1D
UK Renal Association	Renal organization	2011	At-risk for CKD	Guideline 1.4 – CKD: Detection and monitoring of CKD: We recommend that patients who are at increased risk for developing CKD should be offered screening tests to detect CKD.	1B

data from high-income countries in North America (the United States and Canada), Europe (Netherlands, Switzerland), Asia (Japan), and Australia. The majority of studies took a healthcare perspective while two studies adopted a broader social perspective. Screening frequency varied from annual to biannual, to several year intervals, and some evaluated on–off scenarios. The majority of included studies determined cost ratios by measuring cost to QALYs; however, two studies used cost to LYG as the summary measure (Table 4.2). Proteinuria-based studies yielded a wide range of cost ratios ranging from $14 000 to more than $160 000 per QALY among the general population, from $5000 to more than $50 000 per QALY among people with diabetes, and from $23 000 to more than $70 000 among hypertensive populations (Figure 4.4). In eGFR-based studies, the cost ratio was around $100 000 per QALY for the general population in two studies and $20 000 per QALY for diabetes patients in a single study (Figure 4.4).

Although population-based screening offers potential benefits such as early identification and treatment of affected patients, it also has drawbacks, such as identification of patients with mild disease who may not need additional treatment [59]. Findings show that screening for moderately increased albumin excretion (microalbuminuria), which is a marker of early-stage CKD, is cost-effective for patients with diabetes or hypertension [22, 36, 68]. Early detection, appropriate risk stratification, and subsequent treatment of CKD may delay or prevent many associated complications, with concomitant increase in cost [7, 69].

Mass screening of the general population for CKD is not recommended because it is not cost-effective for low-risk groups [23, 41]. In contrast, targeted screening of high-risk individuals, such as those with diabetes or hypertension or both, is cost-effective [23, 33]. Screening also is a cost-effective strategy for certain high-risk ethnic groups, such as African Americans and indigenous people of Canada, who are at increased risk of kidney failure and its numerous complications [31]. The cost-effectiveness of a screening program for proteinuria among US adults with hypertension and diabetes has been clearly demonstrated in terms of reducing death and slowing the progression of kidney disease by using an ACEi or ARB [59].

Overall, the cost-effectiveness ratio of screening versus the usual care (no screening) is unfavorable for the general population ($282 818 per QALY saved). Just 0.0022 QALYs per person are gained by preventing of one new case of ESKD and seven deaths per one million persons per year. For individuals with hypertension, the cost-effectiveness ratio of screening versus no screening is considered highly favorable ($18 621 per QALY-saved) [22], with 0.03 QALYs per person gained through the prevention of 14 new cases of ESKD and 104 deaths per 1 million persons per year. For persons with diabetes, the cost-effectiveness ratio of screening versus no screening is overwhelmingly positive ($217 per QALY saved), with a gain of 0.10 QALYS per person due to the prevention of approximately 84 new cases of ESKD and 541 deaths per 1 million persons per year [22]. The results of a similar study carried out among members of the Canadian indigenous community demonstrate that screening and treatment for CKD is highly cost-effective, with a cost-effectiveness ratio of $23 700 per QALY saved. The cost-effectiveness ratio of CKD screening is even more profound in the most remote communities accessible only by air travel, at $7790 per QALY saved [7]. Integrating additional benefits of screening and treatment into the existing framework may improve the cost-effectiveness of the given screening intervention [7, 22]. In previous studies,

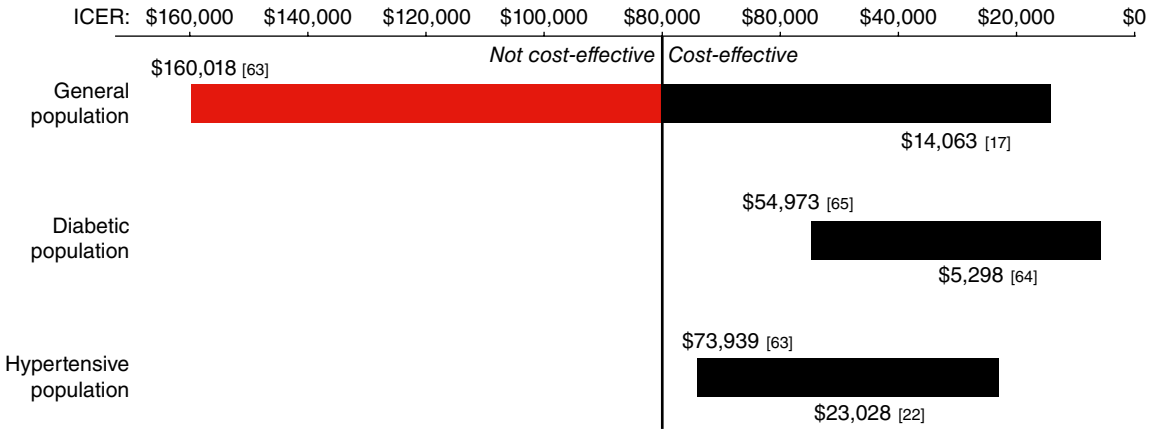

Figure 4.4 Tornado plot comparing reported incremental cost-effectiveness ratios (ICERs) of CKD screening in selected populations.$80 000 ICER selected based on 1–3 times gross domestic product per capita threshold for most G8 (Group of 8) countries. *Source:* Adapted with permission from [8] © 2014 Elsevier.

researchers have considered the impact of albuminuria screening on the reduction of cardiovascular events and found screening to be cost-effective, even for the general population [62, 70]. Some potential benefits of screening include the reduction of cardiovascular events among patients with diabetes through the use of blood pressure lowering medication, and the potential for increased utilization of statins in newly identified CKD cases [71–73]. In addition, newer therapies such as sodium-glucose cotransporter 2 inhibitors can provide benefits for patients with type 2 diabetes and high cardiovascular risk [74].

Multiple factors could influence the efficacy of these treatment modalities, such as prevailing usage rates for each pharmacotherapy, the underlying prevalence of untreated diabetes in screened communities, and ancillary effects of screening programs such as community education, increased awareness, and lifestyle interventions [7]. Overall, the effectiveness of CKD screening and treatment could be better measured in a cluster randomized trial that can better capture multiple concurrent effects and their influences on patient outcomes [7]. Direct and indirect cost savings associated with screening are primarily achieved through the prevention of new (and expensive) ESKD cases [64]. Years of life saved through the death prevention effects of ACEi and ARB therapies are augmented by the prevention of ESKD cases and their associated high mortality [22, 60]. A lack of cost-effectiveness arises when the prevalence and incidence of proteinuria are very low (leading to few preventable cases of ESKD), and also when the risk of death is very low [64]. Physicians must consider many factors when making decisions regarding early disease detection. Numerous studies [22, 60, 64] have elucidated the key variables that might improve cost-effectiveness, including adherence to ACEi or ARB therapy, the incidence of proteinuria, sensitivity, and specificity of testing, the effectiveness of ACEi or ARB therapies in slowing the progression toward ESKD or preventing death, and decreased frequency of screening [22, 60, 68].

Summary

Screening the general population for early CKD is not cost-effective and therefore is unwarranted. Selective screening should be directed toward high-risk groups (older persons and persons with hypertension and diabetes, and some ethnic groups such as African Americans and indigenous populations of Canada, the United States, and Australia). Adherence to ACEi or ARB pharmacotherapy in preventing death or progression toward ESKD and the frequency of screening play prominent roles in the cost-effectiveness of screening members of the general population.

Decision makers often are pressured to adopt policies that are not necessarily economically sound. However, in a healthcare environment characterized by scarce resources and competing demands, it is essential to consider how to maximize value. Economic evaluations introduce an evidence-based perspective to these decisions. In the case of CKD, the most recent evidence indicates that CKD screening is warranted only for high-risk patients, especially those with diabetes and hypertension, to prevent associated cardiovascular morbidity and mortality. More research is needed to evaluate the armamentarium available for CKD screening and its cost-effectiveness.

Introduction

Chronic kidney disease (CKD) is a major public health issue, with the global prevalence currently estimated to range between 8.7% and 18.4% [1]. CKD is independently associated with an increased risk for end-stage renal disease (ESRD), cardiovascular events, and all-cause mortality, but at the individual level these associations do not necessarily provide prognostic information for providers or patients [2–4]. Accurate risk prediction integrated into clinical practice, based on clinically relevant risk factors, would allow physicians to determine patient-level risk of adverse events at point of care, and in turn stratify patients based on their risk for adverse events [5].

Clinical methods of estimating risk provide assistance to clinicians and patients in shared decision making, ultimately ensuring that patient-centered care is provided [6, 7]. While data-driven decision making is critical to improve patient outcomes, there is no guarantee that accurate estimation of risk translates into improved decision making nor to overall improved outcomes. With the effective use of these risk prediction models, most patients with stage 3 CKD (glomerular filtration rate [GFR] <60 ml/min/1.73 m^2) can be stratified into the low-risk category and have the potential to be treated solely by their primary care provider, allowing for observation and avoidance of premature intensive treatment modalities. Conversely, those at high risk can be referred to nephrology for urgent care [8]. On the same note, models predicting progression toward ESRD can guide decisions about treatments aimed at slowing the progression of kidney disease, assist with dialysis planning and transplantation, and help triage highest-risk referrals to nephrologists [9]. Models that accurately predict cardiovascular disease (CVD) in patients with CKD may help identify patients whose profiles warrant more intensive cardiovascular risk management, such as antiplatelet therapy and lipid-lowering medications. The creation of such clinical decision tools is based on the collection of clinical and demographic variables and longitudinal follow-up. In addition to demographic risks, several biomarkers have been evaluated for their association with CKD disease severity and progression. This chapter will review conventional biomarkers, novel biomarkers, and recently validated risk scores for predicting CKD progression and outcomes (Tables 5.1 and 5.2).

Individual Predictors of CKD Progression

Biomarkers are biological parameters used to differentiate between normal and abnormal physiological processes. For patients with CKD, biomarkers may reflect changes in renal function and thus may aid in predicting health outcomes, specifically progression of CKD or development of CVD [11]. There are conventional biomarkers that have been utilized for many years as well as newer, more novel markers to predict CKD progression.

Conventional Biomarkers

Estimated Glomerular Filtration Rate

Perhaps the best indicator of future CKD progression is current burden of CKD. It has been appreciated for several decades that once glomerular filtration rate (GFR) has decreased to below a critical level, CKD tends to progress

Table 5.1 Prediction of chronic kidney disease [10].

Marker	Recommendation	Certainty of evidence	Strength of recommendation
KDOQI	Simple calculation of risk from eGFR and proteinuria	Observational studies	Strong
KRFE	Risk prediction using three, four, or eight variables	Validated in multiple large cohorts	Moderate/strong
MCMC	Risk prediction using nine clinical variables	Validated in multiple large cohorts	Moderate/strong

Table 5.2 Prediction of cardiovascular disease.

Scoring	Recommendation	Certainty of evidence	Strength of recommendation
eGFR	Independently associated with risk of CVD	Multiple observational studies	Strong
Proteinuria	Independently associated with CVD risk and outcome	Multiple observational studies, several RCT aimed a decreasing proteinuria	Strong

toward ESRD and is therefore the best indicator of global kidney function [12–15]. This observation suggests that the loss of a critical number of nephrons provokes a vicious cycle of further nephron loss. The natural history of CKD has been described with large variability depending on definitions, the population being studied, as well as the healthcare environment [16, 17]. Using estimated GFR (eGFR) as a marker of progression to ESRD, the African American Study of Kidney Disease and Hypertension (AASK) was able to identify three distinct patterns of CKD progression: (i) stable/increasing eGFR (less than 2 ml/min/1.73 m^2 decrease per year), (ii) rapid decrease in eGFR (a loss of more than 4 ml/min/1.73 m^2 per year), and (iii) alternating combinations of the previously mentioned categories. The most common pattern found in patients with CKD was a stable/increasing eGFR, with 58% of patients falling under this category [18]. The fact that only a minority of patients will develop ESRD further supports a need for risk stratification development in order to appropriately allocate treatment decisions. Almost all models that attempt to predict renal functional decline include an assessment of eGFR as a critical factor.

Albuminuria/Proteinuria

Proteinuria is another index of kidney disease severity in CKD patients, as it often results from glomerular injury [11]. In several longitudinal studies of patients with CKD, higher baseline proteinuria was indicative of a rapid decline in GFR [16–22] In a similar manner, baseline urinary albumin/creatinine ratio (ACR) in patients with diabetic nephropathy was found to be a strong indicator of ESRD [23, 24]. Proteinuria itself may pose as a risk factor for CKD progression, as one study using dipstick urinalysis concluded that proteinuria was the most predictive biomarker of ESRD risk over a 10-year period [25]. In many glomerular diseases, changes in proteinuria have also been associated with changes in renal prognosis, though these associations have not always been consistent. As with eGFR, the prognostic role of proteinuria/albuminuria is well established and it should be considered as a potent biomarker of CKD progression. As depicted in Figure 5.1, the 2012 Kidney Disease Improving Global Outcome (KDIGO) color-coded prognosis chart includes only eGFR and degree of albuminuria in risk assessment [26, 27].

Hypertension

Hypertension is common in both adults and children with CKD [28, 29]. Among patients with CKD, those with higher blood pressure have significantly faster GFR decline and the presence of hypertension has consistently been associated with rapid progression [17, 29–32]. This finding has led to recommendations regarding more intensive management of hypertension in patients with CKD [33]. While blood pressure appears to impart a deleterious effect on CKD progression in a continuous fashion without a specific "threshold" value, for convenience most prediction models that include blood pressure as a factor simply dichotomize blood pressure to hypertensive or not.

Serum Bicarbonate/Metabolic Acidosis

Metabolic acidosis is another common consequence of CKD and often causes impaired renal acid clearance [34].

Guide to Frequency of Monitoring (number of times per year) by GFR and Albuminuria Category				Persistent albuminuria categories Description and range		
				A1	A2	A3
				Normal to midly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30–300 mg/g 3–30 mg/mmol	>300 mg/g >30 mg/mmol
GFR categories (ml/min1.73 m^2) Description and range	G1	Normal or high	≥90	1 if CKD	1	2
	G2	Midly decreased	60–89	1 if CKD	1	2
	G3a	Mildly to moderately decreased	45–59	1	2	3
	G3b	Moderately to severely decreased	30–44	2	3	3
	G4	Severely decreased	15–29	3	3	4+
	G5	Kidney failure	<15	4+	4+	4+

Figure 5.1 Prognosis of CKD dependent on eGFR and degree of albuminuria, with recommended frequency of follow-up. Green, low risk (if no other markers of kidney disease, no CKD); yellow, moderately increased risk; orange, high risk; red, very high risk. *Source:* KDIGO [26]. © 2013 KDIGO

The majority of relevant studies have indicated that lower serum bicarbonate levels, even within normal range, are independently associated with CKD progression [7, 35–40]. Bicarbonate supplementation as a treatment for metabolic acidosis, either as oral sodium bicarbonate or a diet rich in fruits and vegetables, has been shown to decrease the rate of GFR decline in multiple small single-center studies [38–40]. Recent studies have shown that metabolic acidosis has additional end organ effects including impacts on cognition and endothelial function; new nonalkali treatments for metabolic acidosis are currently under development [35, 41–44].

Serum Phosphate and FGF23

Various studies have indicated that elevated serum phosphate levels are independently associated with renal injury in CKD [7, 45, 46]. However, this has been contradicted by a large study including 10 672 CKD patients, which found no association between higher serum phosphate and risk of progression toward ESRD [47]. Though not a conventional biomarker in clinical practice, phosphatonin fibroblast growth factor 23 (FGF23), a hormone involved in calcium and phosphate regulation, has also been suggested as an independent predictor of CKD progression [48, 49]. Elevated levels of FGF23 in CKD patients were independently associated with progression to ESRD, as well as cardiovascular events [50–52].

Uric Acid

Another biomarker which has been used to predict CKD progression is serum uric acid level [53–56]. An evaluation of children and adolescents in the Chronic Kidney Disease in Children Study (CKiD) cohort revealed that hyperuricemia is associated with a more rapid renal decline [56]. Compared to subjects with the lowest uric acid levels, those with intermediate and frankly elevated uric acid experienced a more rapid decline in eGFR. Uric acid levels remained significantly associated with progression even when controlling for other risk factors such as hypertension, proteinuria, initial GFR, and glomerular etiology, all of which were also significant in multivariate analysis. A 2018 meta-analysis of adults with CKD analyzed several randomized controlled trials (RCTs) done to evaluate the effects of uric acid lowering therapy on the disease progression [53]. The analysis included a total of 832 subjects with CKD randomized to uric acid lowering treatments versus placebo. Active treatment conferred a 3.88 ml/min/1.73m^2 (1.26–6.49 ml/min/1.73m^2) mean difference in eGFR. Additionally, risk of worsened kidney function or ESRD or death was significantly reduced with uricosuric pharmacotherapy. These data suggest that elevated uric acid represents a risk prediction tool and potentially a therapeutic target to slow CKD progression.

Novel Biomarkers

Recently, a number of novel biomarkers have emerged as potentially new clinically-relevant risk prediction tools, but more research is needed to determine their full impact on CKD progression. For example, although levels of *neutrophil gelatinase-associated lipocalin (*NGAL*)* have been found to be overexpressed in patients with AKI [57] and are highest in CKD patients [58], the Chronic Renal Insufficiency Cohort (CRIC) study found that while urinary NGAL levels were independently associated with ESRD, they did not significantly improve prediction of CKD progression over predictions using only eGFR decline and proteinuria [59]. The *glycoprotein kidney injury molecule-1 (*KIM-*1)* is usually only present in the urine of patients with AKI or CKD [60]. One study found that serum KIM-1 levels increased with CKD progression and were independently associated with ESRD [61]. Through the Multi-Ethnic Study of Atherosclerosis, it was also determined that doubling of urinary KIM-1 levels was associated with an eGFR decrease greater than 3 ml/min/1.73 m^2 per year [62]. Elevated levels of *soluble urokinase-type plasminogen activator receptor (*suPAR*)* have also been observed in patients with renal disease, specifically glomerulosclerosis [11]. One study investigating suPAR determined that higher baseline levels were independently associated with CKD. Despite this, 30% of patients with a normal eGFR (>90 ml/min/1.73 m^2) were also found to have increased baseline suPAR levels, indicating that elevation may be a result of other biological processes, such as inflammation [63]. Lastly, the kidney-specific *glycoprotein uromoduliun (*UMOD*)* is known to have gene variants associated with eGFR decline and is associated with the development of CKD. One genome-wide association study using data from 3203 Icelandic CKD patients discovered a variant adjacent to the UMOD gene on chromosome 16p12 had an association with CKD and increasing creatinine levels [64, 65]. However, another study found that among 879 individuals of the Heart and Soul Study, UMOD single-nucleotide polymorphism variants influenced UMOD levels, but not CKD development [66].

The Role of AKI in Predicting Future CKD

Historically, clinicians assumed that patients who completely recovered from acute kidney injury (AKI) would regain baseline renal function. However, recent studies have contradicted this by demonstrating that a previous history of AKI is indeed associated with an increased risk of CKD and associated mortality [67]. To assess this association, one study looked at 343 AKI patients with a preadmission eGFR greater than 45 ml/min/1.73 m^2 who survived for at least 30 days after discharge without dialysis. The authors concluded that those who required dialysis for their AKI during hospital admission had a 28-fold increase in the risk of developing CKD stage 4 or 5, and had more than double the risk of mortality when compared to those who did not need dialysis [68].

Due to increasing evidence indicating the high likelihood of CKD development in post-AKI patients, there are ongoing efforts to develop a risk prediction model to identify which of these patients are at the highest risk. Using a cohort of 5351 patients diagnosed with an AKI, risk prediction models were developed that utilized variables of age, serum albumin, diabetes, baseline eGFR, mean serum creatinine, and severity of AKI as assessed by the RIFLE score (risk, injury, failure, loss, and end-stage kidney disease) or need for dialysis, non-African American ethnicity, and time spent at risk. External validation was performed using 11 589 patients admitted for pneumonia or myocardial infarction (MI), and yielded good prediction accuracy (area under the receiver operating characteristics [AUROC] value = 0.81–0.82) [69]. Further investigations are required that specifically include study populations with a higher proportion of women before clinical implementation.

CKD Risk Scores

Clinical prediction rules or models (sometimes called clinical decision tools) are tools that are created to assist clinicians in patient-level decisions [70–72]. Designed by multivariate analysis, these scoring models complement clinical decision making by suggesting diagnostic or therapeutic actions or providing prognostication of some clinical outcome. The goal of validated models is to improve individual patient outcomes and the cost-effectiveness of care [71]. Development of a clinical prediction model involves multiple steps, including (i) identification of important predictor variable (listed above in the case of CKD), (ii) assigning relative weights to each factor to create a combined score, (iii) assessing the score's predictive ability, including calibration and discrimination, and then (iv) validation of the model using both internal and external data.

Calibration is the agreement between the predicted probability of the outcome of interest and the observed frequency. It is usually plotted graphically as the observed outcome frequency against the mean predicted outcome probability (or risk). Goodness of fit for calibration can

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

then be statistically tested. Discrimination refers to a model's ability to distinguish individuals who have the model outcome from those who remain event free, usually reported as the area under the receiver operating characteristic (ROC) curve (logistic regression c-statistic.) Models usually perform well within the data sample they are developed, as is often demonstrated using internal validation. External validation, therefore, is advocated to ascertain utility of the model in clinical practice. Several techniques of external validation are available [70, 73]. For a more comprehensive review, Moons and colleagues provide an in-depth analysis of clinical decision models in a two-article series [70, 71].

Investigation of risk factors/biomarkers used in predicting the development and/or progression of CKD has resulted in the discovery of a relatively small number of risk factors common to different forms of CKD. These risk factors are currently routinely being used to guide routine clinical practice, for example the revised KDIGO risk classification system uses GFR and albuminuria to categorize patients into CKD stages [26, 74]. This has led to the development of renal risk scores, which have the potential to be used in predicting the development and progression of CKD. Progress has already been made in developing a variety of risk scores to facilitate more accurate risk prediction, applying to those with and without CKD. We will now review several models that have been developed to predict risk.

The Kidney Failure Risk Equations

To predict the progression toward ESRD in patients with CKD, Tangri and colleagues developed the Kidney Failure Risk Equations (KFREs) in 2011, using data from a cohort of 3449 patients with late stage CKD [7]. Variables used in the eight-variable equation were age, sex, eGFR, albuminuria, serum calcium, serum phosphate, serum bicarbonate, and serum albumin. Simpler three-variable (age, sex, and eGFR) and four-variable (age, sex, eGFR, and albuminuria) models were also developed. While both of these simplified models performed well (Table 5.3), the eight-variable model performed best with respect to discrimination, calibration, and reclassification in an external validation cohort.

To assess the global functionality of the KFREs, a validation study of the equations was performed using 35 cohorts consisting of 720 000 patients with late-stage CKD across four continents. After a 4-year follow-up, the KFREs achieved accurate estimation of 23 829 cases of ESRD (c-statistic 0.90, 95% confidence interval [CI] 0.89–0.92 at 2 years; c-statistic 0.88; 95% CI 0.86–0.90 at 5 years). It was also found that the simplified four-variable equation produced similar discrimination compared to the eight-variable equation (c-statistics were 0.89 vs. 0.90 at 2 years and 0.86 vs. 0.88 at 5 years, respectively) [75].

Table 5.3 Hazard ratios and goodness of fit for sequential models in the development data set for three, four, and eight-variable kidney failure risk equations (KFREs).

Variable	Three-variable model	Four-variable model	Eight-variable model
Baseline GFR, per 5 ml/min/1.73 m^2	0.54	0.57	0.61
Age, per 10 years	0.75	0.8	0.82
Male sex	1.46	1.26	1.16
Log spot urine ACR[a]		1.60	1.42
Serum albumin, per 0.5 g/dl			0.84
Serum phosphate, per 1.0 mg/dl			1.27
Serum bicarbonate, per 1.0 mEq/l			0.92
Serum calcium, per mg/dl			0.81
c-statistics	0.89	0.91	0.92
Akaike Information Criterion[b]	4834	4520	4432
P value	<0.001	<0.001	<0.001

[a] Hazard ratio for ACR represents a 1.0 higher ACR on the natural log scale. For the average patient with 20 mg/g of albuminuria, this represents an increase to 55 mg/g.
[b] Null values for c-statistic and Akaike Information Criterion are 0.50 and 5569, respectively. Higher values for c-statistic and lower values for Akaike Information Criterion indicate better models.

Newer Prediction Models

Several newer prediction models have also been developed and some are now available online. In 2018 Grams et al. developed models using data from over 250 000 individuals across 30 countries who participated in the international CKD Prognosis Consortium with eGFR < 30 ml/min/1.73m^2 [76]. The Markov Chain Monte Carlo (MCMC) model predicts 2- and 4-year risk of renal replacement therapy, cardiovascular (CV) event, or any cause of death using nine common predictor variables: age, sex, ethnicity, eGFR, systolic blood pressure, ACR, and any history of smoking, diabetes, or prior CVD (available at

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. http://ckdpcrisk.org/lowgfrevents). This new model has significant overlap with KFRE (age, sex, eGFR, and albuminuria), though the additional variables provide an improved predictive ability in validation trials (within cohort R2 ranged from 0.89 to 0.97). A comparison of the predicted versus observed outcomes in various trials using both KFRE and the Grams MCMC model is shown in Figure 5.2 [76].

Successful clinical implementation of risk models requires both a validated risk prediction model and determination of absolute risk thresholds. Using these to guide therapy decisions will allow for a cost-effective treatment plan. Figure 5.3 demonstrates both the eGFR criteria (top) and the suggested KFRE risk-based thresholds (bottom) that prompt transition between different levels of care [77].

Transition from Primary Care to Nephrology

Patients with CKD will often develop hypertension and anemia, which are often managed under the supervision of primary care physicians [78]. However, these patients may be at higher risk for developing ESRD, resulting in a need for referral to nephrology in order to delay CKD progression, in turn preventing dialysis and reducing mortality risk [64, 79]. Implementing risk equations in the primary care setting may guide the appropriate timing of nephrology referrals. The 2012 KDIGO guidelines include recommendations for referral to specialty care, though the utility of this recommendation has not been subject to critical review [26].

Some have argued that if patients have a moderately reduced eGFR, they should be monitored at 3- or 6-month

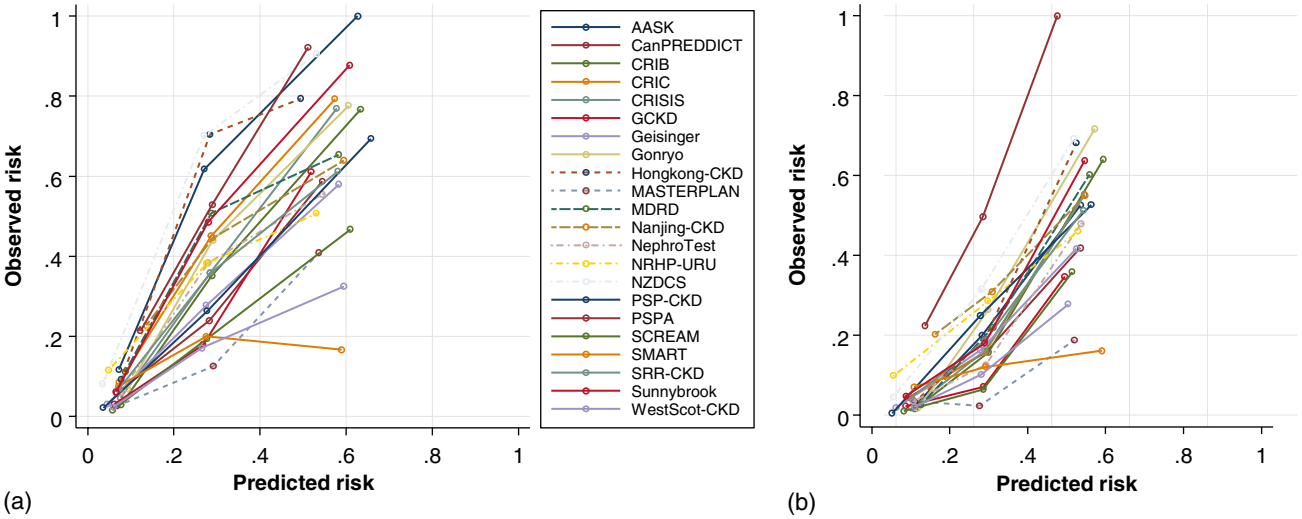

Figure 5.2 Calibration of the predicted versus observed 2-year risk of ESRD for (a) the kidney failure risk equation (KFRE) and (b) the MCMC model. intervals, whereas those who are at a lower risk can be followed on an annual basis [80]. The KDIGO recommended frequency of follow-up is depicted in Figure 5.4.

Interdisciplinary Care

Interdisciplinary nephrology-led teams, which include nursing, pharmacy, and dietetic professionals, may improve the course of treatment, in turn ensuring timely dialysis initiation and lowering mortality risk. Ideally risk stratification would ensure these teams are not overburdened with low-risk CKD patients, thereby preventing inappropriate allocation of limited healthcare resources [18]. Following issues with excess demand for interdisciplinary care in Ontario, Canada, the Ontario Renal Network adopted a risk-based cutoff for clinical resource eligibility. The cutoff for interdisciplinary care was a 2-year risk of ESRD exceeding 10% or an eGFR less than 15 ml/min/1.73 m^2. As a result, the number of patients eligible was drastically lowered, as the previous threshold was solely based on an eGFR of less than 30 ml/min/1.73 m^2. Due to the implementation of this criterion, a proportion of patients with an eGFR between 30 and 45 ml/min/1.73 m^2 were also found to be eligible as they had a high risk of ESRD development. As a result of this change in cutoff, $6 million was saved annually for the healthcare system [81]. In the United States, the opposite may be happening with unacceptably late nephrology referral.

Dialysis Access and Modality Planning

It is currently the standard of care to recommend dialysis modality planning to patients with an eGFR less than 30 ml/min/1.73m^2, despite the fact that the majority of these patients will never progress to ESRD [82]. The weighing of risks and benefits when it comes to modality planning (hemodialysis vs. peritoneal dialysis) is paramount. The process of dialysis planning, including the creation of an arteriovenous fistula (AVF), the standard method of access for patients on hemodialysis, however crucial, may create anxiety for patients and caregivers. Furthermore, older adults are at a higher risk of AVF failure and subsequent adverse events, including heart failure and steal syndrome. Additionally, older adults who are at a low risk of progressing to kidney failure often have competing morbidities, further discouraging AVF formation [83]. By implementing risk prediction models such as the KFRE, AVF insertion can be guided properly to avert some of these risks while providing optimal treatment to low-risk CKD patients. The efficacy of implementing KFREs was simulated in 2014 using the Sunnybrook hospital cohort. The study concluded that a cutoff of 20% annual risk of

GFR categories (ml/min1.73 m^2) Description and range				Persistent albuminuria categories Description and range		
				A1	A2	A3
				Normal to midly increased	Moderately increased	Severely increased
				<30 mg/g <3 mg/mmol	30–300 mg/g 3–30 mg/mmol	>300 mg/g >30 mg/mmol

ESRD calculated by the KFREs was more effective than eGFR-based cutoffs in predicting the need for AVF insertion and dialysis [84].

Predicting Cardiovascular Disease in CKD Patients

CKD substantially increases the risk of CVD in patients, but it is also itself a consequence of CVD. One study found that amongst hospitalized patients with congestive heart failure (CHF), the prevalence of late-stage CKD was 60.4% and it was 51.7% for those with MI [85]. When accompanying heart disease, CKD also increased the risk of mortality and ESRD in patients [86]. This may be a result of the shared risk factors of CVD and CKD, which include atherosclerosis, obesity, metabolic syndrome, hypertension, diabetes mellitus, dyslipidemia, and smoking. Renal atherosclerosis has been found in 39% of patients undergoing elective coronary angiography [87].

eGFR and Cardiovascular Risk

In the United States, individuals with CKD experience a 10-fold increased risk of vascular disease compared to those without kidney disease [88, 89]. This finding may be due to significant overlap of risk factors between CKD and CVD [90–92]. The excess CV mortality appears to begin early in the advancing CKD process and increases with worsened eGFR [76, 93]. Current CVD risk prediction models have proven to be unreliable when patients have concurrent CKD [94]. Bansal et al. developed a prediction tool that has shown promise in assessing 5-year mortality risk in patients with CKD but not ESRD (c-statistic 0.72, 95% CI 0.68–0.74). Their model incorporates age, sex, race, eGFR, urine ACR, smoking status, diabetes mellitus, and history of CHF or stroke. While this model has been externally validated in 789 participants (c-statistic 0.69, 95% CI 0.64–0.74), patients with CKD stages 4–5 were underrepresented in the validation study and therefore further investigation of this demographic is required prior to successful clinical implementation [95]. Researchers from Glasgow evaluated the effects of eGFR and proteinuria on CVD outcomes using data from 440 526 participants in the UK Biobank [96]. Their simple prediction model, created in 2019, uses different eGFR to predict CVD. The most successful model used cystatin C-based eGFR.

Proteinuria/Albuminuria and Cardiovascular Risk

Proteinuria/albuminuria predicts not only renal progression but is an ominous marker of other outcomes as well, most notably cardiovascular events. Multiple analyses have since established that ACR predicts all-cause mortality and cardiovascular death independent from baseline CKD and other covariates [97–101]. Early studies revealed a link between degree of microalbuminuria and poor outcomes in patients with type 2 diabetes [102]. Analysis of Framingham participants revealed that proteinuria predicted poor outcome in the general population as well [103]. Hillege analyzed a Dutch cohort of 40 548 adults and found a dose–response relationship between urinary ACR and both CV and non-CV mortality [98].

Future Considerations

Although some disagreement on the validity of various risk factors discussed in this chapter still remains, a relatively small group of risk factors appear to be common to most current studies. As a result, much progress has been made in developing risk scores based on these select variables in their ability to aid in predicting the progression of CKD, and with the development of risk prediction models. Future studies should focus on a more critical review of the aforementioned biomarkers and genetic factors utilized in risk score development, although the costs of measuring such markers is likely to be much higher than simple risk factors used at the present time. Accurate risk scores can align risk and resources, while allowing for personalized care for patients with CKD. Therefore, it is imperative to implement these risk scores into routine clinical practice, in turn helping patients and clinicians navigate the transition from CKD to dialysis.

Chronic Kidney Disease in Disadvantaged Populations

Magdalena Madero[1] and Diego Aguilar[2]

[1] *Department of Nephrology, National Institute of Cardiology, Mexico*
[2] *PRS Population Health, Clinical Trial Service Unit and Epidemiological Studies Unit, BHF Centre of Research Excellence, Nuffield Department of Population Health, University of Oxford, UK*

Introduction

Chronic kidney disease (CKD) is an established global public health problem that represents a key determinant for poor health outcomes [1–4]. In recent decades it has been increasingly recognized that CKD is more frequent and has poorer outcomes among populations or communities considered "disadvantaged" in both the developed and developing world [1, 5–8]. Such communities include "ethnic, socio-economically deprived, and other minority groups that are at greater risk of developing CKD," according to the International Society of Nephrology [9]. The causes of CKD in disadvantaged populations are varied and reflect exposures to environmental, socioeconomic, and other factors that contribute to a reduction in nephron mass over time. In any one individual, perinatal factors, nutritional factors, exposure to toxins, and infections may all contribute to the development of CKD. The entity CKD of uncertain etiology (CKDu) is one condition that is over-represented in disadvantaged populations.

Apart from being more frequent, kidney disease among disadvantaged populations tends to be underdiagnosed. When detected, access to care is limited and, frequently, suboptimal [8]. Irrespective of the underlying cause of CKD, the combination of those two factors – underdiagnosis and suboptimal treatment – contributes to poor clinical outcomes. Moreover, the development of end-stage kidney disease (ESKD) in communities in which access to renal replacement therapy (RRT) is limited or nonexistent forces households to incur substantial out-of-pocket expenses, perpetuating the poverty cycle. Additionally, disadvantaged populations are a recurrent source of organ donors for other populations, frequently victims of illegal traffic practices, which contributes to the depletion of an already scarce pool of grafts available to disadvantaged persons.

Given the complexity and systemic nature of this problem, the required interventions are interdisciplinary and multidimensional. Therefore, it is not only a matter incumbent to the medical community. Only global-scale efforts involving multiple stakeholders will be able to close the observed gaps in kidney care that disadvantaged populations experience. Key partnerships between governments, nongovernmental organizations, researchers, and clinicians are paramount to achieve an improvement in outcomes. The World Health Organization (WHO) has established sustainable health goals that are only possible with a concerted multidisciplinary approach. This chapter presents the available evidence of the distribution of CKD in disadvantaged populations across the globe, with a particular focus on the challenges and opportunities in the detection and treatment of CKD among such populations.

Epidemiology

According to a recent meta-analysis that pooled data from 100 studies of diverse quality comprising 6 908 440 patients, an estimated 11% of people worldwide are affected with CKD stages 3–5 [10]. Table 6.1 shows the CKD prevalence estimates for different regions in this study. The prevalence of CKD varied substantially across regions, which was partially attributable to substantial heterogeneity between the studies included as well as differences in quality.

Nonetheless, the observed differences can also be explained by true variations in the prevalence of kidney disease among regions. Remarkably, the global prevalence of CKD appears to be higher than that of diabetes, which has been reported to be about 8.8% [11], underscoring the relevance of CKD to global health.

Another study that pooled data from 33 reports with gender- and age-specific prevalence of CKD in representative population samples estimated that nearly 500 million individuals have CKD, of which almost 80% live in low-middle-income countries (LMICs) [12]. Importantly, the age-standardized prevalence of CKD was higher in men and women from LMICs when compared to men and women from high-income countries. Despite the observed disparities between developed and developing countries, the epidemiological trends of CKD in LMICs, including the causes of kidney disease and their distribution across the population, are either unknown or poorly characterized [13, 14]. There are reasons to believe that the causes of CKD are widely heterogeneous in LMICs. As a result of an accelerated demographic transition and urbanization, most of these countries have experienced an unprecedented upsurge in noncommunicable diseases [15]. A sedentary lifestyle and unhealthy diet are intertwined in densely crowded cities with limited public health and heathcare infrastructure, resulting in high rates of underdiagnosed and suboptimally treated hypertension and diabetes. These populations are enormously vulnerable for adverse kidney outcomes. For instance, reports from Mexico City show that CKD is strikingly frequent among population with diabetes [16]. A prospective analysis of a large cohort in this population recently reported that adults (35–84 years) with diabetes had a 20-fold higher risk of dying from kidney disease compared with those without diabetes [17]. This excess risk is most likely due to suboptimal management of diabetes: those with diabetes had a mean glycated hemoglobin of 9.0% and poor glycemic control was associated with increased mortality risk [18].

The etiology and epidemiological determinants of kidney diseases in areas like Africa, Asia, and Latin America differ from what is observed in Europe and North America and even within regions can vary substantially [14]. As shown in Table 6.2, apart from diabetes and hypertension, communicable diseases such as HIV, malaria, and schistosomiasis may be important contributors to the burden of CKD in sub-Saharan Africa, even though evidence of their attributable fractions is limited or absent [19, 20].

Definitions and Theoretical Framework

According to the WHO, social determinants of health (SDH) are defined as "the conditions in which people are born, grow, live, work and age" [21]. SDH are mostly responsible for health inequities, "the unfair and

Table 6.2 Environmental factors associated with CKD.

Factor	Description
Heavy metals	*Lead*: particularly important in LMIC; contained in paint, gasoline, adulterated gasoline, contaminated food and water, soil, mines, garages *Cadmium*: sources include tobacco, batteries, fuel, industrial waste, certain South-Eastern Asian medicinal herbs or foods *Arsenic*: fish contamination, fuel, cereals treated with ethyl mercury as pesticide *Uranium*: contaminated food or water
Other toxins	*Aristolochic acid* associated with chronic tubulointerstitial nephritis and urothelial cancer; the causal agent of Balkan endemic nephropathy Exposure to other *chemicals* used for consumer activities or medical treatment; industrial chemicals; occupational chemicals apart from heavy metals (e.g. methylene chloride, trichloroethylene, toluene); most associated with acute disease and/or accentuated progression of underlying disease
Occupational exposures	*Mesoamerican nephropathy* affecting agricultural workers; most likely mechanism consists in repeated subclinical episodes of AKI due to dehydration during work shifts; uric acid crystalluria might be involved in kidney damage; several other potential synergistic factors (e.g. NSAIDs, fructose-high beverages, alcohol consumption, pesticides) *Sri Lanka, India, and Pakistan*: contamination of water/food by unknown agent (industrial chemicals, agrochemicals, heavy metals suggested)
Medications	*NSAIDs* (linked with AKI, but not yet with CKD); mis-regulated alternative or novel therapies or medications (usually counterfeit); *herbal remedies*
Infections	Related to poor hygiene conditions in LMICs; parasites (e.g. schistosomiasis, malaria, leptospirosis, tuberculosis, etc.); enteric and diarrheal diseases; HIV-associated nephropathy; hepatitis B and C viruses

avoidable differences in health status seen within and between countries" [21]. Therefore SDH, and the resulting disparities in health, are key components of what is considered a "disadvantaged population" [22, 23]. However, the definition most widely accepted for "disadvantaged population" is not restricted to those at a greater risk of kidney disease due to SDH, and further includes "ethnic, socio-economically deprived, and other minority groups" [9]. Even though the definition of minority groups largely derives from sociodemographic phenomena (i.e. the definition of a minority is relative to a majority in a population), [24] the concept of ethnicity is closely related with genetic ancestry and, subsequently, with a complex cluster of social and biological factors. The definition of "disadvantaged populations" can therefore be ambiguous, as a myriad of factors can predispose individuals and populations to kidney disease. Three main factors, however, can be identified as underlying and sometimes overlapping causes of disadvantage: (i) socioeconomic factors that affect health behavior and access to care, (ii) biological factors that predispose to adverse kidney outcomes, and (iii) environmental factors, e.g. labor conditions and exposures to nephrotoxic agents. These factors are not necessarily a direct cause of kidney disease but may act as mediators on the causal pathway (Figure 6.1).

Socioeconomic Factors

Socioeconomic status (SES) usually encompasses education, occupation, and income as proxies for measurement of social and economic wellbeing. Lower SES has consistently been associated with increased morbidity and all-cause mortality [25]. Frequently, access to health – frequently measured as insurance status – and risk behaviors have been suggested as the mechanisms explaining the link between SES and health. However, it has become clear that those factors do not fully account for the associations observed, and other more complex factors such as social isolation and adversity may be involved [22]. This is not different for CKD, where the incidence and prevalence of CKD and the progression of disease varies by SES, being higher at lower SES levels [26, 27]. For instance, low income or education below high school level have been associated with the presence of albuminuria in the United States [28]. In the Chronic Renal Insufficiency Cohort, lower income and education were associated with lower estimated glomerular filtration rate (eGFR) [29]. Progression of CKD into ESKD is more likely among individuals with low income and education [30–32]. Additionally, those with ESKD who have less education or are unemployed are less likely to receive a transplant [33, 34] and more likely to experience dialysis complications such as peritonitis [35, 36] or graft rejection if they receive a transplant [37]. Irrespective of the mediating factors in the association between SES and CKD, it is clear that a low SES confers a greater risk of developing CKD and having poor outcomes, and therefore such segments of the population can be considered disadvantaged.

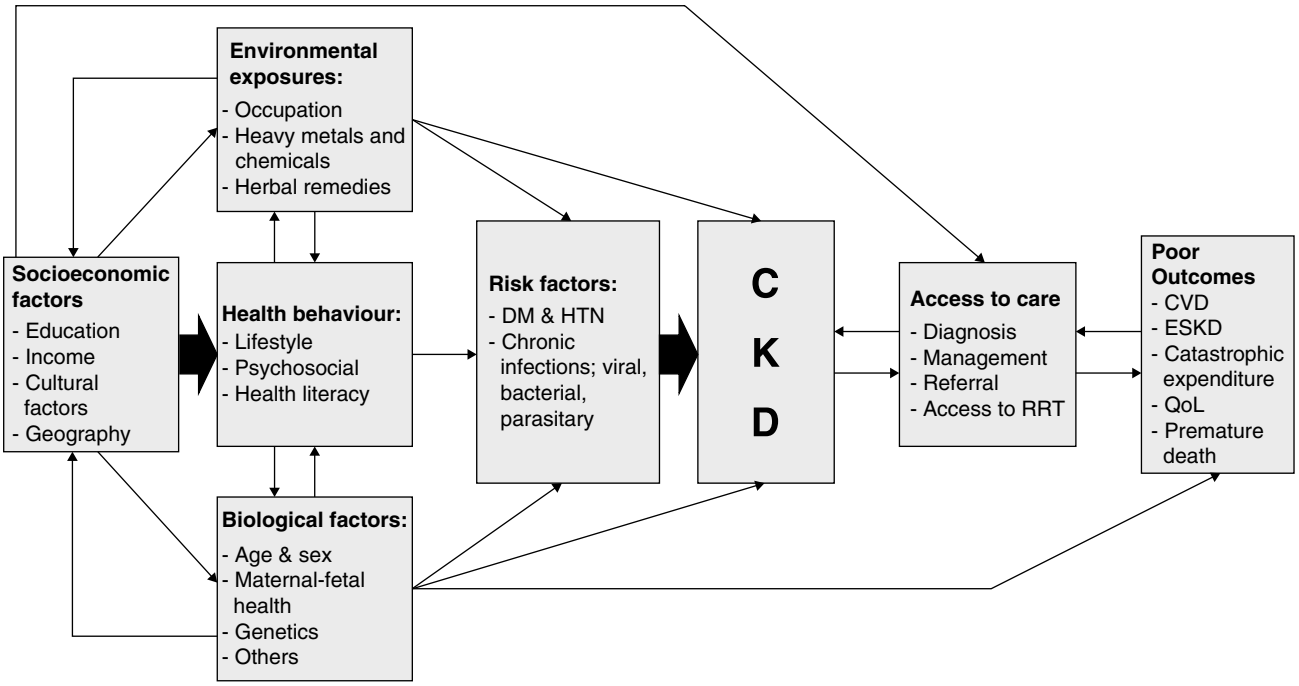

Figure 6.1 Theoretical model: interaction of socioeconomic, environmental, and biological factors and their impact on health behavior, risk factors, and direct causes of CKD, access to care, and outcomes. CKD, chronic kidney disease; CVD, DM, ESKD, end-stage kidney disease; HTN, QoL,

Environmental Exposures

Environmental exposures associated with the development of kidney disease are well known [38–40]. They include heavy metals such as lead, arsenic, mercury, and cadmium, other toxins such as the aristolochic acid (the cause of the Balkan endemic nephropathy), industrial and agricultural chemicals, occupational exposures, which are not fully delineated but appear to correlate with specific occupations (e.g. Mesoamerican nephropathy and agricultural workers), medications and herbal remedies, and infections (Table 6.3). Some of these factors have been recently linked with the emerging CKDu hotspots around the globe [38, 60]. Defined as "countries, regions, communities, or ethnicities with higher than an average incidence of CKD" [61], these hotspots are currently of major research interest, even though there is a paucity of evidence to establish a cause–effect relationship in most cases [13]. Importantly, most of these hotspots are located in LMICs with limited health resources, and thus are closely linked to socioeconomic factors. The cases arise mainly from socioeconomically deprived communities, mostly consisting of working-class individuals whose income directly depends on their ability to continue working in the very conditions that potentially expose them to kidney injury. Frequently, affected communities lack social security and have limited availability of public health protection programs. Associated with this deprivation comes a lack of health resources, both infrastructure and trained professionals. This limited capacity for systematic research has hindered efforts to accurately identify hotspots for disease and reliably estimate incidence rates [13, 44, 61].

Biological Factors

Apart from aging, there are two main determinants that predispose individuals to developing kidney disease and can be considered inherently biological: genetics and developmental programming. Genome-wide association studies and other novel sequencing techniques have identified at least 50 genetic regions or variants associated with adverse kidney outcomes and the development of CKD [62]. As genetic variants are inherently linked with ancestry and vary across populations, population-based genetic studies have given key insights into kidney function traits and have been helpful toward understanding the distribution of kidney disease in specific populations.

In the United States, a major disparity in CKD has long been documented between black and nonblack populations [56]. African Americans have historically had higher progression of diabetic and nondiabetic kidney disease. Even though African Americans represent about 13% of the US population, they comprise 33% of incident cases of ESKD. Moreover, the lifetime risk of ESKD in African Americans is an estimated 8.2% (compared with only 2.7% in European Americans) [57], with a disproportionate number of patients requiring RRT.

Table 6.3 Description of identified CKD hotspots or disadvantaged populations with CKD.

Region	Cause or type of CKD	Comments	Certainty of evidence (GRADE)
Sub-Saharan Africa	HIV-related	HIV-related GN in countries with high prevalence of the infection [20]; certain genetic variants in the APOL1 gene may predispose to HIV-related nephropathy in African population [41]; the prevalence of CKD among populations with HIV is estimated to be around 12% in sub-Saharan Africa [19]	High ●●●●
	Malaria	Mostly caused by *Plasmodium falciparum* [20]; immune-mediated glomerular and tubular disease [42]; 250 million cases of malaria per year of which 90% in sub-Saharan Africa; 445 000 deaths in 2015, of which 91% in sub-Saharan Africa; renal involvement (i.e. AKI) in at least half of malaria deaths [42, 43] Limited evidence of a direct association of malaria and CKD	
Central America and Mexico	Mesoamerican nephropathy	Working conditions; unknown etiology; repeated episodes of acute kidney injury which evolve into overt CKD; possibly related with heat-stress, exposure to agrochemicals, use of NSAID and other over-the-counter drugs [13, 44, 45]	Low ●●○○
	Diabetic nephropathy	Unhealthy diet and sedentary lifestyle; high rates of overweight and obesity; high prevalence of diabetes with suboptimal management [17, 18]; high prevalence of CKD among those with diabetes and or hypertension, with most of them being undiagnosed [16, 46]; higher risks of kidney-associated death [17, 18]	High ●●●●
Southern Asia	Sri Lanka nephropathy	Chronic tubule-interstitial nephritis in agricultural and construction workers; unknown cause; exposure to cadmium through food chain and pesticides exacerbated by genetic factors [47] or selenium deficiency [48] suggested as possible causes; clinically similar to MeN [38]	Low ●●○○
	Andhra Pradesh, India	Coastal regions known as Udannam area; unknown cause; contamination of drinking water suspected, but no evidence found of chemicals above permissible limits [49]	
Oceania	Australian Northern Territory and Maori and Pacific communities in New Zealand	Higher incidence of CKD among rural aboriginal communities in central Australia; probably associated with higher prevalence of overweight and obesity as early as from childhood; a potentially strong role of developmental origins of disease [27, 50–52]	Low ●●○○
Europe	Balkan endemic nephropathy	Endemic along the Danube river Most likely cause is consumption of aristolochic acid obtained from wheat frown in fields contaminated with *Aristolochia clematitis* [53–55]	Moderate ●●●○
North America	African-American communities	Genetic predisposition for CKD (APOL1 high-risk variants) in combination with health disparities [56, 57]	High ●●●●
	Hispanic agricultural workers	AKI among agricultural workers after workshifts; potentially similar to MeN [58, 59].	Low ●●○○

It was recently discovered that two coding variants of the *Apolipoprotein L1* (APOL1*)* gene on chromosome 22q13 were associated with higher rates of focal segmental glomerulosclerosis (odds ratio 10.5) and hypertension-attributed ESKD (odds ratio 7.3) [63, 64]. Interestingly, these two variants are common in individuals of recent African ancestry, mostly absent in European populations, and appear to be protective against African sleeping sickness as *Apolipoprotein* L-1 has an active lytic role in trypanosomes. Moreover, it has been proposed that these variants may be involved in the development of HIV-associated nephropathy [41], sickle cell kidney disease [65], and severe lupus nephritis [66].

Understanding the role of *APOL1* is paramount for assessing the burden of CKD among African Americans and, globally, in populations with African ancestry. It is estimated that about five million African Americans possess at least two *APOL1* nephropathy variants, which puts these populations at a higher risk of developing CKD. APOL1-associated kidney disease could potentially account for up to 40% of the total burden observed in African Americans [57]. The interaction of *APOL1* with environmental – potentially modifiable – risk factors and other genes represents a major area of interest for research that will allow a more detailed phenotyping of kidney disease, particularly in those individuals with poor response to therapies for blood pressure control and proteinuria reduction. The example of APOL1 underscores the important role that genetic factors may have in the burden of kidney disease and its clustering in specific populations. Research on interactions between genes and environment is still at an early stage, although it is an area of great interest for CKD hotspots. Some examples include Sri Lanka nephropathy and a single-nucleotide polymorphism in the SCL13A3 gene, which appears to predispose to CKD [47]. Likewise, a gene in 3q25 could explain the familial clustering of the Balkan endemic nephropathy [53]. Further studies are, however, still required to replicate and confirm such associations.

In addition to genetic and lifestyle factors as determinants of noncommunicable diseases, the "developmental origins of disease" has emerged as a comprehensive pathophysiological model of disease risk, which may be of particular relevance to the kidney [67]. This model proposes that individuals at greatest risk of kidney disease [68, 69] – as well as diabetes, [70, 71] hypertension, [72] and cardiovascular disease [73, 74] – are those who experienced adverse physiological conditions such as maternal malnutrition [75, 76] during gestation, resulting in low birth weight and underdevelopment of fetal kidneys. Furthermore, consequent rapid weight gain after birth is associated with childhood and adulthood obesity [77–79], a well-known risk factor for diabetes, hypertension, and kidney disease. Likewise, low birth weight, prematurity, and small size for gestational age have been associated with reduced nephron mass and an increased risk of developing CKD and hypertension in adult life [80]. The global impact of these risk factors is substantial. In LMICs, a total of 43.3 million deliveries were either premature or small for gestational age in 2010 [81], thus giving them a higher risk of developing noncommunicable diseases including kidney disease [67]. Albeit a reduced nephron number may not be sufficient to develop CKD in adult life, the interaction of such predisposition with high-risk genetic variants, environmental factors, and other stressors (e.g. episodes of acute kidney injury) may become relevant in a fraction of cases. A life course approach that assesses the interaction between genetics, perinatal, childhood, and adulthood exposures is likely to better inform our understanding of the development of CKD in disadvantaged populations [14, 44].

There are important gaps to be addressed in the understanding of biological factors and kidney disease [38]. First, education and awareness of clinicians, researchers, and patients is still limited. This is particularly relevant in terms of translation of research findings into therapeutics, as well understanding the attributable fraction of genetics to the overall burden of kidney disease. Second, the majority of genetic research is carried out in populations of European ancestry, even though indigenous and other disadvantaged populations have shown higher rates of kidney disease. This lack of diversity substantially hinders the generalizability of genetic findings, raises the issue of potentially misclassifying benign variants as pathogenic [82], and limits the understanding of kidney disease among disadvantaged populations. An improved knowledge of genetic and developmental determinants of kidney disease and their interaction with environmental factors may provide important insights into renal pathophysiology, which in turn could facilitate the development of more effective prevention strategies and pave the way for novel therapeutics.

Challenges in the Diagnosis of CKD Among Disadvantaged Populations

There are several challenges which need to be systematically addressed in the context of CKD in disadvantaged populations. These include lack of awareness, strategies for screening, workforce capacity, and availability of laboratory tests.

Awareness

Lack of awareness is a major barrier to tackling the public health issue of CKD. This is particularly problematic in LMICs, where the majority of individuals with CKD go undetected [23]. It is estimated that only one-third of individuals with CKD are diagnosed worldwide [4]. A population-wide study in the United States in high-risk individuals reported that the prevalence and awareness of CKD were, respectively, 23.4% and 11.9% for Asians and Pacific Islanders respondents, 29.5% and 8.6% for European Americans, 20.3% and 11.1% for Hispanics, 22.8% and 6.3% for African Americans, and 29.2% and 6.8% for Native Americans [83]. A study in China reported that the prevalence and awareness of CKD were 5.7% and 1.0% [84], whereas in another study from this country, only 8% of rural Chinese individuals with CKD were aware of having the disease [85]. Finally, a study from Mexico reporting prevalence of CKD in high-risk populations showed that only 1% of the participants were aware of having CKD despite 71% of them having had a doctor's appointment in the last year [16]. Further reports show that the proportion of the CKD population that is aware of their condition is low in many other LMICs, including Tanzania (10%) [14], Senegal (23%), and Taiwan (3.5%) [86]. These data suggest that the gap in awareness is important in all populations, but may be substantially larger in LMICs.

Screening

A major challenge in the diagnosis of CKD is deciding if a screening program – either in the general population or restricted to high-risk individuals – is appropriate [87]. Wilson and Junger proposed 10 criteria in 1968 to help decision-makers in the implementation of screening programs. In disadvantaged populations, special consideration of the availability of diagnostic tools and treatment options that are affordable and sustainable must be prioritized. The arguments in favor of screening for CKD in disadvantaged populations are, first, that the burden is substantial, as shown by the observed high prevalence, the low rate of awareness, and unduly high risks of premature death and morbidity reported among such populations. Second, that the economic burden of CKD is substantial and appears to be higher in LMIC, for both households and health systems [4]. Third, the natural history of CKD is relatively well understood. The progression of CKD from its early stages to kidney failure ranges between 12 and 15 years, although the range can be variable [88]. This window allows for the implementation of effective strategies that can slow the progression of disease and/or prevent complications, such as treatment of hypertension, maintenance of good glycemic control, and the use of lipid-lowering therapy [89, 90]. There is, however, uncertainty surrounding CKDu hotspots since little is known about the natural history of disease and there is no evidence of the effectiveness of therapy. Nevertheless, the global consensus is that an early diagnosis is preferred with the objective of identifying the cause of kidney injury and preventing progression and the requirement of RRT [2].

Diagnostic Tools

A related challenge is the selection of tests for screening and diagnosis. There is very limited evidence to guide choices, and decisions should be based on local and regional resources as well as the cultural acceptability of each mode of testing. An initial approach with risk scores and questionnaires to identify high-risk individuals is potentially useful for large-scale screening. The models used for predicting the risk of having CKD and its progression are largely based on European or North American populations and often require measuring biomarkers. This is a major inconvenience in resource-poor settings where laboratory testing is not readily available [87, 91]. In addition, the diagnosis and staging of CKD require the measurement of both glomerular filtration rate and albuminuria [89], with multiple tests available. The quality of such tests in LMICs varies widely, with limited use of validated tools [19, 92]. These differences could potentially explain the heterogeneity observed in the estimates of CKD prevalence in these populations. In a 2014 systematic review and meta-analysis on the epidemiology of CKD in sub-Saharan Africa that included 90 studies from 96 sites, the measurement of urine protein was the most common method for determining the presence of kidney disease (62 out of 90 studies [69%]) [19]. Only 22 studies (24%) used the Cockcroft–Gault formula and 17 (19%) used the Modification of Diet in Renal Disease (MDRD) formula to eGFR. This study reported an overall prevalence of CKD of 13.9% (95% CI 12.2–15.7). Substantial variability was found between countries, with estimates ranging from 2% in Cote d'Ivoire to 30% in Zimbabwe. Apart from differences in sampling procedures, this heterogeneity was also attributed to differences in the measurement methods. One plausible solution to facilitate screening and diagnosis of CKD in resource-limited settings is the use of point-of-care tests for measuring creatinine [93] and albuminuria [94]. Although these methods are not as reliable as laboratory-based measurements, they offer advantages including prompt decision-making by the clinician, avoidance of time-consuming logistics for transportation of specimens (of major relevance for

isolated tropical communities in which samples can be damaged by heat), and cost savings for patients through reductions in clinic visits.

Other Challenges

There are several additional challenges associated with diagnosing CKD in disadvantaged populations, including diversity in the underlying causes of kidney disease and a lack of consensus on diagnostic criteria for specific diseases, i.e. mesoamerican nephropathy and other cases of unknown etiology. The limited availability of reliable and validated measures of kidney function is compounded by a paucity of adequately trained health professionals, particularly in under-resourced communities.

Challenges and Opportunities in Treatment

Given the high costs associated with provision of RRT, the main focus of therapeutic interventions should be on CKD prevention, slowing disease progression, and avoiding complications.

Early Prevention Programs

These programs are centered on early and aggressive management of risk factors, and have been shown to be cost-effective for cardinal risk factors such as diabetes and hypertension [95]. Interventions may include early detection using low-cost tools such as albuminuria testing, and the use of renoprotective agents such as renin angiotensin aldosterone system blockers.

Access to Optimal Care for CKD

Limited access to primary care and specialist nephrology care is a common problem in LMICs. There is scope for international training programs to enhance capacity in CKD care in these countries, for example the fellowship opportunities provided by the International Society of Nephrology. In addition, efforts should be made to widen the availability and affordability of medications with proven benefit for CKD patients, such as antihypertensives and lipid-lowering medications.

Availability of RRT

ESKD in disadvantaged populations has an unduly poor outcome. A retrospective study in Nigeria that included 760 patients with incident ESKD showed that the majority were offered hemodialysis (73%), with only a small proportion having access to peritoneal dialysis (1%) or transplantation (<1%). The remaining 25% received conservative management due to unaffordability of dialysis or ongoing viral infection which precluded their access to hemodialysis. Moreover, only 5% of those who initiated hemodialysis were able to afford treatment for longer than 3 months [96]. A similar scenario has been described in India, where less than 10% of patients requiring RRT receive it and of those >70% die within the first 12 weeks due to inability to afford sustained treatment [97, 98]. Likewise, in Asian countries without funded renal programs, around 90% of patients with ESKD die within months of diagnosis due to a lack of access [60]. As the costs of dialysis rise to US$20000–100 000 per year [99], for a great proportion of individuals from disadvantaged communities RRT becomes prohibitively expensive.

A systematic review and meta-analysis that pooled data from 123 countries and included 93% of the worldwide population estimated that, in 2010, 2.618 million individuals received RRT, of which 2.050 million (78%) received dialysis and the remainder a transplant [8]. It was conservatively estimated that the number of patients needing RRT was 4.902 million, but it could be closer 9.701 million. Thus, between half (2.284 million, 47%) and up to three-quarters (7.083 million, 73%) of individuals requiring RRT worldwide did not receive it, which translated to at least 2.284 million premature deaths. Notably, an alarming disparity between the need for and the receipt of RRT was found in terms of income level. Of all those receiving RRT in 2010, 92.8% resided in high-income or high-middle income countries. This represents a striking 70-fold prevalence gradient [6]. By contrast, only 7.2% resided in low-income countries where 96% of the patients requiring RRT did not receive it. This proportion decreases to 88% in LMICs and 58% in high-middle income countries, which suggests that access to RRT is socially graded. The projections from this meta-analysis estimated that by 2030 the number of individuals requiring RRT will more than double to a total of 5.439 million, with the greatest increase in Asia and Africa, the regions where the population is expected to grow the most.

Unhealthy aging has been largely documented as the result of gains in economic development and increases in life expectancy in the developing world and is arguably the demographic reason pushing the expected increase in the demand of RRT. This is of relevance in those disadvantaged populations in which unhealthy behaviors have increased the prevalence of risk factors for CKD such as hypertension and diabetes. Countries must prepare their health systems to face the challenge ahead and meet the demands of RRT in the present and foreseeable future.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. RRT rationing resulting from limited facilities and resources in low and middle-income countries is complex. Key areas of opportunity in regard to RRT include establishing registries of dialysis and transplantation in all countries. Likewise, identifying patients who need RRT but do not receive it is important. Open sharing of methodology, sampling frameworks, and innovative strategies between countries could potentially facilitate this work in countries without a registry.

Health Literacy

Limited health literacy affects 25% of the population with CKD and this percentage is likely higher in disadvantaged populations and has been associated with adverse outcomes in CKD populations [100]. A recent meta-analysis that examined 13 studies found that limited health literacy was significantly associated with hospitalizations, emergency department use, missed dialysis sessions, cardiovascular events, and mortality [101].

Conclusion

CKD in disadvantaged populations is increasingly recognized in low-, middle- and high-income countries and is due in part to rising incidence and prevalence of hypertension and diabetes in those populations, as well as unique genetic, environmental, and socioeconomic factors. Implementation of effective prevention programs and improvements in quality of care for the diverse causes of kidney disease in each population is required. Such programs must be tailored to local requirements so that they can meet the epidemiological, cultural, and societal needs of the communities they serve, and ultimately translate into better clinical outcomes. Identifying the major risk factors in each community is paramount to maximize the efficacy of any intervention. Similarly, prioritizing low-cost interventions, such as albuminuria testing followed by treatment with blockers of the renin-angiotensin system or bicarbonate supplementation for metabolic acidosis, may have a significant impact on CKD prevention and disease progression. Only by tracking these outcomes can the implementation of practical interventions be appropriately evaluated. Inequity in health is at the very core of the observed disparities in CKD burden among disadvantaged populations. It is a moral imperative to solve the existing disparities, especially given the evidence that, in some cases, the lack of access to RRT is due to inefficient allocation of available resources rather than a lack of them [102]. The WHO has established sustainable development goals for universal health coverage. It is paramount that efforts from global health organizations are championed by researchers and clinicians at every level to achieve an improvement in CKD care worldwide.

[2] *Section of Nephrology, Department of Medicine, University of Chicago, Chicago, IL, USA*

Introduction

Acute kidney injury (AKI), previously known as acute renal failure, refers to a sudden reduction in kidney function. This acute reduction in kidney function typically manifests as a fall in urine output and/or a rise in blood urea nitrogen and creatinine, two blood biomarkers that are filtered and excreted by the kidney and are readily measured in the clinical laboratory. While initial descriptions of AKI focused on the most severe forms of disease, over the past 15 years there has been a growing recognition that small changes in serum creatinine are associated with adverse outcomes, including longer hospital length of stay and death. Thus, a major focus of the field for the past 15 years has been the development of consensus definitions and approaches to defining AKI. These have been important to moving the field forward because they have allowed comparison of studies across settings and disease subtypes.

In this chapter, we will review the consensus definitions for AKI, along with recent work to develop consensus regarding acute kidney disease (AKD) that does not meet the technical definition of AKI and recovery from AKI. We will also review common settings in which AKI may occur and the epidemiology of the disease, along with the potential role of novel biomarkers in disease recognition and classification.

Overview/Definition

In 2004, the Acute Dialysis Quality Initiative (ADQI), a consensus group of intensivists and nephrologists, proposed the Risk, Injury, Failure, Loss, and End-stage (RIFLE) classification system for AKI (Table 7.1) [1]. A major goal was to ensure that studies in the literature were comparable: because of differences in the definition of acute renal failure used in prior studies (e.g. ranging from a 0.5 mg/dl rise in creatinine to the need for renal replacement therapy [RRT]), the incidence and outcomes of AKI varied widely. That is, AKI defined as a 0.5 mg/dl increase in creatinine was much more common and associated with better outcomes than AKI defined as the need for RRT.

Importantly, the RIFLE criteria defined three levels of decreased kidney function (risk, injury, failure; Table 7.1) along with loss of kidney function (persistent AKI, defined as the need for RRT for 4 weeks) and end-stage renal disease. The rationale for defining different levels of disease severity was that earlier AKI recognition might allow for earlier treatment (including supportive care and nephrotoxin avoidance, for example), recognizing that there is an inherent tradeoff between sensitivity and specificity that may occur when small changes in serum creatinine are used to define AKI. In addition, the RIFLE criteria defined AKI using changes in either serum creatinine or urine output, with the rationale that these are both markers of decreased kidney function. However, it should be noted that studies prior to the development of the RIFLE criteria almost universally used serum creatinine, not urine output, to define acute renal failure. In addition, at the time the RIFLE criteria were published, the literature on the predictive value of graded reductions in urine output for adverse outcomes was limited, with no data to support the concept that the urine output criteria proposed were in any way "equivalent" to the creatinine-based AKI criteria. Subsequent studies have suggested that AKI defined by

Table 7.1 Comparison of consensus AKI definitions.

Stage	Urine output (common to all three)	Creatinine (KDIGO)	Creatinine (AKIN)	RIFLE category	Creatinine (RIFLE)
1	<0.5 ml/kg/h for 6–12 h	1.5–1.9 times baseline over 7 days or ≥0.3 mg/dl absolute increase over 48 h	1.5–2 times baseline or ≥0.3 mg/dl absolute increase within 48 h	Risk	≥1.5 increase in SCr within 7 days, sustained for ≥24 h
2	<0.5 ml/kg/h for ≥12 h	2.0–2.9 times baseline	>2–3 times baseline	Injury	≥2 increase in SCr
3	<0.3 ml/kg/h for ≥24 h or anuria for ≥12 h	≥3.0 times baseline, or increase to ≥4.0 mg/dl or initiation of RRT	>3.0 times baseline, or increase to ≥4.0 mg/dl (with an increase of 0.5 mg/dl) or initiation of RRT	Failure	≥3.0 increase in SCr or increase to ≥4.0 mg/dl (with an increase of 0.5 mg/dl) or initiation of RRT
				Loss	Complete loss of kidney function >4 weeks
				End-stage kidney disease	End-stage renal disease >3 months

Urine output criteria are common to all three. The ADQI RIFLE definition incorporated three categories of injury and two outcomes that varied by severity. Outcomes were eliminated from the subsequent Acute Kidney Injury Network (AKIN) and KDIGO definitions. The AKIN definition incorporated smaller changes in SCr and the KDIGO definition added more definitive time frames to the definition.

urine output criteria is much more common than AKI defined by creatinine criteria. Isolated AKI by urine output criteria is generally associated with a significant increase in the risk of death compared to those with no AKI, but generally lower risk compared to those with isolated AKI by creatinine criteria; those with AKI by both urine output and creatinine criteria have the greatest risk of death [2–5]. However, despite these caveats, creating consensus criteria for both changes in serum creatinine and urine output to define AKI was a critical step to moving the field forward. Finally, the RIFLE criteria recognized that relative changes in serum creatinine are important, that is, in someone with normal kidney function (e.g. baseline creatinine of 0.8 mg/dl), an increase in serum creatinine to 1.6 mg/dl represents a larger change in renal function than a rise of the same absolute magnitude in an individual with underlying chronic kidney disease (e.g. a rise from 4.0 to 4.8 mg/dl). Therefore, inherent in the RIFLE criteria is knowledge of a baseline creatinine. In the absence of a baseline creatinine, the RIFLE criteria proposed the use of a creatinine that represents an estimated glomerular filtration rate (eGFR) of 75 ml/min/1.73 m^2 by the Modification of Diet in Renal Disease (MDRD) estimating equation (also referred to as MDRD-75).

Following a number of studies suggesting that small absolute changes in serum creatinine are also associated with an increased risk of adverse outcomes, the RIFLE criteria were modified slightly by the Acute Kidney Injury Network (AKIN) [6]. These studies included a large retrospective study by Chertow et al. [7], which demonstrated that a 0.3–0.4 mg/dl increase in serum creatinine was associated with a 1.7-fold higher odds of death in multivariable analysis adjusting for age, gender, chronic kidney disease, and diagnosis codes. Thus, a 0.3 mg/dl increase in serum creatinine over 48 hours was added to the definition of mild (Stage 1) AKI (see Table 7.1). Importantly, both "loss" and "end-stage kidney disease" were recognized to be outcomes of AKI and dropped from the definition.

In 2012, Kidney Disease Improving Global Outcomes (KDIGO) comprehensively reviewed the field of AKI to develop a series of consensus guidelines focused on AKI diagnosis and treatment [8]. As part of these guidelines, the RIFLE and AKIN criteria were combined into the KDIGO definition (Table 7.1). In addition, the concept of AKD was introduced. This comprises AKI, along with a decrease in eGFR <60 ml/min/1.73 m^2, decrease in glomerular filtration rate (GFR) by ≥35% or increase in serum creatinine (SCr) by >50% for less than 3 months. Subsequently, a staging system for AKD analogous to that for AKI has been proposed, though this definition has not been as well validated [9]. Along the same lines, criteria to define and stage kidney recovery have yet to be well standardized and are, when creatinine is used as the measure of kidney function, potentially confounded by changes in nutritional status and muscle mass (see below for additional discussion).

Classification of AKI

Since at present the majority of care for AKI is supportive and focused on the underlying etiology (e.g. volume resuscitation for the patient with volume depletion and "prerenal" physiology), it is imperative to search for and identify the primary cause of AKI [10]. Careful history-taking, chart review, and physical examination remain the fundamental tenets of the workup. Specific causes of AKI that may warrant cause-specific therapy include acute interstitial nephritis (withdrawal of offending medication, steroids), vasculitis/acute glomerulonephritis (consideration of immunosuppression), thrombotic microangiopathy (consideration of pheresis or monoclonal antibody therapy targeting the complement pathway), and urinary tract obstruction (relief/decompression of obstruction).

Broadly speaking, AKI can be subdivided into prerenal, intrarenal, and postrenal etiologies (Table 7.2). Prerenal physiology refers to any cause of decreased kidney perfusion, which may be due to volume depletion itself. Alternatively, decreased kidney perfusion may occur due to other pathologic conditions, including heart failure, liver disease, nephrotic syndrome, and impaired venous return in the setting of abdominal compartment syndrome. Intrarenal failure may be due to damage to the vasculature, glomerulus, tubules, or interstitium. Finally, postrenal AKI is due to obstruction anywhere along the collecting system. In particular in those who have had a kidney transplant or who have a solitary kidney, it is essential to assess for and rule out obstruction. In hospitalized patients, the most common form of AKI is acute tubular necrosis (intrarenal) due to ischemia, nephrotoxins, or

Table 7.2 Classification of AKI by etiology.

Decreased renal perfusion, e.g. "prerenal" states	
Hypovolemia	Increased losses; poor oral intake
Reduced cardiac output	Heart failure, cardiac tamponade, massive pulmonary embolism
Renal vasomodulation/shunting	Medications (NSAIDs, ACE/ARB, cyclosporine, iodinated contrast), hypercalcemia, hepatorenal syndrome, abdominal compartment syndrome
Systemic vasodilation	Sepsis, hepatorenal syndrome
Intrarenal causes	
Vascular	Renal artery stenosis
Microvascular	Thrombotic microangiopathies, cholesterol emboli
Glomerular	Rapidly progressive (crescentic) glomerulonephritis
	Immune complex diseases: IgA nephropathy, post-infectious, lupus, mixed cryoglobuminemia with MPGN
	Pauci-immune glomerulonephritis: ANCA-associated and ANCA-negative
	Some causes of nephrotic range proteinuria may associate with AKI: in particular light-chain cast nephropathy
Tubulointerstitium	Acute interstitial nephritis: medications, infection, lymphoproliferative disease
	Pigment nephropathy: rhabdomyolysis (myoglobin), massive hemolysis (hemoglobin)
	Crystal nephropathy: uric acid (tumor lysis), acyclovir, sulfonamides, protease inhibitors (indinavir, atazanavir), methotrexate, ethylene glycol, acute phosphate nephropathy, oxalate nephropathy
	Myeloma-associated AKI (cast nephropathy)
	Acute tubular necrosis: ischemia (shock), medications
	Sepsis-associated AKI
Postrenal	
Bladder outlet	Benign prostatic hypertrophy, strictures, blood clots
Ureteral	Bilateral obstruction (or unilateral with one kidney): stones, malignancy, retroperitoneal fibrosis
Renal pelvis	Papillary necrosis (NSAIDs), stones

Etiologies of AKI can be broadly divided into prerenal, intrarenal, and postrenal causes and then further subdivided.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sepsis. At present, the classification of AKI is based predominantly on history/clinical context and may be supported by laboratory testing. The laboratory studies will depend on the suspected etiology of AKI and may include a serologic workup for vasculitis or a peripheral blood smear to assess for hemolysis if thrombotic microangiopathy is suspected. Urinalysis and urine microscopy may be helpful. In particular, the presence of casts in the urine may provide insight into the cause of AKI (Table 7.3). However, casts are not required for these diagnoses. Urinalysis scores which quantify the number of renal tubular epithelial cells or cast elements per microscopic fields have been repeatedly shown to be specific for AKI and correlate with AKI severity (in this case, with acute tubular necrosis as the etiology of AKI) [11–13]. Widespread acceptance has been hampered by the lack of large-scale validation and the relatively modest sensitivity for urine microscopy for detecting AKI [11, 14–16]. Table 7.4 summarizes several of the published urinalysis risk scores.

Table 7.3 Overview of urine cast types with typical associations.

Waxy	Chronic kidney disease
Hyaline	Prerenal azotemia
Granular	Acute tubular necrosis
Dark/muddy brown	Acute tubular necrosis
White blood cells	Interstitial nephritis
Red blood cells	Glomerulonephritis

Table 7.4 Review of urine microscopy scoring systems for the diagnosis of AKI due to acute tubular necrosis.

Study	Scoring system
Chawla et al. [11]	Grade 1: No casts or RTE Grade 2: At least 1 cast or RTE but <10% of LPF Grade 3: Many casts or RTEs (between 10% and 90% of LPF) Grade 4: Sheet of muddy brown casts and RTEs in >90% of LPF
Perazella et al. [12]	0 points: No casts or RTE seen 1 point each: 1–5 casts per LPF or 1–5 RTEs per HPF 2 points each: ≥6 casts per LPF or ≥6 RTEs per HPF
Bagshaw et al. [14]	0 points: No casts or RTE seen 1 point each: 1 casts or 1 RTEs per HPF 2 points each: 2–4 casts or RTEs per HPF 3 points each: ≥5 casts or ≥5 RTEs per HPF

RTE, renal tubule epithelial cells; LPF, low power field; HPF, high power field.

Limitations of SCr to Define AKI

With regards to defining AKI itself, in individuals with limited muscle mass (e.g. older adults, those with end-stage liver disease), SCr may overestimate eGFR because it is a breakdown product of creatine derived from muscle. Across the world, SCr measurements are now harmonized to IDMS standard materials, so there is not much variation in the laboratory measurement of serum creatinine. However, at high levels, chromogens, both endogenous and exogenous (e.g. bilirubin, uric acid, ascorbic acid, some cephalosporins, and ketones), may interfere with the creatinine assay [8]. Thus, there has been tremendous interest in identifying other endogenous filtration markers (e.g. functional markers) that are not associated with muscle mass to define chronic kidney disease (e.g. cystatin C [17]). However, changes in markers including cystatin C have not been as well-studied in the context of AKI, so there is no consensus regarding absolute biomarker levels or changes in biomarker levels that could be used to define AKI. Finally, there is growing interest in other filtration markers, including proenkephalin [18], but more studies are needed.

Biomarkers of AKI/AKD

While there have been numerous publications on the role of novel biomarkers in the risk stratification, diagnosis, prognosis, and long-term outcomes of AKI, to date there has not been the formal inclusion of these novel tests into diagnostic criteria and none have gained wide clinical acceptance. Regardless, these investigations have helped to focus the ideal characteristics of a novel biomarker specific for AKI/AKD. Such biomarkers should (i) be organ specific and allow differentiation between the traditional causes of AKI (intrarenal, prerenal, and postrenal), (ii) detect AKI early in the course and predict the course/future implications of AKD, (iii) identify the source/nature of AKI, (iv) be site-specific and able to inform pathologic changes in various segments of renal tubules and correlate with the histology on kidney biopsies, and (v) be easily and reliably measured in a noninvasive, rapid manner, which implies that the marker is stable in its matrix and relatively inexpensive to measure.

The concept of functional versus damage markers of kidney injury is similar to diagnostic models from other aspects of medical care. It is common to see functional biomarkers (e.g. electrocardiograms or imaged-based stress tests) paired with damage biomarkers (creatine kinase, troponins). An ADQI consensus statement recommended that the combination of functional and damage biomarkers

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

would be helpful to define AKI. (Figure 7.1) [19]. By stratifying patients across these two domains, a novel cohort with "subclinical AKI" can be identified: those with a change in damage biomarkers in the absence of change in functional biomarkers [20, 21]. This group of patients, who would not be detected by creatinine or urine output-based KDIGO criteria, appears to have the same risk for severe AKI and adverse outcomes (e.g. inpatient mortality) as patients who have a change in functional markers in the absence of change in damage biomarkers (more traditionally thought of as having prerenal azotemia). In a pooled, prospective observational cohort of 2322 subjects (1452 with cardiac surgery and 870 with critical illness), Haase et al. designated subjects as neutrophil gelatinase associated lipocalin (NGAL)-positive or NGAL-negative and creatinine-positive or creatinine-negative. They demonstrated that individuals who were NGAL-positive/creatinine-negative needed RRT more than 16 times more frequently than those who were NGAL-negative/creatinine-negative (odds ratio 16.4, 95% confidence interval 3.6–76.9) [20]. NGAL-positive/creatinine-negative patients were also in ICU and hospital longer and more likely to experience inpatient mortality compared to NGAL-negative/creatinine-negative subjects. The incidence and duration of these outcomes were similar in the NGAL-positive/creatinine-negative and NGAL-negative/creatinine-positive cohorts. This concept of damage biomarker positive/functional biomarker negative patients being at increased risk for adverse outcomes has been validated in other cohorts [22, 23].

In 2014, the combination of urine tissue inhibitor of metalloproteinase-2 and insulin-like growth factor binding protein-7 (TIMP2*IGFBP7) became the first novel AKI biomarker approved by the Food and Drug Administration (FDA). The intended use of TIMP-2*IGFBP7 is to assess the risk of developing KDIGO Stage 2 AKI over the next 12 hours in high-risk critically ill patients [24, 25]. Some studies have shown improved outcomes when supportive care bundles are applied to patients identified by high levels of TIMP-2*IGFBP7 [26, 27], but TIMP-2*IGFBP7 has not yet gained widespread acceptance. In other parts of the world (e.g. Europe and Japan, respectively), urinary NGAL and liver-fatty acid binding protein (L-FABP) can be measured in clinical practice as measures of AKI, though clear thresholds for AKI have not been developed.

As previously mentioned, there has been extensive investigation into several biomarkers of kidney injury in several

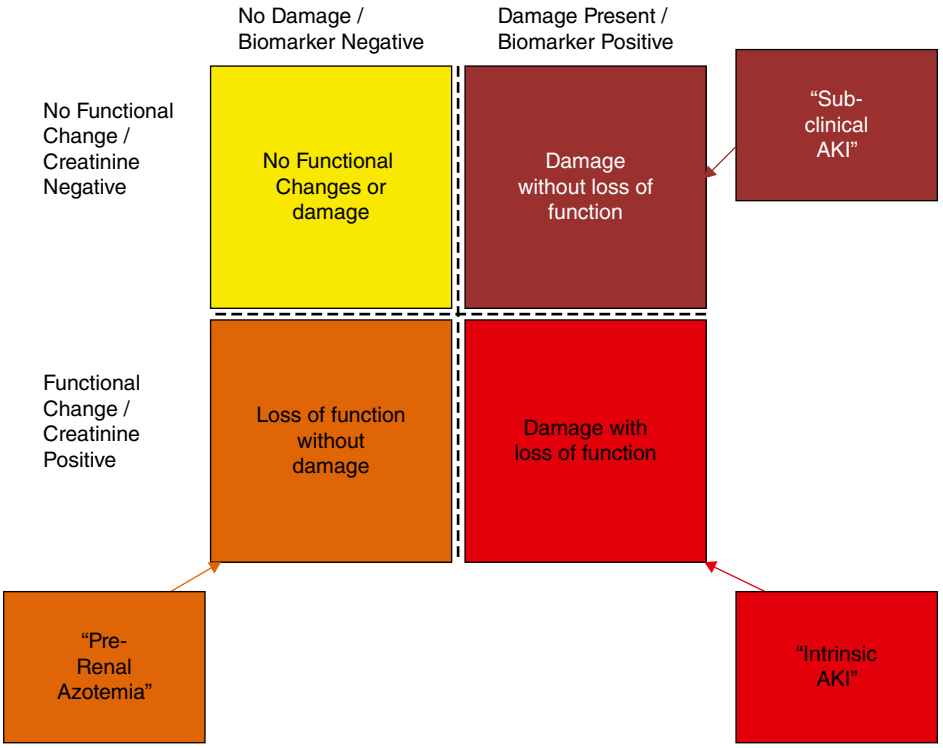

Figure 7.1 The Acute Dialysis Quality Initiative recommended criteria for defining acute kidney injury (AKI) in terms of changes in biomarkers of kidney function (SCr) and biomarkers of kidney damage/injury. This paradigm allows for the combination of injury biomarkers with SCr and has proven useful in the discrimination of patients with AKI and resulted in the concept of "subclinical AKI." *Source:* Adapted from [19].

clinical settings, including after cardiac surgery, critical illness/ICU admission, or admission to the emergency department. In each of these settings biomarkers have been examined to determine their association with a variety of short and long-term outcomes, including but not limited to the early detection of AKI, the temporal nature of the AKI (transient versus persistent), the detection of severe (e.g. dialysis requiring) AKI, and inpatient mortality. It should not be surprising that a single biomarker has not been associated with all of these outcomes across multiple settings, given the biological heterogeneity that underlies the diverse etiologies of AKI. However, this does not diminish the importance of their performance for individual endpoints in specific clinical settings. Table 7.5 summarizes the current state of the ability of biomarkers to detect clinical endpoints related to AKI in a variety of settings. We anticipate continued investigation of these biomarkers as well as novel tests over the course of the next decade.

Epidemiology of AKI: Identification of High-risk Patients

In terms of identification of high-risk patients, both chronic kidney disease and the presence of proteinuria/albuminuria (as dip-stick, protein to creatinine ratio or albumin to creatinine ratio) have been strongly implicated as risk factors for AKI [29–31]. However, in particular in the perioperative setting, preoperative risk stratification, while helpful, does not necessarily robustly predict postoperative AKI because AKI typically is due to a complicated operative course in a high-risk patient. For example, in a classic analysis, using data from more than 33 000 patients at the Cleveland Clinic, a scoring system to identify those at high risk of dialysis requiring AKI was developed, with a robust area under the curve of 0.81 and 0.82 in the test and validation datasets, respectively [32]. However, given the very large size of the low risk group, more dialysis events occurred in the lower risk groups than the highest risk group. Thus, while such scores may be useful for preoperative risk assessment and for enrichment of populations for clinical trials, they are of somewhat limited utility because they typically do not incorporate risk based on the ongoing clinical course/current situation.

Thus, there has been significant interest in risk stratification to identify patients who may benefit from novel/damage biomarker assessment. For example, the urine output following a protocolized intravenous dose of furosemide in the setting of stage 1 or 2 AKI (furosemide stress test, FST) has been shown to reliably predict AKI progression to Stage 3 and the need for RRT [33–35]. As a functional biomarker of proximal tubule and loop of Henle function, the FST has outperformed several damage biomarkers when compared directly [33, 36]. With the renal angina index, patient demographics and other risk factors (comorbidities, procedure/medication exposure) are combined with small changes in serum creatinine and/or urine output and the presence of volume overload to identify patients where damage biomarkers should be measured and may identify those with early AKI or at high risk of AKI [37]. Multiple novel risk scores (some of which include AKI biomarkers) have also been proposed [38, 39]. However, to date no single risk score (or biomarker) has been universally validated.

In addition to this explosion of more traditional risk scores, there is increasing interest in developing complex risk assessment models which can utilize all of the information that is available in the medical record to identify patients at risk for AKI [40–43]. The appeal of such risk assessment models is that they can incorporate the most up-to-date data to evaluate changes in risk. While such electronic biomarkers of AKI represent a potential future option, they will require wide-scale validation prior to becoming part of the standard of care. In the near future, electronic risk scores and biochemical biomarkers (in particular, damage biomarkers) are likely to be incorporated in AKI/AKD definitions.

Epidemiology of AKI: Incidence and Outcomes

The exact incidence and outcomes of AKI will vary depending on the definition used and clinical setting. For example, more severe AKI requiring dialysis in sicker patients (e.g. ICU patients) is associated with a greater risk of death than stage 1 KDIGO AKI in all hospitalized patients. Although AKI has long been recognized to associate with a high risk of short-term adverse outcomes such as death, more recently it has become clear that AKI is associated with an increased risk of a number of long-term adverse outcomes [44, 45], including de novo chronic kidney disease/chronic kidney disease progression, cardiovascular disease, and death. Again, these associations are likely graded, with greater risk associated with more severe AKI. That said, even fully recovered AKI (based on serum creatinine) appears to be associated with an increased risk of adverse outcomes, including chronic kidney disease and death [46]. Thus, in AKI survivors, clinicians should be aware of the increased risk of long-term adverse outcomes.

Prerenal Failure and Obstructive Disease

Mubeen M. Khan and Kevin W. Finkel

Division of Renal Diseases and Hypertension, McGovern Medical School, Houston, TX, USA

Introduction

Prerenal azotemia is the most common form of acute kidney injury (AKI) in hospitalized patients and, if uncorrected, can lead to ischemic parenchymal damage and acute tubular necrosis (ATN) [1, 2]. The clinical syndrome of prerenal failure is characterized by intact tubular function with impaired filtration function because of renal hypoperfusion and usually manifests as low urine volume, reduced urinary concentration of sodium (UNa) and fractional excretion of sodium (FeNa%), and an elevated ratio of blood urea nitrogen to serum creatinine (Cr).

Prerenal failure is the result of either true volume depletion, as occurs with hemorrhage or excessive diuresis, or "effective" volume depletion in circumstances such as congestive heart failure (cardiorenal syndrome), liver failure with ascites (hepatorenal syndrome), and sepsis. The etiologies for prerenal failure are outlined in Table 8.1. In both instances decreased intravascular volume causes baroreceptor stimulation and enhanced adrenergic output, leading to systemic and local regulatory mechanisms aimed at restoring normal perfusion pressure.

At the level of the kidney, a complex interplay between neuroendocrine and vasoactive agents initially compensates for decreased perfusion pressure. Specifically, angiotensin II causes preferential vasoconstriction of the efferent arteriole, increased proximal tubular reabsorption, elevation of glomerular hydrostatic pressure, and a reduced glomerular ultrafiltration coefficient. Because of angiotensin II preferential constriction of the efferent arteriole, with mild to moderate volume depletion, the glomerular filtration rate (GFR) is maintained. With severe volume depletion, frank ischemic ATN may ensue. Since the GFR in such situations is dependent on relative efferent arteriolar vasoconstriction, the use of angiotensin II antagonists, such as angiotensin converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs), can precipitate ATN. The vasoconstrictor effects of angiotensin II are opposed by endogenously produced prostaglandins and nitric oxide. When used acutely in prerenal failure, nonsteroidal anti-inflammatory drugs lead to unopposed vasoconstriction and worsening of renal function.

The differential vasoconstrictor activity of AII between the afferent and efferent arteriole may be best explained by the interaction of AII-mediated vasoconstriction with various local mediators of vasodilation stimulated by AII. This is illustrated by contrasting results between *in vivo* and *in vitro* vasoconstrictor studies. Microperfusion studies have demonstrated a 100-fold greater sensitivity for AII to elicit a vasoconstrictor response in the efferent versus afferent arteriole. In vitro studies, however, failed to show a difference in vasoconstrictor sensitivity in these vascular beds, suggesting that the production of other local factors stimulated by AII may contribute to the differential response. These include prostaglandins secreted by the glomerulus in response to AII. Experimental inhibition of prostaglandin synthesis with indomethacin enhances afferent and efferent arteriole vasoconstriction by AII, with afferent arteriolar response to AII increasing tenfold [3].

In response to decreased renal perfusion, activation of the renin–aldosterone axis and release of antidiuretic hormone also occur, increasing sodium and water retention in an attempt to restore intravascular volume. These temporizing physiologic measures are necessary to maintain perfusion pressures in the face of frank volume depletion but are ineffective in sepsis and clearly deleterious in conditions such as heart failure with pulmonary edema.

Given this background, prerenal failure is not a simple case of hypovolemia that can be corrected by administration

Diuresis	Atheroembolism
Diarrhea	Vasculitis
Excessive sweating	Aortic aneurysm dissection

of intravascular crystalloid or colloid. Treatment must, by necessity, be directed at the underlying pathophysiology that has triggered the compensatory physiologic response common to all etiologies. Therefore, an evidence-based approach to the treatment of prerenal azotemia requires a review of the available data on several subgroups of patients and cannot take a "one size fits all" approach.

Diagnosis

Many causes of prerenal failure are clinically obvious. With reliance on history, physical examination, and certain laboratory findings, patients with true volume depletion are often easily identified and can be treated with aggressive volume repletion. Such patients demonstrate orthostatic hypotension, tachycardia, dry mucous membranes, low urinary output, and poor skin turgor. Other patients require a more careful evaluation for fluid responsiveness. Accurate predictors of fluid responsiveness are essential in the management of hemodynamic instability. For those who are fluid responsive, they guide fluid replacement. For those who are not, they guide vasopressor and inotrope use and help avoid the detrimental effects of excess fluid. Pulse pressure variation (PPV) may be measured in the mechanically ventilated patient and is derived from the arterial waveform. It is defined as the maximum pulse pressure in a respiratory cycle minus the minimum pulse pressure divided by the mean of these two values [$PPV = 100 \times (PP_{max} - PP_{min})/PP_{mean}$] In a systematic review to determine the ability of dynamic changes in arterial waveform-derived variables, such as PPV, to predict fluid responsiveness and compare these with static indices of fluid responsiveness, dynamic changes of arterial waveform-derived variables during mechanical ventilation were highly accurate in predicting volume responsiveness in critically ill patients when compared with traditional static indices of volume responsiveness, such as CVP [4]. In non-ventilated patients, the passive leg raise (PLR) has been shown to be predictive of a response to a fluid challenge. In this maneuver, the patient is passively moved from a 45-degree semi-recumbent position to supine with legs raised and held to 45 degrees for one minute. Baseline measurement (e.g., cardiac output) is obtained before the maneuver and repeated afterward. In a prospective, observational study, Duus, et al investigated the reproducibility of PLR vs fluid bolus using non-invasive cardiac output monitor (NICOM) for assessment of fluid responsiveness in spontaneously breathing ED patients. They enrolled 109 patients and each patient received two PLR and two boluses. PLR was strongly correlated with fluid responsiveness as measured by NICOM, whereas the boluses were less strongly correlated. In addition, PLR technique was more reproducible than the fluid bolus technique [5]. POCUS has also been used increasingly in recent years. One such use to assess volume status is IVC measurements. In a systematic review and meta-analysis, Orso, et al reviewed 26 studies that investigated the role of IVC collapsibility or distensibility or IVC diameter in critically ill patients (both ventilated and non-ventilated). Ultimately, they found that ultrasound evaluation of the diameter of the IVC and its respiratory variations was not a reliable method to predict fluid responsiveness [6]. Although much has been made of the utility of urinary indices in AKI (vide infra), they are unnecessary in such situations, and patients promptly respond to volume resuscitation.

CVP and PAOP

Although physicians often rely on central venous pressure (CVP) and pulmonary artery occlusion pressure (PAOP) to guide fluid administration to determine whether or not a patient has true volume depletion, there is little evidence that such measurements are clinically useful. There are no trials that have assessed the utility of these measurements specifically for determining the reversibility of prerenal failure.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The CVP and PAOP are frequently used as means of determining cardiac preload and volume status. However, their use has been criticized because of poor ability to predict which patients will have improvement in their hemodynamic status when given fluid resuscitation [7]. As reviewed by Michard and Teboul, in three of five trials assessing the ability of CVP to predict fluid responsiveness in critically ill patients, defined as an improvement in either stroke volume or cardiac output, there was no significant difference in the baseline CVP measurements between responders and nonresponders. The two remaining studies reported lower baseline values of CVP in responders; however, the marked overlap of individual CVP levels did not allow for the identification of a discriminatory cutoff value. Likewise, baseline PAOP was not significantly lower in responders versus nonresponders in seven of nine studies. Three studies reported a significant difference in the baseline PAOP between the groups, being higher in responders in a single study and lower in responders in two studies. However, in none of the studies could a cutoff PAOP value be found that predicted the hemodynamic response to volume expansion. In normal subjects, Kumar and associates demonstrated a lack of correlation between initial CVP and PAOP values, and both end diastolic volume and stroke volume [8]. Furthermore, changes in both parameters following 31 of saline infusion did not correlate with changes in end diastolic volume and cardiac performance.

In addition, numerous randomized controlled trials (RCTs) and meta-analyses assessing the benefit of pulmonary artery catheters (PAC) in a variety of clinical circumstances have been reported [9–11]. In a meta-analysis of 13 RCTs, the use of PAC neither increased overall mortality and hospital days nor conferred any benefit [12]. Likewise, in an RCT of 676 patients with shock mainly from sepsis, ARDS, or both, early use of PAC did not significantly affect mortality or morbidity, including the need for dialysis [13]. Therefore, in critically ill patients with multiple reasons for prerenal failure (sepsis, capillary leak with third spacing, positive pressure ventilation, hypoalbuminemia, cardiac dysfunction, and liver disease), measurement of CVP and/or PAOP does not improve outcome and has poor predictive value for improvement in renal function.

Urine Output

The development of oliguria (urine output of less than 400 ml/day) does not ensure the presence of prerenal failure. It occurs in both prerenal failure states and numerous other causes of AKI, including ATN, obstructive nephropathy, glomerulonephritis, and atheroembolic disease. Despite the compensatory mechanisms invoked in response to decreased renal perfusion that increase salt and water retention by the kidneys in prerenal failure states, higher urine outputs can ensue in the face of underlying chronic kidney disease, salt wasting states such as adrenal insufficiency and cerebral salt wasting, concomitant use of diuretics, osmotic diuresis, and the presence of nonreabsorbed anions, such as ketones and bicarbonate in the urine.

Urinalysis

Urinalysis is often used to differentiate various causes of AKI. In prerenal failure, the urine is concentrated and the urinary sediment is bland. Bland urinary sediment, however, does not allow for discrimination between true and effective volume depletion. Furthermore, patients with prerenal failure can have abnormal sediment if they have a pre-existing renal disorder, bilirubin in the urine (causing granular casts), or microscopic hematuria and bacteruria from an indwelling bladder catheter. The utility of the urinalysis in differentiating prerenal failure from AKI has been called further into question by the results of two recent systematic reviews on the urinary findings in sepsis-related AKI (human and experimental animal studies). These systematic reviews demonstrated substantial heterogeneity between studies and suggested that the scientific basis for the use of urinary microscopy in septic AKI and, by extension, to differentiating ATN from prerenal failure is weak [14, 15].

On the other hand, Varghese, et al, showed in a recent prospective study that serial microscopic examinations of the urinary sediment revealed diagnostic findings of ATI otherwise not identified in a single examination [16]. This study used two different urinary cast scores developed by Chawla and Parazella, each of which has been previously validated to predict renal outcomes in AKI [17] and [18]. With Chawla's cast scoring index, there was a 99.8% interobserver agreement among three nephrologists who independently scored 30 patients with AKI due to ATI. In addition, the ROC AUC curve for the scoring index to predict renal recovery was 0.79, indicating that the scoring index may be useful in predicting renal outcomes. Parazella's scoring system was significantly associated with increased risk of worsening AKI (adjusted relative risk: 7.3; 95% confidence interval: 4.5 to 9.7 for worsening with score of > or =3 versus score of 0) and was more predictive than AKI Network stage at the time of consultation.

Urinary Indices

The measurement of urinary sodium (UNa) and calculation of the fractional excretion of sodium (FeNa%) has been routinely recommended as a means to differentiate oliguric prerenal failure from oliguric ATN, as shown in Table 8.2. In the sentinel study reported by Miller et al., a UNa concentration of less than 20 mEq/l had an 80% sensitivity and specificity for differentiating prerenal failure from ATN in the face of oliguria [19]. The FeNa% performed even better, with sensitivity and specificity of 98% and 95%, respectively. The utility of either measurement was significantly less in the absence of oliguria. However, there are numerous exceptions to the general rule [20–22]. Both UNa and FeNa% can be low, suggestive of prerenal failure with AKI from rhabdomyolysis, radiocontrast nephropathy, acute glomerulonephritis, multiple myeloma, amphotericin B toxicity, and early

Table 8.2 Urinary indices in ARF.

	Number of patients with condition/total number of patients		
Index and range	**Prerenal failure**	**Oliguric ATN**	**Nonoliguric ATN**
Urine Na (mEq/l)			
<20	18/30 (60%)	0/24 (0%)	2/13 (6%)
20–40	12/30 (40%)	14/24 (59%)	11/31 (35%)
>40	0/30 (0%)	10/24 (41%)	18/31 (59%)
FeNa%			
<1	27/30 (90%)	1/24 (4%)	4/31 (12%)

Source: Adapted from Miller et al. [19].

obstructive nephropathy. Thus, the finding of renal sodium avidity does not allow one to discriminate between true and effective volume depletion nor reliably predict reversibility with volume administration.

Despite these limitations, a recent study demonstrates a potential role for FENa% in patients with cirrhosis. In a prospective analysis of 200 patients with decompensated cirrhosis with AKI, Gowda, et al evaluated the diagnostic utility of FeNa% and fractional excretion of urea nitrogen (FEUN%) for differentiating AKI phenotypes (i.e., prerenal, ATN, and HRS). After determining the optimal cutoffs, they validated their findings in an independent cohort of 50 patients. The AUC for FENa% was 86.6% and for FEUN% was 60.3% for ATN vs non-ATN. The AUC for FENa% to differentiate between HRS and non-HRS was 74.5%. FEUN% could not differentiate HRS vs non-HRS satisfactorily (60.4%). FENa% and FEUN% were unable to differentiate between prerenal and HRS (AUC < 70). Thus, among cirrhotics, FENa% at admission can be used to differentiate ATN from prerenal and HRS.

The use of diuretics can increase urinary sodium loss even in the face of prerenal failure, thus negating the utility of the FeNa%. Since the (FeUN%) is primarily dependent on passive forces, it is less influenced by the administration of diuretics and may be useful in the evaluation of AKI. A group of 102 patients with AKI was divided into three subgroups: prerenal failure, prerenal failure treated with diuretics, and ATN. The FeNa% was low in 92% of the prerenal failure group and 48% of prerenal failure patients receiving diuretics. Both groups had similar and significantly lower FeUN% values than the ATN patients [23].

Treatment

In the patient with clinically obvious volume depletion, adequate fluid resuscitation can be achieved by the administration of crystalloids, such as normal saline or lactated Ringers solution. Such patients often show remarkable improvement in their renal function over a short period of time.

In the complex or critically ill patient, the situation is more challenging. In this population, it is difficult to accurately determine intravascular volume and whether the prerenal failure is due to true or effective volume depletion, while concern is great for the potential harm of indiscriminant fluid administration in the face of acute lung injury or frank ARDS. There is also debate on what type of fluid, colloid versus crystalloid, is best for volume resuscitation in such patients. Although not specifically done to address prerenal failure, review of recent clinical trials in these areas can provide some type of general guideline.

Goal-directed Hemodynamic Management and Fluid Therapy

Previous observational nonrandomized studies have shown that patients who survived critical illness had higher values for cardiac index and oxygen delivery than those who died and that those values were higher than normal physiologic levels [26, 27]. Two studies of surgical patients showed significant decreases in mortality associated with therapy directed at increasing hemodynamic parameters to supraphysiologic values, whereas no benefit was seen in patients with sepsis and mixed groups of critically ill patients [28–31]. Subsequently, two RCTs assessed the benefit of goal-directed hemodynamic therapy in critically ill patients. In one trial of 100 patients randomized to dobutamine or placebo there were no differences in mean arterial pressure (MAP) or oxygen consumption despite higher cardiac index and oxygen delivery in the treatment group [32]. In fact, the treatment group had a significantly higher mortality rate than the placebo group. In another trial of 762 patients randomized into one of three intervention groups, hemodynamic therapy aimed at achieving supranormal values for cardiac index or normal values for mixed venous oxygenation saturation did not reduce morbidity or mortality [33].

In 2001, Rivers et al reported the results of a nRCT on early goal-directed therapy (EGDT) in the treatment of severe sepsis and septic shock [34]. Patients with severe sepsis or septic shock were randomly assigned upon emergency center arrival to either 6 hours of EGDT or standard therapy prior to admission to the ICU. Active intervention aimed at achieving a central venous oxygen saturation of 70% included saline boluses targeted to a CVP level of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

8–12 mmHg, vasopressor agents to maintain a MAP greater than 65 mmHg, transfusion to a hematocrit of 30%, and dobutamine. Although the patients assigned to active intervention received more fluid and blood products in the initial 24-hour period, they experienced a significantly reduced rate of organ failure and death.

Subsequently, the ARDS Clinical Trials Network assessed optimal fluid management in patients in the ICU with acute lung injury [4]. In this RCT, 1000 patients were assigned to either a conservative or liberal strategy of fluid management using explicit protocols applied for 7 days. The mean cumulative fluid balances in the conservative versus liberal groups were −136 and 6992 ml, respectively. Although there was no difference in mortality, the conservative group had significantly reduced ventilator and ICU days, and improved oxygenation. Importantly, conservative fluid management did not increase the need for renal replacement therapy (RRT). Three independent multicenter RCTs evaluated EGDT [24]. All three trials confirmed that there was no survival benefit compared to usual resuscitation. In a patient level meta-analysis from these trial, EGDT did not result in better outcomes than usual care and was associated with higher hospitalization costs across a broad range of patient and hospital characteristics [25].

Crystalloid Versus Colloid Fluids

The putative superiority of colloid over crystalloid fluids in the resuscitation of the critically ill patient has been a source of considerable controversy. Aggressive hydration with crystalloid solutions such as normal saline can worsen interstitial edema and pulmonary function. Colloidal solutions, such as various starches and human albumin, might appear to be attractive alternatives, but there is little solid evidence of their superiority in clinical trials. Systematic reviews of RCTs comparing crystalloids with colloids have yielded conflicting results. Some trials have found an increased mortality rate associated with the administration of human albumin and hydroxyethylstarch, while others have not [35–38]. More recently, a large, randomized, controlled prospective trial of albumin versus saline in almost 7000 critically ill patients found no benefit of one over the other [39]. Specifically, there was no demonstrable effect on mortality, renal function, or the frequency of RRT. Of note, patients with cirrhosis were excluded from this trial, and limited data suggest that albumin is useful to prevent AKI in cirrhotic patients with spontaneous bacterial peritonitis [40].

In a systematic review and meta-analysis that evaluated hemodynamic response to crystalloids/colloids in critically ill adults, central venous pressure was significantly lower with crystalloids vs. albumin (mean difference [MD]: −3.5 mm Hg; $p = .03$) or gelatin (MD: −9.2 mm Hg; $p = .02$). Compared with the albumin group, cardiac index was significantly lower in the crystalloid group (MD: −0.6 L/min/m^2, $p < .001$). All mortality and 90-day mortality were significantly lower for crystalloids compared with HES (relative risk 0.91; $p = .009$ and 0.9; $p = .005$, respectively). These findings suggest that crystalloids are less effective than colloids at hemodynamic stabilization in this population [41]. In a recent Cochrane review assessing the effect of using colloids vs crystalloids in critically ill patients on mortality and need for blood transfusion or renal replacement therapy (RRT), using various colloids vs crystalloids appeared to make little or no difference to mortality. Starches probably slightly increase the need for blood transfusion and RRT [42].

High- chloride Versus Balanced Fluids

Recent attention has shifted toward the potential negative effects of chloride in intravenous fluids on patient outcomes. The concentration of chloride in human plasma is approximately 100 meq/l. In 0.9% saline, it is much higher at 154 meq/l. In Ringer's lactate (LR), it is still somewhat elevated at 109 meq/l, and in Plasma-Lyte, it is more physiologic at 98 meq/l.

Two recent studies from a single center investigated whether fluid resuscitation of noncritically ill (SALT-ED) and critically ill (SMART) patients with balanced crystalloid vs isotonic crystalloid in the emergency department resulted in earlier hospital discharge. The primary outcome was hospital-free days (days alive after discharge before day 28) and the secondary outcome included a composite of major adverse kidney events within 30 days. The type of crystalloid (balanced vs isotonic) administered in the emergency department was assigned to each patient on the basis of calendar month, with the entire emergency department crossing over between balanced crystalloids (mostly lactated ringers) and saline monthly during the 16-month trial. Results showed that the number of hospital-free days did not differ between the balanced crystalloids and saline groups (median, 25 days in each group; adjusted odds ratio with balanced crystalloids, 0.98; 95% confidence interval [CI], 0.92 to 1.04; $P = 0.41$). However, balanced crystalloids resulted in a lower incidence of major adverse kidney events within 30 days than saline (4.7% vs. 5.6%; adjusted odds ratio, 0.82; 95% CI, 0.70 to 0.95; $P = 0.01$) [43]. In the SMART trial, critically patients were assigned to receive saline or balanced crystalloids in a randomized fashion. The primary outcome was a major adverse kidney event within 30 days—a composite of death from any cause, new renal replacement therapy, or persistent renal dysfunction—or 30 days, whichever occurred first. Among the 7942 patients in the balanced-crystalloids group, 1139 (14.3%) had a major adverse kidney event, as compared with 1211 of 7860 patients (15.4%) in the saline group (marginal odds ratio, 0.91; 95% confidence interval [CI], 0.84 to 0.99; conditional odds ratio, 0.90; 95% CI, 0.82 to 0.99; $P = 0.04$). In-hospital mortality at 30 days was 10.3% in the balanced-crystalloids group and 11.1% in the saline group ($P = 0.06$). The incidence of new renal-replacement therapy was 2.5% and 2.9%, respectively ($P = 0.08$), and the incidence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

persistent renal dysfunction was 6.4% and 6.6%, respectively (P = 0.60). The authors concluded that in critically ill adults, the use of balanced crystalloids for IV resuscitation resulted in a lower rate of the composite outcome of death from any cause, new renal-replacement therapy, or persistent renal dysfunction than the use of saline. [44].

Summary

In the complex medical patient, prerenal failure can occur from either true or effective volume depletion. Since both circumstances share the same physiologic derangements, clinical parameters such as urine output and urinary electrolytes do not have any discriminatory power between the two. It is also difficult to predict which patients will benefit from volume resuscitation based on measurement of the CVP or PAOP. Often, the only way to determine if the renal failure is reversible is to provide an empiric "fluid challenge" and assess the clinical response. With regard to approaching the critically ill patient who may be functionally prerenal failure, fluid management is dependent on timing. Early intervention with goal-directed therapy, resulting in a positive fluid balance in the first 24 hours, is associated with reduced organ failure. In patients already in the ICU with lung injury, a conservative fluid approach improves pulmonary function without adverse renal effects.

Cardiorenal Syndrome

A recent classification of CRS proposed by the 7th Acute Dialysis Quality Initiate consensus conference has divided the syndromes into those that are "cardiorenal" referring to when cardiac dysfunction leads to kidney dysfunction and those that are "renocardiac" referring to when primary kidney dysfunction leads to cardiac dysfunction. These syndromes are further classified based on their acuity and the presence of a systemic (non-cardiac, non-renal) illness that may play a role in the pathophysiology [45]. There are 4 major mechanisms implicated in CRS: increased renal venous pressure (ie, venous congestion), neurohumoral imbalances, reduced renal perfusion, and right ventricular dilation and dysfunction [46].

Venous hypertension is thought to result in decreased renal perfusion, raised kidney interstitial pressure, narrowed arterial-to-venous renal pressure gradient, decreased glomerular filtration rate (GFR), maladaptive autoregulatory responses, and other characteristic neurohumoral imbalances. This higher renal venous pressure attenuates glomerular filtration, causes tubule collapse, and may trigger tubulointerstitial fibrosis [46]. (The neurohumoral mechanisms underlying CRS consist of activation of the renin-angiotensin-aldosterone and sympathetic nervous systems as well as increased production of antidiuretic hormone and endothelin 1. These processes increase salt and water retention and systemic vasoconstriction, which in turn decrease renal perfusion. Activation of the previously mentioned systems overrides the vasodilatory effects of natriuretic peptides, nitric oxide, prostaglandins, and bradykinin. Chronic and acute exacerbations of CHF are associated with widespread inflammation and high levels of proinflammatory cytokines, which may further boost cardiac, kidney, and other tissue dysfunction [46].

Renal perfusion is regulated by adenosine receptors involved with tubuloglomerular feedback (TGF) signaling, and maintain intrarenal vascular tone via a number of pathways which, in CRS, result in afferent arteriolar vasoconstriction and efferent arteriolar dilation. Actions of adenosine at the macula densa and mesangium depend on angiotensin, renin, nitric oxide, and prostaglandin levels, which are altered in CRS [46].

Right ventricular dysfunction increases central venous pressure, which in turn increases renal venous pressure. Right ventricular dilation and dysfunction also reduce left ventricular filling and decrease renal arterial pressure. The combination of increased renal venous and decreased renal arterial pressures diminishes the pressure gradient across the glomerulus and decreases GFR [46].

Treatment of Cardiorenal Syndrome

Loop diuretics remain the cornerstone of treatment of cardiorenal syndrome for effecting natriuresis, net negative salt and water balance, and extracellular volume reduction. Extracellular fluid volume reduction in patients with CHF returns hemodynamics to a more optimal position on the Frank-Starling curve. Reducing volume overload improves renal perfusion pressure by decreasing central venous pressure, renal venous pressure, and right ventricular dilation, which improves right and left ventricular performance. Diuretic resistance remains a challenge and is manifested as a failure to to resolve congestion and a low urine Na despite maximal dose of diuretic. This can occur as a result of inadequate dose, nonadherence, pharmacokinetic factors, CKD, hypotension, hypoalbuminemia, antin-atriuretic drugs, nephron remodeling, and neurohormonal braking. This last phenomenon occurs when diuretics reduce extracellular fluid volume to such an extent that the sympathetic nervous system and angiotensin II production are activated, which then stimulate proximal tubular sodium reabsorption, effectively neutralizing the therapeutic effect of the diuretic [46]. Despite the centrality of diuretics in the management of cardiorenal syndrome, there is a paucity of data to guide their use. The Diuretic Optimization Strategies Evaluation (DOSE) trial was a prospective, double-blind, randomized trial of patients with acute decompensated heart failure that compared intravenous furosemide delivered by either a bolus every 12 hours or by continuous infusion and at either a low dose (equivalent to the patient's previous oral dose) or a high dose (2.5 times the previous oral dose). Co-primary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

endpoints were patients' global assessment of symptoms and the change in serum creatinine level from baseline to 72 hours. At the conclusion, the were no significant differences in patients' global assessment of symptoms or in the change in renal function when diuretic therapy was administered by bolus as compared with continuous infusion or at a high dose as compared with a low dose. However, the high-dose strategy was associated with a greater diuresis [47]. With regard to diuretic dosing regimen, Grodin, et al compared the diuretic effect of a urine output-guided diuretic adjustment and standard therapy for the management of cardiorenal syndrome in acute decompensated heart failure. They showed that compared with a standard diuretic regimen, patients who received stepwise intensification of diuretic therapy had greater net fluid and weight loss without being associated with renal compromise [48]. Another strategy to guide dosing is to follow urine sodium concentrations. An intravenous loop diuretic dose that produces a spot urine sodium <50 mmol/l at 2 hours is inadequate and should generally be doubled until a maximal dose is reached (not clearly defined but often up to a bolus dose of 200 to 300 mg of furosemide equivalents) and urine sodium remeasured. Once an adequate natriuretic response is achieved, the dose can be repeated every 6 to 12 h to achieve the goal net negative sodium balance [49]. Addition of low-dose dopamine or low-dose nesiritide to diuretic therapy in patients hospitalized with acute decompensated heart failure and renal dysfunction were studied in the Renal Optimization Strategies Evaluation (ROSE) trial, which showed that neither had a significant effect on 72-hour cumulative urine volume or change in cystatin C level when compared to placebo [50].

ACE Inhibitors and ARBs

The strength of evidence of ACE inhibitors in HF with predialytic CKD is not established given the lack of inclusion of these patients in RCTs for HF. Both CONSENSUS (Cooperative North Scandinavian Enalapril Survival Study) and SOLVD (Study of Left Ventricular Dysfunction) trial demonstrated the benefits of enalapril for HF symptoms and hospitalization reduction. The enalapril group in SOLVD showed a 33% higher likelihood of a serum creatinine rise of >0.5 mg/dL, but no data on progression of CKD, ESKD, or doubling of creatinine were reported [51] A post hoc analysis of SOLVD with HF and CKD demonstrated a mortality benefit even in subjects with higher degrees of CKD [52]. In a propensity score analysis of 1665 patients with HF (EF <45%) and CKD (eGFR <60 mL/min per 1.73 m^2), treatment with an ACE inhibitor or ARB was associated with significant reductions in all-cause mortality (HR, 0.68 [95% CI, 0.74–0.996]; $P=0.04$) [53]. A recent meta-analysis of data from 3 trials in HFrEF that compared combined neprilysin/RAAS inhibition with RAAS inhibition alone. The trials were the IMPRESS (Inhibition of Metallo Protease by Omapatrilat in a Randomized Exercise and Symptoms Study of Heart Failure; n = 573), OVERTURE (Omapatrilat Versus Enalapril Randomized Trial of Utility in Reducing Events trial; n = 5770), and PARADIGM-HF (Prospective Comparison of ARNI With ACEI to Determine Impact on Global Mortality and Morbidity in Heart Failure; n = 8399). The composite outcome of death or HHF was reduced numerically in patients receiving combined neprilysin/RAAS inhibition in all 3 trials, with a pooled HR of 0.86 (95% CI, 0.76–0.97; $P=0.013$). Combined neprilysin/RAAS inhibition compared with ACE inhibitor alone was associated with more hypotension but less renal dysfunction and hyperkalemia in all 3 trials. [54]. In a subset analysis of PARADIGM-HF, treatment with sacubitril/valsartan resulted a slower rate of decrease in eGFR compared with enalapril, including in patients with CKD, despite a modest increased in albuminuria [55]. The recently published HARP-III trial, investigated the effects of sacubitril/valsartan on kidney function and cardiac biomarkers in patients with moderate to severe chronic kidney disease (GFR 20-60 ml/min/1.73 m^2). Over 12 months, sacubitril/valsartan had similar effects on kidney function and albuminuria when compared with irbesartan, but had the additional effect of lowering blood pressure and cardiac biomarkers. Addition of sacubitril to a patient on RAAS inhibition could further reduce cardiovascular risk in patients with CKD, without further worsening the CKD [56]. Data on the safety and efficacy of Mineralocorticoid receptor antagonists (MRAs in heart failure with advanced CKD are limited. In the EMPHASIS-HF trial (Eplerenone in Mild Patients Hospitalization and Survival Study in Heart Failure), the effect of eplerenone on the primary composite of end point on HHF or cardiovascular death was similar in patients dichotomized at an eGFR <60 mL/min per 1.73 m^2 [57a].

Natriuretic Peptides

B-type natriuretic peptide (BNP) is produced by the myocardial ventricles in response to increased stress. BNP results in arterial and venous vasodilation, increased sodium excretion, and suppression of the renin–angiotensin–aldosterone system.

Nesiritide, a synthetic BNP, was assessed in heart failure patients in the Vasodilation in the Management of Acute Congestive Heart Failure trial [57]. Compared to intravenous nitroglycerine, nesiritide significantly lowered PAOP at 1 hour, although there was no difference in the degree of dyspnea. Nesiritide was equally effective in patients with or without renal dysfunction (Cr > 2.0 mg/dl) [58].

In another trial nesiritide was given to patients with recent increases in baseline Cr associated with congestive heart failure exacerbation (mean Cr increase from 1.5 to 1.8 mg/dl) [59]. Compared to placebo, nesiritide resulted in no changes in urine output, sodium excretion, GFR, or effective renal plasma flow. This finding suggests that nesiritide is ineffective in cardiorenal syndrome.

Additionally, the use of nesiritide in congestive heart failure may be associated with an increased risk of acute

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. renal dysfunction and mortality. In a meta-analysis of five randomized trials including 1269 patients, the use of nesiritide was significantly associated with the development of acute renal dysfunction (an increase of Cr of ≥0.5 mg/dl) [60]. Furthermore, in three RCTs that reported mortality rates, the use of nesiritide was associated with a hazard ratio for death of 1.8 ($P = 0.057$) [61].

Ultrafiltration

The CARRESS-HF (Cardiorenal Rescue Study in Acute Decompensated Heart Failure) trial did not show a difference in weight loss with ultrafiltration vs a stepped pharmacologic therapy algorithm in patients hospitalized for acute decompensated heart failure and worsened renal function. However, ultrafiltration was associated with increased creatinine level at 96 hours [62].

A recent Cochrane review looking at the benefits and harms of pharmacological interventions for heart failure in patients with heart failure and CKD concluded that it is uncertain whether these therapies, including nesiritide, make any difference to death, hospitalizations, or adverse effects including worsening kidney function, hyperkalemia, or hypotension [63].

Obstructive Nephropathy

Urinary tract obstruction should always be considered in the differential diagnosis of AKI. Regardless of cause, obstruction of urinary flow leads to renal impairment, which early in the course of the condition is reversible if the obstruction is alleviated. Tubular function is initially affected; however, prolonged obstruction leads to tubular damage and parenchymal atrophy.

Clinical manifestations of urinary tract obstruction vary depending on the location, duration, and degree of obstruction. In patients with complete bilateral obstruction or with an obstructed solitary kidney, anuria (<50 ml urine output in 24 hours) can be the presenting feature, whereas in patients with partial obstruction, the urinary output can vary from oliguria to polyuria. Although pain is more likely to be associated with acute blockage, obstruction may be totally asymptomatic and occur without overt clinical manifestations or suggestive laboratory findings. Therefore, obstructive nephropathy should always be considered as a cause of renal failure when another obvious prerenal failure or intrinsic renal cause is not identified. The location of obstruction is anatomically divided into upper and lower urinary tract at or below the level of the bladder. Common causes of lower urinary tract obstruction include urethral strictures, prostatic hypertrophy, and neurogenic bladder.

Diagnosis of urinary tract obstruction can be difficult. Anuria, flank pain with a palpable mass, or a palpable bladder are obvious clues. Hyperkalemia with a nonanion gap metabolic acidosis is suggestive of a renal tubular acidosis associated with obstruction [64]. The urinary sediment may be bland or demonstrate crystals or hematuria, depending on the etiology of the obstruction. Patients may have very dilute urine due to the presence of an acquired form of nephrogenic diabetes insipidus [65].

Ultrasonography is the most useful test for the presence of obstruction. Although hydronephrosis is usually demonstrated, there are circumstances when hydronephrosis is not seen despite urinary tract obstruction: (i) early in the course of obstruction (12–24 hours) when the collecting system is relatively noncompliant; (ii) in the face of severe volume depletion when glomerular filtration is severely depressed; and (iii) when the collecting system is encased by retroperitoneal lymphadenopathy or fibrosis [66, 67].

Conversely, the finding of hydronephrosis on ultrasound does not prove the presence of obstruction, since it is also seen in high urinary flow states such as diuretic use and diabetes insipidus, pregnancy, previous obstruction, and congenital megaureter. In a series of 192 patients with AKI, hydronephrosis unrelated to obstruction was noted in 11% of patients [68].

Although ultrasound is the preferred imagining modality for initial assessment of obstruction, its use has been supplanted by noncontrast helical computed tomography (CT) scan in the evaluation of flank pain and nephrolithiasis. In a single-center study of 864 patients evaluated for flank pain, 34 underwent both helical CT scan and ultrasound [69]. Compared to helical CT, ultrasound was found to have sensitivity and specificity for renal stones of 81% and 100%, respectively, although the sensitivity for ureteric stones was only 46%. In the same study, the sensitivity and specificity for the detection of hydronephrosis were 93% and 100%, respectively.

In another study, 181 consecutive patients with acute flank pain underwent a combination of helical CT, ultrasound, and unenhanced radiography [70]. When compared with the diagnostic accuracy for ureterolithiasis of combined ultrasound and unenhanced radiography, helical CT had greater sensitivity (92% vs. 77%).

Treatment of obstruction and its timing is dependent on the etiology. Patients with small stones (>5 mm) can be managed conservatively with aggressive hydration and pain control in the absence of infection. Bladder catheterization should be performed if there is reason to suspect that bladder outlet obstruction is present; possible clues to this diagnosis include suprapubic pain, a palpable bladder, or an older man with unexplained renal failure. Measurement of a urinary postvoid residual is often advocated in the detection of outlet obstruction but has not been subjected to any rigorous evaluation. Nor is there a standard method of measurement or definition. Up to one-third of patients with bladder outlet obstruction demonstrated by urodynamic testing do not have an elevated postvoid residual [71]. Upper tract obstruction is relieved with either percutaneous nephrostomy tubes or ureteral stenting, depending on cause, availability, and local expertise.

The duration and severity of obstruction are the major determinants for the recovery of renal function after its correction. The longer the duration of obstruction, the less likely are the chances for complete renal recovery. There are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. few published data on the relationship between duration and obstruction and renal recovery rates. The variability is likely related to the severity and cause of obstruction, the presence of underlying chronic kidney disease, and concurrent infection. Case reports, however, have documented renal recovery after correction of obstruction lasting 12 months [72].

Postobstructive Diuresis

Postobstructive diuresis occurs when there is correction of complete bilateral obstruction or complete obstruction of a solitary kidney. It involves the production of a large volume of urine that results from a defect in urine-concentrating ability, impaired reabsorption of urinary sodium, and solute diuresis from the retained urea and intravenous administration of sodium-containing solutions [73]. Although numerous textbooks discuss the proposed pathogenesis and treatment of postobstructive diuresis, there is very little in the medical literature that describes its clinical course or outcome other than case reports and case series. Patients with relief of complete obstruction are considered at risk for developing postobstructive diuresis. It has been recommended for patients without pulmonary edema, congestive heart failure, or altered consciousness that urine losses be replaced by oral intake. Intravenous fluids are given only if the patients develop orthostatic hypotension, tachycardia, hyponatremia, or a urine output of more than 200 ml/h [74]. In high-risk patients with altered sensorium, congestive heart failure, or pulmonary edema, replacement of half the hourly urine output with half-normal saline has been recommended. If the patient is hyponatremic, normal saline should be used instead. None of these recommendations has been evaluated with rigorous clinical trial. They are considered to be prudent and reasonable based on clinical experience.

Renal failure is a common complication in patients with cirrhosis that accounts for major morbidity and mortality [1]. The definition of acute kidney injury (AKI) is based on small changes or a percentage increase serum creatinine from baseline (Table 9.1). A frequent cause of AKI is hepatorenal syndrome (HRS), which is characterized by renal vasoconstriction and a low glomerular filtration rate (GFR) with minimal renal histologic abnormalities. However, establishing the diagnosis of HRS may be difficult because there are no specific diagnostic tests or markers for this syndrome. In addition, patients with liver disease may develop other types of renal impairment such as those related to volume depletion, acute tubular necrosis, drug toxicity and/or glomerular diseases. HRS develops in patients with advanced cirrhosis and ascites; however, it occasionally occurs in patients with alcoholic hepatitis or acute liver failure [1–4]. Although advances in medical therapy of HRS are highly promising, liver transplantation remains the treatment of choice in suitable candidates. Several controlled and uncontrolled studies demonstrate that the use of splanchnic vasoconstrictors, such as terlipressin, midodrine, octreotide, and/or norepinephrine, in combination with albumin as a plasma expander are effective in reducing serum creatinine and increasing GFR to within normal limits. HRS can be effectively prevented in the setting of spontaneous bacterial peritonitis with intravenous albumin [5, 6]. This chapter will review the pathogenesis, clinical features, therapy, and prevention of HRS.

Table 9.1 Definition and staging of AKI.

Definition:
- Increase in serum creatinine ≥0.3 mg/dl (26.5 μmol/l) within 48 h; or
- A percentage increase in serum creatinine of ≥50% which is known, or presumed, to have occurred within the prior 7 days

Staging:
- Stage 1A: An increase in serum creatinine ≥0.3 mg/dl (26.5 μmol/l) or an increase in serum creatinine of ≥1.5-fold to 2-fold from baseline to a value lower than 1.5 mg/dl (133 μmol/l) from baseline to diagnosis of AKI.
- Stage 1B: An increase in serum creatinine ≥0.3 mg/dl (26.5 μmol/l) or an increase in serum creatinine of ≥1.5-fold to 2-fold from baseline to a value ≥1.5 mg/dl (133 μmol/l) from baseline to diagnosis of AKI.
- Stage 2: An increase in serum creatinine greater than twofold to threefold from baseline.
- Stage 3: An increase of serum creatinine greater than threefold from baseline or serum creatinine ≥4.0 mg/dl (353.6 μmol/l) with an acute increase ≥0.3 mg/dl (26.5 μmol/l) or initiation of renal replacement therapy.

Pathogenesis

HRS represents the end stage of a circulatory dysfunction that occurs late in the natural history of patients with cirrhosis. The main characteristic of HRS is the presence of renal vasoconstriction, which leads to a functional prerenal AKI. This vasoconstriction is a consequence of a continuous process where several underlying mechanisms interact, including changes in systemic arterial circulation, increased portal pressure, impaired cardiac function, and activation of systemic and renal vasoconstrictor factors (Figure 9.1) [7].

Arterial Vasodilation

Portal hypertension, due to an abnormal liver architecture and increased intrahepatic resistance of blood flow, causes the release of nitric oxide and other vasodilator substances

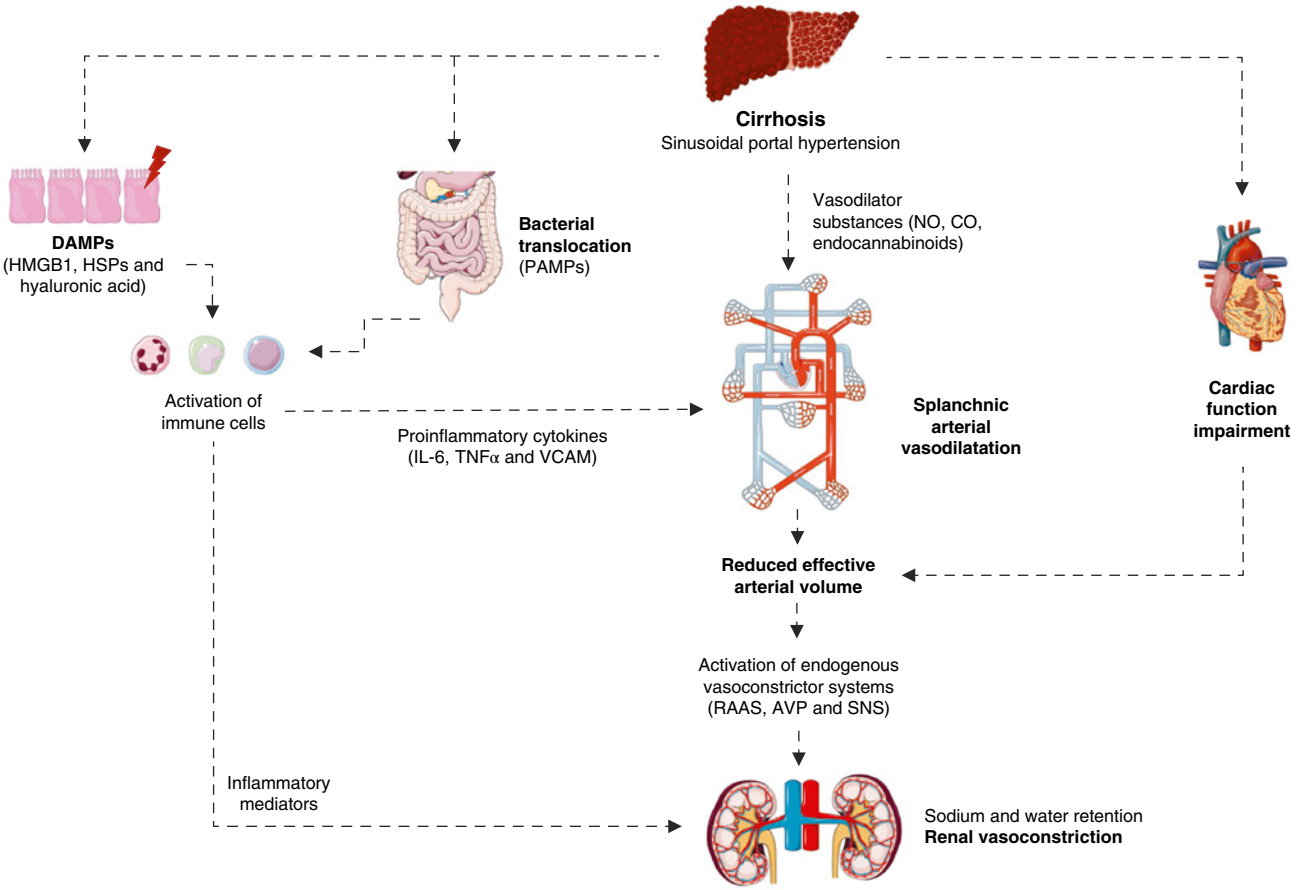

Figure 9.1 Patients with advanced cirrhosis have a marked splanchnic arterial vasodilation triggered by portal hypertension. Splanchnic vasodilation leads to a decreased systemic vascular resistance with the development of effective arterial hypovolemia. The activation of vasoconstrictor systems leads to a marked renal vasoconstriction, low glomerular filtration rate, and development of hepatorenal syndrome. In this advanced stage there is a reduced cardiac output and decreased effective arterial blood volume. Systemic inflammation is altered as well. Pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) of bacterial translocation may lead to a marked inflammatory response. AVP, arginine vasopressin; CO, carbon monoxide; HMGB1, high-mobility group box 1; HSPs, heat shock proteins; NO, nitric oxide; RAAS, renin–angiotensin–aldosterone system; SNS, sympathetic nervous system; TNF, tumor necrosis factor; VCAM, vascular cell adhesion protein.

(i.e. carbon monoxide and endogenous cannabinoids), responsible for splanchnic vasodilatation [8]. Plasma volume accumulates in the splanchnic bed, causing a compensatory response due to a fall in central (effective) blood volume. This activates the renin–angiotensin–aldosterone system (RAAS), the sympathetic nervous system (SNS), and arginine vasopressin (AVP), accounting for sodium and water retention and, in advanced stages, renal vasoconstriction [9–11]. The ongoing action of vasoconstrictor factors acting on the kidney eventually leads to HRS. This occurs because although in the early stages of cirrhosis renal blood flow may be kept within normal limits due to the effect of local renal vasodilators, with time circulating vasoconstrictors overcome the effect of renal vasodilators, leading to severe renal vasoconstriction and reduction in GFR [12, 13]. In some patients precipitating factors such as bacterial infections worsen circulatory dysfunction and may trigger renal vasoconstriction [6, 14]. At this stage, the stimulation of the RAAS, SNS, and AVP is so intense that their vasoconstrictor effects cannot be overcome, and HRS develops.

Reduced Cardiac Output

Circulatory dysfunction in cirrhosis has been the classic defining pathophysiological alteration that leads to HRS; however, evidence suggests that a reduction in cardiac output may play a role as well [15]. As discussed above, a complex interplay between the splanchnic, systemic, and renal circulation comes into play once portal hypertension is established. In the initial stages of cirrhosis in the process of progressive vasodilation, cardiac output (CO) increases to maintain systemic hemodynamic homeostasis. However, with progression to decompensated cirrhosis the

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

progressive effects of splanchnic vasodilatation cannot be overcome by increasing CO. Moreover, in patients with ascites or HRS, CO may be normal or even reduced, which is the extreme expression of the circulatory dysfunction [1, 16, 17]. A consequent decrease in effective arterial blood volume may occur, thereby reducing renal perfusion and possibly contributing to the development of HRS. In fact, the development of HRS occurs in the setting of a reduction in CO and the progression of circulatory and renal dysfunction in cirrhosis is not only due to splanchnic vasodilation but also due to a drop in CO. [18–20] In a study of 23 patients with SBP, eight patients who developed renal failure had a significantly reduced cardiac output compared to those that did not develop renal failure [18]. In a second study, 66 patients with cirrhosis and ascites were longitudinally followed. Twenty-seven (41%) developed HRS, and in all cases CO at the time of HRS was significantly decreased compared to the CO in the same patients measured before the occurrence of HRS [19]. The third study, which included 24 patients with decompensated cirrhosis, showed that in patients with a cardiac index (CI) below 1.5 l/min/m^2, GFR and renal blood flow were lower and serum creatinine was higher. Moreover, the number of patients that developed HRS was higher in the group with low CI [20]. These studies support the concept that HRS occurs in the setting of worsening circulatory function, with a significant decrease in CO in the setting of marked splanchnic vasodilation [18–20]. The exact pathogenic mechanisms that cause this decrease in cardiac output are not completely understood.

Systemic Inflammation

Recent evidence indicates that cirrhosis is associated with increased systemic inflammation and that the grade of inflammation is higher with more severe liver, circulatory, and renal dysfunction [21]. Patients with cirrhosis may have elevated white blood cell count, activated circulating neutrophils and monocytes, plasma C-reactive protein (C-RP), pro-inflammatory cytokines, and systemic oxidative stress. The highest levels of inflammatory cytokines in patients with decompensated cirrhosis are seen in those with acute on chronic liver failure (ACLF), in which AKI frequently occurs [22–25].

The main mechanism of systemic inflammation is the translocation of bacteria and/or pathogen-associated molecular patterns (PAMPs) from intestinal lumen to systemic circulation. Bacterial translocation induces an inflammatory response, with increased production of proinflammatory cytokines (particularly interleukin 6 and tumor necrosis factor-α) and vasoactive factors (i.e. NO) in the splanchnic area, leading to a further vasodilation of the splanchnic circulation (Figure 9.1) [26, 27].

Bacterial infections, particularly SBP, are one of the leading triggers of HRS. Patients who develop HRS associated with SBP have higher levels of IL-6 and TNFα compared with those patients with SBP who do not develop HRS [24]. Moreover, a recent study suggested that HRS is characterized by an elevated systemic inflammatory response with higher serum levels of proinflammatory cytokines, particularly IL-6, TNF-α, and VCAM, compared to pre-renal AKI [28].

Renal Vasoconstriction

Marked renal vasoconstriction in individuals with HRS causes reduced perfusion of the renal cortex and this is evidenced by methods such renal arteriography, duplex Doppler ultrasonography, and paraaminohippuric acid excretion among others [29–35]. Renal vasoconstriction is mainly due to the activation of systemic and local vasoconstrictor factors and the suppression of renal vasodilators. Increased angiotensin II as a result of activation of the RAAS causes renal vasoconstriction [19, 36, 37]. Infections such as SBP which can trigger HRS are associated with significant activation of the RAAS. The SNS also plays a role and plasma levels of noradrenaline are greatly increased in patients with HRS compared to those of patients with cirrhosis without HRS. In addition, noradrenaline levels correlate inversely with GFR [38]. Other vasoconstrictor factors such as endothelin and cysteinyl leukotrienes may also play a pathogenic role [39, 40]. A reduced production of endogenous renal vasodilators such prostaglandins has been suggested as playing a pathogenic role in many patients with cirrhosis and ascites. This is supported by the observation that patients with cirrhosis who receive NSAIDs, which inhibit prostaglandin synthesis, can develop AKI resembling HRS [41].

Diagnostic Approach

Patients with cirrhosis may develop AKI for a variety of reasons aside from HRS. Other forms of AKI include those related to hypovolemia and shock, the use of nephrotoxic drugs, and intrinsic renal diseases. AKI occurs in 20–50% of patients with cirrhosis admitted to hospital for complications of the disease. However, HRS appears in about 10–20% of hospitalized patients with cirrhosis and ascites [3]. The probability of developing HRS in patient with cirrhosis and ascites is 18% at 1 year and 39% at 5 years of follow-up [42].

The initial management of patients with a rising serum creatinine depends on the cause. Therefore, the most important step in treating renal failure in a patient with cirrhosis is to identify its etiology. However, even in the absence of a definitive recognized cause of AKI, the management should be immediately started according to the initial stage (Table 9.1). Irrespective of the stage, diuretics should be discontinued. Similarly, beta-blockers should be temporarily stopped [43]. Other precipitating factors of AKI should be identified and treated, including screening and treatment of infection, volume expansion with albumin when appropriate, Box 9.1 and discontinuation of all nephrotoxic drugs [2]. Volume replacement should be used in accordance with the cause and the severity of fluid loss. Patients with diarrhea or excessive diuresis should be treated with crystalloids, while those with acute gastrointestinal bleeding should be given packed red blood cells to maintain hemoglobin level between 7 and 9 g/dl [44]. In case of no obvious cause, 20% or 25% albumin solution at the dose of 1 g of albumin/kg of body weight (with a maximum of 100 g of albumin) for two consecutive days should be given. An algorithm for diagnosis and management of AKI in cirrhosis is depicted in Figure 9.2.

Clinical Features

Individuals with HRS for the most part exhibit clinical features of advanced cirrhosis, and most have high Model for End-stage Liver Disease (MELD) and Child–Pugh scores, along with low arterial blood pressure and marked urinary sodium retention (urine sodium, ≤10 mEq/l) [42, 46]. The MELD score is a mathematically derived score calculated from serum bilirubin, serum creatinine, and the international normalized ratio for prothrombin time used for organ allocation by liver transplant centers [47]. An updated MELD score including the serum sodium as a variable (MELD-Na) has been implemented in the United States and other countries. This is mainly due to the fact that serum sodium is a strong prognostic factor in patients with advanced liver disease and ascites. In fact, hypervolemic hyponatremia (serum sodium, ≤130 mEq/l) is commonly present in patients with HRS due to increased solute-free water retention because of elevated levels of AVP [48].

AKI and HRS-AKI Criteria

Renal impairment in patients with cirrhosis was previously defined by a serum creatinine value ≥1.5 mg/dl [49]. However, because patients with cirrhosis have a low creatinine production because of reduced muscle mass a low serum creatinine level may result in an overestimation of the GFR [50–52]. A drawback of this cutoff was that it identified patients with a severely reduced GFR (<30 ml per minute) and underestimated the prevalence of this clinical problem. Accordingly, the definition of renal failure in patients with cirrhosis was modified [2]. AKI is now defined as either an absolute increase in serum creatinine of more than or equal to 0.3 mg/dl (≥26.4 lmol/l) in less than 48 hours, or by a percentage increase in serum creatinine of more or equal to 50% (1.5-fold from baseline) in less than 7 days. A new staging system (1A, 1B, 2, and 3) was also introduced, mainly based on the percentage increase of serum creatinine from baseline at the time of the first fulfillment of the criteria together with the value of [53, 54]. This definition has the advantage of detecting earlier phases of kidney dysfunction with the goal of implementing early therapy. Minor increases in serum creatinine detected with the AKI definition are independently associated with increased mortality for hospitalized patients with cirrhosis [55].

Several studies have shown that the new AKI criteria and its stages are prognostic as AKI is associated with increased length of hospital stay and mortality [54, 56, 57]. The definition of the new ICA-AKI criteria also led to changes in the diagnostic criteria of HRS-AKI (Table 9.2). Traditionally HRS was classified into two entities according to severity and progression of kidney failure: type-1 HRS and type-2 HRS [49]. In type 1, patients had a rapid increase of serum creatinine to a level >2.5 mg/dl in <2 weeks and type 2 was characterized with lower serum creatinine levels usually ranging from 1.5 to 2.5 mg/dl. The main change that was made to the classical diagnostic criteria of HRS was the removal of the cutoff value of serum creatinine [2, 45] to allow an earlier diagnosis of HRS-AKI. Therefore, the currently HRS-AKI, includes patients with classical type-1 HRS criteria (serum creatinine ≥2.5 mg/dl), but also those patients presenting with lower values of serum creatinine that fulfill the remaining HRS-AKI criteria and that would not have been included in the classical definition of type-1 HRS. On the other hand, the term type-2 HRS is not included in the current concept of HRS-AKI because is not an acute impairment but rather a chronic impairment of kidney function. Therefore, type-2 HRS is currently considered a form of chronic kidney disease (HRS-CKD) that is characteristic of cirrhosis [2, 45, 58].

Urinary Biomarkers

Differentiating HRS and ATN is quite challenging given that both conditions are common in hospitalized or critically ill patients with cirrhosis. The routine urine biomarkers for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Figure 9.2 An algorithm for diagnosis and management of acute kidney injury (AKI) in cirrhosis. AKI-HRS, AKI-hepatorenal syndrome; ICA-AKI, International Club of Ascites-AKI. [a]Return of serum creatinine levels to <0.3 mg/dl from baseline. [b]Intravenous noradrenaline can be used if terlipressin is not available. The combination of midodrine, octreotide, and albumin is much less effective than terlipressin or noradrenaline plus albumin. *Source:* Modified with permission from Angeli et al. [45].

ATN (urine sodium, fractional excretion of sodium or urine osmolality) are not very useful in patients with cirrhosis because these can be modified by diuretics and also urinary sodium in advanced cirrhosis may be markedly low owing to increased sodium retention [51]. Currently, there are no objective tools with high accuracy for differential diagnosis of AKI, particularly between ATN and HRS-AKI. In this setting, urine biomarkers seem to be very useful in the differential diagnosis and distinguishing structural from functional causes of AKI. The most promising biomarkers are urinary neutrophil gelatinase-associated lipocalin (uNGAL), followed by interleukin-18 (IL-18), albumin, and Liver fatty acid-binding protein (L-FABP) [59–63].

The utility of biomarkers in the field of cirrhosis may be particularly relevant in the differential diagnosis of the type of AKI, especially in distinguishing ATN from prerenal AKI or HRS. The urinary concentration of biomarkers which are upregulated in the setting of tubular injury are increased in patients with ATN compared to patients with prerenal-AKI. uNGAL may help identifying the cause of AKI in patients with cirrhosis, especially in differentiating ATN from HRS [63, 64]. Patients with hypovolemia and

Table 9.2 New diagnostic criteria of acute kidney injury (AKI)-HRS.

- Cirrhosis with ascites
- Diagnosis of AKI according to International Club of Ascites-Acute Kidney Injury (ICA-AKI) criteria
- No response after two consecutive days of diuretic withdrawal and plasma volume expansion with albumin
- Absence of shock
- No current or recent use of nephrotoxic drugs (NSAIDs, aminoglycosides or iodinated contrast media)
- No signs of structural kidney injury. Structural kidney injury is indicated by proteinuria (>500 mg/d), microhaematuria (>50 red blood cells per high-power field), and/or abnormal renal ultrasonography

AKI have low uNGAL levels. The values in patients with HRS are in between those of patients with hypovolemia and AKI and the markedly elevated levels observed among patients with ATN. Moreover, studies suggest that elevated uNGAL is predictive of early mortality in patients with AKI [61]. IL-18 has also been evaluated in patients with cirrhosis, with higher urinary IL-18 levels in patients with ATN as compared to non-ATN AKI [62]. Moreover, urinary IL-18 has also been shown to have a relatively good ability to predict need for renal replacement therapy (RRT) and mortality during hospitalization [61]. Plasma levels of cystatin C seem to be also predictive of AKI in patients with cirrhosis but there are scarce studies. Other urine biomarkers, including albumin and liver fatty acid binding protein have also demonstrated that they have the ability to distinguish ATN from non-ATN in patients with cirrhosis and AKI [59, 62].

Management

The first step of management of patient with HRS is optimization of clinical status with adequate management of fluid balance and blood pressure. Moreover, all patients should have blood, urine, and ascites cultured to rule out bacterial infections. Diuretics should be stopped and low volume therapeutic paracentesis (<5 l) with albumin performed if needed [2, 43, 44] for management of symptoms. Patients need to be hospitalized in a closely monitored acute care unit. A central line may be helpful in assessing volume status after patients receive plasma expansion when ruling out other causes of renal failure, but the routine use of central pressure monitoring has yet to be established. Given that patients are frequently malnourished and require a sodium-restricted diet, a nutritionist should be a part of the team taking care of the patient. Finally, probably the most important aspect of providing care to patients with HRS is assessment of candidacy for liver transplantation. In suitable candidates for liver transplantation, all efforts should be made to improve renal function to obtain a better outcome after transplantation. Current available therapies for HRS-AKI include the use of splanchnic vasoconstrictors and albumin and transjugular intrahepatic portosystemic shunt (TIPS).

Pharmacological Therapy

Although in the past when considering treatment the type of HRS was taken into account, currently it is considered that there is no specific cutoff value of serum creatinine levels for the diagnosis and treatment of HRS-AKI. That said, vasoconstrictor therapy is recommended for those individuals that meet HRS-AKI stage 1B criteria or greater. There is very limited data on the efficacy and side effects of vasoconstrictor therapy in HRS-AKI stage 1a. Systemic vasoconstrictors given with plasma expansion are currently the most effective method form of pharmacologic therapy for HRS [45]. Splanchnic vasoconstrictors are used in conjunction with albumin because they counteract the intense vasodilation of the splanchnic circulation

Box 9.1 Treatment recommendations box, based on GRADE, for AKI-HRS

Comment	Certainty of evidence	Strength of Recommendation
Patients meeting the current definition of **HRS-AKI stage > 1A** should be treated with **vasoconstrictors and albumin**	Moderate	Strong
Terlipressin can be administered by IV boluses (1 mg every 4–6 h) or by continuous IV infusion (2 mg/day)[†]	High	Strong
• In case of **nonresponse** (decrease in SCr <25% from the peak value) after 2 days, the dose of **terlipressin should be increased** in a stepwise fashion to a **maximum of 12 mg/day**		
Albumin solution (20% or 25%) should be used at 20–40 g/day	Moderate	Strong
• Serial assessment of central blood volume aids in titrating the dose		
Noradrenaline can be an alternative to terlipressin[‡]	High	Weak
• Requires a central venous line often in an ICU	Moderate	Weak
Midodrine + octreotide can be an option when terlipressin or noradrenaline are unavailable (but efficacy is lower)

and improve effective arterial blood volume, which in turn suppresses the endogenous vasoconstrictor factors responsible for HRS. Vasoconstrictor drugs used in HRS include terlipressin, noradrenaline, and the combination of midodrine and octreotide. Albumin is used concomitantly with these vasoconstrictors as a means of improving effective arterial blood volume and therefore further suppressing endogenous vasoconstrictor factors (RAAS and SNS) responsible for the intense renal vasoconstriction and reduced cardiac contractility in HRS [65–76]. Pharmacological treatment recommentdations are summarized in Box 9.1.

Vasoconstrictors (Table 9.3)

Terlipressin

Terlipressin is the most commonly used drug for HRS in countries in which it is available. It is a synthetic analog of vasopressin and several studies and at least six randomized controlled trials have proven the efficacy of terlipressin plus albumin in the treatment of HRS [65–68, 73, 76, 78]. According to a recent meta-analysis, reversal of HRS occurs in approximately 35–50% of patients with terlipressin plus albumin vs. 11–14% of patients treated with placebo [79]. Also, an improvement in renal function was observed in 48% of patients with terlipressin plus albumin against 24% of patients receiving placebo [79, 80]. Terlipressin plus albumin seems to confer a survival benefit against placebo, but there are some conflicting results [80, 81].

In the initial studies, terlipressin was administered by repeated intravenous boluses (starting dose of 0.5–1 mg every 4–6 hours, increasing to a maximum of 2 mg every 4–6 hours in case of a reduction of baseline serum creatinine <25%) but a randomized trial compared the efficacy and safety of terlipressin given by continuous intravenous infusion (dose 2 mg/d up to 12 mg/d) against intravenous boluses [82]. The study showed similar response rates between both groups. Moreover, mean effective dose of terlipressin was lower in the continuous infusion group, and that was associated with a lower rate of adverse events. The dose of terlipressin should be increased in a stepwise manner if serum creatinine does not decrease by at least 25% with respect to the pretreatment value after 3 days of treatment. Treatment with terlipressin plus albumin should be continued until serum creatinine is <1.5 mg/dl or close to the baseline value before HRS-AKI. In patients with no response or only partial response the treatment should be discontinued within 2 weeks. Recent studies showed that 55.5% of patients with HRS had a complete response to terlipressin plus albumin, defined as a reduction of serum creatinine by >50% to a final value of <1.5 mg/dl [76, 82]. Patients who respond to treatment have a better survival than nonresponders. In two meta-analyses, the use of terlipressin was associated with a significant improvement in short-term survival [80, 83].

Albumin infusion along with terlipressin is always recommended. The combination of albumin and terlipressin is more effective than terlipressin alone [78]. The dose of albumin in HRS treatment has not been well established, but in most studies 20–40 g/d are given. However, the dose of albumin administered is determined by the level of central venous pressure. Aside from an increase in systemic vascular resistance and cardiac output, albumin has nononcotic effects including antioxidative and anti-inflammatory properties [84–87].

Diarrhea and abdominal cramps are common adverse effects of terlipressin (up to 10%). Other more serious adverse events are uncommon (<5%), including ischemic and cardiovascular events. Although rare, patients can develop angina, intestinal, digital or glossal ischemia, cardiac arrhythmias, or severe hypertension. Patients with established ischemic heart disease and peripheral vascular disease should not be treated with terlipressin.

Norepinephrine, Midodrine, and Octreotide

The use of vasoconstrictors other than terlipressin is an alternative in countries where terlipressin is not available. Noradrenaline is an (alfa)-adrenergic and (beta)-adrenergic receptor agonist with vasoconstrictor effect activity on splanchnic circulation that can also improve renal perfusion. It has been evaluated in four randomized controlled trials compared to terlipressin [69–72]. A meta-analysis compared terlipressin plus albumin with noradrenaline plus albumin and found no difference in the reversal of HRS, 30-day mortality and recurrence of HRS [80]. Although data is limited due to the low number of patients included in the studies ($n = 78$), noradrenaline seems to be as effective as terlipressin in the management of HRS and represents a good alternative treatment [80], however the quality of evidence supporting the use of noradrenaline is low according to a meta-analysis [80]. Noradrenaline must be administered under continuous monitoring and in some countries it cannot be used outside intensive care units.

Midodrine, a selective (alfa)-1-adrenergic receptor agonist, and octreotide, a somatostatin analog, have been evaluated in the management of HRS; there are no placebo-controlled trials and only nonrandomized observational cohort studies in very small series of patients demonstrate a mild improvement in renal function and GFR with suppression of renin, aldosterone, norepinephrine, and vasopressin to normal or near-normal levels [88, 89]. However, this data was not confirmed in a recent randomized control trial, where midodrine and octreotide plus albumin were compared to terlipressin plus albumin, and significant higher response rates were

found in the terlipressin group (70.4% vs. 28.6%) [76]. Therefore, terlipressin is clearly more effective than the combination of midodrine and octreotide.

Aim of Pharmacological Therapy

The most important objective when treating HRS-AKI is to reverse renal failure to provide a successful bridge to liver transplant so that suitable candidates can undergo transplantation with less morbidity and side effects to post-transplant medications and have similar outcomes as patients without HRS-AKI. As mentioned above, response to therapy is considered when there is marked reduction of the high serum creatinine levels, at least below 1.5 mg/dl, which is usually associated with increased urine output and improvement of hyponatremia [45]. Studies suggest that response to treatment with vasoconstrictors and albumin correlates with an increase in mean arterial pressure (MAP). One study showed that patients who experienced a significant increase in MAP during terlipressin treatment had a higher probability of recovering kidney function [90]. Another study also reported that responders to terlipressin had a higher increase in MAP at the end of treatment compared with nonresponders. The improvement of kidney function in patients with HRS treated with vasoconstrictors tightly correlates with the rise in MAP. Therefore, a goal-directed approach to the treatment of HRS based on targeting a rise in MAP during vasoconstrictor therapy may lead to better outcomes [90–92]. Nevertheless, prospective studies evaluating this approach are needed before integrating it into practice. Recurrence of HRS in responders, after the end of the treatment, has been reported in up to 20% of cases. Re-treatment is usually effective, but in some cases continuous recurrence occurs. Patients who respond to treatment with terlipressin plus albumin show a better survival than nonresponders to treatment.

Nonpharmacological Therapy

Liver Transplantation

Liver transplantation is the best available effective therapy for patients with HRS-AKI since it cures liver failure and portal hypertension. Since patients with HRS-AKI have a poor prognosis, this group of patients should be given higher priority for transplantation [93]. In fact, the implementation of the MELD score in many countries has placed these patients at a higher priority level for liver transplant because serum creatinine is a strong variable in the mathematical model [47]. The presence of HRS-AKI at the time of liver transplantation has a negative impact on survival after the operation. Patients with HRS who undergo transplantation have more complications, spend more days in the intensive care unit, and have a higher in-hospital mortality rate than transplanted patients without prior HRS [94].

Although liver transplantation is the treatment of choice, renal function does not completely recover in all patients [94, 95]. The reason for this is not known. Simultaneous liver-kidney (SLK) has been considered for patients with HRS. Recent recommendations for SLK in the United States include patients with AKI with an estimated GFR of $\leq 25\,ml/min/1.73\,m^2$ for 6 weeks or a period of dialysis ≥ 6 weeks, patients with an eGFR of $< 45\,ml/min/1.73\,m^2$ for > 90 days (stage 3B, 4, or 5 CKD), or patients with comorbidities and presence of metabolic diseases [96]. European guidelines suggest that patients with end-stage liver disease who have a GFR of $< 30\,ml/min/1.73\,m^2$ or type 1 HRS requiring RRT of > 8–12 weeks and patients with renal biopsy samples revealing $> 30\%$ fibrosis and glomerulosclerosis should receive simultaneous liver and kidney transplant [45]. SLK is also indicated in patients with cirrhosis and sustained AKI irrespective of its type, including HRS-AKI when refractory to drug therapy if requiring RRT for ≥ 4 weeks, or if the estimated GFR is $\leq 35\,ml/min/1.73\,m^2$ or measured GFR $\leq 25\,ml/min/1.73\,m^2$ for ≥ 4 weeks [45]. Beyond these two conditions, in a candidate with high priority for liver transplantation due to a high MELD score, the option of SLK may be considered in the presence of risk factors for underlying undiagnosed CKD (diabetes, hypertension, abnormal renal imaging, and proteinuria $> 2\,g/d$) [45].

Transjugular Intrahepatic Portosystemic Shunt

Transjugular intrahepatic portosystemic shunt (TIPS) is a nonsurgical intervention performed percutaneously that creates a connection (by means of a prosthetic shunt) within the liver between the portal and hepatic vein, thereby reducing portal pressure. This method has been used as an alternative therapy to surgical shunts for cirrhotic patients bleeding from esophageal or gastric varices who are refractory to endoscopic and medical treatment. The rationale for using TIPS in HRS is based on the fact that reduction of portal pressure improves circulatory function and suppresses RAAS and SNS activity. Four uncontrolled studies indicate that TIPS may improve renal function and GFR as well as reduce the activity of RAAS and SNS in patients with cirrhosis and HRS. Improvement in renal function observed in these uncontrolled

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. studies after TIPS placement alone was slow and successful in approximately 60–70% of patients. However, studies assessing TIPS for type 1 HRS have only included patients with preserved liver function and excluded those with a history of hepatic encephalopathy, Child–Pugh scores of ≥12, or serum bilirubin of >5 mg/dl. As existing data are limited and the applicability of TIPS in these patients is very low, TIPS placement should not be recommended in the setting of HRS-AKI [89, 97, 98].

Renal Replacement Therapy

RRT is not recommended as a first-line treatment in patients with HRS-AKI, but it should be considered in nonresponders to vasoconstrictors. Indications for RRT are the same in patients with cirrhosis as in the general population, including severe and/or refractory electrolyte or acid-base imbalance, severe or refractory volume overload, and/or symptomatic azotemia. However, published data on RRT in patients with cirrhosis are scant, with controversial effects on survival [99, 100]. Alternative dialysis methods such as the molecular adsorbent recirculating system (MARS) and albumin dialysis have been evaluated. These systems remove protein-bound solutes from plasma, such as bilirubin, bile acids, and cytokines, that are not well removed by conventional hemodialysis or hemofiltration. Although these treatments may have some potential beneficial effect, they should still be considered experimental and further controlled studies are clearly needed before advocating their use in the management of patients with HRS [101, 102]. Treatment guidelines do not recommend MARS for the management of HRS in clinical practice.

Prevention

In SBP, intravenous albumin (1.5 g/kg at diagnosis of infection and 1 g/kg 48 hours later) mitigates the risk of development of HRS because it counteracts an enhanced arterial splanchnic vasodilation triggered by the infection, causing an even more reduced effective arterial blood volume with additional activation of vasoconstrictor systems. The incidence of HRS in patients with SBP not administered albumin was 33% and only 10% in those who received albumin. In addition, there was less in-hospital mortality in those receiving albumin (10%) than in those not receiving albumin (29%) [6]. Albumin is not effective in the prevention of HRS associated with infections other than SBP [103, 104]. Prophylaxis with norfloxacin in patients with cirrhosis and ascites reduces the incidence of SBP and delays the development of HRS, but can increase the risk of infections caused by multidrug-resistant organisms [105]. Previous studies suggested that the use of pentoxyfilline decreased the incidence of renal failure in patients with alcoholic hepatitis. However, recent data do not confirm these results [106–109].

Summary

HRS-AKI is a devastating complication of patients with cirrhosis and ascites. Triggers of AKI such the use diuretics and nephrotoxic drugs, infections, hypovolemia, and parenchymal kidney disease should be sought for and promptly managed. Differential diagnosis of HRS-AKI from other forms of AKI, such as ATN, is often difficult. Specific biomarkers such as NGAL or IL-18 may aid in the correct diagnosis of AKI in cirrhosis but have not yet been introduced into clinical routine. Vasoconstrictors such as

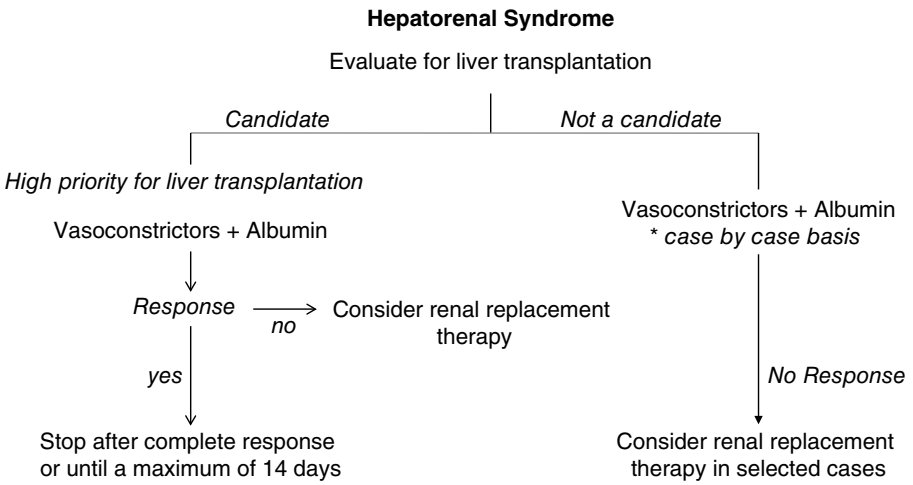

Figure 9.3 Treatment algorithm of AKI-HRS depending on whether the patient can undergo liver transplantation.

terlipressin and noradrenaline in combination with intravenous albumin are the first-line therapy for HRS-AKI. Liver transplantation is considered a definitive and effective treatment for HRS and patients with cirrhosis and HRS-AKI should be prioritized for liver transplantation. An algorithm for management of AKI in cirrhosis is summarized in Figure 9.3.

Acute Tubular Necrosis

Amanda DeMauro Renaghan and Mitchell H. Rosner

Division of Nephrology, University of Virginia Health System, Charlottesville, VA, USA

Introduction

Acute kidney injury (AKI) is defined as a rapid deterioration in kidney function resulting in a reduction in glomerular filtration rate (GFR) and a failure of the kidneys to excrete nitrogenous waste products and to maintain fluid, electrolyte, and acid-base balance [1]. The two most common etiologies of AKI are prerenal azotemia, caused by reversible renal hypoperfusion, and acute tubular necrosis (ATN) [2–6]. ATN results from intrinsic parenchymal damage mediated by endothelial and epithelial cell injury, intratubular obstruction, and immunologic and inflammatory processes. ATN is a histopathologic and pathophysiologic entity that can stem from a variety of distinct renal insults, often seen in combination, and these can be divided broadly into ischemic (prolonged volume depletion, hypotension), septic, and nephrotoxic (medications, radiocontrast dye, rhabdomyolysis) categories [2]. Ischemic ATN is seen most commonly and occurs on a continuum beginning with prerenal azotemia [1, 5]. When prerenal insults are severe or prolonged they may give rise to tubular damage [1]. Histology reveals dilation of proximal tubular lumens, flattening of the tubular epithelium, simplification and loss of brush border, and vacuolization (Figure 10.1) [7]. These histological changes are reflected in the urinalysis, which typically reveals the presence of cellular debris and "muddy brown casts" which consist of sloughed and necrotic epithelial cells (Figure 10.2) [8].

ATN is common, however the incidence and outcomes vary significantly depending on the definition used and the patient population studied [2]. The landmark Program to Improve Care in Acute Renal Disease (PICARD) study was an observational study of a cohort of 618 patients with AKI in the intensive care units (ICUs) of five academic centers in the United States. Ischemic ATN was the presumed etiology for 50% of all patients with renal failure, while an additional ~12% were attributed to unresolved prerenal factors and ~25% to nephrotoxic ATN [5]. It is important to note that the diagnosis of ATN is often inferred based upon clinical characteristics, since kidney biopsies are not routinely performed in patients with AKI. While several classes of agents have been investigated, thus far no specific pharmacologic strategies have proven effective for preventing or treating ATN. Therefore, it is essential that clinicians focus on preventative measures such as maintaining adequate systemic perfusion and limiting nephrotoxin exposure, especially in those deemed to be at highest risk.

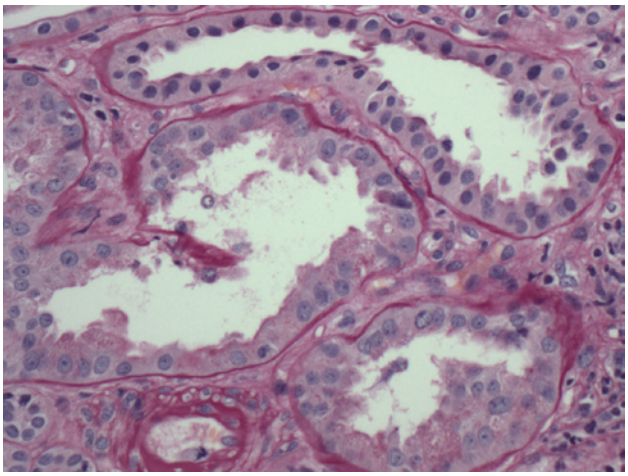

Figure 10.1 High-power image demonstrating flattened epithelium with loss of the brush border and cells becoming disconnected from the basement membrane as seen in acute tubular necrosis. *Source:* Image courtesy of Helen P. Cathro, University of Virginia Health System, Division of Renal Pathology.

Figure 10.2 Muddy brown casts as seen in a patient with acute kidney injury and presumed acute tubular necrosis due to sepsis.

Definition

ATN is a histopathologic and pathophysiologic entity that is the end result of numerous ischemic, nephrotoxic, and inflammatory insults. In many cases, the decline in kidney function may be more prominent than the severity of histologic change, and necrotic cell death may not be readily apparent [2, 9–11]. Clinical manifestations of ATN vary by patient and the type of insult. While some patients maintain normal urine flow, others may develop a decline in urine output (oliguria) and subsequent signs and symptoms of volume overload. Similar to the metabolic derangements seen in other forms of AKI, reduced GFR and impaired tubular function in ATN may lead to hyperkalemia, metabolic acidosis, and azotemia. These may range from mild to severe and life-threatening. In some cases, other kidney manifestations of a toxic insult may be present such as glomerular disease (nonsteroidal anti-inflammatory agents) or tubular dysfunction such as the Fanconi syndrome (ifosfamide) or sodium and magnesium wasting (cisplatin).

Epidemiology

While it is clear that AKI is commonly encountered in clinical practice, the reported incidence varies depending on the definition used and the patient population evaluated [2, 12, 13]. In one study of 20 126 patients with a mean age of 64 years admitted to an Australian tertiary care hospital, almost 20% of patients met criteria for AKI as defined by the RIFLE (Risk, Injury, Failure, Loss, and End-stage) criteria. Importantly, multivariate logistic regression analysis showed that all RIFLE criteria were significantly predictive factors for hospital mortality, with an almost linear increase in odds ratios (ORs) from Risk to Failure (ORs: Risk 2.5, Injury 5.4, Failure 10.1) [13]. An even higher incidence of AKI has been demonstrated in the intensive care setting, with one retrospective cohort study of 5383 patients admitted to the ICUs of a single tertiary care academic center revealing an AKI incidence of 67%. Again, increased hospital mortality was seen with progressive RIFLE stage [12].

The vast majority (two thirds or more) of cases of AKI in hospitalized patients can be attributed to ATN or prerenal injury [3–6]. This attribution is often based upon compatible history and diagnostic findings and not based upon histology, and to our knowledge there are no studies that have systematically evaluated the causes of AKI in hospitalized patients based on biopsy findings. In a study by the Madrid Acute Renal Failure Study Group, ATN was identified in 45% of patients, while prerenal azotemia was determined to be the cause of AKI in 21% of patients [4]. In the PICARD study, an observational cohort study of 618 patients with AKI in the intensive care setting, ischemic ATN occurred in >50% of cases, while nephrotoxic ATN played a role in 25% of cases [5].

Certain patients and populations are at greater risk for the development of ATN based on age, comorbidities, severity of illness, and exposures to procedures and medications. The elderly, diabetic patients, those with preexisting chronic kidney disease (CKD) or hypertension, those with renal artery stenosis, and those taking nonsteroidal anti-inflammatory drugs (NSAIDs), angiotensin-converting-enzyme (ACE) inhibitors, or angiotensin-receptor blockers (ARBs) may be at increased risk for ischemic ATN due to impaired renal autoregulation [9]. The combination of an ACE inhibitor or an ARB along with an NSAID is a particularly high-risk scenario especially in states of volume depletion, where renal autoregulation and perfusion can be severely impaired [14]. Other populations at high risk for the development of ATN include (i) patients in ICUs, where 35–56% of cases of AKI are attributed to sepsis; (ii) postoperative patients, in particular those underdoing abdominal aortic aneurysm surgery, surgery to correct obstructive jaundice, or combined coronary artery bypass graft (CABG) surgery with valve surgery; and (iii) patients receiving iodinated radiocontrast dye (especially when delivered intra-arterially and at high doses) [2, 15–22].

Pathophysiology

Histology

The histologic lesions of ATN predominantly affect the proximal tubules (PTs) and vary with the severity of kidney injury and the stage of evolution of the lesion. On light

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

microscopy, ATN typically manifests as dilation of proximal tubular lumens, flattening of the tubular epithelium, simplification and loss of brush border, and vacuolization (see Figure 10.1) [7]. Downstream, distal tubular casts and obstruction may be present and result from the binding of desquamated tubular cells and debris to Tamm-Horsfall protein [23]. Interstitial edema with mild to moderate leukocyte infiltration can be seen. Morphologic changes may be subtle, and frankly necrotic cells may not be present even in those with marked functional impairment [2, 9–11]. For this reason, many clinicians and pathologists prefer the term "acute tubular injury" (ATI) to "ATN" [11].

Ischemic ATN

Phases of Ischemic ATN

Much remains to be discovered about the complex biology of ATN. Current research suggests that the course of ischemic ATN progresses across five phases: prerenal, initiation, extension, maintenance, and repair. During the *prerenal* phase, alterations in renal blood flow (RBF) lead to a decrease in intraglomerular pressure, however a variety of cellular and vascular adaptations are able to maintain renal epithelial integrity [24]. These alterations may be the result of volume depletion (vomiting, diarrhea, use of diuretics), hypotension (shock), cirrhosis (splanchnic vasodilation), heart failure (primarily through venous congestion and increased intra-abdominal pressure), selective renal ischemia (renal artery stenosis, cross-clamping of the renal artery during surgery for renal cell carcinoma), or drugs that cause afferent arteriolar constriction (NSAIDs, calcineurin inhibitors) or efferent arteriolar dilation (ACE inhibitors, ARBs) [1, 25]. The *initiation* phase of ischemic ATN occurs when hypoperfusion is sufficiently severe or prolonged to deplete adenosine triphosphate (ATP), leading to tubular cell injury and a continued decline in GFR [24]. The subsequent *extension* phase is characterized by (i) vascular endothelial damage, which contributes to severely reduced blood flow, persistent hypoxia, microvascular obstruction, coagulopathy, and further injury to tubular epithelial cells; and (ii) a pronounced inflammatory response mediated by an influx of leukocytes and the release of chemokines and cytokines that enhance the inflammatory cascade [24]. During the *maintenance* phase, GFR nadirs as cells undergo migration, apoptosis, and proliferation in an attempt to reestablish cellular and tubular integrity. Blood flow returns toward normal. Finally, during the *recovery* phase, GFR begins to improve as cellular differentiation and repair occur. It is in this phase that epithelial polarity is reestablished and cellular and organ function is restored [1, 24]. Incomplete recovery and/or conversion from a physiological to a pathological repair response, driven by a combination of improper tubule repair, vascular dropout, hypoxia, and persistent activation of the immune system may lead to fibrosis and CKD [24].

Tubular Factors

The abrupt fall in GFR seen in ATN has traditionally been attributed to an interplay between tubular and hemodynamic abnormalities [26]. Ischemic insults to the kidney preferentially cause cell damage and death of tubular epithelial cells, leading to decreased kidney function. These cells are especially susceptible to ischemic injury because of their high demand for oxygen and ATP to drive transport functions, along with their location in an environment of very low oxygen tension [27]. Cells in the S3 segment of the PT and the thick ascending limb of Henle are most prone to ischemic injury due to a combination of low medullary blood flow and countercurrent diffusion of oxygen causing lower partial pressure of oxygen (pO2) [28].

Renal ischemia leads to a loss of cytoskeletal integrity and cell polarity, with shedding of both necrotic and viable PT brush border cells into the tubule lumens [2]. This is thought to be driven, in part, by redistribution of sodium/potassium ATPase and integrins from the basolateral to the apical membrane [29–31]. Additional biochemical pathways that have been implicated in severe cell injury and ATN include (i) depletion of ATP; (ii) increased tissue concentrations of reactive oxygen species; (iii) intracellular acidosis; (iv) increased concentrations of cytosolic calcium; (v) increased activity of phospholipases; (vi) release of proteases from the tubular cell brush border; (vii) mitochondrial injury; and (viii) cell apoptosis [2, 26, 32, 33]. As cells desquamate and enter the lumen, backleak of filtrate may occur into the vascular space across the damaged tubular epithelium, potentially contributing to further decline in GFR, especially when intratubular pressure is increased due to intratubular obstruction [26, 34].

Renal Blood Supply

In ATN, RBF can decrease by as much as 30–50%, with a disproportionate decrease in medullary blood flow relative to total RBF contributing to pronounced medullary ischemia [2, 35–38]. A variety of mechanisms have been proposed to explain this and include (i) increased vasoconstriction in response to endothelin, adenosine, angiotensin II, thromboxane A_2, leukotrienes, and sympathetic nerve activity; (ii) decreased vasodilation in response to nitric oxide, prostaglandin E_2, acetylcholine, and bradykinin; (iii) structural damage to endothelial and vascular smooth muscle cells; and (iv) increased leukocyte-endothelial adhesion, vascular obstruction, leukocyte activation, and inflammation from release of chemokines and cytokines [32]. In addition, the combination of continued

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

filtration and impaired tubular reabsorptive function leads to increased sodium chloride delivery to the macular densa, ultimately activating tubuloglomerular feedback (TGF) and causing afferent arteriolar constriction with resultant further decline in GFR [32, 39].

Septic ATN

Sepsis is a frequent cause of AKI in hospitalized patients [15, 16, 20, 21]. While previously thought to induce ATN through decreased renal perfusion and systemic hypotension, more recent data suggest that septic ATN may be associated with systemic vasodilation, high-output cardiac failure, and increased RBF ("hyperdynamic sepsis"). In one study of ewes treated with *Escherichia coli* infusion to induce sepsis, RBF was found to be significantly increased. Importantly, recovery from sepsis was associated with relative renal vasoconstriction and return in RBF back to control levels [40]. In a follow-up study, sepsis induced by *E. coli* was again associated with increased RBF, along with oliguria and reduced GFR. Infusion of angiotensin II restored arterial pressure, decreased RBF, and led to a significant increase in urine output and normalization of creatinine [41]. One possible explanation for these findings is that kidney injury in this state may occur due to preferential dilation of the efferent arteriole, leading to a decrease in intraglomerular pressure and drop in GFR [42].

Nephrotoxic ATN

Nephrotoxic ATN may be associated with exposure to a variety of exogenous and endogenous toxins, some of which are shown in Table 10.1. Exogenous toxins include medications that impair renal autoregulation and predispose patients to prolonged prerenal ischemia and subsequent ATN (NSAIDs, ACE inhibitors, ARBs), as well as drugs that are directly toxic to renal tubules, including many antimicrobial, iodinated radiocontrast, and antineoplastic agents. Other exogenous toxins, such as acyclovir and methotrexate, may cause ATN through intratubular crystal precipitation and obstruction. ATN secondary to the production of endogenous toxins may occur in patients with rhabdomyolysis or, less commonly, hemolysis. In these cases, AKI is caused by the release of heme pigment from myoglobin and hemoglobin, respectively, ultimately leading to (i) tubular obstruction; (ii) direct proximal tubular cell injury; and (iii) vasoconstriction with reduced medullary blood flow [43, 44]. Additionally, endogenous production of abnormal paraproteins (as in multiple myeloma) and uric acid (as in tumor lysis syndrome) may injure renal tubules through precipitation and intratubular obstruction [45].

Table 10.1 Mechanisms of nephrotoxin-induced acute tubular necrosis.

Mechanism of injury	Toxin
Exogenous toxins	
Altered intraglomerular hemodynamics (prolonged prerenal injury predisposing to ATN)	Afferent vasoconstriction: NSAIDs Calcineurin inhibitors Iodinated radiocontrast agents
	Efferent vasodilation: ACE inhibitors ARBs
Direct tubular toxicity	Antimicrobials: Aminoglycosides, outdated tetracyclines, vancomycin Amphotericin B Cidofovir, tenofovir Pentamidine
	Antineoplastic agents: Cisplatin Ifosfamide
	Recreational drugs: Synthetic cannabinoids
	Miscellaneous: Acetaminophen Calcineurin inhibitors Iodinated radiocontrast agents Mannitol Sucrose-containing IVIG formulations Zoledronate
Intratubular obstruction	Acyclovir, indinavir, methotrexate, sulfonamides
Endogenous toxins	
Intratubular pigments	Rhabdomyolysis (may be precipitated by medications [statins, haloperidol] and drugs of abuse [cocaine, alcohol])
	Hemolysis (may be precipitated by quinine, quinidine, sulfonamides)
Intratubular obstruction by proteins	Multiple myeloma (cast nephropathy)
Intratubular precipitation	Uric acid (tumor lysis syndrome)

ACE, angiotensin-converting-enzyme; ARB, angiotensin-receptor blocker; ATN, acute tubular necrosis; IVIG, intravenous immunoglobulin; NSAID, nonsteroidal anti-inflammatory drug.

Diagnosis

History and Physical Examination

Determining the etiology of AKI begins with a careful evaluation of the patient's history and physical examination. For example, a history of vomiting, diarrhea, or hypotension, combined with physical examination findings of volume depletion, may point toward prerenal AKI or ischemic ATN. Recent exposure to nephrotoxic medications or iodinated radiocontrast dye may suggest nephrotoxic ATN. A careful and thorough history of drug and other potential nephrotoxin exposure is critical.

Urine Sodium Concentration and Fractional Excretion of Sodium

Fractional excretion of sodium (FENa) is a measure of the extraction of sodium and water from the glomerular filtrate; it is the ratio of the sodium filtration rate to the overall GFR as estimated by the renal filtration of creatinine:

$$\frac{[\text{urine sodium}]\times[\text{plasma creatinine}]\times 100}{[\text{plasma sodium}]\times[\text{urine creatinine}][46]}$$

FENa has traditionally been used to distinguish between prerenal azotemia and intrinsic forms of AKI such as ATN in patients with oliguria. In cases of prerenal AKI, and in early ischemic ATN where tubular function remains intact, urinary sodium concentration (UNa) should be low (<20 mmol/l) and FENa should be <1%, while in established ATN with impaired tubular function, UNa will be higher (usually >40 mmol/l) and FENa will be >1% [2, 46].

While these urine indices may help differentiate prerenal azotemia from ATN in some cases, there are limitations to the use of UNa and FENa. For example, in the presence of CKD or diuretic use, the diagnostic accuracy of urine chemistries to distinguish these conditions decreases. A low fractional excretion of urea (FEUrea) (<35%) is more sensitive than FENa for distinguishing prerenal from intrinsic renal failure when diuretics have been recently administered [47]. For instance, in a prospective study of AKI patients, a FEUrea ≤35% was less sensitive than a FENa ≤1% in differentiating between prerenal disease and ATN in patients not treated with diuretics (48% vs. 78%) and was more sensitive (79% vs. 58%) but less specific (33% vs. 81%) in patients who were treated with diuretics [47]. Additionally, ATN in the setting of rhabdomyolysis, hemolysis, sepsis, or recent contrast administration has been shown to be associated with low UNa (<10 mmol/l) and FENa <1% [48–52]. Given these limitations, measurements of UNa and FENa must be interpreted in the context of patient's overall clinical course and exposure history.

Urine Microscopy

The histologic changes of ATN are reflected in the urinalysis, which classically reveals the presence of cellular debris and "muddy brown casts" consisting of sloughed and necrotic epithelial cells. Perazella and colleagues demonstrated the high value of urine microscopy for the diagnosis of ATN using a urinary sediment score. In patients with a high pretest probability of ATN, the presence of any casts or renal tubular epithelial (RTE) cells (score ≥2) resulted in very high positive predictive value (100%) and low negative predictive value (44%) for a final diagnosis of ATN [8]. In a subsequent study, the same group determined that a urinary sediment score may be useful to predict worsening of kidney injury due to ATN during hospitalization [53]. A subsequent systematic review assessing the utility of urine microscopy for differentiating prerenal AKI and ATN in hospitalized patients determined that the presence and number of RTE cells and RTE cell casts and/or granular casts in the urine sediment may be useful in predicting more severe kidney damage as reflected by nonrecovery of AKI or need for dialysis [54].

The Role of Novel Biomarkers

In more recent years, a number of investigational biomarkers have been studied with the goals of (i) detecting AKI at an earlier stage ("subclinical AKI" occurring prior to a rise in serum creatinine [SCr]); (ii) determining the location and severity of kidney injury; and (iii) predicting outcomes such as the development of CKD following AKI [55].

Urinary kidney injury molecule-1 (KIM-1) is a biomarker that has shown promise for both the early diagnosis of AKI and the differentiation of ATN from other etiologies of kidney disease. In one case-control study of 20 children who underwent cardiopulmonary bypass surgery with or without the subsequent development of AKI (defined as a >50% increase in SCr from baseline within 48 hours), urinary KIM-1 increased postoperatively only in those children who developed AKI [56]. In another study, normalized urinary KIM-1 levels were significantly higher in patients with biopsy-proven ATN compared to those with other forms of kidney disease.

The Translational Research Investigating Biomarkers and End Points for Acute Kidney Injury (TRIBE-AKI) consortium conducted a prospective, multicenter cohort study in adults undergoing cardiac surgery to assess whether postoperative measures of urine interleukin-18 (IL-18), urine neutrophil gelatinase-associated lipocalin (NGAL), or plasma NGAL could identify patients destined to develop AKI and other adverse outcomes. Results revealed that urine IL-18 and urine and plasma NGAL levels peaked

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

within 6 hours after surgery. After multivariable adjustment, the highest quintiles of urine IL-18 and plasma NGAL were associated with 6.8-fold and 5-fold higher odds of AKI, respectively, compared with the lowest quintiles. Elevated urine IL-18 and urine and plasma NGAL levels associated with longer length of hospital stay, longer ICU stay, and higher risk for dialysis or death [57].

More recently, the multicenter Sapphire study discovered and validated two novel cell cycle arrest urine biomarkers for risk stratification of AKI, tissue inhibitor of metalloproteinases-2 (TIMP-2) and insulin-like growth factor-binding protein 7 (IGFBP7) [58]. The primary endpoint was Kidney Disease Improving Global Outcomes (KDIGO) stages 2 and 3 AKI within 12 hours of sample collection. The combination of TIMP-2 and IGFBP7 produced an area under the receiver operating characteristics curve (AUC) of 0.80, which was significantly superior to all previously described biomarkers for AKI. Additionally, risk for major adverse kidney events (death, need for renal replacement therapy [RRT], or persistent renal dysfunction) within 30 days elevated sharply for [TIMP-2]·[IGFBP7] above 0.3 $(ng/ml)^2/1000$ and doubled when values were >2.0 $(ng/ml)^2/1000$. Based in part on these observations, a point of care device measuring these two biomarkers was approved by the Food and Drug Administration (FDA) in 2014 to aid in the rapid and early identification of patients at high risk for developing AKI.

The above data clearly suggest potential value for next-generation biomarkers for both early diagnosis of and prognostication in AKI, however many questions remain about the best ways to apply these markers in clinical practice, and it remains to be seen whether early knowledge of risk of AKI will translate into improved clinical outcomes [55]. In addition, the sensitivity and specificity of these biomarkers for the specific diagnosis of ATN versus other forms of AKI is not yet determined. In this regard, a single-center trial examined the effect of a "KDIGO bundle" consisting of optimization of volume status and hemodynamics, avoidance of nephrotoxic drugs, and preventing hyperglycemia in high-risk patients defined by urinary [TIMP-2]·[IGFBP7] >0.3 $(ng/ml)^2/1000$ undergoing cardiac surgery. The primary endpoint was the rate of AKI defined by KDIGO criteria within the first 72 hours after surgery. AKI was significantly reduced with the intervention compared to controls (55.1 vs. 71.7%; ARR, 16.6%). The implementation of the bundle resulted in significantly improved hemodynamic parameters at different time points, less hyperglycemia, and use of ACE inhibitors/ARBs compared to controls. Rates of moderate to severe AKI were also significantly reduced by the intervention compared to controls. This promising study suggests that biomarker-guided interventions may be of benefit in decreasing the rate and progression of AKI [59].

Prognosis

Renal Recovery After ATN

The duration and outcome of ATN vary depending on the length and severity of the initial insult and the presence or absence of recurrent ischemia and/or repeated exposure to nephrotoxins [60, 61]. While the majority of patients return to or near their previous level of kidney function, recovery does not occur in all cases [62]. Progression from AKI to CKD and end-stage renal disease (ESRD) is an area of increasing interest and active research, largely focusing on understanding the mechanisms of injury and maladaptive repair after ATN with the goal of slowing or halting progression [63].

Schiffl and colleagues prospectively evaluated critically ill patients with normal baseline kidney function who developed clinically diagnosed severe ATN necessitating RRT. At discharge, 57% of the 226 surviving patients had normal kidney function, while 33% had mild to moderate renal failure (SCr 1.3–3 mg/dl), and 10% had severe renal failure (SCr 3–6 mg/dl). Multivariate analysis showed that neither patient characteristics (age, gender, comorbid conditions), severity of illness (APACHE III, number of failed organs), nor mode and duration of RRT were related to recovery of renal function. The authors concluded that, when critically ill patients with normal baseline kidney function survive the precipitating cause of ATN, the vast majority will recover sufficient renal function [62].

Not surprisingly, pre-existing CKD represents a major risk factor for the development of more severe AKI, greater need for RRT, and lower probability of renal recovery [64]. Additional risk factors for irreversible decline in kidney function include (i) older age; (ii) hypoalbuminemia; (iii) comorbidities including diabetes and heart failure; and (iv) more severe AKI requiring RRT [65, 66].

Mortality After ATN

Several studies have demonstrated an association between AKI during hospitalization and in-hospital and long-term mortality.

In the Acute Kidney Injury-Epidemiologic Prospective Investigation (AKI-EPI) study, a total of 1032 ICU patients out of 1802 total patients (57%) developed AKI by KDIGO criteria. Increasing AKI severity was associated with hospital mortality when adjusted for other variables (ORs: stage 1 = 1.679, stage 2 = 2.945, stage 3 = 6.884) [67].

Importantly, AKI has been shown to represent a risk factor for long-term mortality even in those patients who experience normalization of SCr after AKI. Bucaloiu and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

colleagues used a propensity score-matched cohort method to retrospectively evaluate the risk of death after reversible, hospital-associated AKI in patients with normal pre-hospital kidney function. Of patients alive at 90 days, 1610 patients with reversible AKI were matched with 3652 controls. At a median follow-up of just over 3 years, the risk of death associated with reversible AKI was significant (hazard ratio, 1.50) in Cox proportional hazard models. Adjustment for the development of CKD during follow-up attenuated but did eliminate this increased risk (hazard ratio 1.18). Based on this data, investigators concluded that a resolved episode of hospital-associated AKI has important implications for the longitudinal surveillance of patients [68].

Loss of Renal Reserve as a Predictor and Consequence of ATN

Renal functional reserve (RFR) can be used to measure the capacity of the kidney to increase GFR under conditions of physiologic stress and may serve as a functional marker that assesses susceptibility to injury. One method of measuring RFR is to measure changes in GFR in response to a high-protein meal. In a recent study, preoperative RFR was lower in patients who experienced AKI and predicted AKI with an AUC of 0.83. Patients with preoperative RFRs not greater than 15 ml/min/1.73m^2, despite normal resting GFRs, were 11.8 times more likely to experience AKI [69]. Thus, measurement of RFR preoperatively may identify patients who are likely to benefit from preventive measures or to select for use of biomarkers for early detection. In a follow-up to this study, AKI patients displayed a significant decrease in RFR (from 14.4 to 9.1 ml/min/1.73 m^2) and patients without AKI but with positive postoperative cell-cycle arrest biomarkers also experienced a similar decrease of RFR (from 26.7 to 19.7 ml/min/1.73m^2). In contrast, patients with neither clinical AKI nor positive biomarkers had no such decrease of RFR. Thus, AKI, and even AKI defined by biomarkers (but not elevations in SCr), is associated with persistent falls in RFR and highlights the long-term deleterious effects of this occurrence [70]. Further studies are needed in this area.

Prevention

Many studies have been performed to determine if any approaches can minimize the risk of ATN when patients are faced with a high-risk clinical scenario, such as sepsis, major surgery, or the need for certain antibiotics or iodinated radiocontrast dye. This section seeks to review the studies currently available that guide best practice and inform our evidence-based recommendations for the prevention of ATN. An exhaustive list of the various compounds and strategies that have been reported is beyond the scope of this chapter. Thus, representative examples are discussed and other compounds and strategies are listed in Tables 10.2 and 10.3.

Avoiding Nephrotoxic Medications and Mitigating Risk of ATN

Aminoglycosides

Aminoglycosides remain important therapies for the management of life-threatening gram-negative infections [48]. Nephrotoxicity represents the major dose-limiting toxicity of these drugs, occurring in approximately 10–25% of patients [119–123]. Toxicity is mediated primarily by damage to PT cells, impairing tubular reabsorption and compromising cell viability [124].

More than 60 trials have been conducted to evaluate the benefits of altering the dosing schedule of aminoglycosides, with the goal of limiting uptake by PT cells. Blaser and König evaluated the results of 24 randomized clinical trials including 3181 patients comparing once-daily versus multiple-daily dosing regimens for amikacin, netilmicin, and gentamicin. Analysis revealed superior results for once-daily regimens with respect to clinical and bacteriological efficacy. While nephrotoxicity occurred less frequently with once-daily dosing (4.5% vs. 5.5%), results did not reach statistical significance [72]. In another meta-analysis of similar size, Barza et al. demonstrated a reduction in nephrotoxicity with once-daily dosing, but no difference in patient mortality [73]. Hatala et al. evaluated 13 studies and revealed a trend toward reduced nephrotoxicity with once-daily dosing that did not reach statistical significance, while Ferriols-Lisart and Alós-Almiñana analyzed 18 studies including 2317 patients and demonstrated a reduction in summary odds of nephrotoxicity with once-daily aminoglycoside dosing [74, 75]. Two additional meta-analyses by Munckhof et al. and Ali and Goetz failed to show a significant difference in the rates of kidney injury [71, 76].

The cumulative conclusions of these analyses indicate that once-daily dosing strategies generally lead to less AKI when compared with multiple-dose strategies, though the benefits of this approach are modest [125].

Amphotericin B

Amphotericin B remains an important antifungal therapy. Unfortunately, nephrotoxicity is common and may occur in close to 25% of patients receiving conventional (nonlipid-based) formulations [126, 127]. Renal toxicity may take the form of renal tubular acidosis, impaired renal concentrating

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 10.2 Prevention of acute tubular necrosis in select high-risk settings.

Risk setting	Select key studies	Results of studies	Recommendation	Certainty of evidence	Strength of recommendation
Aminoglycosides	Ali and Goetz [71] (M)	No significant difference in the incidence of nephrotoxicity with SDD vs. MDD	We suggest that, in patients with normal kidney function in steady state, aminoglycosides be administered in a single daily dose rather than multiple daily doses. We also recommend that, for patients with CKD stage 3b and later, aminoglycosides be avoided unless there are no other alternatives.	Moderate	Strong
	Blaser and König [72] (M)	Trend toward decreased nephrotoxicity with SDD vs. MDD (4.5% vs. 5.5%); did not reach statistical significance			
	Barza et al. [73] (M)	Reduced risk of nephrotoxicity with SDD vs. MDD			
	Ferriols-Lisart and Alós-Almiñana [74] (M)	Reduced summary odds of nephrotoxicity with SDD vs. MDD			
	Hatala et al. [75] (M)	Trend toward decreased nephrotoxicity with SDD vs. MDD; did not reach statistical significance			
	Munckhof et al. [76] (M)	No significant difference in the incidence of nephrotoxicity with SDD vs. MDD			
Amphotericin B	Anderson [77] (M)	Supplementing dietary sodium chloride intake with 150 mEq intravenously or orally before or at time of drug administration "will likely prevent much of the observed nephrotoxicity" associated with amphotericin B	We recommend the administration of a saline load (1 l of 0.9% sodium chloride IV) prior to amphotericin B administration.	Moderate	Strong
	Llanos et al. [78] (RCT)	Creatinine clearance decreased in patients pretreated with dextrose in water, but remained unchanged in patients pretreated with 0.9% saline			
	Botero Aguirre and Restrepo Hamid [79] (Cochrane systematic review)	Significantly lower risk of nephrotoxicity with liposomal amphotericin B vs. conventional amphotericin B deoxycholate	We suggest using lipid formulations of amphotericin B rather than conventional formulations of amphotericin B except in circumstances were the efficacy of conventional formulations may be greater.	Moderate	Strong
Vancomycin + piperacillin-tazobactam	Chen et al. [80] (M)	Increased risk of AKI with concurrent use of vancomycin + piperacillin-tazobactam vs. vancomycin + other β-lactam	We recommend using piperacillin-tazobactam cautiously in those patients receiving vancomycin. Use should be limited to those who have appropriate indications. Alternative antibiotics should be considered whenever possible.	Moderate	Strong
	Giuliano et al. [81] (M)	Increased risk of AKI with vancomycin + piperacillin-tazobactam vs. vancomycin ± other β-lactam			
	Hammond et al. [82] (M)	Increased risk of AKI with concomitant vancomycin + piperacillin-tazobactam vs. vancomycin without piperacillin-tazobactam			
	Luther et al. [83] (M)	Increased odds of AKI with vancomycin + piperacillin-tazobactam vs. vancomycin monotherapy, vancomycin +cefepime or carbapenem, and piperacillin-monotherapy; NNH = 11			
	Mellen et al. [84] (M)	Increase in the incidence of nephrotoxicity with vancomycin + piperacillin-tazobactam vs. vancomycin alone or in combination with cefepime or meropenem

Iodinated radiocontrast dye[a]	Brar et al. [85] (RCT)	Decrease in CIN with LVEDP-guided 0.9% saline volume expansion vs. standard hydration group (6.7% vs. 16.3%) in patients undergoing cardiac catheterization	We recommend IV volume expansion for patients at risk for CIN without contraindications to volume expansion.	Moderate	Strong
	Jurado-Román [86] et al. (RCT)	Decreased incidence of CIN with 0.9% saline vs. no hydration in the setting of emergent PCI for STEMI (11% vs. 21%)			
	Luo et al. [87] (RCT)	Lower rate of CIN with 0.9% saline vs. no hydration after PCI for STEMI (20.4% vs. 35.2%)			
	Nijssen EC et al. [88] (RCT)	No difference in rate of CIN between 0.9% saline and no prophylaxis (2.6% vs. 2.7%); not an especially high-risk group (low rate of CIN, 65% had only mild CKD with eGFR 45–59 ml/min/1.73m^2, only 48% received intra-arterial contrast)			
	Trivedi et al. [89] (RCT)	Decreased risk of CIN 0.9% saline vs. unrestricted oral intake (1/27 vs. 9/26 patients)			
	Weisbord et al. [90] (RCT)	No significant difference in primary endpoint (composite of death, need for RRT, or persistent decline in kidney function at 90 days) or CIN with IV 1.26% BIC vs. 0.9% saline	We do not recommend the routine use of sodium bicarbonate solution over NS for the prevention of CIN.	Strong	Strong
	Zoungas et al. [91] (M)	Lower pooled risk of CIN with BIC (RR, 0.62); significant heterogeneity; small, poor-quality studies more likely to suggest benefit; no clear effects on risk of RRT, heart failure, or mortality			
	Weisbord et al. [90] (RCT)	No significant difference in primary endpoint (composite of death, need for RRT, or persistent decline in kidney function at 90 days) or CIN with PO NAC vs. placebo	We do not recommend the routine use of N-acetylcysteine for the prevention of CIN.	Strong	Strong
Rhabdomyolysis	Gunal et al. [92] (case series)	16 crush injury victims; time between rescue and initiation of IVF significantly longer in victims requiring RRT	We recommend early and aggressive hydration in all patients with rhabdomyolysis with CK values >5000 U/l or increasing CK values in the absence of volume overload.	Moderate	Strong
	Ron et al. [93] (case series)	7 patients with crush injury treated immediately with alkaline solute diuresis on extraction; no patient developed ARF (attributed to prompt administration of IVF)			
	Brown et al. [94] (retrospective chart review)	No difference in rates of ARF, dialysis, or mortality with BIC/MAN vs. without BIC/MAN among patients with CK >5000 U/l; trend toward improved outcome in subgroup with CK >30 000 U/l	We do not recommend the routine use of mannitol to prevent or treat rhabdomyolysis given the risks of volume depletion and hypernatremia, and conflicting evidence regarding potential benefit.	Low	Weak
	Kim et al. [95] (RCT)	Significant difference in incidence of rhabdomyolysis (CK >5000 U/l) with early urine alkalization group vs. hydration alone in patients admitted with doxylamine overdose	Use of bicarbonate-based fluids to prevent or treat rhabdomyolysis may be considered in patients in whom a diuresis has been established with 0.9% saline. Bicarbonate infusion should be discontinued and isotonic saline resumed for arterial pH ≥7.5, serum bicarbonate >30 mEq/l, or if symptomatic hypocalcemia develops.		
	Scharman and Troutman [96] (systematic literature review)	27 studies; 3 studies concluded no significant difference in rates of ARF with BIC vs. no BIC; no evidence supported a preferred fluid type; interpretation limited by lack of controlled trials and heterogeneity

Table 10.2 (Continued)

Risk setting	Select key studies	Results of studies	Recommendation	Certainty of evidence	Strength of recommendation
Surgery (all types)	Zacharias et al. [97] (Cochrane systematic review)	Investigated preventative strategies including dopamine and its analogues, diuretics, CCBs, ACE inhibitors, NAC, ANP, and erythropoietin; no group showed a significant change in mortality or kidney injury in treatment groups vs. controls	We do not recommend the routine use of these interventions for the prevention of AKI/ATN in the perioperative setting.	Very low	Weak
Cardiac surgery	Lamy et al. [98] (RCT)	Lower rate of AKI at 30 d with off-pump vs. on-pump CABG; no difference in renal failure requiring RRT or death; increased risk of early revascularization	We suggest that off-pump coronary artery bypass graft surgery not be selected solely for the purpose of reducing perioperative AKI.	Low	Weak
	Nigwekar et al. [99] (M)	Reduction in overall AKI (OR, 0.57) and AKI requiring RRT (OR, 0.55) with off-pump vs. on-pump CABG; limited by lack of uniform definition for AKI and heterogeneity			
	Seabra et al. [100] (M)	Significant 40% lower odds of postoperative AKI and a nonsignificant 33% lower odds of need for RRT compared with off-pump vs. on-pump CABG			

[a] For a more detailed discussion of the prevention and treatment of CIN, please see Chapter 11 on contrast-induced nephropathy.
ACE, angiotensin-converting-enzyme; AKI, acute kidney injury; ANP, atrial natriuretic peptide; ARF, acute renal failure; ATN, acute tubular necrosis; BIC, sodium bicarbonate; BIC/MAN, sodium bicarbonate + mannitol; CABG, coronary artery bypass graft; CCB, calcium channel blocker; CIN, contrast-induced nephropathy; CK, creatine kinase; CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate, IV, intravenous, IVF, intravenous fluid; LVEDP, left ventricular end-diastolic pressure; M, meta-analysis; MDD, multiple daily dosing; NAC, *N*-acetylcysteine; NNH, number needed to harm; NS, normal saline; OR, odds ratio; PCI, percutaneous coronary intervention; RCT, randomized controlled trial; RR, relative risk; RRT, renal replacement therapy; SCr, serum creatinine; SDD, single daily dosing; STEMI, ST elevation myocardial infarction.

Table 10.3 Select agents investigated for the prevention of acute tubular necrosis.

Agent or procedure for prevention of ATN	Select key studies	Results of studies	Recommendation	Certainty of evidence	Strength of recommendation
Dopamine	Bellomo et al. [101] (RCT)	No significant difference in renal function, need for RRT, ICU or hospital length of stay, or mortality in critically ill patients with early renal dysfunction receiving low-dose dopamine (2 mcg/kg/min) vs. placebo	In the absence of convincing evidence of benefit, and in light of potential risks, we do not recommend the routine use of dopamine for prevention of AKI.	High	Strong
	Friedrich et al. [102] (M)	Increased urine output and improvement in SCr on day 1 with low-dose dopamine (≤5 mcg/kg/min); no sustained improvement in renal function, decrease in need for RRT, or decrease in mortality (did not separate prophylactic from therapeutic trials)			
	Kellum and Decker [103] (M)	No significant benefit of low-dose dopamine (<5 mcg/kg/min) for prevention of AKI			
Fenoldopam	Bove et al. [104] (RCT)	Similar rates of AKI with the use of fenoldopam vs. dopamine in high-risk patients following induction of anesthesia for cardiac surgery	In the absence of high-quality adequately powered trials and consistent data demonstrating improvement in patient-centered outcomes, and in light of the risk of hypotension, we suggest not using fenoldopam to prevent ischemic ATN.	Low	Weak
	Gillies et al. [105] (M)	Reduction in risk of AKI in patients receiving fenoldopam vs. placebo; no difference in mortality or need for RRT; high risk of bias in 5/6 studies			
	Landoni et al. [106] (M)	Lower risk of AKI in fenoldopam-treated patients vs. placebo or other therapy (primarily low-dose dopamine); no significant increase in complications; heterogeneous populations; 6 studies lacked placebo controls			
	Morelli et al. [107] (RCT)	Lower rate of AKI (increase in SCr above 1.7 mg/dl) in patients treated with prophylactic fenoldopam vs. placebo; no significant difference in rate of severe acute renal failure (SCr >3.4 mg/dl)			
Loop diuretics	Bove et al. [108] (M)	Significant improvement in survival in patients treated with preventative furosemide bolus(es) vs. any comparator (standard care, 0.9% saline, 0.9% saline ± mannitol, or furosemide infusion)	We do not recommend the routine use of loop diuretics for the prevention of ATN.	Moderate	Strong
	Hager et al. [109] (RCT)	No significant difference in post-operative decline in creatinine clearance between low-dose furosemide (1 mg/h) and placebo groups; increased incidence of hypokalemia with use of furosemide			
	Ho et al. [110] (M)	No significant difference in in-hospital mortality or need for RRT with the use of furosemide to prevent acute renal failure			
	Ho et al. [111] (M)				
	Lassnigg et al. [112] (RCT)	Increased rate of AKI in patients randomized to receive furosemide (0.5 mcg/kg/min) vs. 0.9% saline or low-dose dopamine

Table 10.3 (Continued)

Agent or procedure for prevention of ATN	Select key studies	Results of studies	Recommendation	Certainty of evidence	Strength of recommendation
Natriuretic peptides	Nigwekar et al. [113] (Cochrane systematic review)	Decreased need for RRT but no difference in mortality in patients receiving prophylactic low-dose ANP compared to high-dose ANP or controls; authors acknowledged paucity of high-quality, adequately powered data	In the absence of high-quality adequately powered trials, and in light of the risk of hypotension, we suggest not using natriuretic peptides to prevent ischemic ATN.	Low	Weak
	Nigwekar et al. [114] (M)	Natriuretic peptide administration (ANP, BMP, urodilantin) was associated with a reduction in need for RRT and a nonsignificant trend toward reduction in 30 days or in-hospital mortality; most studies were small and lacked adequate power to reach statistical significance on their own			
Remote ischemic preconditioning	Menting et al. [115] (Cochrane systematic review)	RIPC by cuff inflation made little or no difference in SCr (postoperative days 1–3), need for dialysis, length of hospital stay, or all-cause mortality compared with no RIPC prior to surgery (renal transplant excluded)	In the absence of clear benefit, we do not recommend the routine use of RIPC for the prevention of ischemic ATN.	High	Strong
Statins[a]	Billings et al. [116] (RCT)	No reduction in the risk of AKI (0.3 mg/dl increase in SCr within 48 hours) in patients undergoing cardiac surgery with use of high-dose atorvastatin vs. placebo; increased AKI among statin-naïve CKD patients	In the absence of clear benefit, we do not recommend the routine use of statins for the prevention of ischemic ATN.	High	Strong
	Park et al. [117] (RCT)	Acute perioperative atorvastatin use not associated with lower incidence of AKI (AKIN criteria) or improved clinical outcomes after valvular heart surgery compared with placebo			
	Prowle et al. (RCT) [118]	Short-term perioperative atorvastatin use not associated with reduction in AKI (RIFLE R or greater) or smaller increases in urinary NGAL			

[a] For a discussion of statin administration as it pertains to the use of iodinated radiocontrast dye, please see Chapter 11 on contrast-induced nephropathy.
AKI, acute kidney injury; AKIN, Acute Kidney Injury Network; ANP, atrial natriuretic peptide; ATN, acute tubular necrosis; BNP, brain natriuretic peptide; CKD, chronic kidney disease; ICU, intensive care unit; NGAL, neutrophil gelatinase-associated lipocalin; M, meta-analysis; RCT, randomized controlled trial; RIFLE, Risk, Injury, Failure, Loss of kidney function, and End-stage kidney disease criteria; RIPC, remote ischemic preconditioning; RRT, renal replacement therapy; SCr, serum creatinine concentration.

ability, electrolyte abnormalities (hypokalemia, sodium, and magnesium wasting), and ATN [128]. In attempts to minimize kidney injury, several preventative strategies have been investigated, including salt loading (volume expansion) and the use of lipid-based formulations.

Volume Expansion (Salt Loading) In response to animal data suggesting that enhanced TGF contributes to the nephrotoxicity of amphotericin B, a number of studies have evaluated the utility of salt loading through saline infusion with the goal of decreasing sensitivity to TGF and preserving GFR [129].

In 1995, Anderson published a meta-analysis of the five available human studies investigating the role of salt loading. He concluded that 150 mEq of sodium chloride daily intravenously or orally will likely prevent much of the observed nephrotoxicity and should be carried out routinely [77]. Anderson's conclusions were based largely on one placebo-controlled trial, in which patients treated with thrice-weekly amphotericin for leishmaniasis were randomized to receive either 1 l of 0.9% saline or 1 l of 5% dextrose in water immediately prior to each amphotericin B dose [48]. Results showed a reduction in creatinine clearance in the control group compared with patients in the saline group ($P < 0.05$). None of the patients sustained an increase in SCr to values greater than 1.7 mg/dl [78].

There has been minimal recent research in this area, and it is unlikely that any randomized trials will be conducted due to practical and ethical considerations. While the data above is clearly limited, there appears to be minimal harm in giving patients a saline load (1 l of 0.9% sodium chloride intravenously) prior to amphotericin B administration, and this should be considered the standard of care.

Use of Lipid-Based Amphotericin B Formulations Several animal and human studies suggest that lipid-based formulations of amphotericin B (either lipid complex or liposomal) may decrease the incidence and severity of kidney injury.

In a recent systematic Cochrane review, 10 randomized controlled trials (RCTs) comparing amphotericin B sodium deoxycholate with liposomal amphotericin B were meta-analyzed. The liposomal formulation was found to be significantly safer in terms of nephrotoxicity, defined as a ≥2-fold increase in SCr from baseline (RR, 0.49). The sensitivity analysis performed did not change the significance of difference in favor of the liposomal formulation, and the overall certainty of evidence was determined to be moderate based on GRADE Working Group criteria [79].

Vancomycin and Piperacillin-Tazobactam

Vancomycin is a known cause of nephrotoxic ATN, with incidence of AKI ranging from 5% to 43% depending on the population studied [130–132]. Risk factors include vancomycin exposure (trough levels 15 mg/l or higher, larger AUC, longer duration of therapy), host susceptibility to vancomycin (increased body weight, pre-existing kidney dysfunction, critical illness), and concurrent nephrotoxin therapy [130].

Since 2011, multiple studies have demonstrated an increased risk of AKI with the use of vancomycin in combination with piperacillin-tazobactam, and five meta-analyses have been conducted to investigate this proposed increased risk [80–84]. Giuliano et al. evaluated 15 observational cohort studies including a total of 3258 patients and documented an association with the development of AKI with vancomycin + piperacillin-tazobactam compared with vancomycin ± beta-lactam (OR, 3.649) [81]. Additional studies have demonstrated similar findings [80, 82, 84]. In the largest meta-analysis, the overall occurrence rate of AKI was 22.2% for the vancomycin + piperacillin-tazobactam group compared with 12.9% for the comparator groups (vancomycin monotherapy, vancomycin + cefepime or carbapenem, piperacillin monotherapy), yielding an overall number needed to harm of 11 [83].

Taken together, these studies provide compelling evidence supporting an increased risk for AKI in those patients treated with vancomycin and piperacillin-tazobactam. This combination should be initiated cautiously and only in patients with appropriate indications for use.

Iodinated Radiocontrast Dye

Iodinated radiocontrast dye is a common cause of ATN, with incidence of contrast-induced nephropathy (CIN) reported to be as high as 15–25% (depending on the exact definition and agent used) in certain high-risk populations receiving intra-arterial injections [133–135]. These include patients with pre-existing renal impairment or certain risk factors such as diabetes, congestive heart failure, or concurrent administration of nephrotoxic medication [125, 136, 137]. A number of measures (hydration, types of contrast, and medications) have been investigated in attempts to prevent CIN [137]. Of these, the most critical appears to be optimization of volume status, and we recommend the administration of isotonic fluids prior to and for several hours after the administration of iodinated contrast in at-risk patients without contraindications to volume expansion (see Table 10.2) [125]. For a detailed discussion of the pathophysiology, prevention, and treatment of contrast-induced AKI, see Chapter 11 [Weisbord and Gallagher].

Treatment

Many drug classes and strategies have been studied as potential treatments for established ATN, and several representative examples are outlined in Table 10.4. Unfortunately, the results of these investigations have been largely disappointing. Because no single effective treatment for ATN has been identified, the mainstays of therapy remain appreciation of AKI risk, early detection of injury, initiation of appropriate supportive care, and avoidance of further harm [154]. Treatment priorities must include (i) discontinuation of nephrotoxic medications whenever possible; (ii) optimization of hemodynamics and RBF; (iii) attention to volume management with caution to avoid both hypovolemia and fluid overload; (iv) correction of electrolyte and acid-base derangements; and (v) timely initiation of RRT in appropriately selected patients.

Discontinuation of Nephrotoxic Medications

All patients with established ATN require a thorough review of their medications. Nephrotoxic drugs (NSAIDs, ACE inhibitors, ARBs, aminoglycosides) and agents such as iodinated radiocontrast dye should be avoided or stopped, if possible. Additionally, medication doses should be adjusted to account for reduced renal clearance.

Optimization of Hemodynamics and RBF and Volume Management

Early measures to treat established ATN must include optimization of cardiac output and maintenance of hemodynamics to ensure adequate systemic perfusion and RBF; the specific approach will vary based on patient factors and the clinical scenario (hypovolemic shock, tumor lysis syndrome, heart failure) [2].

Close attention must be paid to volume status. While volume depletion should be corrected when present, there is a growing body of evidence documenting poorer patient outcomes with excessive fluid administration. In the Fluid and Catheter Treatment Trial (FACTT), a conservative fluid strategy (achieved through the protocolized use of furosemide to target low central venous pressure or pulmonary capillary wedge pressure) was associated with decreased ICU length of stay and decreased length of mechanical ventilation in patients with acute lung injury without an increase in nonpulmonary-organ failures or need for dialysis [155]. Additionally, a positive fluid balance at 72 hours post-admission has been shown to be associated with increased mortality, and some data suggest that a positive fluid balance as early as 12 hours may be associated with increased risk of death [156–159].

An association between positive fluid balance and mortality has been demonstrated in patients with established AKI [142, 145]. In a secondary analysis of AKI patients from a multicenter, prospective cohort study in 10 Italian ICUs, higher mean fluid balance was associated with greater mortality, and diuretic use was associated with better survival in this population (adjusted HR, 0.25) [145]. Using data from the FACTT, 306 AKI patients were identified and included in a post hoc analysis. Grams et al. showed that post-AKI fluid balance was significantly associated with 60-day mortality in both crude and adjusted analysis, and that higher post-AKI furosemide doses had a protective effect on mortality but no significant effect after adjustment for post-AKI fluid balance [142]. While the data does not support the routine use of diuretics in euvolemic patients with established ATN (who may develop volume depletion and subsequent worsening of ischemic kidney injury), diuretics and/or RRT may be considered in those with evidence of volume overload. For a review of relevant studies investigating the role of loop diuretics in the treatment of ATN, see Table 10.4.

Correction of Electrolyte and Acid-Base Disturbances and Timely Initiation of RRT

Metabolic derangements seen in established ATN include hyperkalemia, hyponatremia, hyperphosphatemia, and acidemia, and these may range in severity from mild to life-threatening. Rapid rises in serum potassium concentration, as may occur in the presence of oliguria and tissue breakdown (rhabdomyolysis, tumor lysis syndrome), are especially worrisome. In these cases, emergency treatment may be required.

Despite extensive research, debate continues regarding the optimal timing, modality, and dosing of RRT in ATN. The KDIGO Clinical Practice Guideline for AKI suggests initiation of RRT emergently when life-threatening changes in fluid, electrolyte, and acid-base balance exist. In the absence of emergent indications, KDIGO suggests that clinicians consider the broader clinical context, the presence of conditions that can be modified with RRT, and trends in laboratory results when making the decision to start RRT (recommendations not graded) [125].

Conclusions

ATN is a common clinical problem associated with increased risk of CKD and mortality. Unfortunately, while several classes of agents have been investigated, thus far no specific pharmacologic strategies have proven effective for

Table 10.4 Select agents investigated for the treatment of established acute tubular necrosis.

Agent or procedure for treatment of AKI	Select key studies	Results of studies	Recommendation	Certainty of evidence	Strength of recommendation
Alkaline phosphatase	Pickkers et al. [138] (RCT)	No significant improvement in short-term (7 days) creatinine clearance with human recombinant AP (vs. placebo) in critically ill patients with sepsis-associated AKI	In the absence of data demonstrating consistent improvement in patient-centered outcomes, we suggest not using alkaline phosphatase for the treatment of AKI.	Moderate	Strong
	Pickkers et al. [139] (RCT)	Significant ($P = 0.02$) difference in favor of AP relative to controls for the primary endpoint (progress in renal outcome variables as measured by ECC and requirement and duration of RRT) at 28 days; ECC 50 ± 27 to 108 ± 73 ml/min (mean ± SEM) in AP group vs. 40 ± 37 to 65 ± 30 ml/min for placebo ($P = 0.01$); reductions in RRT requirement and duration did not reach statistical significance			
Dopamine	Friedrich et al. [102] (M)	Increased urine output and improvement in SCr on day 1 with low-dose dopamine (≤5 mcg/kg/min); no sustained improvement in renal function, decrease in need for RRT, or decrease in mortality (did not separate prophylactic from therapeutic trials)	In the absence of convincing evidence of benefit, and in light of potential risks, we do not recommend the use of dopamine for the treatment of AKI.	High	Strong
	Kellum and Decker [103] (M)	No significant benefit of low-dose dopamine (<5 mcg/kg/min) for treatment of AKI			
	Lauschke et al. [140] (RCT)	Increase in renal vascular resistance with low-dose dopamine (2 mcg/kg/min) in patients with ARF (vs. decrease in renal vascular resistance without ARF); concern for worsening of renal perfusion in dopamine-treated patients			
Loop diuretics	Cantarovich et al. [141] (RCT)	No difference in survival or rate of renal recovery with high dose furosemide (25 mg/kg/d IV or 35 mg/kg/d PO) vs. placebo; increased UOP in furosemide group without reduction in number of treatments or time on dialysis	We suggest not using diuretics to treat AKI, except in the management of volume overload.	Moderate	Weak
	Grams et al. [142](RTC, post hoc analysis)	Higher post-AKI fluid balance associated with increased 60-day mortality; higher post-AKI furosemide associated with improved survival (no significant effect after adjustment for post-AKI fluid balance)			
	Mehta et al. [143] (retrospective cohort study)	Increased risk of death and nonrecovery renal function with use of furosemide, bumetanide, metolazone, and/or hydrodiuril vs. no diuretics			
	Shilliday et al. [144] (RCT)	Randomized to receive torsemide, furosemide, or placebo in addition to dopamine and mannitol; no decrease in rate of renal recovery, need for RRT, or death with diuretics despite increased UOP			
	Teixeira et al. [145] (prospective cohort study, secondary analysis)	Higher MFB in nonsurviving AKI patients vs. surviving AKI patients; higher MFB independently associated with 28-day mortality; diuretic use associated with better survival in patients with higher MFB and lower MUV			
	Uchino et al. [146] (prospective cohort study)	No significant difference in patient mortality associated with the use of diuretics (almost exclusively furosemide) vs. no diuretics in critically ill ICU patients

Table 10.4 (Continued)

Agent or procedure for treatment of AKI	Select key studies	Results of studies	Recommendation	Certainty of evidence	Strength of recommendation
Fenoldopam	Brienza et al. [147] (RCT)	Randomized to receive fenoldopam (0.1 mcg/kg/min) or dopamine; lower SCr in fenoldopam group after 4-day infusion (change from baseline, −0.041 vs. -0.09 mg/dl, $P = 0.02$); no decrease in need for RRT	In the absence of data demonstrating consistent improvement in patient-centered outcomes, and in light of the risk of hypotension, we suggest not using fenoldopam for the treatment of established ischemic ATN.	Low	Weak
	Bove et al. [148] (RCT)	No difference in need for RRT or 30-day mortality with fenoldopam vs. placebo; significantly more hypotension in fenoldopam group (26% vs. 15%, $P = 0.001$); stopped early for futility			
	Tumlin et al. [149] (RCT)	Trend toward lower 21-day mortality and decreased need for RRT with fenoldopam vs. placebo, but not statistically significant (underpowered, 11% absolute risk reduction)			
Insulin-like growth factor-1	Hirschberg et al. [150] (RCT)	In patients with sepsis and hypotension or hemodynamic shock, no differences noted in changes in GFR, urine output, need for RRT, or mortality with IGF-1 vs. placebo (mean treatment period 10.6 days)	In the absence of data from high-quality trials demonstrating improvement in patient-centered outcomes, we do not recommend the routine use of IGF-1 for the treatment of established AKI.	Moderate	Strong
Natriuretic peptides	Allgren et al. [151] (RCT)	No significant difference in overall dialysis-free survival at 21 days with anaritide (0.2 mcg/kg/min) vs. placebo; improved dialysis-free survival in subgroup with oliguria receiving anaritide; increased incidence of hypotension in anaritide group (46% vs. 18%, $P = 0.001$)	In the absence of data demonstrating consistent benefit in patient-centered outcomes, and in light of the risk of hypotension, we suggest not using ANP to treat ATN.	Moderate	Weak
	Lewis et al. [152] (RCT)	No statistically significant difference in dialysis-free survival or mortality with anaritide (0.2 mcg/kg/min) vs. placebo; greater incidence of hypotension (SBP <90) in the anaritide-treated group (95% vs. 55%, $P < 0.001$)			
	Nigwekar et al. [110] (Cochrane systematic review)	No difference in mortality with either low- or high-dose ANP; low-dose ANP associated with reduction in need for RRT; high-dose ANP associated with more adverse events (hypotension, arrhythmias); authors acknowledge paucity of high-quality, adequately powered data			
	Swärd et al. [153] (RCT)	61 postoperative patients with heart failure and AKI (not ischemic ATN) randomized to h-ANP (50 ng/kg/min) or placebo; decreased need for RRT and improved dialysis-free survival in h-ANP group vs. placebo; no significant difference in incidence of hypotension			

AKI, acute kidney injury; ANP, atrial natriuretic peptide; AP, alkaline phosphatase; ARF, acute renal failure; ATN, acute tubular necrosis; ECC, endogenous creatinine clearance; GFR, glomerular filtration rate; h-ANP, human atrial natriuretic peptide; ICU, intensive care unit; IGF-1, insulin-like growth factor-1; IV, intravenous; M, meta-analysis; MFB, mean fluid balance; MUV, mean urine volume; PO by mouth, RCT, randomized controlled trial; RRT, renal replacement therapy; SEM; standard error of the mean; SBP, systolic blood pressure; UOP, urine output.

preventing or treating this condition. Thus, the approach to ATN centers on identifying patients at increased risk, minimizing ischemic and toxic exposures, early detection of kidney injury, and aggressive supportive care, including the maintenance of adequate hemodynamics and management of electrolyte and acid-base derangements.

Iodinated Contrast and Acute Kidney Injury

Steven D. Weisbord[1] *and Martin Gallagher*[2]

[1] *Renal Section and Center for Health Equity Research and Promotion, VA Pittsburgh Healthcare System and Renal Electrolyte Division, University of Pittsburgh School of Medicine, Pittsburgh USA*
[2] *Renal & Metabolic Division The George Institute for Global Health Newtown, NSW, Australia*

Acute kidney injury (AKI) is a widely recognized complication of intravascular administration of iodinated contrast media. The pathophysiology of contrast-associated acute kidney injury (CA-AKI) is thought to be related to hemodynamic perturbations in the kidney from contrast, direct toxic effects of contrast on tubular epithelial cells, and the generation of reactive oxygen species following contrast administration. While typically defined by small increments in serum creatinine within several days following contrast administration, the incidence of CA-AKI varies based on the precise definition employed, clinical characteristics of the patient population, and nature of the procedure being performed. The primary patient-related risk factor for CA-AKI is underlying kidney impairment, while absolute and effective circulating volume also increases risk. A multitude of studies have demonstrated that CA-AKI is associated with serious adverse short- and long-term outcomes, including death. However, it is currently unknown whether these associations are causal. This is important as a growing number of studies suggest that patients with chronic kidney disease (CKD), who are elevated risk for CA-AKI, are less likely to undergo indicated contrast-enhanced procedures such as coronary angiography compared with patients without CKD, likely out of fear by providers of precipitating CA-AKI. As CA-AKI is a potentially preventable form of renal injury, there has been substantial effort to identify interventions to reduce risk. Studies over the past several decades inform the current evidence basis for the prevention of this condition. Understanding the data that inform the current evidence basis for prevention is essential to minimize the burden of AKI related to contrast and to enhance the appropriate implementation of clinically indicated contrast-enhanced procedures in patients at risk for this iatrogenic condition.

Pathophysiology

The potential harms of the intravascular administration of radiological, iodine-based contrast media have been appreciated for over 60 years, with the recognized risk of AKI well described since the 1970s [1]. A series of pathophysiological processes likely underlie the development of contrast-induced CKI (Figure 11.1). After iodinated contrast is administered into the systemic circulation, blood flow to the outer renal medulla decreases while active transport and oxygen requirements in the distal nephron increase.

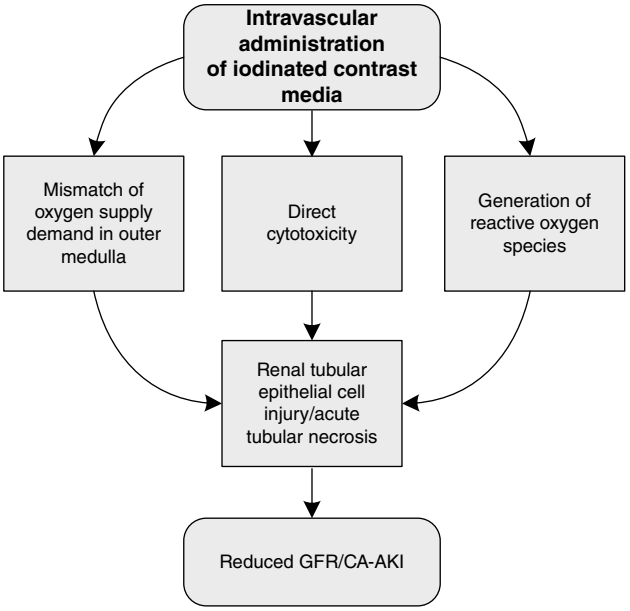

Figure 11.1 Potential processes underlying the pathophysiology of CA-AKI.

The resulting mismatch in oxygen supply and demand in an anatomical portion of the kidney with low baseline oxygen reserve leads to ischemia of tubular epithelial cells [2, 3]. Further epithelial cell injury results from both the direct toxicity of the filtered iodinated contrast and the generation of injurious reactive oxygen species [4–9]. After being filtered at the glomerulus, iodinated contrast enters the tubular lumen where it has been shown to have cytotoxic effects that result in tubular epithelial cell necrosis [6–8, 10]. Contrast administration also leads to increased production of oxygen free radicals in the kidney that further contribute to epithelial and endothelial cell injury [11–17]. The cumulative result of these effects is acute tubular necrosis and an abrupt decline in kidney function.

Nomenclature and Definition

Historically, AKI following the administration of iodinated contrast media was referred to as contrast nephropathy or contrast-induced nephropathy. More recently, the Kidney Disease Improving Global Outcomes (KDIGO) organization proposed the term contrast-induced AKI [18, 19]. However, in many patients, other factors along with contrast administration likely contribute to the observed decline in kidney function. Consequently, contrast-associated AKI (CA-AKI) may be a more appropriate term. CA-AKI has commonly been defined by an increment in serum creatinine of ≥0.5 mg/dl or ≥25% within 48–72 hours of contrast administration. While this definition is highly sensitive, it has poor specificity for contrast-induced damage as multiple other factors, including fluid shifts, medications, and atheroembolic disease can cause an increase in serum creatinine, with or without underlying kidney injury, independent of the effect of contrast. Nonetheless, this continues to be among the most commonly used definitions of this condition. In keeping with efforts to establish a unifying definition of AKI that is independent of etiology, CA-AKI has also been defined based on an increase in serum creatinine of ≥0.3 mg/dl within 48 hours [18]. However, this definition also has poor specificity. In light of the issues associated with defining a condition based on nominal increments in a biological parameter (i.e. serum creatinine) that is not specific for kidney injury, efforts to identify other biomarkers that better define and more accurately predict the prognosis of CA-AKI are needed.

Incidence

The reported incidence of CA-AKI has varied across studies due to differences in patient characteristics and procedural variables, as well as the criteria employed to define the development of AKI. Weisbord et al. demonstrated that CA-AKI, defined by an increase in serum creatinine of ≥25%, developed in 13.2%, 8.5%, and 6.5% of patients following nonemergent noncoronary angiography, coronary angiography, and contrast-enhanced computed tomography, respectively [20]. In a study of 1111 hospitalized patients by Shema et al., CA-AKI, defined as an increase in serum creatinine of ≥0.5 mg/dl within 1–5 days, was identified in 44% of diabetic patients with underlying kidney disease [21]. D'Elia et al. demonstrated that 33% of patients with CKD developed CA-AKI, defined based on an increase in serum creatinine of ≥1.0 mg/dl following angiography [22]. Hence, the incidence is highly dependent upon the definition used, the characteristics of the patient population, and the nature of the procedure for which radiocontrast is administered.

Over the past decade, a series of studies have questioned the relationship between intravascular radiocontrast administration and CA-AKI, demonstrating comparable rates of AKI between patients who underwent radiographic procedures without contrast and patients who underwent contrast-enhanced procedures [23–31] (Table 11.1). Bruce et al. investigated the incidence of AKI, defined by an increase in serum creatinine ≥0.5 mg/dl or decrease in estimated glomerular filtration rate (eGFR) ≥25%, among 11 588 patients who underwent computed tomography either with ($n = 5790$) or without ($n = 7484$) intravenous (IV) contrast [23]. Among those with CKD, the incidence of AKI following computed tomography without contrast (8.8%) was comparable to the incidence following computed tomography with IV contrast (9.7% with iso-osmolal iodixanol and 9.9% with low-osmolal iohexol). Several subsequent studies demonstrated similar findings [26, 28, 32–34]. McDonald and colleagues conducted a meta-analysis comprising 13 studies with nearly 26 000 patients and reported a nonstatistically significant lower risk for AKI following IV contrast-enhanced procedures compared to unenhanced procedures (relative risk 0.79, 95% confidence interval [CI] 0.62–1.02) [35]. While the majority of such studies examined patients undergoing computed tomography, others have broadened the study population. In a study of hospitalized patients, Wilhelm-Leen et al. demonstrated a lower risk for AKI among hospitalized patients who received intravascular contrast as part of any type of procedure during their hospitalization compared with patients who did not receive contrast (5.1% vs. 5.6%, adjusted odds ratio [OR] 0.93, 95% CI 0.88–0.97) [26]. Caspi et al. demonstrated a similar incidence of AKI in a cohort of 2025 patients with ST segment elevation myocardial infarction treated with percutaneous intervention compared with 1025 patients treated with fibrinolysis (10.3% vs. 12.1%,

Table 11.1 Studies comparing incidence of CA-AKI based on receipt of contrast.

Authors	Type of procedure	AKI with contrast (%)	AKI without contrast (%)	OR/RR (95% CI)
Bruce et al. [23]	CT	9.9/9.7[a]	8.8	Not reported
Ehrmann et al. [31]	Not specified	7.5	5.3	1.57 (0.69–3.53)
McDonald et al. [30]	CT	4.8	5.1	0.94 (0.83–1.07)
McDonald et al. [28][b]	CT	9.9	16	0.68 (0.55–0.84)
McDonald et al. [29]	CT	31	34	0.88 (0.75–1.05)
Hinson et al. [27]	CT	10.6	10.2	1.05 (0.94–1.18)
Caspi et al. [25]	Coronary angiography[c]	10.3	12.1	0.79 (0.60–1.05)
Zealley et al. [24]	Not specified	10.9	10.7	0.91 (0.82–1.00)
Wilhelm-Leen et al. [26]	Not specified	5.1	5.6	0.93 (0.88–0.97)

[a] Data denote AKI rates with iohexol and iodixanol, respectively.
[b] Comparison is for patients with stage 3 CKD.
[c] With percutaneous intervention.
AKI, acute kidney injury; CA-AKI, contrast-associated acute kidney injury; OR, odds ratio; RR, relative risk.

$P = 0.38$) [25]. In analyses that included propensity score matching, AKI rates remained comparable in patients who were and were not treated with percutaneous intervention (8.6% vs. 10.9%, $P = 0.12$).

While collectively these studies suggest that the administration of intravascular contrast does not increase the risk for AKI, most are retrospective in design and have limited capacity to adjust for the effects of unmeasured confounding. Specifically, patients at higher baseline risk for CA-AKI were likely to have selectively undergone radiological tests without intravascular contrast. Without understanding and accounting for the factors that might influence provider decision making regarding the use of contrast, the reported relationships are likely to be confounded by differences in baseline characteristics between those who did and those who did not receive contrast. This is best illustrated by the fact that certain of these studies demonstrated lower rates of AKI among patients who were administered intravascular contrast compared to those who did not receive contrast [26]. As contrast media are not nephroprotective, this observation strongly implies differential use of contrast based on clinicians' perceptions of patients' baseline risk for AKI. Accordingly, it is inappropriate to conclude based on these studies that the risk for AKI is independent of contrast administration in patients undergoing radiographic/angiographic procedures.

Risk Factors

Patient-related

Risk factors for CA-AKI are categorized as patient-related and procedure-related (Table 11.2). Patient-related conditions that augment the risk for CA-AKI are those that impair the capacity of the kidneys to effectively counteract the pathophysiological processes that lead to the development of CA-AKI. Pre-procedural kidney impairment is the most potent patient-related risk factor for CA-AKI, with lower levels of kidney function corresponding with higher degrees of risk [43]. In a study of 378 hospitalized patients undergoing nonrenal angiography, D'Elia et al. demonstrated a markedly higher incidence of CA-AKI among those defined as azotemic (blood urea nitrogen ≥30 mg/dl and serum creatinine ≥1.5 mg/dl) compared to nonazotemic patients (33% vs. 2%). Pre-existing azotemia was the only significant risk factor for CA-AKI in this study [22]. McCullough et al. documented a strong association of baseline kidney disease with risk of CA-AKI in a large population of patients undergoing angiography [38]. The findings from a trial by Rudnick et al. that compared different contrast agents suggest that diabetes, while not an independent risk factor for CA-AKI, substantially amplifies the risk in those patients with existing CKD [44]. Intravascular volume depletion, either absolute (e.g. GI losses) or effective (e.g. heart failure, liver failure), also increases the risk for CA-AKI [45, 46]. Similarly, the consumption of selective or nonselective nonsteroidal anti-inflammatory medications, which inhibit vasodilatory prostaglandins in the kidney, may also increase the risk for CA-AKI [47]. Other patient-related factors that have been linked with CA-AKI include increasing age, hypertension, anemia, and proteinuria; however, the independent associations of these factors with CA-AKI remain unproven as each is strongly linked with the presence and severity of CKD [48–51].

Table 11.2 Association of CA-AKI with short-term mortality risk.

Study authors	*n*	CA-AKI definition	OR 95% CI
Clec'h et al. [36]	143	↑ Serum creatinine ≥25% or ≥0.3 mg/dl	3.48 (1.10–11.46)
Levy et al. [37]	357	↑ Serum creatinine ≥25% to ≥2.0 mg/dl	5.5 (2.9–13.2)
Shema et al. [21]	1 111	↑ Serum creatinine ≥50% or ↓ eGFR ≥25%	3.9 (1.2–12.0)
McCullough et al. [38]	1 826	↑ Serum creatinine >25%	6.6 (3.3–12.9)
From et al. [39]	3 236	↑ Serum creatinine ≥25% or ≥0.5 mg/dl	3.4 (2.6–4.4)
Rihal et al. [40]	7 586	↑ Serum creatinine >0.5 mg/dl	10.8 (6.9–17.0)
Bartholomew et al. [41]	20 479	↑ Serum creatinine ≥1.0 mg/dl	22 (16–31)
Weisbord et al. [42]	27 608	↑ Serum creatinine 0.25–0.5 mg/dl	1.8 (1.4–2.5)

CA-AKI, contrast-associated acute kidney injury; CI, confidence interval; eGFR, estimated glomerular filtration rate; OR, odds ratio.

Procedure-related

Factors associated with the radiological procedure itself also affect the risk for CA-AKI. The administration of larger volumes of radiocontrast increases the risk. Although the precise volume above which risk increases significantly not been definitively determined, various formulas to calculate the upper threshold dose in milliliters of contrast have been proposed. These include multiplying the body weight (in kg) by 5 and dividing by the patient's serum creatinine (mg/dl), or alternatively multiplying the patient's eGFR by 2 [52–55]. The performance of sequential radiocontrast procedures over a short period of time also increases the risk for CA-AKI. High-osmolal contrast media are associated with an increased risk compared with low- and iso-osmolal contrast [44, 56]. More widespread use of low and iso-osmolal contrast likely explains, at least in part, the trend toward lower overall rates of CA-AKI [57].

The intra-arterial administration of contrast appears to confer a higher risk compared with IV administration, although it remains unclear if the differential risk relates to the route of contrast administration or underlying characteristics that differ across patients undergoing different types of procedures. For example, Weisbord et al. demonstrated lower rates of CA-AKI following IV administration of contrast in the setting of computed tomography (6.5%) as compared with the intra-arterial administration for coronary (8.5%) and noncoronary angiography (13.2%) in patients with CKD [20]. However, differences in clinical characteristics such as diabetes mellitus, heart failure, or severity of CKD, along with differential utilization of preventive interventions such as IV fluids may have accounted for the differing incident rates across procedure types.

Associated Outcomes

Association with Short-term Adverse Outcomes

CA-AKI has been associated with an increased risk for short-term mortality (Table 11.2) [36–42]. McCullough et al. demonstrated that patients who developed CA-AKI following angiography with percutaneous coronary intervention were more likely to die during the index hospitalization compared to patients who did not develop CA-AKI (7.1% vs. 1.1%, I < 0.0001) [38]. Several other observational studies reported an increased incidence of short-term mortality risk associated with the development of CA-AKI [36, 37, 39–42] (Table 11.2). Data from clinical trials also document this association. In a clinical trial of acetylcysteine, Marenzi et al. reported a higher incidence of in-hospital death among patients who developed CA-AKI compared with patients without CA-AKI (26% vs. 1.4%, $P < 0.001$) [58]. Similarly, in a trial comparing IV fluids, Maioli et al. demonstrated that patients who experienced CA-AKI had a higher incidence of in-hospital death than patients who did not develop CA-AKI (11.1% vs. 0.2%, $P = 0.001$) [59]. CA-AKI has also been associated with increased duration of hospitalization, as noted in a study by Adolph et al., who found that the development of CA-AKI was associated with an average prolongation in hospitalization of 2 days [60].

Association with Longer-term Adverse Outcomes

Several studies demonstrate that CA-AKI is associated with increased longer-term risk of mortality and more rapid progression of underlying CKD [40, 59, 61–68] (Table 11.3).

CA-AKI, contrast-associated acute kidney injury; CI, confidence interval; HR, hazard ratio.

Solomon and colleagues reported that the development of CA-AKI was associated with a more than threefold increased risk of death, stroke, myocardial infarction, and/or end-stage kidney disease at 1 year following angiography [64]. Goldenberg et al. reported that patients with transient CA-AKI manifested a larger decrement in kidney function 2 years following angiography compared with patients who did not experience CA-AKI (ΔeGFR -20 ± 11 ml/min/1.73 m^2 vs. -6 ± 16 ml/min/1.73 m^2, $P = 0.02$), a finding consistent with other types of AKI [61]. James et al. demonstrated more rapid deterioration of kidney function over 3 months following angiography among patients who had developed CA-AKI compared to those without this condition (decrement in eGFR 0.8 ml/min/1.73 m^2/yr vs. 0.2 ml/min/1.73 m^2/yr) [66].

Potential Clinical Implications of Data Associating CA-AKI with Adverse Outcomes

While consistent in demonstrating associations of CA-AKI with serious, adverse short- and long-term outcomes, these and similar past studies have not established whether the associations are causal. CA-AKI, defined by small increments in serum creatinine, may simply be a marker of a population of patients with more significant vascular disease and propensity for hemodynamic instability that places them at heightened risk for serious events. This fact is particularly pertinent given research documenting the underutilization of clinically indicated, potentially life-saving contrast-enhanced procedures in patients with CKD [69–72]. This practice is referred to as "renalism" and is likely driven by providers' fear of precipitating CA-AKI.

Chertow et al. compared the use of invasive coronary care, including coronary angiography, percutaneous coronary intervention, and coronary artery bypass surgery, for the treatment of acute myocardial infarction in 15 093 patients with CKD and 42 191 without CKD [73]. In analyses accounting for the appropriateness of coronary angiography, those with CKD were around half as likely to undergo this procedure than patients without CKD (OR 0.47, 95% CI 0.40–0.52), and patients with CKD who did undergo coronary angiography were also less likely to proceed to revascularization (55% vs. 62%, $P < 0.0001$). Concern for the risk of CA-AKI was a hypothesized explanation for the underutilization of angiography and revascularization in subjects with CKD.

Renalism has also been documented among patients with CKD presenting with ST elevation myocardial infarction (STEMI). Nauta et al. found that rates of percutaneous coronary revascularization were lower in patients with STEMI and stage 4 CKD compared to those with STEMI but without CKD [72]. The findings of these studies documenting renalism are particularly relevant considering data from multiple studies demonstrating improved survival among patients with CKD who undergo coronary angiography and revascularization in the setting of acute coronary syndrome [74]. A study by Wright et al. of 1786 patients with CKD demonstrated that initial invasive coronary care was associated with 35% and 50% relative reductions in in-hospital mortality compared with conservative medical therapy in patients with ST elevation myocardial infarction and non-ST elevation myocardial infarction, respectively [75]. In a more recent study of patients with non-ST elevation acute coronary syndrome, James et al. found that among those with stage 3 CKD, early performance of coronary angiography was associated with lower long-term mortality (risk ratio 0.66, 95% CI 0.52–0.85) compared with conservative management, without a corresponding increase in risk for the development of end-stage kidney disease (risk ratio 0.88, 95% CI 0.42–1.86) [76].

Collectively, these studies suggest that patients with CKD are less likely to undergo contrast-enhanced procedures than those without CKD and that this practice may be resulting in an increase in serious adverse outcomes. It is hypothesized that the underutilization of contrast-enhanced procedures in those with CKD is due to provider fear of causing CA-AKI. The importance of these observations is underscored by the absence of data establishing a causal link between CA-AKI and adverse downstream events. Efforts to examine whether CA-AKI causes adverse outcomes or simply serves as a marker of patients more likely to experience such events are essential. Until research answers this question, an important focus is ensuring that patients at risk for CA-AKI undergo indicated procedures, albeit with the implementation of evidence-based care to prevent this iatrogenic condition.

Prevention

Overview

CA-AKI is potentially preventable as the principal risk factors are well known and the timing of contrast administration is frequently known in advance, which facilitates the timely implementation of preventive care in patients most likely to benefit. Identifying patients at heightened risk for CA-AKI allows for the consideration of alternative imaging procedures that do not necessitate intravascular contrast, but that provide comparable diagnostic information. For at-risk patients who require procedures with intravascular contrast, evidence-based prevention should be implemented to reduce the risk for kidney damage.

Research on preventive strategies for CA-AKI has focused on comparing different contrast agents, using renal replacement therapy to filter iodinated contrast from the vasculature prior to glomerular filtration, administering pharmacologic agents to oppose the nephrotoxic actions of contrast, and expanding the intravascular space and enhancing urine volume with IV fluids to mitigate the adverse hemodynamic and tubular effects of contrast in the kidney.

Selection of Contrast Agent

Iodinated contrast media are commonly categorized based on their osmolality. First-generation contrast agents were ionic derivatives of tri-iodobenzoic acid with osmolalities of approximately 1500 to over 2000 mOsm/kg; accordingly, they were termed "high-osmolal" contrast media. Second-generation agents were nonionic monomers or ionic dimers with lower osmolalities (600–1000 mOsm/kg) and were referred to as "low-osmolal" contrast. Compared with high-osmolal contrast, the low-osmolal agents were associated with lower rates of CA-AKI. The Iohexol Cooperative Study was a clinical trial of 1196 patients undergoing coronary angiography that demonstrated a lower incidence of CA-AKI with low-osmolal iohexol compared with high-osmolal diatrizoate (3.2% vs. 7.1%, $P = 0.002$) [44]. A meta-analysis by Barrett and Carlisle that included results from this trial documented a lower risk of CA-AKI with low-osmolal contrast compared to high-osmolal contrast (OR 0.61, 95% CI 0.48–0.77) [56]. Among patients with impaired kidney function, low-osmolal contrast was associated with an even lower risk of CA-AKI compared with high-osmolal agents (OR 0.5, 95% CI 0.36–0.68).

The development of a third-generation contrast agent, iodixanol, a nonionic dimer that was iso-osmolal to plasma, led to comparisons with low-osmolal media. Initial trials suggested lower rates of CA-AKI with iodixanol compared with certain low-osmolal agents (i.e. iohexol, ioxaglate), while other studies demonstrated similar risk for CA-AKI [77–84]. Clinical practice guidelines from the American College of Cardiology/American Heart Association cite a lack of sound data to support the preferential use of iodixanol compared with low-osmolal contrast agents [85]. Similarly, the European Society of Urogenital Radiology supports use of iso- or low-osmolal contrast in patients at elevated risk of CA-AKI [86].

Renal Replacement Therapies

Iodinated contrast media remain largely in the extracellular space, have low protein binding, and are highly water soluble. Hence, they can be efficiently removed from the circulation by renal replacement therapies. Lee et al. randomized 82 patients with advanced CKD undergoing coronary angiography to receive prophylactic hemodialysis or not, in addition to IV saline and demonstrated a smaller decrement in creatinine clearance and lower likelihood of requiring chronic hemodialysis in those who received prophylactic dialysis [87]. Unlike this study, most other trials of prophylactic hemodialysis either failed to demonstrate a benefit or reported a higher risk for CA-AKI associated with prophylactic hemodialysis [88–93]. Continuous renal replacement therapy (CRRT) also removes iodinated contrast from the vascular space, and there have been two randomized clinical trials of continuous veno-venous hemofiltration that have suggested benefit [94, 95]. Both of these studies utilized change in serum creatinine relative to baseline as their primary outcome, an endpoint confounded by the lowering of serum creatinine by the intervention itself. As such, prophylactic renal replacement therapy as either intermittent hemodialysis or CRRT is not indicated to prevent CA-AKI.

Pharmacological Agents

A multitude of clinical trials have investigated various pharmacological agents for the prevention of CA-AKI. Disappointingly, much of this literature has been susceptible to type 1 error and bias, and no prophylactic pharmacological treatments have been definitively demonstrated to be effective (Table 11.4).

By blocking active sodium transport in the ascending limb of the loop of Henle and reducing oxygen utilization, loop diuretics have been the subject of several studies. A clinical trial by Solomon et al. that compared IV hypotonic saline alone to IV hypotonic saline with either furosemide or mannitol reported a lower incidence of CA-AKI among patients who received peri-procedural IV hypotonic saline alone compared with IV hypotonic saline with furosemide (11% vs. 40%, $P = <0.02$) [96]. The lack of benefit with furosemide in this study mirrored the findings of an earlier study that found a higher risk for CA-AKI with the use of this agent [97]. A subsequent study by Majumdar et al. that attempted to ensure preservation of euvolemia despite diuretic administration again found increased risk of CA-AKI associated with administration of furosemide and mannitol [98].

On the basis of studies demonstrating renal vasodilatation when used in low doses, dopamine has been examined as a potential preventive therapy [99–101]. Initial studies suggested a beneficial effect on reducing CA-AKI, yet subsequent clinical trials with larger numbers of patients found no benefit [99, 101, 102]. Weisberg et al. compared dopamine with IV hypotonic saline with IV hypotonic saline and found no difference in the incidence of CA-AKI overall, yet reported that diabetics who received dopamine experienced higher rates of CA-AKI [101]. Fenoldopam is a selective dopamine receptor agonist that was found in early, mostly small nonrandomized studies, to prevent the development of CA-AKI [103–108]. As with dopamine, larger, methodologically stronger studies failed to demonstrate a benefit of fenoldopam [109].

A study by Kurnik et al. compared atrial natriuretic peptide (ANP), which has renal vasodilatory properties, with placebo in 247 patients with CKD and found no benefit for the prevention of CA-AKI in the ANP group [110]. Conversely, in a trial of 254 patients with CKD undergoing angiography, Morikawa et al. reported a lower incidence of CA-AKI among patients who received ANP and IV fluids compared to patients who received just IV fluids [111]. Notwithstanding the discordant findings on the benefit of ANP, this treatment has potentially deleterious side effects, such as reductions in systolic blood pressure, so its use for the prevention of CA-AKI is currently not recommended.

Adenosine has been implicated in the pathogenesis of CA-AKI. Accordingly, studies have evaluated antagonists of adenosine, including theophylline, for the prevention of this condition [112, 113]. In a trial by Early et al. that enrolled 80 patients, theophylline was not found to be effective for the prevention of CA-AKI [112]. Conversely, a study by Huber et al. of 100 patients with CKD undergoing coronary angiography demonstrated that pre-procedure theophylline was associated with a lower incidence of CA-AKI compared with placebo. Consistent with the findings of clinical trials, meta-analyses of theophylline have reported discordant findings [114–116]. Recognizing the potential adverse side effects of theophylline, particularly in patients with underlying cardiovascular disease, its use to prevent CA-AKI is not current recommended.

A multitude of clinical trials have investigated statins for the prevention of CA-AKI, many of which suggested a benefit, particularly with high intensity doses. The results of subsequent meta-analyses reflected the findings of the clinical trials upon which their results were based [117, 118]. However, a number of these studies enrolled lower risk patients and many used small increments in serum creatinine as the primary outcome, which may be problematic in light of the observation that the administration of

Table 11.4 Pharmacological interventions investigated for contrast-associated acute kidney injury prevention.

Ineffective	Effectiveness not determined
Mannitol[a]	Atrial natriuretic peptide
Loop diuretics[a]	Theophylline/aminophylline
Dopamine[a]	Statins
Fenoldopam[a]	Prostaglandin analogs
Calcium channel blockers	Allopurinol
N-Acetylcysteine	Acetazolamide
Sodium bicarbonate	

[a] Potentially deleterious.

rosuvastatin may result in an increase in eGFR [119]. Consequently, there is insufficient evidence at present to conclude that statins are protective against CA-AKI.

N-acetylcysteine (NAC) is an antioxidant with vasodilatory effects that has been investigated in numerous trials over nearly 20 years as a preventive intervention for CA-AKI. The initial clinical trial of NAC by Tepel et al. randomized 83 patients undergoing computed tomography to receive oral NAC or placebo and demonstrated a lower incidence of CA-AKI with NAC (2% vs. 21%, $P = 0.01$) [120]. Since the publication of this study, dozens of clinical trials have examined NAC for the prevention of CA-AKI, but the literature has again been susceptible to type 1 error and variable study quality, yielding divergent results [58, 120–144]. Numerous meta-analyses sought to reconcile the incongruent findings of the clinical trials, yet similarly reported discordant results [116, 145–154]. The two largest studies, the Acetylcysteine for Contrast Nephropathy (ACT) trial and the Prevention of Serious Adverse Events Following Angiography (PRESERVE) trial, have provided more definitive evidence that NAC is not efficacious for the prevention of CA-AKI. The ACT trial randomized more than 2300 patients undergoing angiography to receive NAC or placebo and found no reduction in the risk for CA-AKI with NAC. Notwithstanding this finding, this study was limited by the inclusion of many patients at low risk for CA-AKI. Using a 2×2 factorial design, the PRESERVE trial randomized 2495 patients with CKD undergoing angiography to receive 1200 mg of oral NAC prior to and for 4 days following the procedure, and 2498 patients with CKD to receive matching oral placebo [155]. The results demonstrated no difference in the incidence of the primary trial endpoint comprised of 90-day death, need for dialysis, or persistent impairment in kidney function between patients randomized to receive NAC and those randomized to placebo (OR 1.02, 95% CI 0.78–1.33). Similarly, there was no difference in the incidence of CA-AKI, which was a secondary trial endpoint (OR 1.06, 95% CI 0.87–1.28). These two large trials provide sufficiently sound evidence that NAC has no role for the prevention of CA-AKI or associated serious, adverse outcomes.

Clinical trials of other agents including calcium channel blockers, prostaglandins, acetazolamide, and mannitol have been inconclusive, yet like the clinical trials of many pharmacological therapies were limited by small numbers of patients, reliance on a surrogate primary study endpoint defined by small increments in serum creatinine, and, in some cases, inclusion of patients at very low risk for kidney injury. Consequently, current recommendations for the prevention of CA-AKI do not incorporate the administration of any of these pharmacological therapies.

Intravenous Crystalloid

Administration of intravenous crystalloid is believed to reduce the risk of CA-AKI by counteracting contrast-induced vasoconstriction in the kidneys and by reducing the concentration and viscosity of contrast media in the tubular lumen [156]. Initial observational studies suggested a benefit of IV fluid, but were limited by the lack of randomization. A clinical trial by Trivedi et al. randomized patients undergoing coronary angiography to receive IV isotonic saline for 12 hours prior to and 12 hours following the procedure or unrestricted fluid by mouth [157]. The trial was stopped early after demonstrating a substantially lower incidence of CA-AKI among patients who received IV saline compared with oral fluid (3.7% vs. 34.6%, $P = 0.005$). Mueller et al. randomized over 1600 patients undergoing coronary angiography to receive peri-procedural IV 0.45% saline or 0.9% saline [158]. The administration of isotonic saline was associated with a lower incidence of CA-AKI than hypotonic saline (0.7% vs. 2.0%, $P = 0.04$), although the study population was at generally low risk for CA-AKI as evidence by the low event rates in both study arms.

Notwithstanding the limitations of these and other studies, IV isotonic saline was considered the standard treatment to prevent CA-AKI. It should be noted that a recent clinical trial questioned the need for IV fluid to prevent CA-AKI. The A MAstricht Contrast-Associated Nephropathy Guideline (AMACING) trial randomized 660 patients who were undergoing procedures with IV or intra-arterial contrast to receive IV isotonic saline or no IV fluids. Designed as a noninferiority trial, the investigators documented that a strategy of no IV fluids was not inferior to a strategy of IV saline for the prevention of CA-AKI (2.6% vs. 2.7%, absolute difference −0.10%, 95% CI −2.25 to 2.06) [159]. Despite this surprising result, key methodological issues, including under-enrollment (only 660 of 1300 planned patients were randomized), low rate of enrollment of patients undergoing procedures with intra-arterial contrast (48%) and interventional procedures (16%), and inclusion of a relatively large population of patients with less advanced CKD (i.e. eGFR 45–60 ml/min/1.73 m^2) substantially diminished the validity of the results.

Over the past 15 years, investigators have focused on comparing IV isotonic sodium bicarbonate with IV isotonic sodium chloride based on the hypothesis that enhanced urinary alkalinization with HCO_3^- decreases the generation of reactive oxygen species and may attenuate tubular epithelial cell injury compared with Cl^-. Merten et al. examined this hypothesis in a clinical trial that randomized 119 patients and documented that IV isotonic sodium

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

bicarbonate was associated with a lower incidence of CA-AKI compared with IV isotonic saline (1.6% vs. 13.6%, $P = 0.02$) [160]. A proliferation of clinical trials followed with discordant results [59, 60, 161–168]. Multiple systematic reviews and meta-analyses reported results that were as disparate as the component clinical trials [162, 168–177]. More recently, Solomon et al. compared IV isotonic sodium bicarbonate to IV isotonic saline in 391 patients with eGFR <45 ml/min/1.73 m^2 undergoing angiography and found no differences in the incidence of a primary composite outcome of 6-month death, need for dialysis, or sustained 20% decrease in eGFR (14.9% vs. 16.3%, $P = 0.78$) [178]. This study also documented no difference in the incidence of CA-AKI between the study arms. The largest trial comparing the efficacy of sodium bicarbonate to saline was the PRESERVE trial, which randomized 4993 high risk patients to receive IV isotonic sodium bicarbonate ($n = 2511$) or IV isotonic sodium chloride ($n = 2482$) prior to, during, and following angiography [155]. Compared with IV saline, IV sodium bicarbonate use was not associated with a decreased risk for 90-day death, need for dialysis, or persistent impairment in kidney function (OR 0.93, 95% CI 0.72–1.22) or in the risk for CA-AKI (OR 1.16, 95% CI 0.96–1.41) [155]. A subsequent subgroup analysis of the PRESERVE trial found no benefit of IV sodium bicarbonate compared with IV sodium chloride among study participants who underwent percutaneous coronary intervention [179].

A series of small studies examined the efficacy of inducing a very high urine flow (>300 ml/h) with saline and furosemide using a device that permits accurate matching of urine flow and IV saline administration for the prevention of CA-AKI. A recent meta-analysis by Shah et al. that comprised three clinical trials and 586 patients demonstrated a reduction in CA-AKI, major adverse clinical events, and need for renal replacement therapy with this device compared with standard preventive care comprised principally of conventional isotonic IV fluid administration [180]. However, as pointed out by the authors, these findings were based on small, underpowered studies and require confirmation in larger, adequately powered clinical trials.

While heart failure is recognized as a risk factor for CA-AKI, there are data that the administration of IV fluids to patients with heart failure is both effective and safe. The Prevention of Contrast Renal Injury with Different Hydration Strategies (POSEIDON) trial randomized 396 patients who were undergoing coronary angiography and compared a standard regimen of IV isotonic saline (3 ml/kg for 1 hour prior to and 1.5 ml/kg/h during and for 4 hours following the procedure) with a strategy of IV isotonic saline based on the left ventricular end-diastolic pressure value at the beginning of angiography [181]. As compared to the standard treatment group, who received IV isotonic saline at 1.5 ml/kg/h during and for 4 hours after the procedure, the experimental group received IV isotonic saline based on the measured left ventricular end-diastolic pressure (i.e. 5, 3, or 1.5 ml/kg/h for left ventricular end-diastolic pressure measurements of <13, 13–18, and >18 mmHg, respectively). CA-AKI occurred less commonly in the left ventricular end-diastolic pressure-guided group (6.7% vs. 16.3%, relative risk 0.41, 95% CI 0.22–0.79, $P = 0.005$) compared with the standard IV saline group. The overall rate of pulmonary compromise related to IV fluid administration was very low [181]. A similar study by Qian et al. demonstrated a lower incidence of CA-AKI in patients who received IV saline administered based on central venous pressure measurements compared with patients who received standard IV saline treatment [182]. The overall rate of acute heart failure during IV fluid administration was very low and comparable across patient groups (3.8% vs. 3.0%, $P = 0.5$).

Limitations of Clinical Trials on Preventive Interventions

Many of the clinical trials investigating preventive interventions for CA-AKI had important methodological limitations. Most importantly, the vast majority of trials used small increments in serum creatinine as their primary outcome, based on observational data associating such biochemical perturbations with serious, adverse events. That such correlations exist is not in dispute, but it is essential to recognize that for these serum creatinine changes to truly be considered a "surrogate" for serious adverse clinical events, they "must track with the frequency of the end point (i.e. serious clinical events) both as an epidemiologic marker and as a therapeutic responder" [183]. Definitive evidence that the changes in serum creatinine that define CA-AKI track with changes in subsequent clinical outcomes is lacking. Thus, although CA-AKI remains defined by small changes in serum creatinine, definitive clinical trials require the use of more meaningful outcomes.

The use of small changes in serum creatinine as the surrogate primary endpoint has resulted in multiple clinical trials that are susceptible to type 1 error with inflated event rates, small sample sizes, and inadequate statistical power to discern effects of the interventions on key patient-centered outcomes. Clinical trials focused upon far more serious patient-centered outcomes (e.g. death, need for dialysis) as the primary study outcome require markedly larger samples sizes, as was demonstrated with the PRESERVE trial [155]. As such, all trials of treatments to prevent CA-AKI need to use clinically significant events as

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

their primary outcome until there is sound evidence that prevention of small changes in serum creatinine also diminishes these "hard" outcomes.

Current Recommendations for Prevention

Identifying patients at high risk for CA-AKI and determining if alternative imaging procedures that can avoid intravascular iodinated contrast with comparable diagnostic yield are available should be the initial step in efforts to prevent this condition. For most patients who require procedures with the use of intravascular contrast, all modifiable risk factors should be addressed. Nephrotoxic medications such as nonsteroidal anti-inflammatory medications should be discontinued prior to contrast administration and held until CA-AKI has been ruled out. The lowest required dose of either low or iso-osmolal contrast should be used. Isotonic IV sodium chloride should be administered prior to, during, and after the procedure, particularly for patients with lower eGFR values and those undergoing angiography [155]. While IV isotonic sodium bicarbonate is an acceptable alternative, it offers no advantage over IV isotonic saline and poses a small risk for compounding errors as there is currently no commercially available "off-the-shelf" form. For hospitalized patients, isotonic IV saline can be administered at a rate of 1 ml/kg/h for 12 hours preceding, during, and for 12 hours following the procedure if the timing of the procedure permits. An alternative regimen, particularly for outpatients and those undergoing more urgent procedures, includes IV isotonic saline at a rate of 3 ml/kg/h over 1–2 hours prior to and 6 ml/kg infused over 2–6 hours following contrast administration. IV isotonic saline should be administered to patients with nondecompensated heart failure with careful monitoring of patients' respiratory status. There is no current role for the use of pharmacological agents for the prevention of CA-AKI. Similarly, studies to date do not support the discontinuation of diuretics or blockers of the renin-angiotensin aldosterone axis prior to contrast administration. While a meta-analysis by Wu et al. that comprised 14 studies demonstrated a higher risk for CA-AKI among patients receiving angiotensin converting enzyme inhibitors or angiotensin receptor blockers at the time of angiography compared with patients not receiving these medications, that authors acknowledged this finding was based on low-level evidence from small observational studies [184]. Furthermore, the initiation or discontinuation of these agents at the time of contrast administration may confound the interpretation of small changes in serum creatinine. Assessing for the development of CA-AKI by monitoring serum creatinine 48–96 hours following contrast administration is important to identify the development of this condition and to provide supportive care to attenuate the risk for further renal parenchymal damage.

Conclusion

AKI remains a common iatrogenic event following procedures that involve the intravascular administration of iodinated contrast. The pathophysiology of and risk factors for CA-AKI have been demonstrated in past studies, as have the associations of this condition with serious, adverse short- and long-term outcomes. Such associations, which have not been confirmed to be causal, have likely led to the underutilization of clinically indicated diagnostic and therapeutic contrast-enhanced procedures in patients with CKD. Patients with clear clinical indications for procedures that require intravascular contrast should undergo such procedures, albeit with the implementation of evidence-based preventive care. The cornerstone of prevention presently is the peri-procedural IV administration of isotonic crystalloid, preferably sodium chloride. Well-designed, adequately powered studies that utilize clinically relevant primary outcomes and that enroll high-risk patients are needed to expand our understanding of the clinical implications and prevention of this iatrogenic condition.

Miscellaneous Etiologies of Acute Kidney Injury

Christina Mariyam Joy and Anitha Vijayan

Division of Nephrology, Washington University in St. Louis St. Louis USA

Introduction

This chapter will review some of the less frequent causes of acute kidney injury (AKI): acute interstitial nephritis (AIN), atheroembolic renal disease, cast nephropathy, crystalline nephropathies, and renovascular syndromes. Due to the relative rarity of these conditions, there are few randomized controlled trials to guide management. However, several observational and retrospective studies provide some insight into the clinical features, natural histories, and therapeutic responses.

Acute Interstitial Nephritis

Definition, Etiology, and Pathogenesis

AIN is a hypersensitivity reaction that causes AKI by immune-mediated tubular injury localized to the kidney interstitium with sparing of the glomeruli. The first description of AIN was by Biermer in 1860 [1]. In 1898, Councilman used the term acute interstitial lesions to describe the histopathological changes noted in autopsy specimens of children who had succumbed to scarlet fever, diphtheria, and other infectious diseases [2]. In 1946, sulfonamides became one of the first drugs noted to cause intestinal nephritis [3] followed by penicillin and methicillin in 1968 [4]. The true incidence of AIN is difficult to ascertain but data from various literature searches provide estimates of 0.5–3% of all kidney biopsies and 5–27% of biopsies done for AKI [5–7]. The etiology of AIN is estimated to be drug-induced in as many as 78% of cases in developed countries while infectious etiologies are noted in 50% of cases from developing countries.

AIN is a delayed hypersensitivity reaction mediated by T-cells, which may occur through diverse mechanisms, including molecular mimicry with tubular epitopes or deposition of immunogenic portions of the inciting agent in the kidney interstitium, either alone or as a hapten [8]. This is usually not dose-dependent, but idiosyncratic with recrudescence in disease activity upon re-exposure to compounds with similar biochemical structure, often with multiorgan involvement. Newer chemotherapeutic agents, including immune checkpoint regulators and programmed cell death proteins, cause dose-dependent toxicity by immune upregulation [9]. On histology, there are focal to diffuse interstitial infiltrates composed of T-cell predominant lymphocytes. Immune complexes or antitubular basement membrane antibodies are infrequently noted, suggesting that humoral immunity may also be involved [10, 11]. Granulomatous interstitial nephritis (GIN) has been identified in approximately 0.5–0.9% of all kidney biopsy specimens. Approximately 17.5–45% of GIN is attributed to drug toxicity [12]. The most common etiologies of AIN are drugs (70%), autoimmune diseases (20%), infections (4%), and idiopathic (5%) [5] (Table 12.1). Antibiotics (49%), proton pump inhibitors (14%), and nonsteroidal anti-inflammatory drugs (NSAIDs; 11%) accounted for the majority of cases, although any drug can potentially cause AIN [5]. The offending drug may be difficult to identify due to polypharmacy [13].

Clinical Features

The classical signs and symptoms of drug-induced AIN include a triad of rash, fever, and eosinophilia [14], which suggests an allergic type reaction. However, it should be noted that the constellation of the three findings is an exception and not the rule. These allergic symptoms may be absent, especially in those cases associated with NSAID, where nonspecific symptoms of acute kidney failure including nausea, vomiting, malaise, and fatigue maybe seen. Oliguric or nonoliguric kidney dysfunction can occur. The latent period for disease manifestation is

Table 12.1 Etiology of acute interstitial nephritis.

Drugs	Antibiotics	Penicillin[a] (penicillin, ampicillin, and methicillin), cephalosporins, fluoroquinolones[a] (ciprofloxacin, levofloxacin), rifampin[a] and sulfonamides[a] (including cotrimoxazole) Abacavir, acyclovir, indinavir
	NSAIDs	Celecoxib, diclofenac, fenoprofen, indomethacin, meloxicam, sulindac Mesalamine, sulfasalazine
	Antacid/antisecretory	Esomeprazole, omeprazole, pantoprazole Cimetidine, ranitidine, famotidine
	Chemotherapeutic agents	Atezolizumab, iplilimumab, nivolumab, pembrolizumab Sorafenib, sunitinib Adriamycin, BCG, bevacizumab, bortezomib, gemcitabine, lenalidomide, pemetrexed
	Diuretics	Chlorthalidone, hydrochlorothiazide, metolazone, furosemide, amiloride, triamterene
	Antihypertensive	Captopril, lisinopril, losartan, amlodipine, nifedipine
	Anticonvulsants	Carbamazepine, levetiracetam, phenobarbital, phenytoin, valproic acid
	Miscellaneous	Allopurinol, atorvastatin, carbimazole, feboxustat, gemfibrozil, leflunomide, sildenafil
Infectious agents	Bacteria	*Brucella* spp.,[a] *Campylobacter jejuni*, *Corynebacterium diphtheriae*, *Chlamydia* spp., *Escherichia coli*, *Legionella* spp., *L. interrogans*, *Mycobacterium tuberculosis*,[a] *Mycoplasma pneumoniae*, *Rickettsia* spp., *Salmonella* spp.,[a] *Staphylococcus* spp., *Streptococcus* spp., *Yersinia pseudotuberculosis*
	Virus	Cytomegalovirus, Epstein–Barr virus,[a] hantaviruses, hepatitis B virus, human immune deficiency virus, herpes simplex virus, measles virus, polyomaviruses
	Parasites	*Leishmania donovani*, *Toxoplasma gondii*[a]
Systemic diseases		Sarcoidosis,[a] Sjogren's syndrome,[a] systemic lupus erythematosus, tubulointerstitial nephritis and uveitis syndrome,[a] Antineutrophil cytoplasmic antibody-associated vasculitis, other vasculitis

[a] Denotes association with granulomatous interstitial nephritis.

usually 3 weeks after the initiation of the offending drug in 80% of individuals, with an average of 10 days (although can range from 1 day to more than a year). NSAIDs have a slightly longer latency of 2–3 months. The temporal relationship between the initiation of a new drug and the development of kidney injury may also aid in making the diagnosis. Disease manifestations develop within 3 weeks of initiation of the offending drug in about 80% of patients, with an average latency of onset of 10 days (range 1 day to >1 year) [8]. The duration of onset may be longer when associated with NSAIDs, with a mean latent period of 2–3 months [15]. When AIN is associated with a systemic disease, the clinical features of the respective diseases may be present (Table 12.2).

Laboratory Diagnosis

Urinalysis in patients suspected to have AIN often show hematuria and/or sterile pyuria, but these are nonspecific findings. The presence of white blood cell (WBC) casts is more specific, although they can also be seen in pyelonephritis and certain proliferative glomerulonephritis. Eosinophiluria (urine eosinophils >1% of the urine WBCs) can be seen, usually detected more reliably with Hansel's stain than with Wright's stain [23]. However, the diagnostic utility of testing for urine eosinophils has recently been invalidated and is no longer recommended. In a retrospective study of 566 patients who had urine eosinophil testing and a kidney biopsy within a week of each other, 91 patients had evidence of AIN on pathology. Urine eosinophils at 1% and 5% cutoff had sensitivities of 30.8% and 19.8% and specificities of 68.2% and 91.2%, respectively [24]. Urine chemistries are not useful in distinguishing AIN from other etiologies of AKI. Fractional excretion of sodium can either be above or below 1% [25].

Other laboratory abnormalities that may be present include metabolic acidosis secondary to renal tubular acidosis, low specific gravity due to a concentrating defect, glycosuria, or phosphaturia secondary to Fanconi syndrome. Mild proteinuria is common, but sometimes it may be in the nephrotic range. Though heavy proteinuria has been reported with AIN from various drugs, it is classically associated with NSAIDs. Concomitant minimal change glomerulopathy may be seen in NSAID-associated AIN, although the exact incidence is unclear. One paper noted that 70% of patients with NSAID-associated AIN had

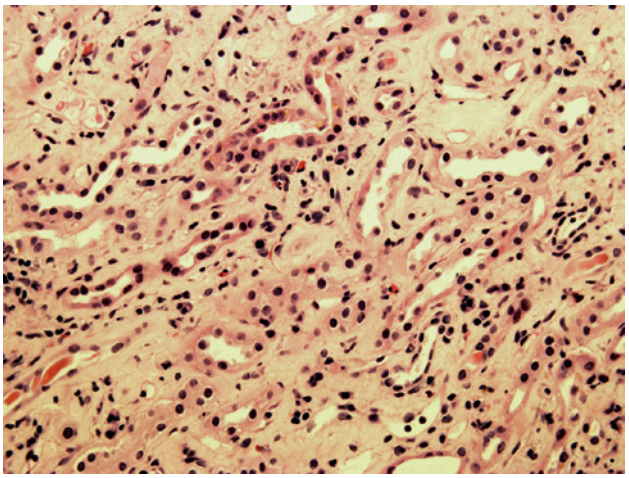
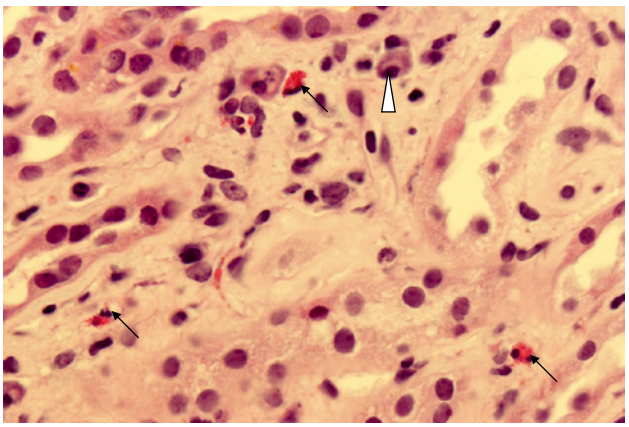
nephrotic range proteinuria [8]. Signs of multiorgan dysfunction, such as elevated transaminases and hemolysis, are occasionally seen.

Kidney imaging may reveal normal to large kidneys with increased echogenicity, although this is a nonspecific finding [25]. Gallium scintigraphy and 2-[18F]-fluor o-2-deoxy-D-glucose-positron emission tomography (FDG-PET) scanning have shown some promise in diagnosis of AIN, but lacks sufficient sensitivity and specificity to be recommended as diagnostic tools. Kidney biopsy is the gold standard for the definitive diagnosis of AIN. A cellular infiltrate consisting mostly of T-cells and macrophages with edema increases the separation of tubules from one another, and there may be tubulitis or frank tubular necrosis in severe AIN (Figure 12.1a,b). Neutrophils, eosinophils, and plasma cells can often also be found in the cellular infiltrate. The presence of neutrophils may be associated with better response to steroid therapy [26]. Occasionally there is granulomatous inflammation, which might provide clues as to the offending agent, since this is associated with a limited list of causes (Table 12.1). Immunofluorescence and electron microscopy usually do not reveal the presence of immune complexes, but tubular basement membrane deposition can rarely be seen. Glomeruli are usually normal, but electron microscopy may reveal foot process effacement in NSAID-associated AIN. A summary of the relevant laboratory findings is given in Table 12.2.



(a)



(b)

Figure 12.1 Acute interstitial nephritis (AIN), drug-induced, with hematoxylin and eosin stain. Note the presence of interstitial edema and predominantly mononuclear inflammatory cells separating the normally adjacent tubules (a). A few eosinophils (arrows) and a plasma cell (arrowhead) can be seen on higher power (b). *Source:* Courtesy of Rosa Davila MD, Washington University School of Medicine.

Course and Treatment

Given the polymorphic nature of the disease and the multiple potential causative agents, AIN does not have a uniform course or response to treatment. In the prototype, methicillin-induced AIN, the prognosis was excellent, with complete recovery of kidney function noted in 90% of patients after a mean period of 1.5 months after cessation of the drug exposure [2]. In nonmethicillin, drug-induced AIN, chronic kidney disease (CKD) is an expected sequela in 36–40% of cases [2]. The prevalence of CKD is even higher (56%) with NSAID-induced AIN [27]. In one series consisting of seven cases of infection-associated AIN, all had complete renal recovery. However, in this case series the inciting infections were readily treatable or self-limited [13, 27]. Indeed, the prognosis for AIN may depend on the promptness of elimination of the inciting agent, with those etiologies associated with milder symptoms and therefore delayed diagnosis (e.g. NSAIDs, chronic infections, sarcoidosis) having worse prognosis than those with more acute and dramatic presentations (e.g. methicillin, rifampin, acute bacterial, or viral infections) (Table 12.2).

Due to the heterogeneity of AIN and severity of the illness, most studies that guide therapy in AIN are retrospective and there is a dearth of randomized controlled trials to define therapeutic strategies. Clearly, the most important therapeutic maneuver is prompt removal of the inciting agent. Corticosteroids have been used in the treatment of hypersensitivity, although the benefits of its use remain controversial. Clarkson et al. studied 60 patients with AIN (92% drug-induced), 60% of whom were treated with corticosteroids, and found no difference in serum creatinine at 1 year between those who received and did not receive corticosteroids [28]. In contrast, Gonzales et al. reported that use of steroids was beneficial, especially when started early, being associated with a lower final serum creatinine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. and less need for renal replacement therapy (RRT) [29]. In a single center, retrospective analysis from 1993 to 2011 which studied 133 patients with biopsy proven AIN (70% drug-induced AIN), 49% of patients with drug-induced AIN achieved complete recovery after initiation of corticosteroids. An additional 39% of patients had partial recovery and 12% had no recovery. Correlates for poor recovery included longer duration of exposure to the drug and time to initiation of steroids [5]. A more recent, large, single-center retrospective study from London included 187 eligible patients with AIN out of 3983 native kidney biopsies, and 158 patients were treated with steroids. It was concluded that steroid-treated patients had higher eGFR at all follow-up intervals up to 24 months. Fewer patients were dependent on RRT at the end of 6 months and 24 months (3.2% and 5.1%) when compared to patients not treated with steroids (20.6% and 24.1%, respectively) [30]. An attempt to match steroid-treated with untreated patients showed greater improvement in renal outcomes, although this was not statistically significant. Based on their results, the authors suggested a regimen of prednisolone at 1 mg/kg with a maximum dose of 60 mg daily, with rapid weaning over 8–12 weeks to prevent worsening of kidney function. However, one must be careful in extrapolating this data to all patients with AIN, since this study only looked at patients with biopsy proven AIN and may not have included those who had improvement in renal function after prompt withdrawal of the offending agent at the onset of kidney injury.

One retrospective series described the use of mycophenolate mofetil in eight cases of steroid-dependent AIN, defined as worsening kidney function with steroid withdrawal, even after a 6-month course of corticosteroids. Only two of the eight cases were thought to be drug-induced, with the remaining cases being idiopathic or associated with systemic diseases such as sarcoidosis or collagen vascular disease. Treatment with mycophenolate mofetil resulted in a stabilization or slight improvement in kidney function (mean creatinine decreased from 2.3 to 1.6 mg/dl); however, an average of 2 years of therapy was required [31]. More recently a case report demonstrated benefit of antithymocyte globulin in a patient on RRT as the result of steroid refractory AIN who achieved independence from hemodialysis following treatment [32].

Given these data, a reasonable treatment strategy would be to reserve corticosteroids for patients with idiopathic AIN, systemic diseases for which corticosteroids have a proven role (e.g. sarcoidosis, Sjögren's syndrome, vasculitides), or cases with characteristics associated with worse renal prognosis. The latter includes delayed onset of kidney recovery after removal of the inciting agent (>1 week), prolonged exposure to the offending agent (>2–3 weeks), preexisting CKD, and histology with intense and diffuse interstitial infiltrate, granuloma formation, or significant fibrosis and tubular atrophy. If corticosteroids are considered, then they should be given early, as this is associated with improvement in kidney function [33]. A frequently used regimen is oral prednisone, 1 mg/kg, with the duration of therapy guided by the improvement in kidney function, usually 3 weeks. The presence of conditions that can be exacerbated by corticosteroid therapy (e.g. slow-healing wounds, brittle diabetes, or active infection) should dissuade the clinician from this option. Furthermore, studies have suggested that corticosteroids do not alter the course of NSAID-induced AIN [28], but if poor prognostic factors are present, treatment can still be considered. Other immunosuppressants should be reserved for cases that are not responsive to withdrawal of the inciting agent alone when corticosteroid resistance or dependence occurs.

Atheroembolic Renal Disease

Definition, Prevalence, and Pathogenesis

Atheroembolic renal disease causes progressive AKI and acute kidney disease (AKD) resulting from inflammation in the renal microvasculature caused by cholesterol crystals and lipid debris. The dislodged atheromatous plaques can travel through the bloodstream and affect any organ, including the kidneys, skin, brain, and gastrointestinal system. Atheroembolism often occurs after an inciting event (like cardiac catheterization, vascular surgeries, etc.) or use of systemic anticoagulation but may occur spontaneously. The first description of atheroembolic disease was by Panum in 1883, but the nature of cholesterol embolization was described by Flory in 1945 [34].

The disease is often under recognized. From various autopsy studies, the incidence was about 1% but increased to 4.0–6.5% in people 60 years or older [35]. There is usually an inciting event leading to plaque destabilization and distal showering of lipid debris. Plaque destabilization may occur from vessel wall trauma from vascular surgery or endovascular procedures of which coronary angiography is the most common iatrogenic procedure causing atheroembolism. Although less common as an inciting factor, systemic anticoagulation and thrombolytics are thought to prevent protective thrombus formation over ulcerated plaques, thereby increasing risk of atheroembolism.

In atheroembolism, the cholesterol-containing debris lodge in small arterioles, inciting thrombus formation, and causing distal ischemia and infarction. Within 5 days there may be recanalization of the thrombus, but an inflammatory foreign body arteritis ensues. Because the cholesterol is not soluble and it is never successfully cleared by phagocytes, inflammation persists and leads to progressive

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. fibrosis and later obliteration of the lumen of the small vessel. With involvement of multiple arterioles, the result is persistent, patchy ischemia of several nephrons, instigating progressive renal insufficiency.

Clinical Features and Laboratory Findings

Atheroembolic renal disease is preeminently a disease of the elderly (mean age 66–70 years), with a male predominance (4 : 1). It has a higher incidence in whites than African Americans (30 : 1) [36]. It is possible that this discrepancy represents under-recognition of the disease in the African American population, as the characteristic skin changes may by missed in dark-skinned individuals. The major risk factors include age more than 60 years, male gender, comorbidities like diabetes mellitus and hypertension, and tobacco use. Also, patients with significant aortic atherosclerosis have a higher incidence of cholesterol embolic disease [34]. The onset of disease is quite variable, ranging from 3 days to 3 months (as the embolic shower is often unpredictable). As mentioned earlier, in addition to the kidneys, any organ system may be involved, including skin, gastrointestinal, and brain. Transient eosinophilia (seen in 48%) and elevated erythrocyte sedimentation rate and occasionally hypocomplementemia may be present [37]. The characteristic skin changes include livedo reticularis or "blue toe" syndrome. These constellations of clinical and laboratory features often mimic a systemic vasculitis (Table 12.3).

Renal histology reveals empty clefts in arcuate and interlobular arteries and, less commonly, afferent arterioles. These result from the dissolution of lipid from these sites by the fixation process leaving voids at the sites of cholesterol crystals. Depending on the age of the lesion, varying degrees of arteritis and intimal fibrosis can be seen (Figure 12.2). In severe, acute cases there may be signs of acute tubular necrosis (ATN). Late in evolution, patchy glomerular sclerosis and tubular atrophy may be visualized in areas supplied by the affected vessels. Similar arteriolar inflammation or fibrosis can be found in other tissues, especially the muscle, gastrointestinal tract, and skin. Biopsy of skin lesions may have the highest diagnostic yield, with a reported sensitivity of 92% [43].

Table 12.3 Clinical findings in patients with renal atheroembolic disease and frequency of occurrence.

Clinical finding	Frequency of occurrence (%)
Signs and symptoms	
New-onset, accelerated, or labile hypertension	78
Skin findings (cyanotic or ulcerated digits or scrotum, livedo reticularis on back or lower extremities, nodules, less commonly purpura)	80
GI symptoms (nausea, abdominal pain, GI bleeding)	24
CNS symptom (focal neurologic deficits, progressive dementia)	11
Retinal emboli (Hollenhorst plaque on fundoscopy)	19
Fevers	Uncommon
Laboratory findings [reference]	
Microscopic hematuria [38, 39]	53
Mild proteinuria (rarely nephrotic associated with a secondary collapsing FSGS or accelerated hypertension) [39, 40]	9
Eosinophiluria (by Hansel's stain)	88
Peripheral blood eosinophilia [41]	48–88%
Hypocomplementemia [41]	<15–12
Various markers of ischemic organ injury (elevated creatinine kinase, amylase/lipase, transaminases)	Not uncommon
Elevated erythrocyte sedimentation rate and/or C-reactive protein	Very common
Renal artery stenosis by Doppler or angiography [38, 42]	44

CK, creatine kinase; CNS, central nervous system; FSGS, focal and segmental glomerulosclerosis; GI, gastrointestinal.
Unless otherwise indicated, frequency data come from combining three case series of *clinically significant* kidney disease totaling 171 patients.
Source: Belenfant et al. [38], Thadhani et al. [39], and Scolari et al. [42].

Course and Management

Three patterns of disease evolution are apparent in atheroembolic renal disease [44]. An acute course (20–30% of cases) resulting from a massive embolic load is characterized by an abrupt deterioration in kidney function and multiorgan involvement within a week after the inciting event. More common, however, is the subacute course (56%), which represents repeated smaller embolic showers and their subsequent inflammatory endothelial response. Thus, there is a stepwise deterioration in kidney function averaging 3–8 weeks. The third entity involves a slowly progressing renal insufficiency secondary to chronic ischemia mimicking hypertensive nephrosclerosis or ischemic renovascular disease. This is often underdiagnosed because of the paucity of systemic organ involvement and the failure to obtain kidney biopsy.

Progression to dialysis dependence occurs in one-third of the patients who survive the initial insult. Preexisting CKD and a history of significant claudication confers greater risk for this outcome. Some mild improvement in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Figure 12.2 Renal atheroembolic disease, hematoxylin and eosin stain. Arrows represent cholesterol clefts remaining in an intralobular artery where lipid had been present prior to the fixation process. The early inflammatory arteritis composed of eosinophils, neutrophils, and macrophages is later replaced by a giant cell foreign body reaction (arrowhead), intimal proliferation, and fibrosis. *Source:* Courtesy of Helen Liapis MD, Washington University School of Medicine.

kidney function can occur with time, from progressive hyperfiltration by the remaining nephrons. As a result, 21–32% of patients on chronic dialysis from atheroembolic renal disease can recover enough kidney function to stop dialysis [38, 41, 45]. Early studies revealed a grim outcome for patients with acute, multivisceral atheroembolic disease, with 1-year survival rates of 13–36% [39, 46]. Death usually occurs from cardiac ischemia, heart failure, stroke, or gastrointestinal ischemia with malnutrition [39, 44, 45]. An aggressive supportive regimen specifically targeting these mechanisms of mortality was prospectively evaluated in a population with acute multivisceral atheroembolic disease [38].

The principles of treatment for atheroembolic disease are intended to decrease the ischemic damage and prevent recurrent embolization. The mainstay of treatment is often preventative and supportive. The major preventative measures include avoiding anticoagulation (if feasible after carefully considering risks and benefits) and avoiding any further invasive procedures that might trigger further plaque disruption. To delay progression, blood pressure control and judicious use of statins and renin-angiotensin-aldosterone system (RAAS) blockers should be considered. Nutritional replacement, including parenteral replacements, may be needed in settings of intestinal ischemia. With advanced kidney failure, dialysis should be considered.

Several adjunctive therapies to improve renal outcome have been attempted in cases of atheroembolic renal disease. Belenfast et al. [38] determined that low-dose corticosteroids (0.3 mg/kg of prednisone) improved nutritional intake and symptoms in 18 patients with recurrent atheroembolic disease. Other studies have used high doses of steroids with variable benefits. Prospective studies have shown beneficial effects of statins in the progression to end stage renal disease (ESRD). Observations have shown that statins help to decrease lipid level, stabilize plaques, and are anti-inflammatory. Lipoprotein aphesis is known to significantly reduced cholesterol levels and has been recommended for use in patients with high risk [47, 48]. Surgical procedures such as endoluminal stenting could provide a definitive treatment, although this is often not feasible because the disrupted plaque is difficult to identify or the patient may be too fragile to undergo any surgical intervention. If endovascular procedures are required in high-risk patients, strategies such as "no-touch" techniques to minimize plaque disruption, and embolic protection devices may help to prevent the development of atheroembolic disease [49–51].

Atheroembolic disease generally has poor prognosis as it is associated with multiorgan system involvement, often with irreversible damage. About 30–55% of patients with acute/subacute onset of kidney failure need dialysis, of whom 21–28% have renal recovery and 23–32% progress to ESRD. Preexisting CKD and hypertension are determinants for progression to ESRD [39, 42].

AKI Associated with Malignancies

Cast Nephropathy

Definitions and Etiology

Multiple myeloma (MM) is a hematological malignancy characterized by abnormal proliferation of monoclonal plasma cells in the bone marrow. It is the second most common hematological malignancy, diagnosed in approximately 13% of all hematological malignancies, and the American Cancer Society estimates a lifetime risk of 0.76% in the United States. The definition of renal impairment in MM, as defined by the International Myeloma Working Group (IMWG) criteria, includes a serum creatinine level of ≥2 mg/dl or creatinine clearance of <40 ml/min [52]. Based on these criteria, kidney involvement can range from 20% to 30% of patients with MM. AKI associated with plasma cell dyscrasias can result from (i) prerenal AKI secondary to hypercalcemia and/or volume depletion; (ii) glomerular disease from light-chain deposition disease or amyloidosis; and (iii) tubulointerstitial disease from cast nephropathy and drug-induced AKI (from intravenous bisphosphonates). Other etiologies of AKI in MM include glomerular diseases (e.g. membranoproliferative glomerulonephritis, light-chain deposition disease, amyloidosis) associated with paraproteinemia and, to a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

lesser extent, tumor lysis syndrome (TLS), which will be discussed separately. In the updated Diagnostic Criteria and Staging System for MM only light-chain cast nephropathy is defined as myeloma defining illness [53].

Myeloma cells synthesize free light chains (FLCs) which are freely filtered by the glomerulus. These proteins are then reabsorbed by the megalin and cubulin receptors of the proximal convoluted tubule [54]. When the filtered load exceeds the maximal reabsorption of the receptors, they are excreted in the urine and referred to as Bence–Jones proteins. The FLCs may interact with Tamm–Horsfall protein (THP) causing tubular obstruction inducing inflammation and resultant interstitial nephritis and fibrosis [55].

Clinical Features and Laboratory Findings

Cast nephropathy is suspected when patients present with rapidly declining kidney function in the setting of FLCs detected by plasma or urine immunofixation or by serum FLC measurement. IMWG recommends a 24-hour urine protein electrophoresis and a serum FLC assay. In the setting of reduced kidney function, the serum FLC may be elevated, but not in a clonal pattern. If a clonal serum FLC is >500 mg/l, quantitative urinary albumin excretion should be assessed. In glomerular causes of AKI, the predominant urinary protein is albumin; but when albumin ≤10% of total urinary protein, the diagnosis is likely to be cast nephropathy and kidney biopsy can be avoided. If quantitative urinary light chains are <1 g/day, an alternate diagnosis should be considered and a kidney biopsy may be warranted.

The definite diagnosis is obtained from kidney biopsy. On light microscopy, cast nephropathy is manifested by the presence of large lamellated eosinophilic casts in the distal convoluted and collecting tubules. Features of interstitial inflammation and nephritis are also seen (Figure 12.3). The casts are comprised primarily of monoclonal light chains but also contain albumin, THP, fibrin, and polyclonal light chains.

Course and Treatment

Treatment of cast nephropathy includes general measures and disease-specific treatments. General measures include adequate volume expansion, correction of hypercalcemia and hyperuricemia, discontinuation of potential nephrotoxic medications, such as NSAIDs and angiotensin converting enzyme inhibitors (ACEI), and angiotensin receptor blockers (ARBs), loop diuretics, and avoidance of iodinated intravascular contrast.

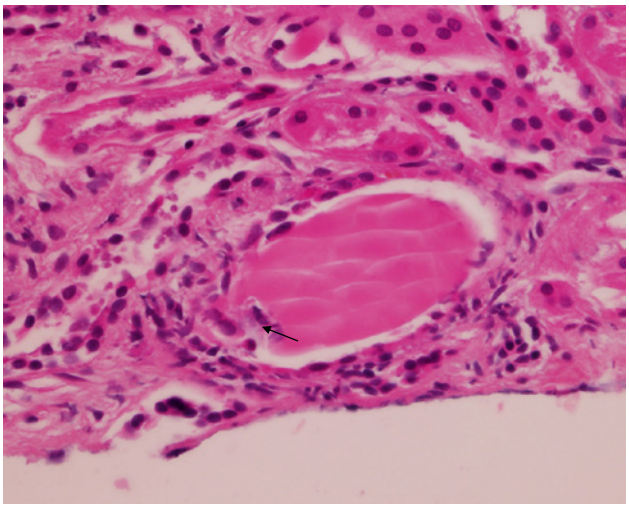

Figure 12.3 Myeloma cast nephropathy, with hematoxylin and eosin stain. There is a characteristic eosinophilic, "corrugated paper" appearance of this cast that is adherent to the wall of the tubule. There is resulting tubular cell toxicity and inflammation, with an interstitial infiltrate and cells engulfing the cast at its point of adherence (arrow). *Source:* Courtesy of Helen Liapis, MD, Washington University School of Medicine.

Newer chemotherapeutic agents have increased overall survival in MM. Renal protective chemotherapy with thalidomide or bortezomib aims at rapidly decreasing FLC concentrations. Bortezomib-based regimens have been associated with improved kidney function and are the treatment of choice [54, 56, 57]. A Cochrane meta-analysis with 16 studies and 5626 patients suggested better survival rates and longer time without progression with bortezomib. Metabolized by liver, it can be safely administered to patients with kidney failure. Thalidomide and lenalidomide are also targeted chemotherapy for MM. In one study of 133 patients, renal recovery was noted in 77%, 55%, and 43% of patients treated with bortezomib, thalidomide, and lenalidomide, respectively [57]. In a multivariate analysis, bortezomib had superior results with respect to probability of response as well as the median response time compared to the other two agents. A retrospective cohort study analyzing autologous stem cell transplant and renal recovery showed that 14 out of 15 patients with advanced kidney failure, who received transplant remained dialysis dependent despite hematological recovery; however, it is important to note that having kidney failure did not exclude them from this curative therapy [58].

The idea that therapeutic plasma exchange (TPE) would be effective in removal of FLC stems from the fact that FLC have small molecular masses. Trials evaluating the role of TPE in cast nephropathy were performed before the advent of newer bortezomib-based regimens. Burnette et al. analyzed 14 patients from 2004 to 2010 who

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

received TPE and bortezomib, and showed full renal recovery in 43% of patients in 6 months [59]. Given the lack of sufficient data from current literature, the role of TPE in cast nephropathy remains nebulous and cannot be recommended. Two recent trials – EuLite and MYRE – evaluated the role of high-cut-off hemodialysis (HCO-HD) along with concomitant chemotherapy in the treatment of biopsy confirmed cast nephropathy [60, 61]. In both trials, the primary outcome of dialysis independence at 30 days was not significantly different between the HCO-HD arm versus the control groups. In the MYRE study, dialysis independence at 6 months was superior to conventional treatment alone (35% vs. 57%, $P = 0.04$) [61, 62]. It should be noted that there was a higher incidence of death due to infections in the HCO-HD arm in the MYRE study, but 11% of patients in the HCO-HD arm compared to 4% in the conventional HD arm had infection at baseline. There was no difference in infectious complications in the EuLite trial. HCO-HD is not FDA approved for treatment of cast nephropathy in the United States. The IMWG recommends that HCO-HD can be considered as an adjunct to bortezomib-based chemotherapy in patients with MM and severe kidney impairment (grade B evidence) [63].

AKI Secondary to Bisphosphonate Therapy

Intravenous bisphosphonates are widely used in the treatment of hypercalcemia of malignancy. Both zoledronate and pamidronate have been associated with AKI. Acute tubular injury and collapsing focal segmental glomerulosclerosis have been described [64]. The 2015 European Myeloma network guidelines [65] recommend measuring creatinine clearance, serum electrolytes, and urine albumin in all patients receiving bisphosphonates (grade 1A). These drugs should be avoided if CrCl <30 mg/dl (grade 1A). Dose reduction is necessary for zoledronate with no change in infusion time (grade1A) whereas pamidronate should be given over a 4-hour infusion (grade 1C). Clodronate can be used as alternative in patients with CrCl >12 ml/min (Grade 2C). To prevent hypocalcemia, calcium and vitamin D supplementation should be administered. (Grade 1A).

Tumor Lysis Syndrome

TLS is one of the most common hematological emergencies. TLS describes an array of biochemical abnormalities secondary to cell lysis that occur spontaneously or after initiation of cytotoxic chemotherapy. The cell damage releases intracytoplasmic molecules, including proteins, electrolytes, and nucleic acids, into systemic circulation, causing hyperuricemia, hyperkalemia, hyperphosphatemia, and hypocalcemia. Multiorgan failure, including AKI, life-threatening cardiac arrhythmias, seizures, and death, is known to occur. The Cairo–Bishop diagnostic criteria for laboratory and clinical TLS are shown in Table 12.4.

TLS is most commonly described in malignancies with large tumor burden: non-Hodgkin lymphoma, especially Burkitt's lymphoma, acute and chronic leukemias, and MM [67–69]. Certain solid organ tumors like germ cell tumors, neuroblastoma, breast, and small cell lung cancer, especially when associated with widespread metastasis, also predispose to TLS. Although previously described with chemotherapy, other forms of treatment, including corticosteroids, tamoxifen, radiotherapy, and newer targeted therapy with biologicals, can also cause TLS. Elevated serum lactate dehydrogenase (LDH) is an additional risk factor predisposing to TLS [70].

Pathophysiology

Uric acid is the end product of the metabolism of purine nucleotides in humans and higher primates. Uric acid is freely filtered by the glomerulus, but in contrast to previous studies, recent data suggest that our understanding of the tubular handling of uric acid is incomplete [71]. Uric acid is actively reabsorbed and secreted at the proximal tubule via complicated interplay among various transport pathways involving urate transporter 1 (URAT1), glucose transporter 9 (GLUT9), and organic anion transporters (OATs), among others [71]. Uric acid crystallization occurs when concentration in the tubules exceeds the solubility, and this usually occurs in setting of low urine volume and acidic

Table 12.4 Cairo–Bishop definition of tumor lysis syndrome [66].

Laboratory tumor lysis syndrome (LTLS)	Two or more occurring within 3 days before or 7 days after chemotherapy • Uric acid ≥ 8 mg/dl or 25% increase from baseline • Potassium ≥ 6 mEq/dl or 25% increase from baseline • Phosphorus ≥ 4.5 mg/dl or 25% increase from baseline • Calcium ≤ 7mg/dl or 25% decrease from baseline
Clinical tumor lysis syndrome (CTLS)	LTLS with one or more of the following: serum creatinine ≥1.5 upper limit of normal cardiac arrhythmia or death seizures

pH. Hyperphosphatemia results when tumor cells with high metabolic rates and turnover die, releasing high levels of intracellular phosphorus into bloodstream, overwhelming the kidney's capacity to eliminate it. In spontaneous TLS, severe hyperphosphatemia is less likely, since the surviving tumor cells, with their high metabolic rate, rapidly recycle released phosphate. Phosphorus binds with calcium cations, causing hypocalcemia, and calcium phosphate complexes can precipitate in the kidney and other tissues. Patients can develop signs and symptoms of hypocalcemia, including tetany and seizures. AKI in TLS is thus thought to be secondary to uric acid and calcium phosphate crystal nephropathy. In addition to the crystalline pathway, vasoconstriction and inflammation also play a role in the pathogenesis of AKI.

Management

The management of TLS can be divided into preventative and therapeutic measures. Patients who are at high risk for TLS should be closely monitored for electrolyte abnormalities and metabolic acidosis. General measures such as avoidance of nephrotoxic drugs including NSAIDs and radiocontrast is necessary. Volume expansion with the use of crystalloids to maintain a urine output of ≥2 ml/kg/h [72] helps ensure adequate glomerular filtration and high tubular flow rates, thereby enhancing excretion of uric acid, phosphorus, and potassium, and minimizing the risk of uric acid and calcium phosphate precipitation. Even though uric acid is soluble in alkaline urine, urine alkalization can decrease the solubility of calcium phosphate and increase the risk for calcium phosphate nephropathy. Ideally this should be initiated 2 days prior to the initiation of chemotherapy. Also, alkalosis leads to increased binding of calcium to albumin, reducing ionized calcium, and hence routine alkalization of urine is not recommended [69, 72].

Allopurinol (which gets converted to oxypurinol in vivo) is a competitive inhibitor of the enzyme xanthine oxidase. Oxypurinol competes with purines and decreases their conversion to uric acid. Hence it is most effective in the prevention of hyperuricemia [73]. However, the drug also inhibits the conversion of xanthine to uric acid, hence there is a risk of formation of xanthine crystal in the renal tubules [70]. A large study including 1172 adults and children, treated with intravenous allopurinol, was found to decrease uric acid level in 57% of adults when used for treatment and by 93% when used prophylactically [73]. Febuxostat is a newer xanthine oxidase inhibitor that is metabolized in the liver and hence can be used safely in patients with kidney insufficiency [70]. Rasburicase is a recombinant uricase enzyme that converts uric acid into allantoin, which is 5–10 times more soluble in urine than uric acid. The dosing approved by FDA is 0.2 mg/kg in a 30-minute intravenous infusion once daily for up to 5 days [74, 75]. Rasburicase does not require renal dosing. It can cause methemoglobinemia and hemolysis in patients with glucose-6-phosphate dehydrogenase deficiency hence all patients should be checked for enzyme activity prior to starting rasburicase [76].

Most patients with AKI will not require dialysis and will recover kidney function, although patient and renal prognosis may be worse with spontaneous TLS. Before the availability of rasburicase, hemodialysis was often initiated early in order to rapidly reduce uric acid levels, with a 50% reduction occurring after 6 hours of hemodialysis (clearance of 70–145 ml/min) [77]. Rasburicase results in more prompt reduction of uric acid and eliminates this indication for RRT. However, when significant hyperphosphatemia is present, early RRT may still be required along with noncalcium-based phosphate binders to prevent further phosphate precipitation and/or hypocalcemia. Treatment of hypocalcemia with intravenous calcium without first lowering the phosphorus should be reserved for symptomatic patients or those with EKG changes as calcium administration in the setting of hyperphosphatemia can cause calcium phosphate precipitation. Even though phosphorus clearance is high (approximately 50–90 ml/min) with intermittent hemodialysis (IHD), the short duration of IHD (usually 4 hours/day) is not sufficient to achieve negative phosphorus balance. The longer duration of treatment offered by continuous or prolonged intermittent RRT is more effective for phosphorus clearance and should be considered for patients with TLS [78].

Crystalline Nephropathies

Definition, Etiology, and Pathogenesis

Crystalline nephropathies describe the kidney injury that results from the intratubular precipitation of substances. Uric acid nephropathy was discussed earlier and this section will focus on other crystalline nephropathies. Intratubular crystal formation and deposition of a substance is promoted by three mechanisms: (i) high concentrations of the offending agent in the tubular fluid; (ii) prolonged intratubular transit time; and (iii) decreased solubility [79]. The first two mechanisms occur in the setting of decreased effective circulating volume, which results in proximal tubular sodium and water reabsorption, resulting in high concentration of the offending agent in the distal tubule along with decreased distal flow rates. Underlying CKD is an important risk factor for the crystalline

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nephropathies. In CKD, the amount of compound excreted per remaining functioning nephron is increased, raising the likelihood of intratubular precipitation. The third mechanism, decreased solubility, is often dependent on the distal tubular fluid pH. Compounds with pKa < 7, such as uric acid, calcium oxalate, sulfonamides, methotrexate, and triamterene, tend to precipitate in acidic urine, whereas compounds with pKa > 7, such as indinavir and calcium phosphate, tend to precipitate in alkaline urine. Once crystals are formed in the tubular lumen, the tubular epithelial cells attempt to phagocytose and digest the crystals with proteolytic enzymes, resulting in direct cellular toxicity and necrosis. Crystal-induced toxicity can also lead to significant peritubular inflammation, sometimes mimicking AIN [80, 81].

Inadequate dose reduction for the level of kidney function is frequent, leading to increased drug exposure. The clinical contexts in which the more common crystalline nephropathies occur are summarized in Table 12.5. Besides TLS, other causes of crystalline nephropathy include calcium oxalate, acyclovir, sulfonamides, methotrexate, indinavir, and triamterene. Ethylene glycol intoxication is discussed separately due to its unique pathogenic mechanisms and treatment strategies.

Clinical Features

Extensive crystal deposition results in pain from distention of the renal capsule and is similar in nature to the pain due to nephrolithiasis. Oliguria is uncommon unless there is bilateral obstruction. In certain cases (especially with indinavir and sulfonamides), macroscopic lithiasis and its characteristic presenting symptoms can exist alone or concomitantly with intratubular crystal nephropathy [88, 90]. Precipitation of calcium with phosphates and oxalates can lead to symptomatic hypocalcemia, leading to paresthesia, tetany, and lethargy. High levels of acyclovir seen in AKI can lead to hallucinations, delirium, and myoclonus. Methotrexate can cause stroke-like symptoms (not dose-related) as well as nausea, rash, and mucositis (usually dose-related).

Laboratory Findings

Urinalysis and microscopic examination of the urine sediment are often nonspecific, generally revealing hematuria, pyuria, and mild proteinuria. Although the offending substances have unique crystal morphologies on urine microscopy, finding urine crystals may not be independently diagnostic. Urine microscopic images of some crystals are shown in Figure 12.4a–e. Absence of crystals on urine microscopy can occur when there is tubular obstruction and hence does not rule out crystal nephropathy. Conversely, the presence of crystals does not prove their pathogenic role because calcium oxalate, calcium phosphate, and uric acid crystalluria may be seen in normal individuals. Furthermore, crystalluria has been found in patients without AKI in frequencies varying from 100% of healthy individuals receiving a single 100-mg dose of triamterene and ascorbic acid (for urinary acidification) to 17% of all patients taking indinavir [90].

Ultrasound may reveal bilaterally enlarged and echogenic kidneys and can identify concomitant macroscopic lithiasis. Kidney biopsy is sometimes required to make a definitive diagnosis. Light microscopy may reveal crystalline deposits (usually in the distal tubules), with a surrounding interstitial infiltrate that may contain giant cells as part of a foreign body reaction. Evidence of ATN can also be present, secondary to direct tubular cell toxicity. Polarized microscopy may demonstrate birefringence, depending on the offending agent (Figure 12.5a,b). A summary of the characteristic laboratory findings is outlined in Table 12.5.

Course and Management

In most cases of crystalline nephropathy, the renal prognosis is excellent if further exposure to the precipitating substance can be avoided. In drug-related crystalline nephropathies, recovery of kidney function is expected to occur within days to weeks after cessation or dose reduction of the offending drug. An exception is the use of phosphate-containing colonoscopy preparation, causing phosphate nephropathy. Although there was likely selection bias for more severe cases, the largest series characterizing this disease found that none of 21 affected patients returned to their previous level of kidney function and four progressed to require chronic dialysis [82].

The mainstay in preventing crystalline nephropathy is avoidance of the two most frequent predisposing factors: volume depletion and drug overdosing relative to the level of kidney function. Establishing a brisk urine output (e.g. 100–150 ml/h or greater) in high-risk patients is extremely important. For substances with pKa < 7 (e.g. uric acid, calcium oxalate, sulfonamides, methotrexate, triamterene) urinary alkalization by administering intravenous isotonic bicarbonate solutions or oral citrate can be considered. Urine pH should be periodically followed to ensure an appropriate level of alkalization to achieve pH > 7.15. Excess alkalization of urine can lead to precipitation of calcium phosphate crystals and should be avoided. Acetazolamide may be added if a metabolic alkalosis ensues. Attempting to acidify the urine to increase the solubility of weakly basic compounds is dangerous

Table 12.5 Causes of crystalline nephropathy, their distinctive clinical and laboratory features, and strategies for prevention and treatment.

Inciting agent [reference]	Clinical context	Laboratory findings	Prevention and treatment	Disease course
Phosphate [82]	TLS, especially post treatment form Phosphasoda bowel prep with risk increased by ACEi/diuretic use, advanced age, CKD, and/or female gender • Rhabdomyolysis (rare)	Crystalluria with weakly birefringent, long prisms, often in rosettes Hyperphosphatemia out of proportion to kidney insufficiency Hypocalcemia Hyperkalemia out of proportion to kidney insufficiency High LDH in TLS, rhabdomyolysis, and hemolysis Kidney biopsy: von Kossa-positive crystals	*Prevention* Forced diuresis[a] Noncalcium-based phosphate binders *Treatment* Forced diuresis[a] Noncalcium-based phosphate binders Avoid treatment of hypocalcemia unless symptomatic or ECG changes present Consider early initiation of RRT, especially CRRT	Incidence of CKD higher in cases caused by phosphasoda
Uric acid [83, 84]	TLS, especially spontaneous form Rhabdomyolysis (rare) HGPRT deficiency (rare)	Crystalluria with brownish, strongly birefringent, rhomboid plates, rosettes, or needles UA >15 mg/dl (peaking 2–3 days after initiation of treatment in TLS) Urine UA/urine Cr >1 (<0.75 suggests alternative diagnosis) Hyperkalemia out of proportion to kidney insufficiency Elevated LDH in TLS and rhabdomyolysis	*Prevention* Forced diuresis[a] Allopurinol or rasburicase *Treatment* Rasburicase RRT (if rasburicase not available)	Full renal recovery expected in the absence of other insults; higher mortality in spontaneous TLS
Oxalate [85, 86]	EG poisoning High-dose i.v. ascorbic acid–xylitol–sorbitol infusions (rare) Primary hyperoxaluria (rare)	Crystalluria with birefringent monohydrate needles or dihydrate envelope shapes appearing >4 h after EG ingestion Hypocalcemia In EG poisoning, osmolal gap >10 mOsm/l and detectable serum and urine EG early with subsequent development of severe anion gap acidosis Kidney biopsy: silver nitrate/rubeanic acid stain-positive crystals	*Prevention* Forced diuresis[a] Consider urine alkalinization Fomepizole for high-risk EG ingestion[b] (ethanol is second line) i.v. thiamine, magnesium, and pyridoxine in alcoholic patients *Treatment* Forced diuresis[a] Consider urine alkalinization Avoid treatment of hypocalcemia unless symptomatic or ECG changes present Fomepizole (ethanol is second line) if EG level >20 mg/dl Early initiation of RRT, especially if EG >50 mg/dl and renal insufficiency or acidosis present	Full renal recovery occurred in 6/9 patients; duration and severity of AKI is predicted by severity of acidosis at presentation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Acyclovir [87]	Associated with intravenous dosing 11% develop AKI with high-dose rapid i.v. bolus	Crystalluria with birefringent needles with occasional engulfment by WBC	*Prevention* Forced diuresis[a] Increase time of i.v. infusion to 1 hour *Treatment* Forced diuresis[a] Decreasing the dose is sufficient in 40–50% of patients	Full renal recovery expected
Indinavir [88]	18.6% develop AKI, especially with longer treatment, smaller body size, and concurrent TMP-SMX	Crystalluria with birefringent plates, fans, or starbursts Isosthenuria common CT with i.v. contrast shows wedge-shaped perfusion defects in up to 50%	*Treatment* Forced diuresis[a] Urologic consultation if concomitant macroscopic obstruction present (not uncommon)	AKI is easily reversible as opposed to the slowly progressive injury seen in indinavir-induced AIN
Methotrexate [89]	2–4% develop AKI with high-dose i.v. therapy; increased risk in older patients and with concomitant use of NSAID or other highly protein-bound drugs which increase free methotrexate levels	Crystalluria with amorphous yellow casts High serum methotrexate level Anemia, leukopenia, or thrombocytopenia possible	*Prevention* Forced diuresis[a] Urinary alkalinization to pH ≥ 8 *Treatment* Forced diuresis[a] Urinary alkalinization to pH ≥ 8 Leucovorin rescue ± thymidine for extrarenal toxicity until methotrexate level <0.05 μmol/l Consider carboxypeptidase G2 (>98% fall in levels by 15 minutes) vs. daily 6-hour high-flux hemodialysis (clears drug in 5.5 days)	Median time to renal recovery to 2–3 weeks
Sulfonamides [90]	Usually with high-dose therapy More common with sulfadiazine (1.9–7.5% incidence in AIDS patients) Low serum albumin may increase risk from higher free drug levels	Crystalluria with variable shapes from shocks of wheat to spheres Positive lignin test (orange urine upon mixing with 10% hydrochloric acid) Densities in parenchyma and in collection system on ultrasound are common	*Treatment* Forced diuresis[a] Urine alkalinization to pH > 7.1 Dose reduction usually sufficient Urologic consultation if macroscopic obstruction present (not uncommon)	Full renal recovery is prompt, sometimes within hours, but median 6 days
Triamterene [79]	Rare; must distinguish from the much more common AIN, or AKI with concomitant NSAID use	Crystalluria with birefringent orange casts and spheres Hyperkalemia out of proportion to renal insufficiency	*Treatment* Forced diuresis[a] Urine alkalinization to pH > 7.5 May require urologic consultation for the more common triamterene stone if obstructed	Full renal recovery is expected

CRRT, continuous renal replacement therapy; CT, computerized tomography; ECG, electrocardiogram; EG, ethylene glycol; HGPRT, hypoxanthine-guanine phosphoribosyl transferase; i.v., intravenous; LDH, lactate dehydrogenase; TLS, tumor lysis syndrome; TMP-SMX, trimethoprim-sulfamethoxazole; UA, uric acid.

[a] Forced diuresis refers to aggressive hydration with judicious use of diuretics to achieve and maintain brisk urine flow rate.

[b] Patients at high risk for organ dysfunction in EG poisoning are those with serum EG of >20 mg/dl, OR with known recent ingestion of EG with osmolal gap >10 mOsm/l, OR strong suspicion of recent ingestion and two of the following: pH <7.3, HCO_3 < 20 mEq/l, osmolal gap >10 mOsm/l, and urinary oxalate crystals [85].

and not recommended. These preventive strategies are based on underlying pathophysiologic mechanisms, and evidence proving reduced renal complications with these measures is lacking, except perhaps with high-dose methotrexate administration.

Treatment of established AKI consists of discontinuation of the drug and, if nonoliguric and in the absence of volume overload, applying many of the same principles used in prevention: forced diuresis (aggressive volume expansion with judicious use of diuretics) and, for weak acids, urinary alkalization. In the setting of AKI, moderate to large doses of diuretics may be required to establish adequate urine flow, and care must be taken with bicarbonate loading to avoid profound alkalosis. Additionally, early initiation of RRT can rapidly decrease the concentration of some inciting agents (e.g. phosphate, oxalate).

High-dose methotrexate causing AKI can in turn increase its serum levels, causing acute systemic methotrexate toxicity from decreased urinary clearance. In addition to large volume hydration and forced alkaline diuresis, leucovorin can be administered to decrease the cytotoxicity of the drug. Glucarpidase (carboxypeptidase) was approved in 2012 for MTX concentrations >1 umol/l to decrease its systemic toxicity if the above measures are unsuccessful in bringing down the levels [91]. Studies have shown daily hemodialysis with high flux dialyzers and sessions of 4–6 hours in duration are effective in removing methotrexate [89]. Again, evidence for improvement in renal outcome with these maneuvers is lacking. See Table 12.5 for details on specific management strategies.

Ethylene Glycol Poisoning

Ethylene glycol (or antifreeze) is metabolized by the hepatic alcohol dehydrogenase into four toxic metabolites: glycoaldehyde, glycolic acid, glyoxylic acid, and oxalic acid. Accumulation of organic anions (glycolate, glyoxylate, and oxalate) leads to a severe anion gap metabolic acidosis. These compounds, especially glycolic acid, are direct cellular toxins and cause multiorgan dysfunction, including cardiotoxicity, ATN, and nervous system depression. In addition, oxalate precipitates with calcium in several tissues, including the renal tubules, causing crystalline nephropathy (Figure 12.4a,b).

The clinical manifestations of ethylene glycol intoxication evolve over time as the alcohol is metabolized. During the first 30 minutes to 12 hours, ethylene glycol causes inebriation, with progression to seizures or coma. Twelve to 36 hours post ingestion, profound acidosis ensues as the concentration of the organic acid increases, leading to Kussumals breathing and cardiorespiratory failure. Twenty-four to 72 hours later, the oxalate end product accumulates in tissues, including the kidneys, resulting in AKI. The timeline is extended when there is co-ingestion of ethanol, which acts as a competitive inhibitor of alcohol dehydrogenase. The focus of treatment in ethylene glycol toxicity involves decreasing the concentration of its toxic metabolites. This can be achieved by (i) reducing organic acid formation by use of competitive alcohol dehydrogenase inhibitors, such as fomepizole or ethanol; (ii) increasing metabolite clearance through early initiation of RRT, and (iii) conversion to less toxic metabolites by cofactor supplementation like thiamine and pyridoxine (Table 12.5). Other causes of oxalate nephropathy include enteric hyperoxaluria after bariatric surgeries and primary oxaluria.

Renovascular Etiologies of Acute Kidney Injury

Renal Artery Thrombosis and Renal Infarction

Acute renal artery thrombosis (RAT) is a rare clinical entity characterized by acute onset of abdominal or flank pain, nausea, vomiting, hematuria, hypertension, and even more rarely AKI. Most common causes of renal infarction are cardioembolic, although the percentage involvement varies with different studies, ranging from 18% to 55.7% [92–95]. Renal artery injury following blunt abdominal trauma and hypercoagulable states like nephrotic syndrome (NS), antiphospholipid antibody syndrome, paroxysmal nocturnal hemoglobinuria, as well as systemic malignancies can predispose to RAT as well. In one large case series, AKI developed in 21% of patients with renal infarction [95]. AKI is unusual with unilateral involvement unless there is baseline CKD. CT scan with intravenous contrast is the imaging modality of choice in suspected RAT, however intravenous contrast should be used with caution in those with kidney injury. Magnetic resonance angiography is another option, but exposure to gadolinium is associated with nephrogenic systemic fibrosis in patients with CKD. For patients with GFR <30 ml/min, including those undergoing dialysis, it is generally recommended that gadolinium exposure be avoided if possible and alternative imaging modalities be pursued [96]. Management of RAT involves systemic anticoagulation with heparin and a bridge to warfarin to maintain therapeutic INR between 2 and 3. There are limited data regarding use of direct oral anticoagulants in this setting. Endovascular procedures like stenting and thrombolysis have favorable outcomes when performed early [97]. Prognosis depends on severity of kidney injury and underlying comorbidities. In the largest series, mortality was 5% and 2% progressed to ESRD [95].

Renal Vein Thrombosis

Renal vein thrombosis (RVT), either unilateral or bilateral, is an extremely rare cause of AKI. The common etiologies are NS and other hypercoagulable states, such as antiphospholipid antibody syndrome. Of all the causes of NS, patients with membranous glomerulonephritis have the highest prevalence of RVT (37%) [98]. In a case series, low serum albumin of less than 2.8 g/dl, rather than proteinuria, was found to have increased risk for thrombotic episodes [99]. Selective renal venogram is considered the gold standard for diagnosis, but it is not routinely performed due to a high risk for contrast-induced AKI as well as vascular complications. In one series, computerized tomography had a sensitivity of 92% and specificity of 100%. A series investigating Doppler ultrasonography revealed a sensitivity of 85% and specificity of 56%, but this modality is heavily operator dependent [98]. Magnetic resonance imaging can also be used, although adequate studies have not evaluated this modality.

Treatment of RVT involves conventional anticoagulation with intravenous heparin and warfarin sodium. Use of thrombolytics in RVT has been reported, but given the risk for bleeding their use should be considered only in patients with severe bilateral RVT with rapidly declining kidney function [100]. There are insufficient data to support the use of primary prophylactic anticoagulation in patients with NS and the decision to pre-emptively anticoagulate a patient should be made on a case-by-case basis. In 2014, a risk calculator based on the Markov decision model was published to calculate the risk vs. benefits for prophylactic anticoagulation for patients with primary membranous nephropathy [101]. Once a patient has developed a thrombotic event, anticoagulation should be continued until the resolution of the NS, since the risk of recurrence is extremely high. There are few case reports of using direct oral anticoagulants for treatment of thrombosis when warfarin is contraindicated, but there is no consensus or evidence for their use at this time.

Introduction

Acute kidney injury (AKI) remains a common condition in hospitalized patients, especially amongst the critically ill in the intensive care unit (ICU), affecting approximately 50–60% of ICU patients [1], and it is an independent risk factor for mortality [2–7]. Unfortunately, the strategies to prevent AKI, aside from prerenal azotemia, contrast-associated AKI, and pigment-induced AKI, remain limited. Recently, several trials have suggested that a renal-protective strategy based on results of urinary biomarkers may be able to prevent AKI and mitigate AKI risk in some clinical situations [8, 9]. However, there remain no effective pharmacologic interventions for the treatment of most forms of intrinsic AKI. As a result, renal replacement therapy (RRT) remains the cornerstone of care in patients with severe AKI and the use of RRT for dialysis-dependent AKI (AKI-D) continues to increase steadily [1, 10]. Over the past three decades there has been a proliferation of modalities of RRT available for the management of AKI to now include intermittent hemodialysis (IHD), acute peritoneal dialysis (PD), continuous renal replacement therapy (CRRT), and "hybrid" therapies (prolonged-intermittent renal replacement therapy [PIRRT]). Despite the increasing technological sophistication of RRT, key management issues, such as the optimal timing of initiation, selection of modality, and dosing of RRT, remain controversial, and the clinical complexity and heterogeneity of patients with severe AKI has made clinical trials addressing these questions challenging.

This chapter focuses on key issues surrounding the use of RRT in the treatment of AKI, summarizing the indications for RRT initiation, the current evidence basis for the optimal timing of initiation of treatment, the selection of modality and dose of RRT, and RRT circuit considerations to optimize RRT circuit performance and function. Unfortunately, this chapter will not be able to address many other important factors to consider when delivering RRT for AKI such as medication dosing and nutrition support in RRT, transitions between therapies and when to stop acute RRT, or modality-specific RRT prescription details. Fortunately, there are many other resources and studies available that address these issues [11–17].

Renal Replacement Therapies in AKI

RRT is at first a misnomer, suggesting that its role is to *replace* kidney function when glomerular filtration rate (or creatinine clearance) has essentially ceased. Rather, RRT should instead be considered a supportive therapy (i.e. renal support therapy) in situations where the metabolic and fluid demands exceed native kidney function [18, 19]. In addition to fluid removal and clearance of waste products, RRT may also limit the negative, distant effects of AKI on nonrenal organs, including respiratory and cardiac dysfunction. Recent advances have made the provision of RRT easier and safer, but it is important to acknowledge that RRT only replaces excretory function (solute clearance and fluid removal) but does not provide or replace any of the myriad other kidney functions (i.e. tubular resorption of electrolytes and nutrients, endocrine regulation, or metabolic functions). Finally, clinicians must recognize that patients with AKI are distinctly different from those with end-stage renal disease (ESRD). The sudden, rapid decline

of kidney function in AKI and multiorgan failure does not permit the body's adaptive responses seen in those with progressive chronic kidney disease.

Modalities

RRT utilizes an extracorporeal circuit containing an artificial membrane (hemodialysis [HD] or hemofiltration) or the patient's own peritoneal membrane (peritoneal dialysis) (see Table 13.1). Hemodialysis refers to the removal of solute and water across a semipermeable membrane by establishing and maintaining a concentration gradient between the blood flowing through the filter and the countercurrent flow of an electrolyte containing dialysate solution across the other side of the membrane (principle of diffusion) [21]. In hemofiltration, water and dissolved solutes are transferred across a semipermeable membrane by means of a transmembrane pressure gradient (principle of convection) [21]. Hemodiafiltration incorporates the removal of solute and water across a semipermeable membrane by both a concentration and transmembrane pressure gradient (diffusion and convection) [21]. PD uses the patient's peritoneum as a membrane across which fluids, electrolytes, and small molecules are exchanged by diffusion.

Further characterization of RRT is based on the duration. As such, there are continuous and intermittent forms of RRT. CRRT includes continuous veno-venous hemofiltration (CVVH), continuous veno-venous hemodialysis (CVVHD), continuous veno-venous hemodiafiltration (CVVHDF), and PD; intermittent techniques include IHD and newer "hybrid" therapies, such PIRRT, which has also been called sustained low-efficiency dialysis (SLED) (Figure 13.1).

Choice of Modality

In clinical practice, the choice of modality depends on the characteristics of the patient, availability of machines, and expertise of the clinical team [20]. Intermittent modalities are generally associated with greater fluctuations in metabolic and fluid status and an increased risk of intradialytic hemodynamic compromise (i.e. hypotension) whereas CRRT provides more sustained fluid removal and solute clearance, and is associated with less fluctuation (Figure 13.1 and Table 13.1). As such, CRRT is recommended for patients who do not tolerate fluctuations in fluid status or shifts in osmotically active molecules such as those patients with hemodynamic instability or acute brain injury [20]. The potential drawbacks of CRRT include greater restriction of mobility, continuous exposure to the extracorporeal circuit, need for anticoagulation, often unrecognized losses of amino acids, vitamins, and micronutrients, alterations in drug pharmacokinetics (PK), and dialysis-induced hypothermia to name a few (Table 13.1).

Intermittent RRT is usually preferred in patients who are hemodynamically more stable and able to tolerate greater fluctuations in fluid and metabolic status. IHD also provides greater minute-to-minute small solute clearance, which makes it far more effective in situations where life-threatening issues require emergent correction such as severe hyperkalemia with marked conduction abnormalities (i.e. complete heart block), acute poisonings, or profound metabolic acidemia. Intermittent RRT also allows more active physical therapy and rehabilitation by providing time off from therapy.

Hybrid therapies are variations of RRT that are usually provided daily for 6–18 hours. They offer some advantages of both intermittent and CRRT, and are often employed during the transition period from CRRT to intermittent RRT. There are multiple terminologies in the literature for hybrid therapies, with the most common being SLED and PIRRT [22].

Acute PD requires the insertion of a peritoneal dialysis catheter. It has theoretical advantages in that hemodynamic disturbances are rare and anticoagulation is not required. PD provides continuous clearance, but fluid removal rate and degree of solute clearance cannot be controlled as tightly as with IHD or CRRT. In addition, the risks of respiratory compromise from increased intra-abdominal pressure, pleural-peritoneal leak and intra-abdominal infection make it generally less suitable in the acute setting in adults, however acute PD remains a commonly used option in neonates and resource-limited settings. In patients with abdominal pathology, PD is usually contraindicated.

CRRT can be delivered as CVVH, CVVHD, or CVVHDF. Historically, diffusion, the clearance mode in hemodialysis, favors the removal of solutes with a lower molecular weight (MW) whereas convection (which underlies the process of hemofiltration) is more efficient at removing both low- and higher MW substances as it permits the transfer of molecules that can be accommodated by the size of the membrane pore. Indeed, there is some evidence that clearance of vancomycin (with MW approximately 1500 Da) can be improved with hemofiltration [23]. There is debate about whether there is a clinical benefit afforded by hemofiltration in the setting of AKI [24]. The potential benefit of removing a wider spectrum of solutes that are too large to be removed by hemodialysis (for instance inflammatory cytokines), would make hemofiltration an attractive therapy for certain types of AKI, for instance sepsis-associated AKI. However, small studies demonstrate that this difference in middle- or large-molecule clearance is low with modern high-flux membranes [25, 26]. Additionally, as

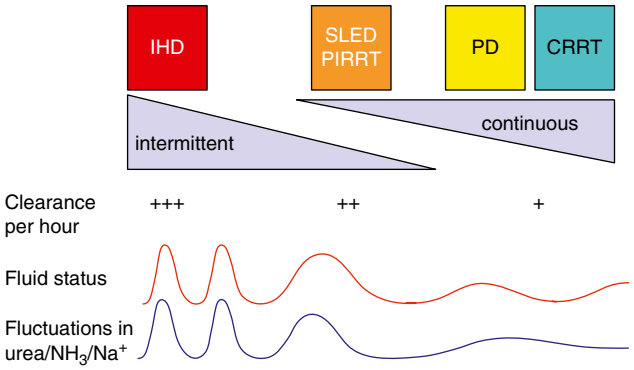

Figure 13.1 Renal Replacement Therapy Modalities in Acute Kidney Injury.

would be expected based on increased filtration fractions, CRRT circuit survival times are generally lower with higher rates of convection (CVVH) [23, 27]. Thus, any difference in minute-to-minute middle- and large-molecule clearance may be negated with less cumulative time on CRRT with higher rates of convection. This effect may be mitigated by CVVHDF combining both diffusion and convection, but there is no clinical data that this mode is superior. Indeed, a meta-analysis comparing hemofiltration and hemodialysis for AKI did not demonstrate any reliable differences in patient survival or kidney recovery [28].

It is commonly believed that CRRT is superior to IHD in critically ill patients but clinical trials have failed to confirm this [20, 29–37]. The propensity for seriously ill and more hemodynamically tenuous patients to receive CRRT rather than IHD, along with the inherent limitations of nonrandomized study designs, confounded many of the early observational studies that compared continuous and intermittent therapies. There are at least seven randomized controlled trials (RCTs) comparing CRRT and IHD (Table 13.2) [29–35]. In a multicenter RCT of 166 patients with AKI, Mehta et al. observed hospital mortality rates of 65.5% in patients randomized to CRRT, compared to 47.6% in patients randomized to IHD ($P < 0.02$) [29]. However, imbalanced randomization resulted in patients in the CRRT arm having greater severity of illness and a higher rate of liver failure, both of which were independently associated with increased mortality. After covariate adjustment, the investigators found no difference in mortality attributable to modality of RRT. Interpretation of this study is confounded further by a high rate of crossover between treatment modalities in both study arms. In a single-center RCT involving 80 patients, Augustine et al. reported more effective fluid removal and greater hemodynamic stability associated with CVVHD compared to IHD, but there was no difference in survival [31]. Similarly, Uehlinger et al. observed no difference in survival in 70 patients randomized to CVVHDF compared to 55 patients assigned to IHD [32].

The Hemodiafe study was a multicenter RCT conducted in 21 ICUs in France which demonstrated no difference in mortality in 184 patients randomized to IHD compared to 175 patients randomized to CVVHDF [33]. This study is particularly notable for the fact that IHD was delivered to

patients despite marked hemodynamic instability, with little crossover between treatment groups. However, in the Hemodiafe study, IHD delivery was tailored to minimize risk of hemodynamic compromise – specifically, initial blood flow was limited to 250 ml/min, dialysate flow to 500 ml/min (both limiting speed of small solute clearance), dialysate sodium concentration was increased to 150 mEq/l (high dialysate sodium concentration is known to minimize risk of intradialytic hypotension), and dialysate temperature was decreased to 35.0°C to increase peripheral vascular resistance and vascular refilling. Mean IHD treatment duration was 5.2 hours and mean net fluid removal during each IHD session was only 2.2 l [33]. In the United States and many other countries, such optimized, tailored, and gentle IHD treatment is less common and challenging to deliver in those with AKI-D, making it difficult to extrapolate these results to daily practice.

The single-center CONVINT (Contininous versus intermittent renal replacement therapy Trial) trial was a prospective RCT comparing daily IHD with CVVH in 252 critically ill patients [35]. Survival rates at 14 days after RRT were 39.5% (IHD) versus 43.9% (CVVH) ($P = 0.50$). All-cause hospital and 30-day mortality rates were not different between the two groups (all $P > 0.5$). No differences were observed in days on RRT, vasopressor days, days on ventilator, or length of stay in hospital [35].

The propensity for hemodynamic instability and intradialytic hypotension during IHD has led to the suggestion that CRRT may be associated with an increased likelihood for recovery of renal function [40–42]. However, multiple meta-analyses comparing outcomes between these modalities of RRT have not found any convincing differences in any relevant patient-centered outcomes [36, 37, 43–46]. One meta-analysis included both randomized and nonrandomized studies and concluded that weaknesses in the quality of the studies significantly limited meaningful comparisons between modalities [43]. Based on weighting of the studies using an a priori assessment of study quality and comparability of severity of illness between treatment arms, the authors suggested that CRRT might be associated with a lower relative mortality risk. Subsequent meta-analyses differed in their criteria for including studies, resulting in minor differences in the calculated odds ratios (ORs) for mortality, but there were no differences in mortality associated with use of IHD or CRRT [36, 37, 44, 45]. The most recent systematic review including 21 RCTs and prospective cohort studies also concluded that RRT modality was not associated with in-hospital mortality or dialysis dependence [46].

Studies comparing other types of RRT are limited. In a small trial of 39 patients randomized to either CVVH or 12-hour PIRRT, cardiovascular tolerability and urea clearances were equivalent but less heparin was needed and acidosis was corrected faster in patients treated with PIRRT [47]. In another RCT in 60 patients comparing CVVHDF to 6–8 hours of PIRRT, there was no difference in ICU or 30-day mortality, but survivors in the PIRRT group had higher renal recovery rates and a shorter length of stay in ICU [39]. Finally, a systematic review and meta-analysis including seven RCTs and 10 observational studies concluded that PIRRT was associated with similar outcomes to CRRT [48].

There is a limited number of studies comparing PD to CRRT in adults. Two studies reported better results with CRRT but the clearance delivered by PD was low [49, 50]. One RCT found that CVVH was superior to PD in infection-associated AKI but the predominance of malaria as the cause of AKI limits the study's generalizability [38].

In summary, an understanding of the benefits and drawbacks of the different types of RRT is essential. Current data do not show superiority of any specific modality of renal support in patients with AKI. Rather than viewing these modalities as competing, we recommend viewing them as complementary therapies. Modality selection for an individual patient requires a consideration of the clinical characteristics of patients, the goals of RRT on a given day, provider expertise, and locally available technology and staffing resources. Importantly, guidelines do endorse the use of CRRT in those with (or at risk for) increased intracranial pressure as data does indicate that IHD causes a greater increase in intracerebral pressure (ICP) during the session compared to CRRT [51, 52]. Finally, as complimentary therapies, the choice of modality may need to be adjusted during the course of critical illness as a given patient's clinical status and renal support needs evolve.

Indications for Acute Renal Replacement Therapy

RRT for AKI (AKI-D) is initiated in approximately 15–20% of all critically ill patients [1]. The incidence of AKI-D in noncritically ill hospitalized patients is less well established and is widely variable across hospital settings and populations. Acute RRT for symptomatic hyperkalemia (or other severe electrolyte disorders), severe acidemia, symptomatic uremia, marked fluid overload leading to severe hypoxic acute respiratory failure, and toxic ingestions remain classic indications. However, there is wide divergence between providers about the severity of a given derangement (i.e. degree of hyperkalemia, blood urea nitrogen [BUN], pH, or fluid overload) that prompts dialysis initiation [53].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. The Kidney Disease Improving Global Outcomes (KDIGO) AKI guidelines [54] recommend that acute RRT should be initiated for "life threatening changes in fluid, electrolyte, and acid-base balance exist." However, it is important to note that KDIGO does not define what these specific life-threatening levels are. The KDIGO guidelines go on to state that the clinician should "consider the *broader clinical context, the presence of conditions that can be modified with RRT, and trends of laboratory tests* – rather than single BUN and creatinine thresholds alone – when making the decision to start RRT" [54]. This puts the onus back on the clinician teams to determine indications for acute RRT initiation in an individualized, patient-centered, goal-driven approach.

Renal support therapy in AKI has several goals: (i) return to and maintain fluid, electrolyte, acid-base, and solute homeostasis; (ii) to prevent complications of uremia; and (iii) to allow other supportive measures (such as antimicrobial or other drug therapy and nutrition support) to proceed without limitations in vulnerably acutely ill patients. However, acute RRT is not without risk and inherent complications – most having to do with RRT access (vascular or peritoneal) complications (infections and traumatic) and circuit-related factors such as need for anticoagulation, circuit-associated blood loss requiring transfusions, circuit failures limiting effective RRT delivery, and extracorporeal removal of medications such antibiotics (resulting in inadequate dosing) and nutrients. Therefore, initiating RRT must weigh the possible (or desired) benefits of therapy against the risks.

Timing of Dialysis Initiation

Decisions surrounding whether and when to initiate acute RRT continue to be amongst the most challenging and vexing issues in the hospitalized and/or critically ill patient over the last 60 years [1, 18, 19, 53–55], particularly in patients in whom imminent life-threatening complications are present.

In-hospital mortality amongst patients with AKI-D remains an all-too-frequent outcome afflicting 40–60% of patients [1, 37]. In a retrospective analysis of more than 10 000 ICU patients with AKI, Liborio et al. demonstrated that the excess hospital mortality at all stages and severities of AKI seems driven by the complications associated with AKI (hyperkalemia, metabolic acidosis, and >5% fluid overload) rather than AKI itself [56]. In theory, timely initiation of RRT might prevent the development of AKI complications, thereby possibly improving outcomes.

Timing of Dialysis: Definition

Throughout the literature, *conventional/delayed/late dialysis* initiation is defined as starting dialysis in an individual with advanced AKI (according to serum creatinine or urine-based criteria) when the patient reaches a predefined "life-threatening" indication for dialysis – symptomatic azotemia, hyperkalemia, severe acidemia, volume overload, and worsening hypoxia. Conversely, *early/preemptive dialysis* has had a wide range of definitions in different studies: lower serum BUN levels, earlier stages of AKI, and shorter time to initiation of dialysis. This has introduced a significant heterogeneity in the literature as to how this *early/preemptive* initiation has been applied. Finally, almost all trials comparing timing of dialysis have been performed in the ICU setting, presumably where the mortality impacts of a certain strategy may have the biggest effect.

Conventional/Delayed/Late RRT

In patients with AKI, it remains difficult to predict the trajectory for renal function and AKI recovery. Traditional tools such as BUN, creatinine, and urine output trends are helpful but have limitations. Some with advanced AKI will recover renal function quickly enough to never to require acute RRT. As mentioned above, acute RRT also carries risks including mechanical or infectious complications from the dialysis vascular access catheter, bleeding, loss of essential substances (e.g. nutrients, drugs), and increased cost, to name a few.

Isolated azotemia is rarely the only complication of AKI in hospitalized patients; encouragingly, studies evaluating the timing of initiation based purely on a BUN level (high or low) have shown no benefit to starting dialysis earlier [19, 55, 57]. This suggests that in those cases with isolated azotemia, a more deliberate, delayed approach to dialysis is likely safe.

More recently, the approach to studying RRT timing has centered on AKI staging according to criteria from the Acute Kidney Injury Network (AKIN) and KDIGO. The two largest trials to date were the Artificial Kidney Initiation in Kidney Injury (AKIKI) trial published in 2016 [58] and the Initiation of Dialysis Early Versus Delayed in the Intensive Care Unit (IDEAL-ICU) trial published in 2018 [59].

Both of these were multicenter trials enrolling critically ill patients exclusively in ICUs in France [58, 59]. They had opposite hypotheses (no benefit of early RRT initiation for AKIKI and benefit of early RRT initiation for IDEAL-ICU) and enrolled adult patients with AKI who did not have specific objective criteria for RRT initiation only if/when

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. they developed KDIGO stage 3 AKI based on creatinine or urine output criteria [58, 59]. AKIKI did require that subjects have a clinical diagnosis of acute tubular necrosis (ATN), while IDEAL-ICU did not [58, 59]. Furthermore, both trials required patients to be critically ill – IDEAL-ICU requiring septic shock (i.e. on vasopressors) and AKIKI requiring shock on vasopressors and/or invasive mechanical ventilation [58, 59]. Both randomized patients who had stage 3 AKI to early versus delayed dialysis with those in the early group starting dialysis within 6 hours (AKIKI) or 12 hours (IDEAL-ICU) of reaching stage 3 AKI [58, 59]. Those in the late groups started RRT when they developed either a prespecified end point (i.e. hyperkalemia, severe acidemia, progressive fluid overload, or advancing hypoxemia) or if patients remained oligo-anuric without signs of renal recovery at 48 (IDEAL-ICU) [59] or 72 hours (AKIKI) [58].

AKIKI enrolled 619 patients and found no difference in the primary outcome of death at 60 days (48.5% in the early group vs. 49.7% in the delayed group, $P = 0.79$) [58]. Furthermore, although while almost all patients in the early group received dialysis, only 50% of patients in the delayed group required initiation of dialysis [58]. IDEAL-ICU enrolled 488 patients but was stopped after the second interim analysis based on the assessment of the safety board that it was futile to continue the study because completion of enrollment was unlikely to change the results of the trial significantly [59]. In the final analyses of the IDEAL-ICU study, 90-day mortality was 58% in the early group and 54% in the delayed group ($P = 0.38$) [59]. Similar to the AKIKI study, not all subjects in the IDEAL-ICU trial received RRT, with 97% in the early group receiving RRT while only 62% in the delayed group got RRT [59]. Of the remaining 38% of the delayed group who did not start RRT, 75% recovered renal function without requiring RRT (70 of the total 242 patients in the delayed group) [59].

In both trials, AKIKI and IDEAL ICU, mortality was lowest in those patients who were randomized to delayed RRT but never received it due to recovery of renal function, and mortality was highest in patients who were randomized to delayed RRT and actually started RRT. For clinicians managing patients with AKI, this constitutes a major challenge because at any point in time it is difficult to predict whether renal function will recover in the following 48 hours or not. While these two trials found no evidence of a survival benefit associated with earlier initiation of RRT, they also identify a need for better risk-stratification tools to differentiate between patients whose renal function will recover spontaneously, so that RRT can be avoided, and patients who will have progressive AKI, so that RRT can be timely started before the onset of fluid overload and serious metabolic derangements.

Limitations of both the AKIKI and IDEAL-ICU trial designs should be noted. Both trials excluded patients in whom there were objective criteria for earlier initiation of renal support, such as severe volume overload, hyperkalemia, and metabolic acidosis. While some have criticized both trials for significant use of intermittent RRT, it should be noted that utilization was equivalent in both treatment arms, that this represented usual care in the health systems where the trials were conducted, and that prior trials, such as the Hemodiafe trial [33], demonstrated no improvement in mortality associated with CRRT. The studies also did not address the question of whether a strategy of even earlier initiation of therapy would provide a survival benefit.

Early/Preemptive RRT: Theoretical Rationale

As Liborio et al. [56] demonstrated, hyperkalemia, acidemia, and fluid overload remain the primary life-threatening complications of AKI. Thus, it has long been postulated that dialysis initiation prior to development of life-threatening AKI complications may improve ICU and AKI outcomes. Over the last 10 years, while imperfect, data have emerged that add fuel to this debate: namely, is survival improved when early or preemptive RRT is started in an effort to prevent the development of emergent, immediately life-threatening indications for dialysis? Earlier RRT initiation may allow for prevention of fluid overload or improved fluid management, minimizing risk of hyperkalemia, and/or improved acid-base and azotemia control [18, 60]. Mitigating and minimizing these AKI complications may have an important impact on nonrenal organ function such as improved pulmonary function, faster liberation from mechanical ventilation, and improved vascular and cardiac function.

It is widely accepted in the critical care literature that fluid overload portends poor ICU prognosis and associates with organ dysfunction and impairment of organ and patient recovery through a variety of putative mechanisms. This association is independent of kidney functional status and more pronounced in patients with AKI, where fluid overload is consistently associated with mortality and lower renal recovery rates [61–64]. Studies by Bouchard et al. [63] and Vaara et al. [64] demonstrated that the presence of fluid overload at the time of acute RRT initiation for AKI doubles the risk of death. Additionally, both studies showed a dose-response relationship whereby a higher percentage of fluid overload led to progressive increase risk of death [63, 64]. When defining early versus delayed acute RRT on the basis of time from ICU admission to RRT initiation (within 2 or >2 days from ICU admission), in a retrospective review of the SOAP (Sepsis Occurrence in Acutely Ill Patients Study) study, Payen et al. showed improved survival in the early

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

RRT initiation group and that the delayed group had higher cumulative fluid balance at the time of RRT initiation [65]. In patients with AKI due to ATN requiring acute RRT, a higher degree of fluid overload at RRT initiation was associated with worse kidney recovery (RRT-dependence) at 1 year [61]. Similary, Woodward et al. showed that in critically ill patients with AKI requiring CRRT, fluid overload >10% at the time of CRRT initiation was independently associated with major adverse kidney events (composite of mortality, RRT-dependence or inability to recover 50% of baseline eGFR (estimated glomerular filtration rate) if not on RRT) evaluated up to 90 days after discharge [66]. However, it should be recognized that while these observational data are hypothesis-generating, there have been no randomized trials demonstrating that early initiation of RRT to optimize fluid overload decreases mortality or promotes organ recovery.

Early Acute RRT Initiation

Prior meta-analyses including RCTs, prospective observational trials, and retrospective trials have suggested an improved survival with earlier initiation of dialysis [67, 68]. Following these meta-analyses and published nearly simultaneously with the AKIKI trial in 2016, Zarbock et al. in the Effect of Early vs Delayed Initiation of Renal Replacement Therapy on Mortality in Critically Ill Patients With Acute Kidney Injury [ELAIN] trial [69] performed a single-center RCT comparing preemptive versus conventional dialysis initiation for AKI in ICU patients. There are some important trial design differences between ELAIN, AKIKI, and IDEAL-ICU that warrant discussion. Most importantly, the inclusion criteria for ELAIN began with patients who had developed KDIGO stage 2 AKI with evidence of ATN despite optimal fluid resuscitation [69]. Participants were required to have ongoing catecholamine infusion requirements at time of enrollment, severe sepsis, refractory fluid overload, or a nonrenal Sequential Organ Failure Assessment (SOFA) score of 2 or higher [69]. This difference in AKI stage at enrollment (stage 2 in ELAIN and stage 3 in AKIKI/IDEAL-ICU) suggests that patients in ELAIN may indeed have received "preemptive" dialysis in the early RRT group. Additionally, the study mandated that all patients receive CRRT at the time of RRT initiation with clear, established guidelines to guide transition to intermittent modes of RRT or for discontinuation of dialysis. Finally, nearly all patients in both arms actually received dialysis.

In ELAIN, subjects were randomized to the early RRT group (starting within 8 hours of reaching stage 2 AKI and enrollment) or the delayed RRT group (starting within 12 hours of stage 3 AKI or an absolute indication [BUN >100 mg/dl, potassium >6 mEq/l, magnesium >8 mEq/l, severe oliguria, or diuretic-resistant organ edema]) [69]. As a single-center study, the total number enrolled was lower than either AKIKI or IDEAL-ICU, with ELAIN enrolling 231 subjects, 112 in the early group and 119 in the delayed group [69]. The primary outcome was 90-day mortality, which was 39.3% in the early group and 54.7% in the delayed group ($P = 0.03$), with a hazard ratio for death of 0.66 (95% confidence interval [CI] 0.45–0.97) for the early group [69]. However, in ELAIN, the median time difference from meeting full eligibility criteria to RRT initiation was only 21 hours (95% CI 18–24 hours) [69]. At a minimum, this begs the question as to whether a 15% absolute risk reduction for death in the early RRT arm of the study can realistically be plausible with such a short time difference between early versus late RRT initiation strategy.

Timing of Dialysis Initiation: Trial Limitations

As illustrated above, there are important limitations in many of the trials performed to date. Additionally, almost all trials have used some version of a creatinine- or urea-based definition of AKI as an inclusion criterion for the study. Given that fluid balance, acidemia, or electrolyte disturbances often drive decision-making and that azotemia is rarely the sole criterion for RRT initiation in the ICU, enrolling patients into clinical trials regarding the timing of RRT solely on the basis of meeting urea- or creatinine-based AKI definitions excludes patients from consideration who do not meet these AKI definitions yet still have indications for RRT such as diuretic-resistant fluid overload. No RCTs to date have evaluated RRT initiation on the basis of fluid balance or diuretic responsiveness alone.

Second, significant heterogeneity exists in study design and definitions of early versus late RRT: what is "early" in one trial may be "late" in another. For example, the early dialysis group in AKIKI [58] and IDEAL-ICU [59] and the late group in ELAIN [69] were determined by the same criterion: stage 3 AKI without complications.

Third, the mode of RRT at initiation varies widely between trials and even within some trials. While the RRT options are varied between studies, the choice of RRT modalities is generally balanced between early and late groups within a given trial in most circumstances. However, relative rates of use of intermittent and continuous therapies as initial RRT modalities should be considered in evaluating the applicability of trial results to individual practice settings where modality utilization may differ.

The largest multicenter, multinational trial, entitled Standard vs. Accelerated Initiation of RRT in Acute Kidney

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Injury (STAART-AKI), is still enrolling but does bear some of these same study design limitations. However, in general, the inclusion criteria for STAART-AKI starts with stage 2 AKI, requires equipoise by the healthcare team in regards to RRT need, and does not mandate initiation of RRT solely by stage 3 AKI criteria.

Timing of Dialysis: Summary

Unfortunately, data remain inconclusive to clearly guide clinical decisions at the bedside. Recognizing this limitation, the KDIGO AKI criteria suggest that clinicians should "consider the broader clinical context, the presence of conditions that can be modified with RRT, and the trends of laboratory tests. . . when making a decision to start RRT" [54]. However, one should keep in mind that these guidelines predate the publication of AKIKI, ELAIN, and IDEAL-ICU trials. While KDIGO AKI guideline review and revisions are ongoing, it would seem that these more recent studies do not argue substantially to change from the recommendation to "consider the broader clinical context of the individual patient" when weighing whether or not to timely initiate acute RRT.

In 2017, Feng et al. published a meta-analysis of nine RCTs on the timing of dialysis, which included the AKIKI trial but not IDEAL-ICU, that found no statistical difference between trials [70]. More recently, Pasin et al. reported a metanalysis including ELAIN, AKIKI, and IDEAL-ICU that concluded that early initiation of RRT in critically ill patients with AKI does not provide a clinically relevant advantage when compared with late RRT initiation [71]. Importantly, this study also points out the heterogeneity in the "early" and "late" initiation of RRT definitions and the need for specific studies in special populations such as sepsis or post cardiac surgery as well as the examination of performance and quality metrics of different RRT modalities in future interventional studies.

The Acute Dialysis Quality Initiative (ADQI) recommends a similar, individualized approach to RRT initiation whereby the demands on renal function and renal capacity are weighed with RRT initiated when significant discordance is seen between renal capacity/capability and demands on kidney function [18]. Critically ill patients have high "renal demands," frequently with significant burdens attributable to disease-related acidemia, fluid management, small solutes and electrolytes, and medication and toxin clearance. However, admittedly it remains difficult to determine which patients may benefit from early application of RRT versus a more patient, deliberate strategy with close observation [72]. Additionally, it remains challenging to predict which patients will need acute RRT and which are destined recover renal function without dialysis. Chawla et al. showed that failure to respond to a formal furosemide stress test (FST) predicted stage 3 AKI and the need for acute RRT (area under the receiver operating characteristic curve, 0.87 and 0.86, respectively) [73]. In a pilot trial that randomized FST nonresponders to early versus conventional RRT initiation, Lumlertgul et al. demonstrated that in ICU patients with AKI, those who responded to the FST had a very low rate of acute RRT needs (only 6/44 responders required RRT) [74]. Renal biomarkers may prove useful to predict RRT needs. Urine tissue inhibitor of metalloproteinase 2 and insulin-like growth factor-binding protein 7 (TIMP-2*IGFBP-7) can risk-stratify those at high risk for progression to severe forms of AKI, with higher values (>2.0) strongly associated with development of stage 3 AKI [75–77]. Research is needed to determine if TIMP-2*IGFBP-7 results or trends over time can discriminate patients who will and will not require RRT, as well as hard outcomes such as death or RRT-dependence.

Dose of Renal Replacement Therapy in AKI

The goal of RRT for AKI management is to optimize solute control and fluid balance according to the specific needs of the patient. It is important to recognize that the dose of RRT is a dynamic metric that should be individualized according to the clinical context of the patient, but should also adhere to best evidence-based practice once the patient achieves a steady-state of solute and volume control.

Intermittent Hemodialysis Dose in AKI

There are limited data regarding the "adequate" per treatment dose of IHD in AKI. Paganini et al. retrospectively evaluated mortality in relation to the delivered dose of HD in critically ill patients with AKI [78]. Among patients at either the low or high spectrum of severity of illness, HD dose had no impact on patient outcome. However, in patients with an intermediate severity of illness score, the delivery of HD dose in excess of the 50th percentile (Kt/V approximately 1) was associated with lower mortality risk than the delivery of lower doses of HD [78]. While these data are consistent with evidence relating dose of IHD to outcomes in patients with end-stage kidney disease receiving maintenance hemodialysis, it should be recognized that these observational data cannot differentiate between the dose of HD per se and patient-specific factors that limited the delivered dose of therapy as the mediator of the increased mortality associated with the lower delivered dose of HD.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. In a study evaluating the effect of treatment frequency of IHD on outcomes among patients with AKI, Schiffl et al. alternately assigned 160 critically ill patients with ATN to daily or alternate-day IHD and found that patients who received daily IHD had both lower mortality 14 days after discontinuation of RRT (28% vs. 46%, $P = 0.01$) and shorter duration of AKI (9 ± 2 vs. 16 ± 6 days, $P = 0.001$) [79]. However, it is important to note that the dose of IHD delivered to the alternate-day treatment group was low (mean delivered Kt/V_{urea} 0.94 ± 0.11). This resulted in a markedly elevated time-averaged BUN concentration, which may have been the reason that this group had a higher incidence of complications, including gastrointestinal bleeding, alterations in mental status, and sepsis [79]. In addition, the alternate-day IHD group had more episodes of intradialytic hypotension when compared to the daily IHD group: 25 ± 5 vs. 5 ± 2, respectively. Nonetheless, while this study demonstrated that increasing the delivered dose of IHD from a very low dose by increasing the frequency of treatment improves survival, one cannot conclude that increasing the frequency of a more "adequate" alternate-day or a thrice-weekly schedule to daily therapy would improve survival.

When examining data related to dose of IHD for AKI, it is important to recognize that several studies have established that there is a significant discrepancy between prescribed and successfully delivered dose, therefore more frequent monitoring of the delivered dose of IHD with pre- and post-BUN is recommended [79–81].

In summary, when evaluating the dose of IHD, both the dose per treatment (Kt/V_{urea}) and the treatment frequency need to be considered. Special considerations in critically ill patients with AKI should be noted, such as different urea generation rates and urea volume of distribution due to volume overload. The KDIGO consensus guidelines recommend a delivered Kt/V_{urea} of 3.9 per week when using IHD for the management of AKI [54]. However, this recommendation is based on the arithmetic sum of a Kt/V_{urea} of 1.3 per individual HD treatment (assuming three HD sessions per week and supported by the average weekly Kt/V_{urea} dose delivered in the less-intensive arm of the ATN trial [82]) but not on urea kinetic modeling [83]. Therefore, a more precise recommendation is that in the absence of specific medical indications (e.g. severe hyperkalemia, acute drug intoxications, volume overload, etc.) in patients with AKI, there is no additional benefit to providing HD more frequently than every other day, with a delivered single-pool Kt/V_{urea} of >1.2 per treatment (urea-reduction ratio [URR] >0.67) [84].

CRRT Dose for AKI

In the case of CRRT, the total effluent rate (ml/kg/h) is used to determine the dose according to the different modalities of CRRT (Table 13.3). There is no consensus in relation to which patient's weight to use (admission weight, ideal weight, or current weight) but we tend to use current weight to account for the acute changes in volume of distribution from fluid expansion (during critical illness and resuscitation for shock) and systemic inflammation.

There are more data regarding the appropriate dosing of CRRT in the literature (Table 13.4). Early work by Ronco et al. randomized 435 patients to one of three CVVH doses, defined by ultrafiltration rates of 20, 35, and 45 ml/kg/h [2]. Mortality was markedly lower in the intermediate- and high-dose arms (43% and 42%, respectively) compared to the low-dose arm (59%, $P < 0.001$). The absence of a survival benefit of high-dose therapy compared to the intermediate dose argued against a linear relationship between dose and outcome. However, it is also possible that a survival benefit from high-dose CRRT was blunted by a competing mortality that was CRRT-dose dependent (i.e. inadequate antimicrobial drug dosing). Similarly, Saudan et al. reported an overall improved mortality when dialysate (CVVHDF) was added to a fixed dose of CVVH thereby increasing the total CRRT dose [86]. In this study, a total of 102 patients were randomized to receive CVVH with a mean ultrafiltration rate of 25 ± 5 ml/kg/h, and 104 patients were randomized to CVVHDF with a mean ultrafiltration rate of 24 ± 6 ml/kg/h and a mean dialysate flow rate of 18 ± 5 ml/kg/h. The addition of diffusive clearance was associated with an increase in 28-day survival from 39% to 59% ($P = 0.03$) and increased 90-day survival from 34% to 59% ($P = 0.0005$). In contrast, Bouman et al. did not observe improvement in mortality with higher doses of CRRT (20 vs. 48 ml/kg/h) [85]. However, the overall study mortality of less than 30% suggests that the enrolled patients were not fully representative of most critically ill patients with AKI requiring RRT. Finally, Tolwani et al. reported no difference in outcomes in 200 patients randomized to

Table 13.3 Total effluent dose according to the different modalities of CRRT.

CRRT modality	Total effluent dose (ml/h)
CVVH or CVVHF	Pre-filter replacement fluid rate (ml/h) + post-filter replacement fluid rate (ml/h) + fluid removal rate (ml/h)
CVVHD	Dialysate rate (ml/h) + fluid removal rate (ml/h)
CVVHDF	Pre-filter replacement fluid rate (ml/h) + post-filter replacement fluid rate (ml/h) + fluid removal rate (ml/h) + dialysate rate (ml/h)

CVVH or CVVHF, continuous veno-venous hemofiltration; CVVHD, continuous veno-venous hemodialysis; CVVHDF, continuous veno-venous hemodiafiltration.

Table 13.4 Interventional studies examining higher vs. standard intensity dose of RRT.

Study	Participants	Interventions	Population	Mortality	AKI recovery
Ronco [2]	425	CVVH 20 vs. 35 vs. 45 ml/kg/h	75% post surgical, 12% septic	59% vs. 43% vs. 42% ($P < 0.002$)	
Bouman [85]	106	CRRT 20 vs. 48 ml/kg/h	58% post cardiac surgery, 100% respiratory failure, 100% inotrope or pressors	31.2% vs. 25.7% (P = ns)	No difference
Saudan [86]	206	CVVHF 25 ml/kg/h vs. CVVHDF 42 ml/kg/h	60% septic	61% vs. 41% ($P = 0.03$)	
Tolwani [87]	200	CVVHDF 20 vs. 35 ml/kg/h	54% septic, 77.5% respiratory failure	44% vs. 51% (P = ns)	
Palevsky (ATN) [82]	1124	CVVHDF 20 vs. 35 ml/kg/h IHD 3/wk HD vs. 6/wk HD	63% septic, 80.6% respiratory failure	51.5% vs. 53.6% ($P = 0.47$)	No difference
Bellomo (RENAL) [88]	1508	CVVHDF 25 vs. 40 ml/kg/h	49.4% septic, 73.9% respiratory failure	44.7% vs. 44.7% ($P = 0.99$)	No difference
Joannes-Boyau [89]	140	SVHF 35 vs. HVHF 70 ml/kg/h	100% septic, 97% respiratory failure	59.2% vs. 62.1% ($P = 0.94$)	No difference
Combes [90]	224	HVHF 80 ml/kg/h + CVVHDF vs. SOC with CVVHDF if needed	Post cardiac surgery with severe shock	36% vs. 36% (P = ns)	No difference

CVVH or CVVHF, continuous veno-venous hemofiltration; CVVHDF, continuous veno-venous hemodiafiltration; HVHF, high-volume hemofiltration; IHD, intermittent hemodialysis; SOC, standard of care; SVHF, standard-volume hemofiltration. P = ns, nonsignificant.

CVVHDF at 20 vs. 35 ml/kg/h of total effluent dose [87]. Survival to ICU discharge or 30 days, whichever was earlier, was 49% in the patients randomized to the higher dose group, compared to 56% of patients randomized to the lower dose group.

Subsequently, two large multicenter studies evaluated dosing of RRT in AKI: the VA/NIH Acute Renal Failure Trial Network (ATN) study [82] and the Randomized Evaluation of Normal versus Augmented Level (RENAL) Replacement Therapy study [88]. The ATN study utilized a strategy that included both HD in hemodynamically stable patients and either CVVHDF or SLED/PIRRT in hemodynamically unstable patients [82]. In the intensive management strategy, HD and SLED/PIRRT were provided daily (except Sunday), and CVVHDF was provided with a total effluent dose of 35 ml/kg/h; in the less-intensive strategy, HD and SLED/PIRRT were provided every other day (except Sunday), and CVVHDF was dosed at 20 ml/kg/h. In both treatment arms, the target delivered single-pool Kt/V_{urea} for HD and SLED/PIRRT was 1.2–1.4 per treatment, with an actual delivered dose during HD of 1.32 ± 0.36. Sixty-day all-cause mortality was 53.6% in the 563 patients randomized to intensive therapy, compared to 51.5% in the 561 patients randomized to the less-intensive therapy (OR 1.09, 95% CI 0.86–1.40, $P = 0.47$). There was also no difference in the duration of RRT, recovery of kidney function, or the course of nonrenal organ failure [82].

The RENAL study randomized 1508 critically ill patients with AKI to a higher intensity CVVHDF ($n = 721$, total effluent dose of 40 ml/kg/h) vs. a lower intensity CVVHDF ($n = 743$, total effluent dose of 25 ml/kg/h) without an option for IHD/PIRRT as initial RRT modality [88]. There was no difference in the primary end-point of 90-day mortality (44.7% in each group, $P = 0.99$). In addition, no differences in 28-day mortality, RRT-dependence, total days of RRT, or nonrenal organ failure were found [88]. A post hoc study of extended follow-up (median of 43.9 months) did not reveal a difference in mortality or RRT-dependence between these two intensity strategies of CRRT dosing [91].

Joannes-Boyau et al. conducted a multicenter randomized trial including 137 critically ill patients with septic shock and AKI to evaluate even higher doses of continuous hemofiltration [89]. The study tested standard-volume hemofiltration (SVHF, $n = 71$, 35 ml/kg/h) vs. high-volume hemofiltration (HVHF, $n = 66$, 70 ml/kg/h) for a 96-hour period based on the hypothesis that HVHF may improve hemodynamics and mortality in critically ill septic patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. by improving removal of sepsis-related pro-inflammatory cytokines, but the results showed no difference in the primary end-point of 28-day mortality (SVHF 59.2% vs. HVHF 62.1%, $P = 0.94$). There was also no difference in secondary outcomes that included 60-day and 90-day mortality, duration of mechanical ventilation, duration of RRT, kidney recovery, and length of hospital stay [89]. A subsequent metanalysis by Clark et al., including four randomized trials, concluded that insufficient evidence exists of a therapeutic benefit for routine use of HVHF for critically ill septic patients with AKI [92]. In a more recent study, Combes et al. conducted a multicenter randomized trial including patients with post-cardiac surgery severe shock to test early HVHF ($n = 112$, 80 ml/kg/h × 48 hours, followed by standard-dose CVVHDF until resolution of shock and recovery of kidney function) vs. standard of care with delayed CVVHDF only for persistent/severe AKI ($n = 112$) [90]. Again, there was no difference in 30-day mortality between groups (36% for both groups). There was also no difference in the secondary outcomes of 60-day and 90-day mortality, ventilator-free days, kidney recovery, and length of hospitalization [90]. However, it is important to note that 43% of the subjects in the standard of care arm did not receive any RRT. In addition, patients in the HVHF arm had more frequent hypophosphatemia, metabolic alkalosis, and thrombocytopenia [90].

In summary, although some small single-center studies have suggested that increased intensity of RRT is associated with improved outcomes, this approach is not supported by data generated from large multicenter studies. Differences between study results most likely reflect differences among study designs (delivered RRT dose, timing of RRT initiation, etc.) and study populations (acuity of critical illness, presence of sepsis, etc.). Wang et al. conducted a meta-analysis of seven randomized clinical trials addressing higher versus standard intensity dose of RRT and concluded that higher intensity RRT does not affect mortality outcomes [93]. However, the authors highlighted that more participants assigned to higher intensity RRT remained dependent on RRT at 28 days (29.7% for the higher intensity group vs. 24.9% for the standard intensity group, relative risk of 1.15, 95% CI 1.00–1.33, $P = 0.05$) [93]. Nonetheless, one should note that kidney recovery (RRT-dependence) was a secondary outcome in all the interventional studies included in this meta-analysis and there may be ascertainment bias of the outcome as higher intensity RRT lowers solute burden and thus possibly reduces solute-driven urine output, which is one of the cornerstone metrics of kidney recovery examination.

As seen with IHD, there is usually a discrepancy between prescribed versus true delivered CRRT dose due to CRRT down time (circuit failures, CRRT therapy fluid bag changes, and procedures, imagining studies or surgery that require temporarily stopping CRRT). Based on the research in CRRT dose, for most critically ill AKI patients, an effective delivered dose 20–25 ml/kg/h is recommended [11, 54, 94]. However, to account for this CRRT down time, it is reasonable to prescribe 25–30 ml/kg/h of total effluent dose for CRRT. Finally, it is critical to recognize that the effluent dose of CRRT should be individualized according to the specific needs of the critically ill patient, who may benefit from higher intensity CRRT in specific scenarios such as severe metabolic acidosis, severe hyperkalemia, or severe hypercatabolic states that require higher intensity solute control. Therefore, it is fundamental to develop a systematic way of iterative assessment and adjustment of RRT goals according to the clinical status of the patient [95].

PIRRT/SLED Dose in AKI

Dosing of dialysis in PIRRT is less well established. It remains unclear which index is best to guide dose in PIRRT (URR, Kt/V_{urea}, effluent flow) [96]. As with IHD and CRRT, PIRRT therapy should be individualized to patients needs to accomplish the specified daily RRT goal (correction of hyperkalemia, acidemia control, fluid removal). Similarly, there are no data to support prolonged exposure to high-dose PIRRT. One option to determine a PIRRT prescription when transitioning from a CRRT device is to first decide on the effluent dose that one would use for that given patient on CRRT (i.e. 25 ml/kg/h, 35 ml/kg/h, etc.), then calculate the total daily effluent needs for the patient based on that CRRT dose (i.e. 30 ml/kg/h × 80 kg = 2400 ml/h × 24 h = 72 000 ml/day = 72 l/day). Finally, divide total effluent needs by the number of hours that PIRRT is planned to give hourly effluent flow rates on PIRRT (72 l/day/10 h = 7.2 l/h = 120 ml/min) [22]. If using a standard HD device, customizing the PIRRT prescription to achieve a Kt/V_{urea} of ~0.7–0.9 per treatment for a total of six treatments per week can provide a weekly Kt/V_{urea} of 3.0–3.5 based on urea kinetic modeling [83], which is above RRT dosing thresholds although data are still limited to provide more conclusive recommendations with the use of PIRRT.

It is important to remember that PIRRT will have widely variable impacts on drug dosing of dialyzable drugs, especially important for antimicrobial agents. Duration of PIRRT, flow rates in PIRRT, and fluid removal during PIRRT will all impact a given drug's pharmacokinetics (PK). There are expanding PK data for many antimicrobials during PIRRT; however, these data are generally based on small PK studies and require that PIRRT be operated under the exact operating characteristics that are described in the published research protocol.

RRT Circuit Considerations

When prescribing and managing acute RRT in AKI, there are many factors beyond the RRT modality, timing of RRT initiation, and RRT dose to consider and that do often affect whether RRT application proves successful at achieving the specified daily goal. These circuit-based factors include dialysis vascular access, use of convective versus diffusive clearance, type of membrane, circuit anticoagulation (especially for CRRT), medication dosing, and many others. We will conclude by addressing some of these topics briefly.

Dialysis Vascular Access

Hemodialysis vascular access is of paramount importance when providing acute RRT for AKI. Insertion is often the rate-limiting step to RRT initiation and poorly functioning vascular access is often the foil of the acute RRT procedure. Given that a well-functioning vascular access is vital for RRT circuit function and, ultimately, being able to achieve the goal-based acute RRT, care must be taken to select the optimal site, appropriate catheter size and length, depth and angle of insertion. If the nephrologist is not the proceduralist for catheter insertion, at a minimum the providers should discuss and agree on these points prior to the procedure to improve the odds of a well-functioning access on initial insertion.

Data to guide catheter insertion remains limited. KDIGO recommends a nontunneled temporary dialysis catheter for RRT in AKI [54]. However, there are cases where AKI recovery is delayed in whom a tunneled longer-term dialysis catheter may be appropriate to lower the rate of catheter-related infection. Additionally, KDIGO recommends varying lengths of catheters depending on site of insertion (internal jugular [IJ] versus femoral) and preferred sites, but these guidelines are not based on evidence and, in our opinion, are inaccurate as the catheter length recommendations are too short and the guidelines eschew the left IJ site [54].

Morgan et al. [97] performed a randomized trial on IJ dialysis catheter length in AKI requiring CRRT comparing shorter versus longer catheters with the goal of achieving a catheter tip in the right atrium (RA) in the long catheter group and superior vena cava position (SVC) in the short group with the primary end-point being CRRT circuit life. Catheter lengths were determined by site and group, with the short catheter group getting 15 cm catheters placed in right IJ veins and 20 cm in left IJ veins (per KDIGO guidelines) and the long catheter group getting 20 cm catheters in right IJ veins and 24 cm in left IJ veins. Positioning of the tip in the RA was achieved in 81% of the longer catheter group and only 9% of the shorter catheter group. Mean CRRT circuit life was prolonged by 6.5 hours (24 vs 17.5 hours, $P = 0.001$) and dialysis delivery was more effective (91% of dialysis dose delivered vs 81%, I = 0.001) in the longer catheter group [97]. There were no differences in complication rates, including rates of atrial fibrillation. RA (or caval atrial junction) insertion is safe with current soft catheter materials and design and there is a very low rate of vascular or atrial erosions due to dialysis catheters [97]. Our and other centers' experience mirror the results of the Morgan study. As a result, we recommend use of catheters that are placed as far distally as possible, with a goal that the tip be at the caval atrial junction or in the right atrium when using the IJ insertion site. Catheters placed in the right IJ vein are preferred as they have a straighter intravascular course and are associated with fewer complications; however we differ from KDIGO in that we favor properly positioned left IJ vein catheters over catheters in the femoral veins.

The KDIGO preference of femoral over left IJ sites is based on older trials where left IJ catheters were unquestionably too short [54]. For example, the Cathedia study group found comparable small solute clearance and similar catheter and dialysis circuit function comparing IJ venous (primarily right) to femoral venous access [98]. However, this study did not specify catheter length or size and 100% of IJ catheters were less than 20 cm in length (usually 16 cm) and no comment was made regarding ultimate catheter tip position. This suggests that the performance of the IJ catheters may have been worse than had they used a longer catheter. Furthermore, in this study, 30% of catheters in the IJ group were placed on the left side, where they still used relatively short catheters (<20 cm), which likely contributed to worse left IJ catheter performance compared to the right IJ and femoral sites [98].

Finally, in a separate study, the Cathedia study group compared infection rates between IJ and femoral vascular access sites, demonstrating that catheter-related infection rates were similar between IJ and femoral sites [99]. However, prespecified subgroup analysis did suggest that infection rates were different in the group with the highest quartile body mass index (BMI) which was BMI > 28 kg/m^2 [99]. Thus, caution is warranted when selecting catheter site for those with BMI > 28 kg/m^2, which is common in US-based ICUs.

Dialyzer Membranes

In the modern era, all membranes used for acute RRT in AKI are high-permeability, high-flux, biocompatible membranes, especially for CRRT, where each device manufacturer generally has a limited selection of membranes.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

With IHD and PIRRT (and with some CRRT machines), the clinician is theoretically free to select from a wider array of membranes available in a given country. However, in practice, a given institution only carries a few options and these are almost always the standard high-flux, highly permeable, biocompatible, artificial, noncellulose based membranes. The typical membrane materials are polyacrylonitrile (AN69), polyarylethersulfone (PAES), and polyethersulfone (PES). There are no data suggesting that one type of membrane provides improved outcomes.

There are copious preclinical and human case series reported from outside of the Unites States on specialized membranes and adsorption devices for selective cytokine, endotoxin or other toxin removal, especially in sepsis, but these specialized membranes are generally not approved for use outside of research studies.

Dialysis Fluids/Solutions and Buffers

With all modes of RRT (IHD, PIRRT, CRRT) there is a wide variety of commercially available dialysis solutions for both dialysate and replacement fluids with varying electrolyte concentrations. Solutions (especially for CRRT) can alternatively be customized and compounded in a given hospital. However, there is a risk of compounding errors and bacterial contamination inherent with compounding large quantities of CRRT fluids [100]. As a result, we recommend the use of commercial solutions. Most commercially available solutions are primarily bicarbonate-buffered solutions, with near abandonment of lactate or acetate as the primary buffer over the last 20 years.

Anticoagulation Strategies

An important advantage of IHD and PIRRT is that the use of anticoagulation is usually not required. However, anticoagulation for CRRT circuit survival is strongly encouraged by KDIGO and we agree [54]. CRRT circuit survival with anticoagulation is improved when using heparin, regional citrate anticoagulation (RCA), direct thrombin inhibitors, and other strategies [101–107]. Systemic anticoagulation with heparin, low-molecular weight heparins, and direct thrombin inhibitors obviously carries risk of systemic bleeding. RCA is well proven in CRRT and has been shown to have superior circuit survival effects when compared to both heparin and no anticoagulation with no systemic bleeding risk and few complications that are easily prevented (i.e. systemic hypocalcemia) with attention to established protocols [101–107]. KDIGO endorses the use of RCA in CRRT for patients both with and without increased bleeding risks [54].

Summary

AKI requiring RRT is common and increasing among hospitalized patients, especially among patients with concomitant critical illness. Generally, prolonged therapies (CRRT and/or PIRRT) are preferred for the most vulnerable and critically ill patients. Care must be taken to individualize the timing of RRT initiation and the dose of RRT to accentuate the benefits of RRT while minimizing the potential harms such as anticoagulation, impacts on drug clearance (especially antimicrobial agents), and nutrition. Finally, we strongly encourage a multidisciplinary goal-driven approach to each day's RRT endeavors. The specific goals for RRT (CRRT, PIRRT, IHD, PD) should be reassessed each day and the RRT plan should be designed to best accomplish the targeted goals (rapid correction of severe hyperkalemia, tailored fluid removal, etc.). Accountability toward achieving the desired goals of therapy should be assured through multidisciplinary quality improvement programs [95]. RRT in patients with AKI continues to be associated with a high mortality rate, but an individualized, dynamic, and goal-driven renal support program could optimize patient outcomes.

GRADE Recommendations

Introduction

The prevalence of kidney disease is rising, with chronic kidney disease (CKD) affecting more than 1 in 10 individuals in Australia, and acute kidney injury (AKI) complicating more than 130,000 hospital admissions each year [1]. Parenchymal renal diseases (glomerular, tubular, or vascular) are leading causes of both CKD and AKI (when pre- and postrenal causes have been excluded), and renal biopsy remains the gold standard method for their diagnosis, assessment of prognosis, and management. There have been many advances in renal biopsy techniques since its inception that have greatly enhanced the success and safety of this procedure. These have included modifications to patient positioning, introduction of real-time imaging guidance, and the use of automated biopsy needles. Performing a kidney biopsy has been shown to change the prebiopsy clinical diagnosis in 44% of cases and to change therapy in 30% of cases [2].

The procedure itself involves the removal of tissue from the renal cortex for histopathological examination by a specialist pathologist. The percutaneous approach is standard, and the procedure is typically guided by ultrasound and performed under local anesthesia, with the patient in the prone position. Both coaxial and noncoaxial needle techniques have been described. Renal biopsy has been found to be safe and efficacious, with an acceptably low risk of complications and with sufficient tissue being obtained in more than 95% of cases [3]. The most common complications are minor and major bleeding, both of which are usually self-limiting and rarely life-threatening. Several risk factors for complications have been identified, including uncontrolled hypertension, coagulopathy, advanced age, and reduced kidney function. The evidence behind Renal biopsy is seen in table 14.1.

Indications

Performing a renal biopsy is warranted if it is needed to diagnose or guide the treatment of a suspected disease which is associated with significant morbidity and/or mortality, if the natural history of the suspected disease can be improved with treatment, and if the treatment for the suspected disease is appropriate for and acceptable to the patient. Renal biopsy is useful to assess the chronicity and activity of a disease, while serial renal biopsy may be performed to assess the natural history or response to treatment. Although there are no defined criteria for performing a renal biopsy, there are many accepted indications:

- *Nephrotic syndrome* is the most frequent indication for renal biopsy. In this setting, biopsy provides information for the diagnosis, staging, and activity of disease [4].
- Persistent proteinuria >1 g per day or persistent proteinuria <1 g per day in the presence of haematuria or renal dysfunction are also common reasons to perform a renal biopsy. In the presence of haematuria, biopsy should only be undertaken after malignancy has been excluded.
- *Systemic diseases with suspected renal involvement* (e.g. systemic lupus erythematosus, multiple myeloma, amyloid) often necessitate renal biopsy to guide decisions surrounding prognosis and treatment.

Table 14.1 Recommendations for renal biopsies.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Education	We recommend that patients and their carers be provided with relevant information regarding the renal biopsy procedure, including why they are having one, and the pre- and post-biopsy complications. It should be provided with clarity and cover the topic in a way that is appropriate for their level of health literacy.	*Low or very low*	Weak [1, 2]
Pre-biopsy medication	We recommend that aspirin is continued in patients with high cardiovascular risk or ceased 3 (to reduce major bleeding) or 7 days prior (to reduce minor bleeding) in patients with low cardiovascular risk. In patients receiving anticoagulation, bridging anticoagulation is recommended in patients with mechanical valves and in those with a high thrombotic risk.	*High*	Strong [3]
	We suggest that desmopressin should be used sparingly and with caution.	*Low or very low*	
Positioning for renal biopsy	We recommend that native renal biopsies be performed in a prone position, that transplant renal biopsies be performed in a supine position, and that biopsies in patients who are obese or who have difficulty lying prone (pregnancy or respiratory difficulty) be performed in the in a supine anterolateral position.	*Moderate*	Weak [4, 5]
Imaging	We recommend that native renal biopsies be performed using real-time ultrasound guidance, with the use of computed tomography localization being used for difficult biopsies.	*Moderate (US guidance)* *Low (CT guidance)*	Weak [6]
Biopsy needles	We recommend the use of spring-loaded 16-gauge needles for native and transplant biopsies.	*Moderate*	Moderate [7]
Post-biopsy care	We recommend strict bed rest following a renal biopsy and a 6-h observation period in patients at low risk of bleeding. Patients at high risk of bleeding should be observed overnight.	*Moderate*	Moderate [8]
	Routine post-biopsy imaging or hemoglobin measurement is not recommended.	*Low (post biopsy tests)*	
Management of bleeding complications	We recommend the use or radiological (glue, gel or coiling) or surgical management to arrest persistent post-biopsy bleeding.	*Low*	Weak

GRADE assessment of the certainty of the evidence (9): High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

- *Unexplained AKI* is an indication for renal biopsy, following exclusion of prerenal or postrenal disease. Glomerulonephritis, interstitial nephritis, and systemic diseases with renal involvement can all present with AKI.
- *Unexplained CKD* may prompt investigation with renal biopsy, although the diagnostic yield is typically low and the risk of bleeding complications is Higher than biopsy of a non disease kidney due to possible smaller and harder to biopsy kidneys. Biopsy in this setting can be useful in assessing the likelihood of disease recurrence following future kidney transplantation.
- *Transplant dysfunction* (impaired biochemical function, proteinuria or hematuria) is another indication for renal biopsy to assess for evidence of allograft rejection, drug toxicity, and recurrence of primary disease.

The decision of whether to proceed with renal biopsy in a diabetic patient can be particularly challenging. Diabetes has become the most common cause of CKD in the western world [5] and diabetic nephropathy can coexist with other causes of parenchymal renal disease. It is currently difficult to predict the degree of diabetic renal injury based on clinical or laboratory findings alone. New-onset nephrotic-range proteinuria or hematuria or a rapidly progressive decline in renal function are common indications for renal biopsy in this population. A recent meta-analysis [6] examining the predictors of nondiabetic kidney disease in 4876 patients across 48 studies

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(range from 3% to 82.9% incidence) found that higher systolic blood pressure, worse diabetes control (worse diabetic control), longer diabetes duration, and the presence of retinopathy reduced the positive predictive value of renal biopsy in diagnosing nondiabetic renal disease.

Contraindications

Absolute contraindications to percutaneous kidney biopsies include coagulopathy and uncontrolled hypertension (>160/100 mmHg). Additional relative contraindications include the presence of small kidneys, hydronephrosis, pyelonephritis, abnormal anatomy (e.g. polycystic kidney disease), a solitary kidney, technical difficulties (patients who are obese, unable to lie flat, or uncooperative), and the special circumstances of pregnancy, amyloid kidney, and the pediatric setting.

When a contraindication to percutaneous renal biopsy exists, alternative methods of obtaining renal tissue can be considered, including open, laparoscopic, and transjugular approaches. These differ in terms of their safety profile and sample adequacy. Open and laparoscopic biopsies are associated with a low risk of bleeding and excellent tissue adequacy, but require general anesthesia and longer recovery time. Sample adequacy is lower with transjugular renal biopsy and there is a risk of contrast-induced nephropathy. Although the reported complication rates of transjugular biopsies are similar to those seen in the percutaneous approach, the baseline risk of individuals clearly differs significantly such that direct comparison of complications rates between the approaches cannot be performed.

Epidemiology

Accurate estimation of the frequency of renal biopsies across the world is particularly challenging. The capacity of a country to perform kidney biopsies, and the number of kidney biopsies performed, will depend on their healthcare infrastructure and the availability of trained practitioners (nephrologists, radiologists, scientists, pathologists). The Global Kidney Health Atlas recently reported that pathological services for renal biopsy were routinely available for 23% of countries, but were rarely or never available in 24% and 14% of countries, respectively. In a recent systematic review of national biopsy registries, regional databases, and single-center cohorts, Fiorentino et al. [6] also found that there was significant variation in the rate of renal biopsies between countries, ranging from 10.8 per million population per year in Romania and Serbia to 215 per million population per year in the United States and Australia. Although hypothesis-generating, their analysis was potentially confounded by their consideration of different time periods (before year 2000 and after), reporting and coding bias, and heterogeneity of the indications for biopsy.

Procedure

Technique

Percutaneous renal biopsies are commonly performed under local anesthetic. Occasionally, in the pediatric setting or in anxious individuals, conscious sedation or general anesthesia is used, which requires the patient to be fasted and monitored closely during and after the procedure. Lignocaine (1% or 2%) is infiltrated from the skin to the renal capsule, and the biopsy needle is advanced along the anesthetized tract. The patient is asked to pause at full inspiration such that the lower pole of the kidney is in contact with the needle tip, and the triggering mechanism of the needle is then released. The lower pole of the left kidney is usually selected for biopsy because it tends to be more caudal and superficial than the right kidney, is away from the major vessels and organs, and is easiest for right-handed operators. Between one and three cores of tissue are sampled and the procedure time is generally between 15 and 30 minutes. No fewer than seven glomeruli and one artery are required for a sample to be considered adequate, while optimally 10 glomeruli and two arteries should be provided for analysis. Real-time evaluation for adequacy by a pathologist or scientist confirms adequate tissue while minimizing the number of passes.

Positioning

Although the percutaneous native renal biopsies were traditionally performed in an upright position, they are now routinely performed with the patient in the prone position, often with a pillow or sandbag under the umbilicus, which is used to splint the kidney. The lateral decubitus position is another possible approach, which has not been found to be different to prone positioning in terms of procedure time or risk of complications [7], but may be more comfortable for some patients, especially those who are unable to lie prone (e.g. during pregnancy). Transplant biopsies are routinely performed in the supine position; the supine anterolateral approach may be appropriate in obese patients. In the setting of kidney transplants, consideration should be given to whether the transplanted kidney is located in the intraperitoneal (e.g. simultaneous kidney pancreas transplant) or extraperitoneal space.

Imaging Guidance

Historically, renal biopsies were done blind or by palpation. However, with the widespread availability and ease of use of imaging techniques, ultrasound-guided renal biopsy has become the standard of care for native and transplant kidney biopsies. Ultrasound may be used for real-time

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

guidance or for surface marking and approximating needle direction and depth. Computed tomography (CT)-guided renal biopsy may be considered preferable in obese patients, patients with complicated anatomy, and those with inadequate kidney imaging on ultrasound since it may offer better resolution and tissue contrast. The Caring for Australasians with Renal Impairment (CARI) guidelines [8] have recently summarized the evidence comparing imaging modalities, reporting that ultrasound guidance is superior to blinded renal biopsy with respect to the number of glomeruli, number of passes, and risk of bleeding complications, but there are insufficient data directly comparing CT and ultrasound guidance. Many of the published studies have been confounded by the use of different needle types and historical cohorts.

Needle Size

Although a number of needle sizes are available, the majority of renal biopsies are performed using 14-gauge (internal diameter 900–1000 μm), 16-gauge (internal diameter 600–700 μm), or 18-gauge (internal diameter 300–400 μm) needles. Both 14-gauge and 16-gauge needles are used in adults, while 18-gauge needles are generally reserved for the pediatric setting since the internal diameter of the needle is only marginally larger than an adult glomerulus (200–250 μm) [9, 10]. When selecting a needle size, bleeding risk and sample adequacy are the key considerations. The conclusion from the recently published CARI guidelines was that 16-gauge needles obtained more diagnostic tissue with the smallest number of passes (predominantly compared to 18-gauge needles) and with the smallest number of minor and major bleeding complications (predominantly compared to 14-gauge needles).

Sample Preparation

Preparation of the renal tissue for processing requires provision of clinical information to the scientist or pathologist and careful handling of the tissue. Normal saline should be used to wash the tissue from the needle. The samples are subsequently placed in the appropriate fixatives and transport media for light microscopy, immunofluorescence, and electron microscopy. If no anatomical pathology scientist is present, specimens may be placed in normal saline for transport (assuming sample examination will occur within a couple of hours). For samples being sent to a referral center, tissue can be divided and prepared prior to dispatch. Fresh tissue is required for immunofluorescence to preserve antigenic activity. A sample for electron microscopy should be placed in 3% glutaraldehyde, if available. The remainder of the tissue should be placed in formalin, for light microscopy only.

Practitioner

Although renal biopsy can be performed by a nephrologist, radiologist, or other practitioner, it is well accepted that experienced proceduralists have lower complication rates. In a survey of practitioners in Europe, renal biopsies were performed in 60% of centers by nephrologists, in 30% of centers by radiologists, and in 10% of centers by both [11]. In many countries, competency in performing renal biopsies is a compulsory component of nephrology training. Two-thirds of nephrology trainees in the United States have learned renal biopsy, but few perform it in their consultant practice. Both Australia and the United Kingdom have recommended that learning skills in renal biopsy be part of nephrology training. There is currently no formal accreditation process for nonproceduralists.

Preprocedure Care

Prebiopsy Evaluation

The prebiopsy evaluation is an essential component of the renal biopsy procedure and should include a detailed clinical history and examination in addition to targeted laboratory testing and imaging to evaluate the risk of bleeding. Relevant aspects of the clinical history relate to knowledge and previous experience of renal biopsy, mobility and ability to lie prone, psychological condition, and level of comprehension (e.g. anxiety, confusion, language barrier). Enquiring about the patient's current and recent medications, as well as previous bleeding difficulty following procedures (e.g. dental work) or a history of a bleeding disorder, is important to assess their risk of bleeding. In all cases, written informed consent must be obtained from the patient or their legally authorized representative prior to the procedure. This may necessitate the use of interpreters.

The recently published CARI guidelines [12] have highlighted the significant psychosocial impact of renal biopsy on patients and caregivers, and a qualitative study by the same group identified the need for better communication, education, and pre- and post-procedure psychological support. Similar studies in other percutaneous biopsies (including breast, cervical, liver, and prostate) have reported similar findings. All patients should receive psychological preparation prior to their procedure to ensure a patient-centered, holistic approach to care and to prevent the adverse physiological sequelae of anxiety, including hypertension, a heightened perception of pain, and a delay in recovery time. Ideally, patients should be provided with information regarding the procedure itself, the sensations

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the patient can expect to feel (e.g. sharpness, numbness), and the expected post-procedure recovery (e.g. mobilization, return to normal activities).

Investigations

Investigations should include a full blood count to quantify hemoglobin and platelet count, a coagulation profile to assess activated partial thromboplastin time and prothrombin time, and an ultrasound to diagnose anatomic abnormalities, including a solitary kidney, small or polycystic kidneys, hydronephrosis, and vascular abnormalities. Although abnormal coagulation should be corrected prior to biopsy, there is in sufficient evidence to inform the specific international normalized ratio (INR) and the platelet threshold at which proceeding with renal biopsy is safe. In most published studies, patients undergoing renal biopsy were required to have an INR below or equal to 1.5, and a platelet count greater than 50 000/μl. However, appropriate values should be individualized, taking into account other factors associated with the risk and consequences of bleeding, such as the use of antiplatelet and anticoagulant agents, and the presence of hypertension, uremia, complex anatomy, and anemia. Transfusion should be considered if serum hemoglobin is<80 g/l and is recommended if <70 g/l.

The use of bleeding time in assessing the risk of bleeding complications remains controversial. It is a poor predictor of the risk of surgical bleeding and its clinical benefit in the setting of percutaneous renal biopsy has not been studied. [13]. Although a correlation between bleeding time and "clinical" bleeding in patients with uremia has been reported, prior knowledge of bleeding time has not been shown to reduce bleeding complications in native or transplant biopsies in the limited available studies [14, 15].

Antiplatelet Agents

The use of antiplatelet medications is very common in the renal biopsy population. In many centers, these agents are routinely discontinued between 5 and 7 days prior to the procedure. However, in a patient with preexisting cardiovascular disease this approach increases the risk of a periprocedure cardiovascular event [16], and results in delayed diagnosis and treatment. Specifically, cessation of aspirin has been shown to increase the risk of stroke by three- to fourfold and to increase the relative risk of recurrent myocardial infarction by 40%, especially when performed soon after a myocardial infarct or percutaneous coronary intervention.

Although the continuation of aspirin has been associated with an increased risk of minor bleeding complications (e.g. hemoglobin drop ≥1.0 g/dl), it has not been associated with an increased risk of major bleeding events (e.g. need for transfusion, interventional, or surgical procedure). Therefore, the current recommendation is to continue aspirin in patients at high risk of cardiovascular events, including those with a history of coronary stent (particularly within 3 months of bare metal stent or 12 months of drug-eluting stent insertion), symptomatic myocardial ischemia or peripheral vascular disease (including patients with a peripheral stent), or previous ischemic stroke. In patients at low risk for a cardiovascular event, aspirin should be withheld for 3 or 7 days to prevent major and minor bleeding complications, respectively. There are limited data examining the safety of continuing clopidogrel at the time of biopsy, and most guidelines recommend that it should be withheld for 7 days prior. Aspirin and clopidogrel can be recommenced 24–48 hours after an uncomplicated procedure since most complications will have occurred within this time.

Anticoagulants

In patients who are taking oral anticoagulants there is a need to balance the bleeding risk against the thrombosis risk. Warfarin should be ceased 5 days prior to renal biopsy in all patients. Bridging anticoagulation should be used in all patients with a mechanical valve, antiphospholipid syndrome, high-risk thrombophilia, or venous thromboembolism within 3 months. The role of bridging anticoagulation is less clear in atrial fibrillation. In low-risk patients, interruption of warfarin without bridging anticoagulation appears to be noninferior to the use of bridging anticoagulation for the prevention of thromboembolism [17]. However, these results may not be generalizable to high-risk atrial fibrillation patients, in whom the decision should be individualized according to patient risk. For patients who receive bridging anticoagulation, low molecular weight heparin should be withheld for 24 hours, while unfractionated heparin should be ceased 4–6 hours prior to biopsy. Anticoagulation can be recommenced 24–48 hours following an uncomplicated procedure. For patients requiring hemodialysis, the biopsy should be performed at least 6 hours after treatment (if heparin is administered) and the use of intradialytic anticoagulation should be avoided the following day. It is important to note that there are no data on the effect of new oral anticoagulants on renal biopsy complication rates.

Desmopressin

A heightened risk of bleeding in the context of uremia is well described [18]. It is likely that many factors contribute to this bleeding propensity, including dysfunctional von Willebrand factor (vWF), platelet membrane abnormalities

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and impaired aggregation, anemia, and increased prostacyclin and nitric oxide levels. The use of procoagulants prior to biopsy (e.g. desmopressin acetate) has been suggested as a potential strategy to lessen minor and major bleeding. Desmopressin is a synthetic analog of antidiuretic hormone, which increases platelet adhesion to the blood vessel wall by augmenting plasma levels of factor VII and vWF. It has been shown to normalize bleeding time in uraemia for up to 4–8 hours (Vigano GL, Mannucci PM, Lattuada A, et al. Subcutaneous desmopressin (DDAVP) shortens the bleeding time in uremia. Am J Hematol. 1989;31(1):32–5.] from CARI) when delivered intravenously at a dose of 0.3 μg/kg over a period of 20–30 minutes.

Despite its use in many units, there is little evidence to support the clinical benefit of desmopressin. A single randomized controlled trial of 162 patients undergoing native renal biopsy compared the use of desmopressin to placebo, showing a 16.8% reduction in minor bleeding, but no difference in post-biopsy hemoglobin [19]. Of note, all patients in this study had preserved renal function and normal coagulation, so the generalizability of their findings is unclear. Moledina et al. conducted an observational study of 159 hospitalized adults who underwent native kidney biopsy in the United States to investigate acute kidney disease. After adjustment for blood urea nitrogen, desmopressin was associated with a lower risk of blood transfusion (odds ratio 0.24, 95% confidence interval [CI] 0.06–0.88). In contrast, a retrospective study of 22 renal biopsies in children showed no difference between desmopressin and placebo. The most serious adverse event of desmopressin (severe hyponatremia) is reported in 1 in 10 000 cases, but other symptoms, including hypotension, tachycardia, facial flushing, nausea, and abdominal pain, can also occur [20, 21].

Other treatments, including tranexamic acid, recombinant erythropoietin to achieve a hematocrit >30%, conjugated estrogens, and cryoprecipitate, have not been formally investigated in the setting of renal biopsy. The impact of dialysis on uremic bleeding is also unclear.

Bleeding Prediction Scores

Mejia-Vilet et al. recently developed a score to predict bleeding complications using a high-risk population of hospitalized patients undergoing renal biopsy in Mexico. They found that CKD features on ultrasound, blood urea nitrogen >50 mg/dl, haemoglobin <11 g/l, and platelet count <150/mm^3 were independent predicters of bleeding complications following renal biopsy. The discriminative power of their model was supported in a small, prospective validation cohort, but external validation has not been undertaken.

Post-procedure Care

The post-biopsy period is critical to detection of major complications of renal biopsy, including hemodynamic compromise, macroscopic haematuria, urinary tract obstruction, and severe loin pain. Although mild pain or discomfort is expected post biopsy, severe pain over the site may indicate bleeding. Based on the findings of early studies [22], patients were historically observed overnight following a renal biopsy. However, several advances in the renal biopsy technique have subsequently enhanced the safety of the procedure. The optimal timing of observation after biopsy in the modern day is debatable and should be guided by the likelihood of complications. In general, at least 4–8 hours of observation are recommended following an uncomplicated biopsy in a low-risk patient, but as many as one-third of complications may occur after 8 hours [14]. Almost all complications are detected by 24 hours [23]. For patients at high risk of complications, and for those who live remotely, overnight observation is often warranted.

During this observation time, vital signs are monitored frequently and every voided urine sample is examined for macroscopic hematuria. Unless contraindicated due to fluid restriction, a high fluid intake is encouraged to reduce the risk of clot formation in the urinary tract. Following discharge, patients should be instructed to seek medical attention in the setting of escalating pain, recurrence or worsening of hematuria, or inability to pass urine. Most published protocols also suggest a period of abstinence from intense physical labor, exercise or heavy lifting for 1–2 weeks after a biopsy, but there is no evidence to support this recommendation.

The utility of routine post-biopsy hemoglobin testing or imaging in predicting clinical complications has not been demonstrated. The presence and size of post-biopsy hematomas on routine imaging does not correlate with the development of clinically significant complications [24], although the absence of a hematoma has a high negative predictive value for bleeding. Routine haemoglobin testing and imaging following biopsy are therefore of limited utility in patients who are otherwise asymptomatic.

Complications

The most common complication after renal biopsy is bleeding, which may manifest as hematuria, perinephric hematoma, loin pain, hypotension, or a drop in hemoglobin. Most minor bleeding can be managed conservatively, but moderate bleeding, indicated by severe pain, large perinephric hematoma or hypotension, should be initially managed with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

blood transfusion. In the setting of severe bleeding, with hemodynamic instability and failure to respond to conservative measures, radiological intervention or surgical management is required to secure hemostasis.

Estimating the risk of bleeding complications after biopsy is made difficult by differences in how bleeding is defined and diagnosed between studies, by variation in patient selection, technique, and needle type, and by likely reporting bias. A recent meta-analysis of 118 064 biopsies (87 studies selected) showed complication rates included perinephric hematoma in 11% of the kidney biopsies, macroscopic haematuria in 3.5%, bleeding requiring blood transfusion in 1.6%, and interventions to stop bleeding in 0.3%. Death attributed to native kidney biopsy was rare, occurring in only an estimated 0.06% of all biopsies [25]. Complication rates were higher in hospitalized patients and those with AKI. Recent further reassurance that outpatient biopsy is safe when a low-risk patient group is selected can be seen in a large single-center uncontrolled study of the outcomes of 824 outpatient kidney biopsies (448 native and 326 transplant kidney) with both a minor or major complication identified in 11.4% of patients within 4–6 hours post biopsy [26]. An older meta-analysis of almost 10 000 biopsies [27] reported that macroscopic hematuria occurred in 3.5% (95% CI 0.3–14.5%) of patients, while 0.9% (95% CI 0.4–1.5%) of patients received a blood transfusion and only 0.6% (0.4–0.8%) required angiography. The incidence of perinephric hematoma is likely to be much higher than other reported complications. Based on studies performing CT-guided biopsies in a historical cohort, as many as 91% of patients have evidence of a hematoma on imaging [28].

In the older meta-analysis, the study-level predictors of bleeding complications included the use of 14-gauge needles (compared with 16-gauge and 18-gauge), higher serum creatinine (>2.0 mg/dl), AKI in >10% of cases, a baseline hemoglobin <12 g/dl, a mean age >40 years, and systolic blood pressure >130 mmHg [27]. The safe blood pressure threshold to prevent bleeding is debatable, with most studies and guidelines recommending a maximum acceptable systolic blood pressure of 140 or 160 mmHg.

Other rare complications include arteriovenous fistula formation (0.1–0.5%), infection, pneumothorax, and injury to adjacent organs, including the liver, spleen, pancreas, and colon. Nephrectomy is required after <0.1% of cases and the risk of death is similarly low.

Transplant Biopsies

There are many single-center studies in the literature addressing the safety of transplant biopsy in the contemporary setting of spring-loaded needles and ultrasound localization and guidance. The reported rates of complications tend to be lower than in native biopsy: hematoma in 1%, major and minor bleeding in 2–3%, hemoglobin decline in <1%, and graft loss in <0.04% [29, 30].

Monoclonal Gammopathies and Paraprotein Disease

It has been suggested in historical cohorts that patients with monoclonal gammopathies and paraprotein diseases are at increased bleeding risk (Colm C. Magee Nephrology Dialysis Transplantation, Volume 21, Issue 12, December 2006, Pages 3601–3602, https://doi.org/10.1093/ndt/gfl578). However, large cohort studies have not supported this, except in reporting a higher risk of hemoglobin decrease >1 g/dl [31–33].

Pregnancy

In the setting of pregnancy, the risk of biopsy must be weighed against any potential benefit of diagnosis and treatment, especially considering that treatment options may be limited due to teratogenicity. Renal blood flow is increased in pregnancy, which may increase complication rates, and modification of biopsy technique may be necessary (e.g. patient positioning). A recent systematic review of 39 studies (mostly retrospective case series) of renal biopsies performed during pregnancy or in the perinatal period [34] found that the complication rate was 7% during pregnancy, compared to only 1% after delivery. All major complications occurred during gestational weeks 23–28. Studies in which biopsy was performed for suspected glomerulonephritis or preeclampsia reported that therapy was altered in 66% of cases. Bleeding Complications after Pediatric Kidney Biopsy- A systematic Review and Meta-analysis .Charles D. Varnell, Hillarey K. Stone and Jeffrey A. Welge Clinical Journal of the American Society of NephrologyJanuary 2019, 14 (1) 57-65; DOI: https://doi.org/10.2215/CJN.05890518.

Pediatrics

Renal biopsy in the pediatric setting has the added difficulty of small kidneys and variable patient cooperation. A recently published systematic review of 23 studies including 5504 renal biopsies reported that between 11% and 18% of pediatric patients develop a hemotoma after biopsy, but only 0.9% require a blood transfusion. As few as 0.7% of biopsies resulted in an additional intervention due to post-biopsy complications. Meta-regression suggested that the use of real-time ultrasound guidance did not modify the risk of hematoma or requirement for blood transfusion or further intervention. In general, pediatric biopsies are performed

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with a spring-loaded device and 18-gauge needle [35]. The number of passes should be ≤3 in 80% of cases. There does not appear to be a difference in the rate of complications between inpatient and outpatient procedures.

Conclusion

Renal parenchymal biopsy remains an invaluable diagnostic and prognostic tool for nephrologists, providing key information that can be used in conjunction with biochemical and urinary testing. In modern-day practice with automated, spring-loaded needles and ultrasound guidance, it has very low complication rates and high diagnostic yield, altering patient management in many cases. Developing a patient-centred approach to renal biopsy, with appropriate education and support, will be the next step to further improving the safety and acceptability of the procedure.

Minimal Change Disease and Focal Segmental Glomerulosclerosis in Adults

Yuemiao Zhang and Jicheng Lv

Peking University First Hospital, Beijing, China

Introduction

Minimal change disease (MCD) and focal segmental glomerulosclerosis (FSGS) are the two key forms of idiopathic nephrotic syndrome (INS). In 1999, evidence-based recommendations for treating adult INS were published in *Kidney International* [1]. In 2012, the Kidney Disease: Improving Global Outcomes (KDIGO) Clinical Practice Guideline for Glomerulonephritis published its first guideline on glomerular diseases [2]. A review of the literature shows that our current clinical and pathogenic knowledge of MCD and FSGS has evolved. Increasing studies report that in addition to idiopathic cases, MCD and FSGS could be caused by multiple factors, such as virus infection, allergies, Hodgkin disease, and medications. As such, MCD and FSGS denote histologic findings, rather than two single diseases. Patients with genetic mutations affecting podocyte biology, including slit diaphragm structure, actin cytoskeleton of podocytes, and foot process structure, may develop their first episode of nephrosis as an adult when it does not respond to immunosuppressive treatment. This indicates that some patients with mutations and who fail immunosuppression may explain some of the variability in observed treatment effects in trials. Although corticosteroids and calcineurin inhibitors (CNIs) are still the cornerstone treatments, new insights into pathogenesis and novel treatment options have been developed, targeting the pathogenic process with more efficacy and fewer adverse effects. For example, rituximab (RTX), a monoclonal antibody targeting B cells, is an efficient and safe alternative. A number of new agents targeting pathogenic factors, such as CD80, have now been tried in the treatment of MCD and FSGS (Table 15.1, Table 15.2).

This chapter examines the evidence for management of MCD and FSGS in adults.

Definition

MCD

The definition of MCD has not changed. It presents as nephrotic syndrome of sudden onset. In adults proteinuria is less selective than in children. Hypertension may be present. A functional impaired glomerular filtration rate is common at onset and normalizes with remission. Light microscopy and immunofluorescence show normal glomeruli. Electron microscopy discloses diffuse foot process flattening and no immune deposits.

FSGS

The onset of nephrotic syndrome can be more insidious than in MCD, except in the so-called glomerular tip lesion, a variant whose response to treatment is comparable to that of MCD [3–5]. In other forms, an explosive onset also seems to entail a response to treatment closer to MCD than in more progressive forms, although considerable overlap exists [6]. Hypertension and renal insufficiency are not unusual from the onset. Proteinuria is not selective. A detailed discussion of the histopathology of FSGS is beyond the scope of this chapter but is available elsewhere [7–9]; it is not covered further here because there are no implications for specific treatment [7].

Remission

Complete Remission

There is general agreement regarding the definition of complete remission (CR): 24 hours proteinuria of ≤0.3 g, with serum albumin of ≥3.5 g/dl and stable renal function.

Table 15.1 Treatment of adult minimal change disease (MCD).

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Prednisone/ prednisolone	We recommend that corticosteroids be given for initial treatment of nephrotic syndrome. We suggest prednisone or prednisolone be given at a daily single dose of 1 mg/kg (maximum 80 mg) or alternate-day single dose of 2 mg/kg (maximum 120 mg). The initial high dose of corticosteroids should be maintained for a minimum period of 4 weeks if complete remission is achieved, and for a maximum period of 16 weeks if complete remission is not achieved. In patients who remit, we suggest that corticosteroids be tapered slowly over a total period of up to 6 months after achieving remission. For infrequent relapses, we suggest using the same initial dose and duration of corticosteroids.	Low	Strong (use of corticosteroids) Weak (dose and duration)
Calcineurin inhibitors (CNIs)	For patients with relative contraindications or intolerance to high-dose corticosteroids, we suggest short-term intravenous methylprednisolone (0.8 mg/kg/day for 10 days) + tacrolimus monotherapy (0.05 mg/kg/day for 16–20 weeks) subsequently tapering over approximately 18 weeks. We suggest oral CNIs for relapsed patients despite cyclophosphamide, or patients of childbearing age. Cyclosporine initiates at 3–5 mg/kg/day or tacrolimus 0.05–0.1 mg/kg/day in two equally divided doses. Following 3 months of stable remission, tapered to reach the minimum dose that maintains remission, for 1–2 years.	*Low*	Weak
Cyclophosphamide	We suggest oral cyclophosphamide 2–2.5 mg/kg/day at a single dose as tolerated for 8 weeks for patients with frequently relapsing MCD and with relative contraindications or intolerance to high-dose corticosteroids.	*Low*	Weak
Mycophenolate mofetil	We suggest oral mycophenolate mofetil for patients intolerant to corticosteroids, cyclophosphamide, and/or CNIs. 500–1000 mg twice daily for 1–2 years.	*Low*	Weak
Rituximab	We suggest using rituximab for patients with frequently relapsing or corticosteroid-resistant MCD.	*Low*	Weak

GRADE assessment of the certainty of the evidence: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.

Partial Remission

Partial remission (PR) has been variably defined among publications. An acceptable definition is 24 hours proteinuria of >0.3 and <3 g and/or a decrease of at least 50% from the baseline level, along with a rise of serum albumin of ≥3 g/dl and stable renal function.

Relapse

The definition of relapse also varies among publications. In general it is defined by recurrence of massive proteinuria (24 hours proteinuria of >3.5 g). Frequent relapse (FR) is generally defined as more than two relapses observed over the last 6 months or more than four relapses observed over any 12-month interval.

Steroid Dependent

Steroid dependent (SD) usually referrers to two consecutive relapses during corticosteroid therapy, or within 14 days of ceasing therapy.

Epidemiology

Clinically, FSGS and MCD share numerous similarities, but show different onset age, treatment responses, and prognosis (Table 15.3). MCD is the most common cause of INS, accounting for 70–90% in children under 10 years old and 10–25% in the adult population with an increase in percentage of FSGS [10]. In addition to age, ethnicity is an important predictor of the percentage of nephrotic patients

with MCD. The percentage of nephrotic patients with MCD is highest in Asian and Caucasian populations, while the percentage of nephrotic patients with underlying FSGS is highest in African-American populations. FSGS is the most common form of glomerular histology in North American (19.1%), the second most common in Europe (14.9%) and Latin America (15.8%), and the fifth-most common in Asia (6.9%) [11, 12]. In recent years, the incidence and the prevalence of nephrotic FSGS have steadily risen [13, 14].

Genetic predisposition is proposed in patients with FSGS because of their familial aggregation and the geographic variation in prevalence. Patients of black African ancestry are twice as likely to develop FSGS than patients of white

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

European origin [18]. This is true of most histological variants, especially the cellular variants [19, 20]. The exception is the glomerular tip lesion [3, 4]. The response to corticosteroid treatment in black people is distinctly worse than in white people [21], although the overall outcome of the disease in each race follows the same trend. In recent years, familial cases with MCD have also been described [22], suggesting a possible genetic origin of the disease. MCD and FSGS are characterized by diffuse foot process effacement. As the intricacies of podocyte cell biology have been unraveled, increasing causative genes regulating slit diaphragm structure (nephrin, NPHS2, CD2AP) and actin cytoskeleton of podocytes (MYO1E, myocin IIA, α-actinin-4) have been identified [23–26]. The role of high-risk APOL1 genotypes in the development of glomerulosclerosis is still under investigation. Genetic testing for pediatric nephrotic syndrome and adult FSGS is controversial, and it can be considered for patients with congenital and infantile forms of nephrotic syndrome (children <1 year of age) or less than the two forms but with steroids resistant nephrotic syndrome (SRNS), nephrotic syndrome associated with other syndromic features, or familial forms of SRNS/FSGS [27]. Genetic FSGS is typically resistant to corticosteroids. The value of routine implementation of genetic testing in adults remains to be resolved in the future [28–30].

Pathophysiology

MCD and FSGS are both examples of pathogenic mechanisms that primarily affect the podocyte (podocytopathies). They are not characterized by immune deposits, but there may be a role for circulating factors in the pathogenesis of both diseases. In recurrent FSGS following kidney transplantation, early renal biopsy shows widespread foot process effacement on electron microscopy, hallmarks of MCD, while repeated biopsy suggests evolution to an FSGS lesion [15] or recovery to be normal when translated into a diabetic nephropathy patient [16]. It is an ongoing debate whether MCD and FSGS represent different stages of one disease or are different disease entities [17].

The role of circulating factors has long been suspected in pathogenesis of FSGS due to several clinical observations, including the recurrence of FSGS in post-transplant patients (about 30% in adults), the induction of proteinuria in experimental animals by plasma fractions from FSGS patients, and the improvement of disease course after treatment with plasma exchange (PE), but with little success for searching the responsible factors [31]. In addition, the therapeutic benefits of immunosuppressive agents and RTX which inhibit cell-mediated immunity and the coincidence of INS in Hodgkin's disease indicate the role of immune disorder in MCD and FSGS [32]. Taken together, MCD and FSGS are likely to be systemic disorders, where circulating factors and/or immune dysfunction are the pathogenic culprit, subsequently causing podocyte injury (Figure 15.1).

Putative Circulating Permeability Factors

suPAR

Soluble urokinase-type plasminogen activator receptor (suPAR) has been suggested to be one of the pathogenic circulating factors [33–35]. The urokinase plasminogen activator surface receptor (uPAR) is a membrane-bound glycosyl-phosphatidylinisotol anchored protein present on multiple cells, including podocytes. In podocytes, uPAR could activate αvβ3 integrin signaling, inducing foot process effacement and proteinuria [33]. However, subsequent studies have suggested that suPAR may be a novel prognostic biomarker for chronic kidney disease, but does not appear to represent the permeability factor in FSGS [36].

CLCF1

Cardiotrophin-like cytokine factor 1 (CLCF1) is another candidate circulating factor which was detected in plasma from patients with recurrent FSGS. CLCF1 is a member of the IL6 family of cytokines. CLCF1 circulates as a heterodimeric cytokine, combining with cytokine receptor-like factor 1 (CRLF1) or soluble ciliary neurotrophic factor receptor alpha (sCNTFRa), which is an effector of the Janus kinase (JAK)/signal transducer and activator of transcription (STAT) signaling [37]. In podocytes, CLCF regulates the glomerular filtration barrier function through the JAK/STAT pathway [38]. In isolated rat glomeruli, CLCF1 increased albumin permeability (Palb) and an anti-CLCF1 monoclonal antibody was able to block the CLCF1-induced increase in Palb. Western blot analysis showed that CLCF1 upregulated phosphorylation of STAT3 in glomeruli. Inhibitors of JAK2 and STAT3 significantly blocked the effect of CLCF1 or FSGS serum on Palb. As such, albuminuria in FSGS might be related to qualitative or quantitative changes in the CLCF1-CRLF1 complex, and JAK2 or STAT3 inhibitors may be novel therapeutic agents to treat FSGS.

Anti-CD40 Antibody

The beneficial effects of RTX in MCD and FSGS suggest the role of autoantibodies in disease pathogenesis. By screening autoantibodies in pretransplant sera from 10 patients with recurrent FSGS and 10 without recurrent FSGS, auto-antibodies against 7 target proteins, including CD40 molecule, protein tyrosine phosphatase receptor O, tumor necrosis factor (TNF) receptor superfamily member 6, Chorionic gonadotropin β, Apoliprotein 2, P2Y purinoceptor 11 and Small nuclear retinoid × receptor α, were identified and validated. Among them, anti-CD40 antibody alone had the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

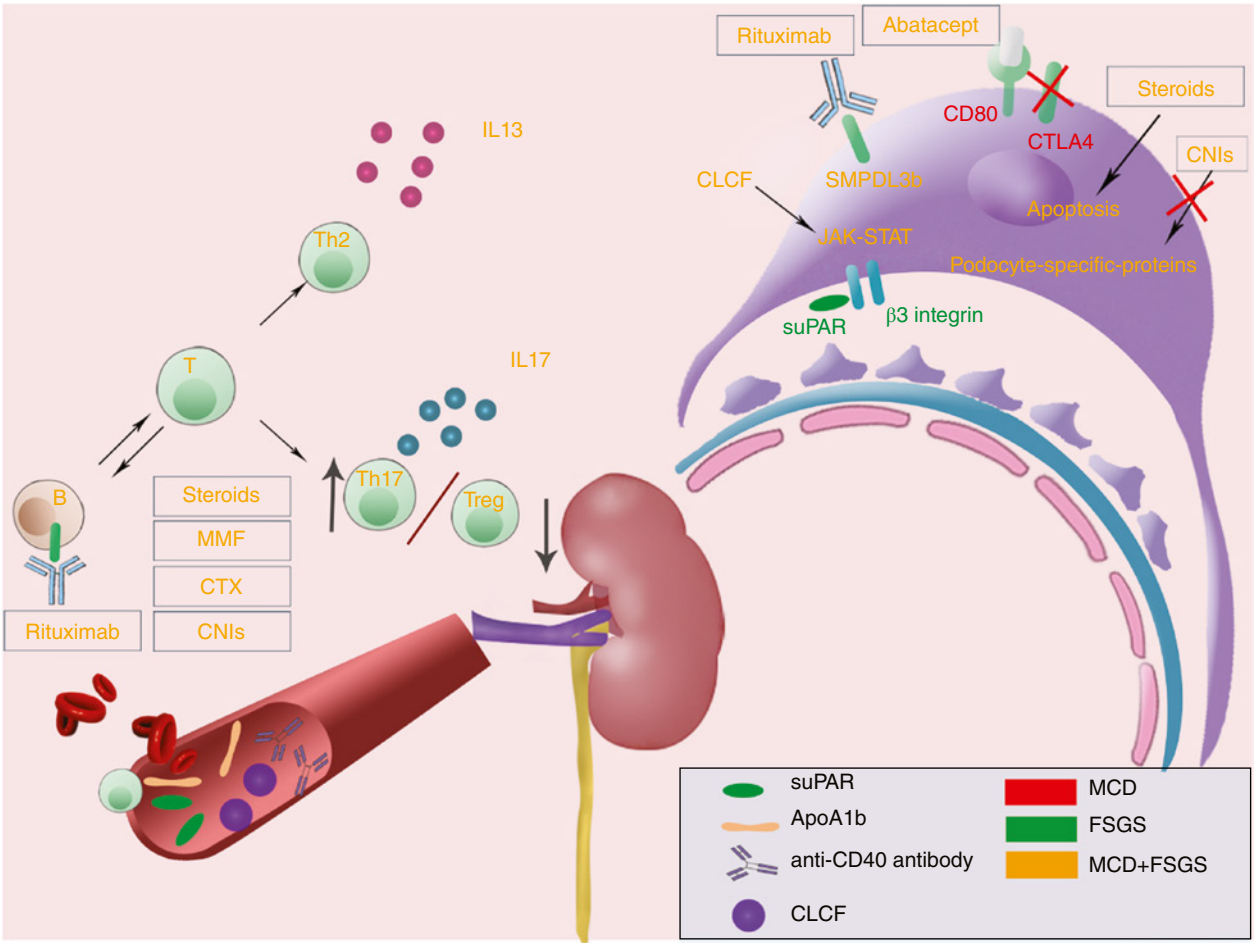

Figure 15.1 Pathogenesis of MCD and FSGS. The podocyte injury caused by circulating factors (suPAR, CLCF, ApoA1b, anti-CD40 antibody) and cytokines (IL13, IL17) secreted by abnormal interactions between T cells and B cells is crucial in disease pathogenesis. Except for their systemic effects, immunosuppressive agents (steroids, MMF, CTX, CNIs) and targeting treatment options (rituximab, abatacept) also show a direct effect on podocyte. Podocyte-related markers and products (CD80, suPAR) can be detected in the urine of patients with MCD and FSGS, providing a noninvasive technique for gathering information about the disease diagnosis and progression. Items mainly involved in MCD are shown in red, in FSGS are shown in green, and in both MCD and FSGS are shown in yellow.

best accuracy of 0.77 in predicting FSGS recurrence. During the phase of remission in recurrent FSGS patients after treatment of RTX plus cyclosporin (CsA), anti-CD40 antibody decreased accordingly. CD40 was stained on podocytes in patients with FSGS but not in normal human kidneys. Anti-CD40 antibody could cause podocyte injury directly by inducing cytoskeletal reorganization both in cultured human podocytes and in wild-type mice. The inhibition effects of monoclonal CD40-blocking antibodies, monoclonal suPAR clocking antibodies, or inhibitor of αvβ3 suggest an interaction between anti-CD40 antibodies and suPAR/β3 integrin pathway [39]. Independent validation in other recurrent FSGS cohorts is needed.

IL-13

The identity of the glomerular permeability factor in MCD has not been determined in humans. Data from animal models have implicated T helper type 2 (Th2)-derived cytokines, particularly interleukin (IL)-13. In rats, systemic overexpression of IL-13 results in albuminuria, hypoalbuminemia, and, on kidney biopsy, up to 80% podocyte foot process fusion by electron microscopy with similar pathologic findings as human MCD. In addition, T cells from patients with nephrotic syndrome spontaneously produce IL-13, while B cells express the IL-13 receptor. T cells from patients with relapsed MCD have increased expression of IL-13 compared with those from patients in remission.

microRNA

microRNAs (miRNAs) are important regulators of gene expression that suppress their target genes. miR-193a was significantly upregulated in isolated glomeruli from FSGS patients. Mechanistically it inhibits the expression of WT1,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a transcription factor and master regulator of podocyte differentiation and homeostasis, which in turn leads to downregulation of genes crucial for the architecture of podocytes, such as podocalyxin (PODXL) and nephrin (NPHS1) [55]. The cause of the increased expression of miR-193a in podocytes of FSGS patients and the miRNA profiles in FSGS and MCD still needs to be addressed.

Immune Disorders

T Cells

Abnormal T cell dysfunction has long been implicated in the pathogenesis of MCD and FSGS. However, no consensus has yet been reached regarding a single cell subset. Some studies have shown elevated levels of IL2, some have suggested a relative predominance of a Th2 cytokine response (IL4), while others reported activation of Th1 cytokine response with increased interferon-γ. Urinary excretion of Th1 and Th2 cytokines cannot discriminate FSGS from MCD. However, urinary Th1 cytokines IL12 was associated with both global sclerosis and interstitial fibrosis, and IL2 and GM-CSF, Granulocyte-Macrophage Colony Stimulating Factor were significantly increased in FSGS patients resistant to treatment. Th2 cytokines, especially IL4, IL5, IL-8, IL10, and IL13, are implicated in frequent relapses of MCD [40, 41]. With the detection of new subsets of T cells, an increased Th17/Treg ratio was determined in adult patients with MCD and FSGS compared to normal subjects, which was associated with proteinuria [42]. Th17 cells are strong candidate drivers for steroid response in immune diseases [43], and the Th17/Treg imbalance returned to normal after effective corticosteroids therapy [42]. Dominance of infiltrating Th17 cells over Treg cells in the renal interstitial was also observed [44].

B Cells

The benefits of B cell-depleting therapy with RTX in MCD add a potential role of B cell in the pathogenesis of MCD. RTX performs its effects through suppressing the interactions between B cells and T cells, and restoring Treg cell populations to keep the Th17/Treg balance normal [45–49]. It also presents direct protective effects on podocyte cytoskeleton stabilization in a sphingomyelin phosphodiesterase acid-like 3b (SMPDL-3b)-dependent manner [50]. It partially prevented SMPDL-3b and ASMase downregulation that was observed in podocytes treated with the sera of patients with recurrent FSGS.

CD80

CD80/B7-1, a transmembrane protein usually expressed on B cells, nature killer cells, and antigen-presenting cells, also expressed on podocytes, which was proposed as a mechanism for proteinuria. It actives T cells by binding to receptor CD28, but inhibits T cell activation by binding to CTLA-4, cytotoxic T lymphocyte-associated antigen-4 expressed on regulatory T cells. CTLA-4 also downregulates CD80 and CD86 expression on APC, Antigen-presenting cells. In α3 integrin −/−, and nephrin −/− mice, CD80 is upregulated. In wild-type mouse models, injection of lipopolysaccharide (LPS) leads to CD80 upregulation in podocytes and proteinuria due to direct action of Toll-like receptor (TLR) ligands on podocytes. Adding tumor necrosis factor α (TNFα) to podocytes causes CD80 upregulation, which further interacts with Neph1 causing slit diaphragm disruption [51, 52]. CD80-deficient mice are protected from LPS-mediated podocyte injury. IL13 or microbial products via TLRs could be factors that induce CD80 expression on podocytes.

A two-hit podocyte immune disorder was postulated in MCD [53]. Initially, CD80 is induced by a microbial agent and/or T-cell cytokine. Impaired production of soluble CTLA4 by decreased circulating Tregs then induces persistent expression of CD80, which causes persistent proteinuria. Administration of abatacept, an inhibitor of CD80, appears to cure patients with severe nephrotic syndrome due to primary FSGS or recurrent FSGS after transplantation [54].

Others

Some other molecules participating in podocytopathy have also been suggested, such as nonmuscle myosin heavy chain-IIA (NMMHC-IIA) and RAP1GAP. NMMHC-IIA is located primarily at cell body and primary processes of podocytes. Expression levels of NMMHC-IIA were significantly decreased in puromycin aminonucleoside-treated rats and patients with idiopathic FSGS [56]. Increased podocyte expression of RAP1GAP, RAP1 GTPase Activating Protein was associated with loss of activated β1 integrin in vivo and in vitro by a mechanism that involves loss of RAP1-mediated activation of β1 integrin. Furthermore, preventing elevation of RAP1GAP levels in injured podocytes maintained β1 integrin–mediated adhesion and prevented cellular detachment [57].

Prognosis

Response to steroid therapy was the most important factor for preservation of renal function. In general, the majority of patients with MCD respond to steroids (80% sensitive rate with remission in 74%) and have preserved renal function for the long term, while FSGS is related to less steroid responsiveness (58% sensitive rate and 30% remission rate) [91]. However, more than two-thirds of adult patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with MCD experienced relapses, and up to a third of patients may become frequent relapsers or steroid-dependent. Younger onset age, steroid without cyclophosphamide treatment, and shorter treatment duration were independent risk factors for relapse [92]. Age is also a factor for steroid-related adverse events in MCD patients [93]. For MCD patients with FR or FSGS patients with less favorable outcome, there is increased early mortality owing to a higher risk of implications, including infections, thromboembolic events, and acute kidney injury (AKI).

Infection

Infectious complications are commonly seen in nephrotic patients due to mass proteinuria and/or use of immunosuppressive agents. Pneumonia is mostly common seen, and primary peritonitis, pneumonia, and cellulitis have also been reported [94, 95]. Accordingly, antibiotics should be applied as per regional practice. In addition, hepatitis B virus reactivation, tuberculosis, and parasite infection should be evaluated, if necessary, during immunosuppression.

Thromboembolic Events

Thromboembolic event is one of the most severe complications in NS. Hypercoagulable state in patients with NS could easily leads to venous thromboembolism (VTE) or arterial thromboembolism (ATE), the most common of which are deep vein thrombosis, renal vein thrombosis, and pulmonary embolism [96]. In a large retrospective cohort study, Mahmoodi et al. evaluated the VTE or ATE events in 298 consecutive patients with NS [97]. In the 10-year follow-up period, annual incidences of VTE and ATE were 1.02% (95% confidence interval [CI] 0.68–1.46) and 1.48% (95% CI 1.07–1.99), respectively. However, over the first 6 months of follow-up, these rates were as high as 9.85% and 5.52%, respectively. The ratio of proteinuria to serum albumin was associated with VTE, while eGFR and multiple classic risk factors for atherosclerosis, such as hypertension, diabetes, and smoking, were predictors of ATE.

AKI

AKI is a common complication of adult patients with MCD (up to 20–25%) [98] and patients with FSGS 39% [91]. It is an independent factor that delays the time to complete remission [99]. MCD-NS patients complicated with AKI had a more severe hypercoagulable state [100], which in turn increases the risk of thromboembolic events. For patients complicated with AKI, contemporary renal replacement therapy could be used, combining with corticosteroids.

Treatment

MCD

Corticosteroids

Corticosteroids remain the mainstay of first-line treatment of MCD in adults. There are still no large randomized controlled trials (RCTs) that provide evidence on the optimal agent, dose, and duration of corticosteroids that should be given. The evidence of using corticosteroids is based largely on extrapolation from RCTs in children [101, 102] and observational studies in adults [103–110]. The drug of choice is oral prednisone or prednisolone Box 15.1. As compared with MCD in children, adults tend to respond more slowly and the responsiveness is also less predictable. Prednisone was suggested to be used as a recommended dose of 1 mg/kg/day, not exceeding 80 mg, until CR (minimum 4 weeks to a maximum of 16 weeks). In the elderly some clinicians use a dose of 2 mg/kg given on an alternate-day basis, although no specific study has addressed the issue of similar efficacy and better tolerability. The issue of corticosteroid toxicity is well-recognized, but although weight gain, diabetes, and osteonecrosis are constantly cited regarding prolonged treatment with corticosteroids in adult MCD, very few published studies have provided specific long-term data on the rates of these complications.

Considering the adverse effects of long-term usage of high-dose corticosteroids, studies have examined enhanced corticosteroid therapy (short-term intravenous methylprednisolone with a low-dose of prednisone and/or another immunosuppressant) [109]. Two very early small RCTs compared intravenous methylprednisolone with or without subsequent oral prednisone to oral prednisone alone [111]. In one study, Yeung found no difference between intravenous methylprednisolone plus oral prednisone compared with oral prednisone alone for CR (relative risk [RR] 0.74, CI 0.50–1.08) in 18 adult patients with MCD. In the other study, Imbasciati observed that oral prednisone, compared with short-course intravenous

methylprednisolone, increased the number of subjects who achieved CR (RR 4.95, CI 1.15–21.26) in 22 patients with MCD. Given the limited number of patients, these two studies might be underpowered and inferiority of intravenous methylprednisolone could not be excluded. Subsequent observational studies suggested that intravenous methylprednisolone and prednisolone use was significantly associated with early remission and lower incidence of relapse compared with prednisolone use alone [108, 109], which was suggested in an Italian RCT in pediatric patients with MCD [112].

In a recent multicenter RCT, tacrolimus (TAC) monotherapy or oral prednisone (1 mg/kg/day, maximum 80 mg/day) after short-term intravenous methylprednisolone (0.8 mg/kg/day) for 10 days showed remission rates of 98.3% (55/56) and 96.2% (51/53), respectively. Although there was no statistically significant difference in remission rates, mean time to remission, and relapse rates between the two groups, adverse events occurred more frequently in the prednisone group than in the TAC group (128 vs. 81) [113]. In a retrospective study, treatment with intravenous methylprednisolone (0.5 or 1.0 g/day for 3 days) followed by oral cyclosporine (2–3 mg/kg/day) and low dose of prednisolone (30 mg/day) showed 100% complete remission rate compared to 85.7% in patients treated with intravenous methylprednisolone followed by oral prednisolone (0.4–0.8 mg/kg/day) and 69.2% in patients treated with oral prednisolone (0.6–1.0 mg/kg/day) alone during the 9-month follow-up. The adverse effects caused by prednisolone were fewer [114].

Although more than 90% of adult patients with MCD achieve CR, about 50% of them experience relapses during the disease course [94, 103, 104, 107, 110]. For patients with infrequent relapse, optimal corticosteroid dose for relapse is still unclear. The KDIGO guidelines recommend the same initial dose and duration. One observational study in children and one in adults suggested lower dose corticosteroid therapy might be helpful to improve the quality of life of patients [110, 115]. For patients with FR or SD, corticosteroid-sparing agents such as cyclosporin (CsA), cyclophosphamide, and mycophenolate mofetil (MMF) are usually needed (discussed in the following sections). A small observational study tested the effects of adrenocorticotropic hormone (ACTH) gel (80 units subcutaneously twice weekly) in 15 subjects with resistant glomerular diseases (MCD = 2, FSGS = 3) for 6 months. One subject with resistant FSGS achieved CR and one subject with resistant MCD achieved PR but relapsed within 4 weeks of stopping ACTH [116]. The evidence should be studied further in controlled trials against currently available therapies for resistant disease.

Alkylating Agents

Only a few patients have been treated with alkylating agents (cyclophosphamide or chlorambucil) in the initial treatment of MCD [106, 117, 118] Box 15.2. Alkylating agents are indicated in multirelapsing cases more than for SR forms (opinion) [103], although true SR is rare in true MCD, that is, cases in which a repeat renal biopsy carried out after 4 months of unsuccessful corticosteroid therapy still shows MCD. In most cases the second histopathologic examination discloses lesions of FSGS that had been overlooked or not sampled on the first biopsy, or had not yet appeared at the onset of NS, which explains the initial failure of corticosteroids [103, 105, 106, 119, 120].

Despite the lack of studies specifically related to adult multirelapsers, it is likely that cytotoxic agents result in prolonged remissions, as shown in RCTs in children. Cyclophosphamide, at 2–3 mg/kg/day, is more commonly used than chlorambucil, without clear evidence of the superiority of one over the other. It should be administered orally and not in the form of intravenous pulses, and presumably, considering the experience acquired with childhood onset cases, for 8 weeks. Alkylating agents entail known hazards of hematologic, infectious, and oncologic side effects, but quantifying these risks is not possible given the available data. In men and women the risk of sterility is significant if the course is prolonged, and the risk increases with increasing age at the time of onset of the therapy.

CNIs

CsA

CsA has been used in adults with MCD since 1986 [1] Box 15.3. Its side effects include hypertension, tremor, gingival hyperplasia, and hypertrichosis. Conversely, CsA has the advantage of not being cytotoxic, does not induce sterility, and entails fewer metabolic disturbances. These reasons may justify its use as first-line treatment in patients at risk of diabetes, osteonecrosis, or infertility. Aside from clinical scenarios in which corticosteroids are contraindicated

[121], CsA first-line monotherapy has been used in many case series (level IV studies) with very low dose [122]. One such study [121] included 86 adult patients with MCD and NS that were resistant to conventional therapy or were SD or multirelapsers. They were treated with the Sandimmune formulation at a dose of 5.18 ± 0.94 mg/kg/day. Superior efficacy was reported in SD patients (CR in 73% of cases and PR in 14%) compared to those who were SR (30% and 26%, respectively). Serum creatinine levels remained stable during CsA treatment. These patients were not all CsA dependent, as ~20–25% were progressively tapered off after 2 years without relapsing [123]. Combination therapy with CsA and corticosteroid agents might further enhance the efficacy and with less corticosteroid toxicity as mentioned above [114], suggesting an additional benefit of lower exposure to corticosteroids. A RCT performed in 52 adult patients with the first relapse of MCD noted that remission was achieved sooner in patients treated with CsA plus 0.8 mg/kg/day prednisone compared to patients receiving only 1 mg/kg/day prednisone [124].

One of the main safety concerns of CsA therapy in INS is the potential for nephrotoxicity. This is a class effect common to all CNIs, including TAC [125, 126] Box 15.3. Previous studies indicated that the dose and type of primary renal disease are two elements to keep in mind when interpreting a decline in renal function [123].

A problem that has appeared since 1999 is that of formulation. Most publications mention "cyclosporine" and do not specify whether they are discussing Sandimmune or Neoral or a generic form of the drug, which may be important because it is known that the better pharmacokinetic profile of Neoral may lead to better efficacy and hence a distinct reduction of dose [125] below the maximum of 5 mg/kg/day recommended for Sandimmune [123].

TAC

Given the FR after withdrawal and the risk of renal toxicity after long-term therapy with CsA, there are several studies focus on detecting the efficacy of TAC to induce CR in adults with MCD. TAC, like CsA, is a CNI that inhibits T-cell-driven elaboration of cytokines. It shows more potent cytokine suppression and seems to cause less toxicity than CsA. In a recent multicenter RCT, TAC monotherapy following short-term intravenous methylprednisolone (0.8 mg/kg/day) for 10 days showed comparable remission rates, remission rates, mean time to remission, and relapse rates with the conventional oral prednisone regimen, but fewer adverse events [113]. In one pilot study, the cumulative CR rates of patients treated with oral TAC (0.05 mg/kg twice daily) and low-dose prednisolone (0.5 mg/kg/day) were 7.7% (1/14), 64.2% (9/14), 71.3% (10/14), 92.9% (13/14), and 100% (14/14) at 1, 2, 4, 8, and 20 weeks respectively [127]. In one small observational study, TAC (0.05–0.1 mg/kg/day) combined with prednisone (0.5 mg/kg/day) showed a remission rate of 90.9% (10/11) with a CR rate of 72.7% (8/11) in CsA-resistant and -dependent adult MCD patients within 2 months [128].

MMF

Studies of MMF in the treatment of MCD in adults are few and are limited to case series and reports [129–131]. Considering the encouraging results obtained in childhood nephrosis, MMF may have a place in the treatment of adult MCD, but so far evidence either supporting or refuting its use is absent.

RTX

RTX, a chimeric monoclonal antibody directed against CD20, is a potential effective and safe treatment in adults with MCD Box 15.4. The use of RTX in adults with FR and immunosuppression-dependent MCD has been reported in case reports [132–134] and small observational studies [135–138] in reducing relapses and sparing immunosuppression. A prospective, multicenter, off–on trial evaluated the efficacy of RTX and rate of recurrences in a cohort of 10 children and 20 adults with FR MCD and FSGS after administration of RTX and discontinuation of immunosuppressants. One year after, all 30 patients were in remission and half of them never presented any recurrence during the follow-up. The total number of relapses, the per-patient annualized relapse rate, the per-patient corticosteroid maintenance median dose, and the median cumulative dose to achieve relapse remission were reduced significantly after treatment with RTX. Renal function improved in all subjects, especially in children and in FSGS subgroups [139]. Similar results were reported extending the observation period to more than 2 years, demonstrating a long-lasting effect of RTX [136, 140–142]. One very small observational study has reported the efficacy of RTX as a first-line therapy in six adult-onset MCD cases [143]. In future RCTs, detecting the efficacy of RTX as both first-line and second-line treatment with extended follow-up will add important information regarding its optimal treatment, relapse, and safety.

Summary

MCD is not uncommon in adults and may assume a multirelapsing course. The majority of patients respond to corticosteroids with CR, but this may require 4 months of treatment, compared with 6–8 weeks in children, with the attendant hazards of corticosteroid toxicity. Enhanced corticosteroid therapy (short-term of intravenous methylprednisolone with a low dose of prednisone and/or with another immunosuppressant) might be alternative option to reduce corticosteroid toxicity. In selected cases, low-dose CNIs can be considered an alternative to corticosteroids, with very little nephrotoxicity. SR may be due to an initially missed diagnosis of FSGS, and resistance should be considered an indication to verify the diagnosis by a repeat kidney biopsy. The place of MMF in the treatment of adult MCD remains to be determined. For patients with FR or conventional treatment-resistant, RTX is a promising option, although the current evidence is limited to observational studies. The strength of evidence supporting these statements is low or very low, being largely based on case series and observational studies (RCTs tending to revise treatment recommendations are summarized in Table 15.4).

FSGS

All forms of FSGS require treatment, irrespective of the histopathologic variant [4, 5, 8, 144]. The goal of therapy is to reduce, if not eliminate, proteinuria. Inducing even a PR reduces the rate of deterioration in renal function [6]. Corticosteroids remain the first-line treatment. Response to corticosteroids is also the best indicator of a better long-term prognosis. In case of failure, a panoply of immunosuppressive drugs have been tried, including new immunosuppressive agents used in solid organ transplantation. A few recent publications on RTX [145] indicate that the anti-CD20 monoclonal antibody may inconsistently obtain remission in cases of FSGS, especially when the NS relapses after renal transplantation.

Corticosteroids

Current consensus remains that corticosteroids with full dose and extended period of time are the first-line of therapy in nephrotic FSGS. In the absence of any RCT data, the evidence mainly based on several observational studies with remission rates ranging from 30% to 60% [20, 146, 147]. The initial

Table 15.4 Summary of findings: treatment of adult minimal change disease (MCD).

Outcomes	No. of participants (no. of studies)	Absolute effect per 1000 patients treated for 1 year (95% CI)	Relative risk (95% confidence interval)	Certainty of the evidence (GRADE)	Conclusion
Intravenous methylprednisolone/TAC vs. intravenous methylprednisolone/prednisone [113]					
Remission rate (CR or PR)	109 (1)	Not estimable	1.02 (0.96–1.09)	Low ●○○○	TAC is noninferior to prednisone after short-term intravenous methylprednisolone
Relapse rate	106 (1)	Not estimable	0.93 (0.62–1.39)	Low ●○○○	TAC and prednisone show similar relapse rates
Adverse event rate	109 (1)	Not estimable	0.83 (0.71–0.98)	Low ●○○○	Adverse events occur more frequently in the prednisone group
CsA/prednisolone (0.8 mg/kg/day) vs. prednisolone (1 mg/kg/day) [124]					
Remission rate (CR or PR)	52 (1)	Not estimable	1.25 (1.01–1.55)	Low ●○○○	Low-dose CsA allows the prednisolone dose to be reduced as compared to therapy with prednisolone alone
Relapse rate	52 (1)	Not estimable	1.20 (0.41–3.47)	Low ●○○○	Combining with or without CsA show similar relapse rates
Adverse event rate	—	—	—	—	Adverse event was not analyzed

response to treatment in adults with FSGS was analyzed by Korbet et al. [144, 148, 149]. The trend before 1980 was to treat for a short time and with low doses of corticosteroids. The highest CR rates, >30%, were observed in cases treated for >5 months, and the lowest, ≤20%, were seen in patients treated for≤2 months. Thus, corticosteroid treatment must be sufficiently long. Full-dose (1 mg/kg/day) prednisone is given for 8–12 weeks, followed in case of remission, even partial, by slow tapering over months to avoid a "rebound" relapse [150]. CR portends a favorable outcome, comparable to that of corticosteroid-responsive MCD [18]. However, a minority of patients with nephrotic FSGS achieve stable remission after tapering corticosteroids to complete withdrawal. Most cases are SD, usually to a high threshold dose. This poses a serious problem, as pursuing indefinite treatment with a high-maintenance dose leads to corticosteroid side effects. Corticosteroid dependency or resistance leads to the need to consider other treatment options aimed at reducing proteinuria, but which trade corticosteroid toxicity for other complications.

In a pilot study, 24 nephrotic patients with idiopathic FSGS, including six SD and 15 SR, were treated with ACTH gel (median dose was 80 units injected subcutaneously twice weekly). After treatment, 29% (7/24) patients showed remission. All remitters had SR ($n = 5$) or SD ($n = 2$) FSGS. ACTH treatment might be an alternative option for SR or SD patients with FSGS, although the response rate is low [151]. In a observational study, 20 patients of post-transplant recurrent and de novo FSGS resistant to conventional therapy with therapeutic PE and RTX received ACTH, and 50% (10/20) of patients achieved CR or PR [152].

Alkylating Agents

The best indication for use of an alkylating agent is the case of a SD or multirelapsing patient, which is rare in nephrotic FSGS. Some studies included patients treated with a combination of cyclophosphamide or chlorambucil and corticosteroids. A RCT in 57 patients by Heering et al. [153] included 23 patients treated for 6 months with corticosteroids and chlorambucil. They achieved 17% CR and 48% PR. Five of the 23 progressed to end-stage renal disease (ESRD). The contributions of other studies to treatment recommendations about alkylating agents are uncertain, such as Martinelli et al.'s case series [154]. In short, there is no strong evidence to recommend alkylating agents in the treatment of FSGS.

CNIs

CsA

CsA has been used for three decades in the treatment of FSGS. It has been shown that its efficacy is greatly increased by a combination with low-dose corticosteroids [121]. Combination of CsA and corticosteroids remains the mainstay of treatment, with good tolerability when CsA dose is low. A retrospective observational study compared high-dose oral prednisone (1 mg/kg/day) with low-dose prednisone (0.5 mg/kg/day) in combination with CsA (3 mg/kg/day) or azathioprine (2 mg/kg/day) as initial treatments. Low-dose prednisone was given to 16 patients with obesity, bone disease, or mild diabetes. Remission rates were comparable; 63% for prednisone ($n = 9$), 80% for prednisone plus azathioprine ($n = 6$), and 86% for prednisone plus CsA ($n = 10$) [155]. Using the Glomerular Disease Collaborative Network (GDCN) Registry, Laurin et al. [156] showed that early use of immunosuppressive therapy with CNIs and/or corticosteroids was associated with improved renal outcome compared with no immunosuppression in 458 adults and children with primary FSGS (HR 0.49, 0.28–0.86). Although there was a trend toward greater survival among patients treated with CNIs, the superiority of CNIs over corticosteroids alone remained unproven.

For SD or SR patients, two RCTs noted the efficacy of CsA [157, 158]. Remission rates are 69% and 60%, but relapse after CsA withdrawal occurred in 61% and 69%, respectively. In the former study [157], CsA (3.5 mg/kg/day) was combined with low-dose prednisone (0.15 mg/kg/day). Long-term renal function was significantly better preserved in the CsA group, suggesting that low-dose CsA-induced PR reduces the rate of progression of nephrotic FSGS patients to renal insufficiency. A comparison was made in 226 patients treated for SR-NS (the majority were FSGS with some cases of MCD), with 127 receiving CsA alone and 103 receiving CsA plus corticosteroids. The proportions of patients with CR, PR, and failure were, respectively, 14% versus 24%, 12% versus 24%, and 74% versus 52%. Thus, CsA combined with low-dose corticosteroids can be considered both an immunosuppressive drug and a steroid-sparing agent to treat resistant forms of FSGS.

Another case series [121] was based on 68 patients treated with 5.18 ± 0.94 mg/kg/day of CsA (Sandimmune formulation). The results on NS were 14 CR (21%), 19 PR (28%), and 35 failures (51%). Other case series have comprised patients treated with CsA (among other immunosuppressants) and support the beneficial effect of CsA for inducing at least PR in nephrotic FSGS.

TAC

There are no RCTs for this medication in FSGS. So far, the experience acquired is mainly in CsA-resistant or -dependent patients. Another small observational study used TAC monotherapy as initial treatment in six patients, and all six patients achieved remission after 6.5 ± 5.9 months [159].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Sirolimus

Autophagy was suggested to be involved in maintaining cellular health in podocyte and autophagic exhaustion was suggested to be central deriver of podocyte injury in FSGS [160]. However, translating this finding into clinical practice dampened the enthusiasm, since treatment with mammalian target of rapamycin (mTOR) inhibition, sirolimus, appears to be ineffective and potentially harmful. The current experience with this drug is controversial and inadequate to allow recommendations on its use in FSGS [161].

MMF

The current experience regarding MMF in the treatment of FSGS seems more or less encouraging [162–164]. A recent RCT compared CsA to the combination of MMF and high-dose dexamethasone in children and young adults with SD-FSGS [165]. No difference in treatment effectiveness was shown between the two groups, and adverse effects were comparable. However, the limitations of this study, regarding the limited number of patients (2.5 patients per center) and the heterogeneous population (children and adults, different ethnity origin), make it difficult to indicate that CsA treatment might be superior.

Monoclonal Antibodies

RTX

The efficacy of RTX in adult-onset FSGS remains conflict [166]. Case series suggest RTX therapy could increase the CR or PR rates, decrease the relapse rate, and stop the concomitant therapy to include corticosteroids and immunosuppressive agents in patients with a severe disease course, a failure of previously used immunosuppressive regimens, and kidney transplantation recipients with recurrent FSGS [134, 167–171]. In a 2-year observational study, a high dose of RTX (eight weekly doses of 375 mg/m^2) failed to improve proteinuria in seven out of eight patients [172]. A multicenter off–on trial primarily evaluated the effects of RTX followed by immunosuppressive agent withdrawal on disease recurrence in 10 children and 20 adults MCD/MesGN ($n = 22$) or FSGS. Overall, the evidence of RTX in FSGS is mainly drawn from case reports or in a retrospective manner with various treatment modes, and several questions remain to be answered, such as dose, duration, and long-term follow-up outcomes.

Fresolimumab

In a phase 2 double-blind, placebo-controlled, randomized study of Fresolimumab in patients with SD primary FSGS, patients received placebo ($n = 10$), fresolimumab 1 mg/kg ($n = 14$), and fresolimumab 4 mg/kg ($n = 12$), respectively. However, none of the patients achieved partial (50% reduction) or complete (<0.3 g/24 h) remission of proteinuria. This small underpowered study has not provided any conclusions yet [173].

Adalimumab

In the Novel Therapies for Resistant FSGS (FONT) phase II study, 21 patients with resistant FSGS were assigned to adalimumab (an anti-TNFα monoclonal antibody), glactose or standard medical therapy. While none of the adalimumab-treated subjects achieved the primary outcome, two subjects in the galactose and two in the standard medical therapy arm had a 50% reduction in proteinuria without a decline in eGFR [174].

Abatacept

Considering the role of CD80 in pathogenesis of MCD, an inhibitor of CD80, abatacept, was suggested to be used in disease treatment. Abatacept (CTLA-4 immunoglobin) is a soluble fusion protein that consists of the extracellular domain of human CTLA-4 linked to the modified Fc portion of human IgG1. It significantly reduced the proteinuria in RTX-resistant recurrent FSGS after transplantation and in one patient with SR primary FSGS with CD80 staining of podocytes in kidney-biopsy specimens [175]. However, the effectiveness of abatacept was not replicated in subsequent studies [176, 177]. Larger RCTs are required to determine its efficacy and safety in the future.

Summary

Nephrotic FSGS, irrespective of its histopathologic variant, is always an indication for a course of full-dose corticosteroids, preferably prednisone (opinion), for a minimum of 4 months prior to labeling the SD patient (opinion). CR portends an excellent prognosis. PR is beneficial, both clinically and in terms of preservation of renal function. In the case of SD, the use of a combination of CsA and low-dose corticosteroids obtains partial or, more rarely, CR in about 50–70% of patients, with a definite advantage regarding long-term preservation of renal function. Among the various other immunosuppressants tried in the treatment of FSGS, MMF has the advantage of no nephrotoxicity, but the studies to date, although positive, have been small and pilot in nature. With our understanding of disease pathogenesis, clinical trials of targeting therapy options with more efficacy and fewer adverse effects are ongoing (RCTs tending to revise treatment recommendations are summarized in Table 15.5).

Plasmapheresis

The rationale for treating nephrotic FSGS with PE is based on the concept of a glomerular permeability factor, postulated by Shalhoub in 1974 [178], and despite this

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. factor being the subject of numerous publications, much remains uncertain about it [179]. There is no evidence that PE modifies the course of FSGS, outside of the particular case of relapse of NS in a kidney transplant recipient [144]. Based on the concept of a "circulating factor," PE has been advocated to remove it, reduce proteinuria, and avoid the progression to renal insufficiency, but there is little evidence for or against its use. In 2001 Bosch and Wendler [180] concluded, in a review of extracorporeal plasma treatment in primary and recurrent FSGS, that there was only poor evidence to support its use, and no significant additional data have been added since that time. A systematic review and meta-analysis of 77 case reports and case series noted that 71% of patients achieved CR or PR after treatment with PE [181].

Similarly, plasma protein adsorption on columns coated with staphylococcal protein A [182] does not seem to remove specifically the elusive circulating factor responsible for the proteinuria, as this experimental protocol also reduces proteinuria in other glomerulopathies [183].

Pregnancy

INS occurring during pregnancy poses a unique situation. The majority of the data relative to the effects of immunosuppressive treatment in pregnancy are based on post-kidney transplantation reports. High-dose corticosteroids entail a risk to the fetus [184]. Alkylating agents are contraindicated. In the CsA era, case reports, center reports, and registry data have supported the concept that successful pregnancy outcomes are possible for mother and newborn in the presence of stable graft function and well-controlled maternal comorbidities, such as hypertension. While the risks of prematurity and low birth weight are greater than those seen in the general population, there has been no increase in the malformation rate of newborns. Successful pregnancy outcomes have been reported in nonrenal CsA recipients as well [185–187]. The available experience with MMF has been limited to organ transplantation [185–187]. Two newborns with malformations were noted in a limited case series with MMF exposure, but other factors may have also been at play. The use of MMF during pregnancy continues to be an unresolved issue. In summary, CsA seems to be the less toxic agent to treat a case of INS during pregnancy, but the data are weak.

Conclusion

Both similarities and differences regarding the clinical characteristics, pathogenesis, treatment responses, and outcomes were shown between MCD and idiopathic FSGS. There is still a debate on whether they are different phenotypes of the same disease or two entities. Corticosteroids and CNIs remain the mainstay treatment in MCD and idiopathic FSGS, while RTX seems to be a promising alternative. Clinicopathological studies and experimental models support the pathogenesis that MCD and FSGS are podocyte disorders caused by circulating factors and/or immune dysfunction. Lifting the veil of these factors and the underlying mechanisms provides diagnostic, therapeutic, and prognostic insights.

Membranous Nephropathy

Katie Trinh[1,2] and Bhadran Bose[1,2]

[1] *Department of Nephrology, Nepean Hospital, Kingswood, NSW, Australia*
[2] *University of Sydney, Sydney, NSW, Australia*

Introduction

Idiopathic membranous nephropathy is a common immune-mediated glomerular disease and remains the leading cause of nephrotic syndrome (NS) in Caucasian adults. Secondary forms may account for up to one-third of cases and are associated with autoimmune diseases (e.g. systemic lupus erythematosus), infections (e.g. hepatitis B and C), medications (e.g. nonsteroidal anti-inflammatory drugs [NSAIDs], D-penicillamine, gold), and neoplasias (e.g. carcinomas) [1]. The association with malignancy increases with age, reaching up to 20% in patients over the age of 60. Because idiopathic and secondary forms have similar clinical presentations, the designation of idiopathic is made only after ruling out secondary causes by a careful history, physical examination, and laboratory evaluation. It is crucial to rule out secondary causes of membranous nephropathy because the management is directed toward removing or correcting the underlying cause.

Natural History

Membranous nephropathy is a chronic disease, with spontaneous remission and relapses. There is great variability in the rate of disease progression, and the natural course is difficult to assess in part due to heterogeneous criteria for indication of biopsy and genetic and geographic disease biology [2–4]. Spontaneous remissions occur in up to 30% of cases, usually in the first 2 years after presentation, but may occur any time. The proportion of patients going into spontaneous remission is much lower when patients are selected who have higher grades of proteinuria at presentation, for example proteinuria of >8 g/24 h. The remaining two-thirds of patients who do not undergo spontaneous remission generally divide equally into either those with persistent proteinuria who will maintain renal function long term or those patients who will progress to kidney failure. In Caucasian patients with nephrotic syndrome, 10-year kidney survival of <70% has been reported [2, 5–8].

Because of its high incidence rate, membranous nephropathy remains the second or third leading cause of end-stage kidney disease (ESKD) among the primary glomerulonephritis types [9]. Even patients who do not progress but remain nephrotic are at an increased risk for life-threatening thromboembolic and cardiovascular events. A rapid change in either the degree of proteinuria or the rate of loss of renal function, especially in a previously stable patient, should raise the possibility of a superimposed condition, for example interstitial nephritis, crescentric glomerulonephritis, sepsis, or renal vein thrombosis.

Clinical Manifestations

Membranous nephropathy affects patients of all ages and races, but it is more common in men than women by a 2 : 1 (male:female) to 3 : 1 ratio. Idiopathic membranous nephropathy has a peak incidence during the fourth and fifth decades of life, and is relatively uncommon in patients under 20 years. At presentation, 60–70% of patients will have nephrotic syndrome. The presence of microscopic hematuria is common (30–40%), but macroscopic hematuria and red cell casts are rare and suggest a different histopathology. At presentation, the great majority of patients

are normotensive, with only 10–20% having hypertension and only a small fraction of patients (<10%) having significant renal insufficiency. Risk of thromboembolism is very high in the first 6 months [10]. The incidence of venous thromboembolism is 9.85% and arterial thrombembolism is 5.52%. The risk is higher if serum albumin <2.8 g/dl [11].

Pathogenesis

Phospholipase A_2 receptor

In the past decade, the understanding of the pathogenesis of idiopathic membranous nephropathy has substantially improved. In 2009, phospholipase A_2 receptor (PLA2R) was identified as the major antigen responsible for autoantibody binding in idiopathic membranous nephropathy [12]. PLA_2R is a transmembrane receptor that is highly expressed in glomerular podocytes and was initially identified in 70% patients with idiopathic membranous nephropathy [12]. Subsequent studies from various cohorts have shown that PLA_2R antibodies are positive in 50–80% of patients with idiopathic membranous nephropathy [13–18]. PLA_2R antibodies are uncommon in patients with membranous nephropathy associated with malignancies. There is genetic polymorphism in PLA_2R-associated membranous nephropathy, which is linked with HLA-DQA1 risk alleles [19, 20]. Furthermore, the presence of HLA DQA1*05 : 01 and DQB1*02 : 01 alleles is associated with higher PLA_2R antibody levels [21].

Thrombospondin Type-1 Domain-Containing 7A

Thrombospondin type-1 domain-containing 7A (THSD7A), like PLA_2R, is a protein highly expressed in podocytes and was identified in European and North American patients with anti-PLA_2R-negative idiopathic membranous nephropathy but not in healthy controls or patients with other glomerular diseases [22]. It occurs in 2.5–5% of all patients with idiopathic nephropathy, which corresponds to 8–14% of patients who are seronegative for anti-PLA_2R antibodies. A recent meta-analysis of 10 studies involving 4121 patients showed prevalence of THSD7A was low at 3% (95% CI 2–4%) of all patients with idiopathic membranous nephropathy, which corresponded with 10% (95% CI 6–15%) of anti-PLA_2R antibody negative patients [23]. However, this meta-analysis was limited by a small number of studies and sample size. Cancer may be more common in patients with THSD7A antibodies [24]. Further studies to elucidate the role of THSD7A as a marker of prognosis and response to therapy are required. Antibodies against PLA_2R and THSD7A coexist but only occasionally [25].

Predicting Factors

Evaluating the prognosis is critical in making decisions regarding treatment [26–28]. Individual factors, such as advanced age, male gender, and selected biopsy findings (e.g. degree of interstitial fibrosis, glomerulosclerosis, vascular damage, or glomeruli with focal segmental glomerulosclerosis), are predictors of prognosis and/or response to immunosuppressive therapy [29]. In addition, the degree of proteinuria may also predict those who are most likely to progress. Pei et al. observed a 47% risk for progression in patients with proteinuria of >4 g/24 h for longer than 18 months and a 66% risk in patients with proteinuria of >8 g/24 h for more than 6 months [30]. The degree of renal impairment at presentation has also been found to correlate with long-term renal survival.

PLA_2R antibodies appear to correlate with disease activity, response to therapy, and prognosis, which may allow them to be used as biomarkers for assessing treatment efficacy [21, 31–33]. Additionally, higher antibody levels are linked to a higher risk of declining renal function, suggesting that these affected individuals may benefit from earlier initiation of immunosuppression [21]. Conversely, favorable outcomes have been shown in patients who do not have PLA_2R antibodies. Spontaneous remission rates are higher in patients with low (negative or lowest tertile) antibody levels (79%, HR 2.72, 95% CI 1.22–6.09, $P = 0.02$) compared to patients with higher antibody levels [33]. In another study of 28 seronegative patients, 91% had spontaneous remission (7 out of 10 had complete remission [CR]) [34].

Response Measurements

The goal of treatment is to achieve either CR or partial remission (PR). Definition of CR or PR is reported differently by different studies. However, the definition reported by Kidney Disease Improving Global Outcome (KDIGO) seems to be more widely agreed upon [35]. KDIGO defines CR as urinary protein excretion <0.3 g/day (urinary protein to creatinine ratio < 300 mg/g or < 30 mg/mmol) accompanied by a normal serum albumin concentration and a normal serum creatinine. PR is defined as urinary protein excretion <3.5 g/day (urinary protein to creatinine ratio < 3500 mg/g or < 350 mg/mmol) and a 50% or greater reduction from peak values accompanied by an improvement or normalization of the serum albumin concentration and stable serum creatinine.

About 30% of membranous nephropathy cases will relapse subsequent to CR [36]. The great majority who do, however, will relapse to subnephrotic-range proteinuria and will have stable long-term function. PR has been also recognized as a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

specific outcome. A review of 350 nephrotic patients with membranous nephropathy found that the 10-year renal survival was 100% in the CR group, 90% in the PR group, and 45% in the no-remission group [37]. Patients with CR or PR have a similar rate of decline: −1.5 ml/min/year in the CR group and −2 ml/min/year in the PR group. In contrast, the no-remission group lost glomerular filtration rate (GFR) at a rate of −10 ml/min/year. Thus, both CR and PR appear to be excellent predictors of long-term renal survival.

Anti-PLA_2R antibody levels have been shown to decline in response to immunosuppressive therapy. In an observational study, high-risk patients receiving oral cyclophosphamide or mycophenolate mofetil in combination with corticosteroids had a rapid decline in anti-PLA_2R antibodies following treatment [38]. Baseline antibody levels did not predict response to treatment but patients who were antibody-negative 5 years following treatment were more likely remain in persistent remission [38]. In another prospective study of 101 patients who received immunosuppression, antibody levels fell by 69–81% (depending on the assay) and proteinuria fell by 38.8% within 3 months [39]. The decline in proteinuria continued up until 12 months, whereas antibody levels remained within low range.

A prospective trial showed that patients treated with rituximab who showed an immunologic response were more likely to achieve remission [40]. The decline in anti-PLA_2R antibodies preceded the corresponding reduction in proteinuria, which may allow response to rituximab to be predicted and subsequent dosing to be determined. In another prospective trial of patients with persistent nephrotic syndrome treated with rituximab, lower antibody titers at baseline and full antibody depletion at 6 months following rituximab treatment strongly predicted remission (HR 7.90, 95% CI 2.54–24.60, $P < 0.001$) [41]. Similarly, in each case of CR ($n = 25$), antibody depletion preceded clinical remission. On average, a 50% reduction in antibody titer preceded a 50% reduction in proteinuria by 10 months.

Treatment

We can rationally assign patients to nonimmunosuppressive therapy or to immunosuppressive therapy according to their risk for renal disease progression. Table 16.1 summarizes GRADE recommendations for the treatment of membranous nephropathy.

Nonimmunosuppressive Therapy

Nonimmunosuppressive therapy is based on controlling edema, dietary protein intake, blood pressure, and hyperlipidemia. Interventions are indicated based on evidence available in adults with proteinuria renal disease.

Blood Pressure

In patients with proteinuric renal disease, including membranous nephropathy, there is high certainty evidence that the target for blood pressure is ≤125/75 mmHg [42]. Angiotensin-converting enzyme inhibitor (ACEi) and/or angiotensin receptor blockers (ARBs) are effective antihypertensive agents that can reduce proteinuria and slow progression of renal disease in both diabetic and nondiabetic chronic nephropathy patients, and for these reasons they are the preferred agents to treat hypertension in proteinuric renal diseases. In the Modification of Diet in Renal Disease study, patients with proteinuria of >1 g/day had a significantly better outcome if their blood pressure was reduced to 125/75 mmHg [43].

Patients need to be instructed to follow a low-salt diet because high salt intake (e.g. 200 mg Na or 4.6 g sodium/day) can significantly impair the beneficial effects of angiotensin II blockade [44].

Lipid Lowering

Statins may have a synergistic antiproteinuric effect when combined with ACEi, but this effect is small and mainly observed in patients with proteinuria of <3 g/24 h. When used in combination with high-dose cyclosporine (CsA), statins may increase the risk of rhabdomyolysis [45].

Thromboembolism Prophylaxis

Prophylactic anticoagulation has been shown in retrospective reviews to be beneficial in reducing fatal thromboembolic episodes in nephrotic patients with membranous nephropathy without a concomitant increase in the risk of bleeding [46]. In general, membranous nephropathy patients who are severely nephrotic (proteinuria of >10 g/day and serum albumin of <2.5 g/dl) are candidates for anticoagulation.

Immunosuppressive Therapy

Several treatment strategies, including a variety of immunosuppressive agents, have been shown to be at least partially successful in reducing proteinuria in membranous nephropathy [47]. The available evidence is presented according to the risk group (e.g. low, medium, and high) that the patients in the studies most closely represent. Table 16.2 summarizes the different risk groups.

Treatment of Low-risk Patients

Evidence to support this approach comes from published validation studies and from data on the clinical relevance of PR [37, 48]. Treatment should be nonimmunosuppressive therapy only, given the excellent prognosis of this group of patients when untreated.

Table 16.1 GRADE recommendations for treatment of membranous nephropathy.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Blood pressure lowering	We recommend using ACEi or ARB to achieve a target blood pressure of ≤125/75 mmHg. ACEi or ARB also help to reduce proteinuria and slow the progression of kidney disease.	Moderate–high	Strong
Low-salt diet	We suggest a low-salt diet because high salt intake (e.g. 200 mg Na or 4.6 g sodium/day) can significantly impair the beneficial effects of angiotensin II blockade	Low	Weak
Lipid-lowering therapy	Statins combined with ACEi have synergistic effect in reducing proteinuria	Low	Weak
Thromboembolism prophylaxis	We suggest prophylactic anticoagulation in patients with proteinuria ≥10 g/day and serum albumin below 2.5 g/dl as they are at high risk of fatal thromboembolism	Low	Weak
Nonimmunosuppressive therapy	We suggest initial treatment with nonimmunosuppressive therapy comprising of ACEi or ARB, low-salt diet and statins for 6 months before starting immunosuppressive therapy. However, patients with high-risk of progression will need to start immunosuppressive therapy earlier.	Moderate	Strong
Cytotoxics and corticosteroids	We recommend a 6-month course of corticosteroids with oral cytotoxic agent as first-line therapy	High	Strong
Calcineurin inhibitor with or without corticosteroids	We recommend calcineurin inhibitor as first-line therapy or for patients who cannot tolerate cytotoxic agents. There is high risk of relapse once calcineurin inhibitors are ceased hence might need long-term treatment with calcineurin inhibitor.	High	Strong
Mycophenolate mofetil with or without corticosteroids	We suggest mycophenolate mofetil with corticosteroids in patients refractory to other agents. There is high risk of relapse.	Low	Weak
Rituximab	We suggest rituximab as first-line therapy or for patients with refractory disease	Low	Weak

Table 16.2 Risk assessment for progressive decline in kidney function.

Low risk	Medium risk	High risk
Patients in the low-risk group are categorized by a <5% risk for progression over 5 years of observation They are defined by normal renal function and proteinuria of ≤4 g/24 h over a 6-month observation period	Patients in the medium-risk group are defined by normal renal function and persistent proteinuria between 4 and 8 g/24 h over 6 months of observation despite the institution of maximum conservative therapy	Patients in the high-risk group are characterized by progressive loss of renal function and/or by persistent high-grade proteinuria of ≥8 g/24 h during the 6 months of observation

Treatment of Medium-risk Patients

Patients in this group should be treated with nonimmunosuppressive treatment for at least 6 months before being considered for immunosuppressive therapy.

Corticosteroids Corticosteroid therapy alone may provide little or no benefit for induction of remission or preservation of kidney function even after the data are adjusted to include only patients with proteinuria at entry of >3.5 g/24 h (Table 16.3).

Cytotoxic Agents Combined with Corticosteroids Cyclophosphamide and chlorambucil in combination with corticosteroids appear to be effective in the treatment of patients with idiopathic membranous nephropathy and preserved renal function, with benefits maintained well beyond the 1-year treatment period, although relapse rates approached 35% at 2 years. The long-term adverse effects of these cytotoxic agents, in particular, effects on fertility and also malignancy are the major drawbacks to the universal application of this form of therapy. The risk of malignancy is not increased for patients treated with cumulative cyclophosphamide doses of ≤36 g but increases significantly in patients with cumulative cyclophosphamide doses of ≥36 g [53]. These studies are summarized in Table 16.4 [8, 54–69].

Table 16.3 Corticosteroid treatment in idiopathic membranous nephropathy.

Author	Year	Type of study	Risk group	n	Treatment regimens	Follow-up (months)	Outcomes/comments
Collaborative Study of the Adult Idiopathic Nephrotic Sydrome (CSAINS) [49]	1979	RCT	Medium	72	Prednisone 100–150 mg PO on alternate days × 8–12 weeks vs. placebo	23	10 of 38 controls, but only 1 of 34 given prednisone had SCr > 5 mg/dl or died Rapid decline of renal function in controls considered unexpected
Cattran [50]	1989	RCT	Medium	158	Prednisone 125–150 mg PO on alternate days × 6 months vs. placebo	48	Proportion of patients with CR similar in the two groups No differences in annual change in CrCl between the two groups No sustained difference in proteinuria
Cameron [51]	1990	RCT	High	107	Prednisolone 45 mg/m^2 on alternate days × 8 weeks vs. placebo	52	No difference in remission rates for NS in either short (6 and 12 months) or long (48 months) term No differences in rates of renal function decline
Short [52]	1987	Prospective nonrandomized study	High	15	MTP 1 g IV × 5 days followed by prednisolone 100 mg, 75 mg 50 mg, then 25 mg on alternate days for 4 weeks, then dose decreasing by a further 5 mg each month	32	Serum creatinine fell by a mean of 46% In 10 patients the beneficial effect was sustained, but in three it had reversed by 6 months In the other two patients the progressive decline of renal function was not influenced

CR, complete remission; CrCl, creatinine clearance; IV, intravenous; MTP, methylprednisolone; NS, nephrotic syndrome; PO, per oral; RCT, randomized controlled trial; SCr, serum creatinine.

Table 16.4 Cytotoxic treatment in idiopathic membranous nephropathy.

Author	Year	Type of study	Risk group	*n*	Treatment regimens	Mean Follow-up (months)	Outcomes/comments
Ponticelli [54]	1984	RCT	Medium	67	MTP 1 g IV × 3 days followed by MTP 0.4 mg/kg PO × 27 days, on months 1, 3, and 5 and CHL (0.2 mg/kg/day) on months 2, 4, and 6 vs. symptomatic therapy	31	At the end of follow-up 23 of 32 treated patients (72%) were in CR or PR, as compared with 9 out of 30 controls (30%).
Ponticelli [55]	1992	RCT	Medium	92	MTP 1 g IV × 3 days followed by MTP 0.4 mg/kg PO × 27 days on months 1, 3, and 5 and CHL (0.2 mg/kg/day) on months 2, 4, and 6 vs. MTP alone	48	At 3 years, 66% remission in MTP/CHL group vs. 40% in MTP group. At 4 years, the difference was no longer statistically significant.
Ponticelli [56]	1995	RCT	Medium	67	MTP 1 g IV × 3 days followed by prednisone 0.5 mg/kg/day × 27 days on months 1, 3, and 5 and CHL (0.2 mg/kg/day) on months 2, 4, and 6 vs. symptomatic therapy	120	92% probability of renal survival in treated compared with 60% in the control group. 8% of treated patients vs. 40% of the untreated group reached ESRD.
Ponticelli [57]	1998	RCT	Medium	87	MTP 1 g IV × 3 days followed by MTP 0.4 mg/kg/day PO × 27 days on months 1, 3, and 5 alternating with either CHL 0.2 mg/kg/day or CYC 2.5 mg/kg/day on months 2, 4, and 6	36	CR/PR in 82% of patients on MTP/CHL vs. 93% on MTP/CYC (P = NS). Side effects lower in the MTP/CYC group.
Jha [58]	2007	RCT	Medium	93	MTP 1 g IV × 3 days followed by prednisolone 0.5 mg/kg/day PO × 27 day on months 1, 3, and 5 and CYC 2 mg/kg/day on months 2, 4, and 6 vs. conservative therapy	120	CR/PR in 72% of patients on MTP/CYC vs. 35% in control group
Murphy [59]	1992	RCT	Medium	40	CYC 1.5 mg/kg × 6 months + DIP/W24 × 2 years vs. symptomatic therapy		Treatment group had less proteinuria. No differences in renal function at 2 years
Donadio [60]	1974	RCT	Medium	22	CYC 1.5–2.5 mg/kg PO × 1 year vs. symptomatic therapy	12	No benefit of CYC on proteinuria, renal function, or histology
Falk [61]	1992	RCT	High	26	Prednisone 2 mg/kg on alternate days × 8 weeks, tapered over 4 weeks, vs. CYC 0.5–1 g/m^2 IV monthly × 6 months + MTP (7 mg/kg) × 3 followed by prednisone (2 mg/kg/alternate days) for 8 weeks, then tapered over next 4 weeks	29	No impact of CYC on renal function, level of proteinuria, or progression to ESRD
West [62]	1987	Case-control study	High	26	CYC 2 mg/kg × 20 ± 4 months ± prednisone vs. prednisone or symptomatic therapy	49	CYC associated with an increased rate of remission of NS and better preservation of renal function. Adverse effects were significant.
Jindal [63]	1992	Case-control study	High	9	CYC (1–2 mg/kg/day) for a mean of 23 ± 4 months (8–54) ± prednisone (6/9 patients; dose 33 ± 9 mg/day) compared to 17 controls receiving prednisone, maximum dose 50–125 mg alternate days in 9/17 and 40–80 mg in 6/17, for a mean of 20 ± 4 months	64–83	CR in 4/9 and PR in 5/9 in CYC group. One patient in the CYC group and 10 patients in control group reached ESRD. Four relapses in 3 treated patients, and 3 of 4 responded to repeat therapy. Of the 7 controls who did not reach ESRD, only 2 had persistent NS.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Torres [64]	2002	Case-control study	High	19	Prednisone (1 mg/kg/day month 1, 0.5 mg/kg/day month 2, 0.5 mg/kg/day months 3–6) together with CHL 0.15 mg/kg/day for the first 14 weeks vs. historic control group on symptomatic therapy	48	At the end of follow-up, 65% of patients in the control group had reached ESRD, 10% had advanced renal failure, and 25% had died. Majority of treated patients showed stabilization or improvement of renal function.
Bruns [65]	1991	Prospective nonrandomized	High	11	CYC, 100 mg/day in all patients + prednisone (60–100 mg alternate days) in 10/11 patients for 1 year	24–25	Serum creatinine decreased in 10 patients on combined therapy by 6 months and remained stable in 7/8 followed long-term. Proteinuria decreased from 11.9 to 2.3 g/day. Similar course observed in the 1 patient on CYC alone.
Warwick [66]	1994	Prospective nonrandomized	High	21	Prednisolone 125 mg alternate days on months 1, 3, and 5 and CHL 10 mg/day on months 2, 4, and 6. Later patients received MTP 1 g iv × 3 at the start first cycle of treatment. Four patients were retreated.	39	Renal function stable or improved in 11/21 patients (52%). Of these 11, PR in 4 and CR in 2. Serum creatinine > 5.7 mg/dl or ESRD in 6 patients (29%). 3 patients died. Side effects + significant complications related to therapy in > 50% of patients.
Branten [67]	1998	Prospective nonrandomized	High	32	MTP 1 g IV × 3 days, followed by prednisone (0.5 mg/kg/day months 1, 3, and 5) and CHL (0.15 mg/kg/day months 2, 4, and 6), or CYC (1.5–2 mg/kg/day for 1 year) + steroids in a comparable dose	26–38	Renal function improved in both groups but the improvement was short-lived in the CHL group. Remissions of proteinuria more frequent after CYC treatment (15/17 vs. 5/15). CHL associated with more side effects.
Du Buf-Vereijken [68]	2004	Prospective nonrandomized	High	65	MTP 1 g IV × 3 days at months 1, 3, and 5, and prednisone 0.5 mg/kg/48 h for 6 months + CYC (1.5–2 mg/kg/day) × 12 months	51	Renal function improved or stabilized in all patients. At the end of follow-up, CR in 16, PR in 31, 4 progressed to ESRD, and 5 patients had died. Overall survival 86% after 5 years.
Mathieson [69]	1988	Prospective nonrandomized	High	8	MTP 1 g IV × 3 days, 0.5 mg/kg/day PO × 27 days, then CHL 0.15–0.2 mg/kg × 28 days × 3 cycles	8	Renal function improved in 6, stabilized in 1, and deteriorated in 1 patient. Proteinuria fell from 15 to 2 g/day. Side effects were severe.

CHL, chlorambucil; CR, complete remission; CYC, cyclophosphamide; DIP/W, dipyridamole/warfarin; IV, intravenous; MTP, methylprednisolone; PO, per oral; PR, partial remission; RCT, randomized controlled trial.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Cyclosporine A CsA can induce a remission (CR or PR) of NS in 50–60% of patients. Prolonged low-dose CsA (~1.5 mg/kg/day) could be considered for long-term maintenance of patients who achieve CR or PR, especially in patients at high risk for relapse [70]. It is important to emphasize that although reduction of proteinuria usually occurs within a few weeks, the majority of CR occurred after more than 6 months of treatment. On the other hand, if after 3–4 months of CsA therapy at adequate doses proteinuria is not significantly reduced, it is unlikely that the therapy will be effective. These studies are summarized in Table 16.5 [72–76].

Tacrolimus Similar to patients treated with CsA, maintenance of remission may require prolonged use of low-dose tacrolimus (TAC). In a single randomized controlled trial in 25 patients with normal kidney function and nephrotic range proteinuria, tacrolimus monotherapy incurred complete remission in 94% of patients prescribed tacrolimus compared to 35% in the control group [77]. A small number of patients (six patients in the control group and one in the TAC group) reached the secondary end point of a 50% increase in serum creatinine, resulting in low certainty evidence for this outcome.

Treatment of High-risk Patients

Corticosteroids

Randomized, controlled trial evidence is available in a small number of patients with high-risk disease. Based on low certainty evidence, corticosteroid therapy alone may offer little or no benefit for preserving kidney function or lowering proteinuria (Table 16.3) [49–52].

Cytotoxic Agents Combined with Corticosteroids Prednisolone combined with chlorambucil may retard progression of kidney failure compared to steroid therapy and supportive treatment alone [78]. The addition of CsA to steroid therapy is likely to have similar clinical effects compared to chlorambucil, although may incur fewer serious adverse events.

A summary of the studies conducted in this group of patients is presented in Table 16.4 [54–69].

Cyclosporine There has been only one controlled trial with 17 participants evaluating CsA in patients with high-grade proteinuria and progressive renal failure [72]. CsA was associated with significant reduction in proteinuria and prevented loss (slope) of renal function [70–75]. A summary of studies is presented in Table 16.5.

Mycophenolate Mofetil There has been a paucity of studies using mycophenolate mofetil for membranous nephropathy leading to low or very low certainty evidence. Current evidence for mycophenolate mofetil is based on nonrandomized studies (Table 16.6) [79–81]. Based on low certainty evidence from uncontrolled studies, mycophenolate mofetil has uncertain benefits in high-risk membranous nephropathy. Based on a study including historical controls treated with cyclophosphamide, relapses may occur more frequently with mycophenolate mofetil therapy [81].

Rituximab Rituximab is a chimeric monoclonal antibody against CD20+ B cells and as membranous nephropathy is an autoimmune disease, rituximab has been studied in the treatment of patients with membranous nephropathy. Prospective uncontrolled studies have been performed evaluating the efficacy of rituximab in idiopathic membranous nephropathy and are summarized in Table 16.7. These studies have led to the hypothesis that rituximab may modify disease progression in membranous nephropathy.

Two randomized controlled studies provide evidence for rituximab in membranous nephropathy. In the small (75 participants) Evaluate Rituximab Treatment for Idiopathic Membranous Nephropathy (GEMRITUX) study, rituximab (375 mg/m^2 on days 1 and 8) may have induced a higher rate of disease remission during extended follow-up (up to 18 months) compared to standard therapy alone [82].

The Membranous Nephropathy Trial Of Rituximab (MENTOR) study (NCT01180036) is a multicenter randomized controlled trial in 126 participants comparing the efficacy and safety of rituximab to CsA in medium- to high-risk patients with idiopathic membranous nephropathy [91]. Patients with proteinuria ≥5 g/day following a minimum of 3 months conservative nonimmunosuppressive therapy were randomized to receive IV rituximab (days 1 and 15, then repeated at 6 months) or oral CsA (3.5 mg/kg/day for 12 months). Based on results in a conference proceeding, participants who received rituximab more frequently achieved CR or PR (odds ratio 6.0, 95% CI 2.7–13.2).

Table 16.7 summarizes the studies using rituximab in membranous nephropathy [41, 82–92]. Together these studies suggest rituximab could be considered as first-line treatment for membranous nephropathy, but we need larger trials with hard endpoints such as ESKD to change our current practice. Most importantly, so far there is no published study comparing rituximab with the current first-line therapy, i.e. combination of cytotoxics and corticosteroids.

Eculizumab Eculizumab is a humanized anti-C5 monoclonal antibody designed to prevent the cleavage of C5 into its proinflammatory by-products. In a randomized

Table 16.5 Cyclosporin A treatment in idiopathic membranous nephropathy.

Author	Year	Type of study	Risk group	*n*	Treatment regimens	Follow-up (months)	Outcomes/comments
Cattran [71]	2001	RCT	Medium	51	Prednisone (0.15 mg/kg/day) plus CsA (3–4 mg/kg/day) vs. placebo plus prednisone × 26 weeks.	19.5	75% of patients in CsA group vs. 22% in control group achieved PR or CR. Relapse rate 43% in CsA group vs. 40% in placebo by week 52.
Cattran [72]	1995	RCT	High	17	CsA 3.5 mg/kg/day × 12 months vs. placebo	21	CsA associated with slower rate of decline in renal function. Sustained remission of proteinuria in 6/8 CsA patients.
Alexopoulos [70]	2006	RCT	Medium	51	CsA 2–3 mg/kg/day and prednisone vs. CsA (same dose) alone for 12 months. Responders were placed on long-term low-dose CsA 1–1.5 mg/kg/day and prednisone vs. CsA alone.	26	After 12 months of treatment, 26 patients in the combination group and 17 patients in the CsA alone group had a CR or PR of proteinuria. Daily CsA dose was higher in nonrelapsers in both groups while relapsers in both groups had lower CsA trough levels
Ambalavanan [73]	1996	Prospective nonrandomized	Medium	41	CsA 4–5 mg/kg/day for 3–6 months. Lupus serology (+) in 12 patients. Retreatment in 20 of 31 patients who relapsed after stopping CsA.	18	CsA lowered median proteinuria by 56% from 7.3 to 3.2 g/24 h. In 6 patients with declining GFR during prolonged CsA therapy, a repeat biopsy showed more prominent immune deposits and thicker GBM.
Rostoker [74]	1993	Prospective nonrandomized	High	15	CsA 4–5 mg/kg × 12–30 months prednisone 1–2 mg/kg/day × 2 months	40	CR or PR in 11/15 (73%) patients. Relapse in 3/9 on CsA withdrawal, but the relapse remain sensitive to CsA. All patients had received corticosteroids (1 mg/kg/day × 2 months) prior to enrollment.
DeSanto [75]	1987	Case series	Medium-Low	5	CsA 7 mg/kg/day for 6 months plus MTP 1–0.3 mg/kg/day for 1 month, reduced to 0.3–0.15 mg/kg on the second month, and then down to 0.15 mg/kg for 4 months	8	All had failed prior cytotoxic therapy. Prompt remission of proteinuria in 4/5 patients. No renal failure.

CR, complete remission; CsA, cyclosporin A; GBM, glomerular basement membrane; MTP, methylprednisolone; PR, partial remission; RCT, randomized controlled trial.

Table 16.6 Mycophonolate mofetil in medium- to high-risk idiopathic membranous nephropathy.

Author	Year	Type of study	Risk group	*n*	Treatment regimens	Median Follow-up	Outcomes
Miller [79]	2000	Retrospective study	Medium–high	16	Mycophenolate mofetil 500–2000 mg/day for 8 months	8 months	6 patients had a ≥50% reduction in their proteinuria, 2 had a minor reduction in proteinuria, 4 had no change, 3 withdrew because of significant adverse effects, and 1 stopped treatment. There were no significant changes in mean serum creatinine, or serum albumin levels.
Choi [80]	2000	Retrospective study	Medium–high	15	Mycophenolate mofetil 500–1000 mg twice daily for a mean of 12 months combined with steroids	12 months	There was 61% reduction of proteinuria (7.8 to 2.3 g/24 h; $P = 0.001$), with 8 patients having PR and 2 patients CR. Renal function improved in 3 of 6 patients with kidney failure.
Branten [81]	2007	Clinical trial with historic controls.	Medium–high	32	Mycophenolate mofetil 1000 mg twice a day for 12 months (intervention). Cyclophosphamide, 1.5 mg/kg/day for 12 months (historical control). Both groups also received methylpredisone IV 1 g three times at months 1, 3, and 5, followed by oral predisone at 0.5 mg/kg every other day for 6 months, with subsequent tapering.	12 mo	Cumulative incidences of remission of proteinuria at 12 months were 66% in the mycophenolate mofetil group vs. 72% in the cyclophosphamide group ($P = 0.3$). There were more relapses in mycophenolate mofetil-treated group.

Table 16.7 Rituximab treatment in idiopathic membranous nephropathy.

Author	Year	Type of study	Risk group	*n*	Treatment regimens	Median Follow-up (months)	Outcomes/comments
Dahan [82]	2017	RCT	Medium–high	75	RTX 375 mg/m^2 on day 1 and 8 + NIAT vs. NIAT alone	17.0	At 6 months, 13 of 37 (35.1%) treated with RTX + NIAT achieved remission vs. 8 of 38 (21.1%) controls ($P = 0.21$). Significantly higher rates of PLA_2R antibody depletion at 3 and 6 months in RTX + NIAT group.
Fiorentino [83]	2016	Prospective nonrandomized	Medium–high	38	RTX 375 mg/m^2 monthly × 6	15	29 of 38 (76.3%) achieved remission: 15 (39.5%) CR and 14 (36.8%) PR. Proteinuria significantly reduced. Renal function stable. No significant adverse events.
Bagchi [84]	2018	Retrospective	High	21	RTX 500 mg × 2 doses 7–10 days apart ± 3rd dose after 4–6 weeks if CD19 not depleted	13	13 of 21 (61.9%) achieved remission: 4 (19.05) CR and 9 (42.9%) PR. One patient relapsed after achieving PR. Renal survival was significantly better in responders ($P = 0.0037$).
Moroni [85]	2017	Prospective nonrandomized	Medium–-high	34	RTX 375 mg/m^2 × 1 dose ($n = 18$) or × 2 2 weeks apart ($n = 16$)	23.9 (mean)	At 12 months, 5 (14.7%) CR, 10 (29.4%) PR, and 19 (55.8%) no response. Outcome similar for one vs. two doses.
Waldman [86]	2016	Prospective nonrandomized	High	13	CsA 3 mg/kg/day for 6 months then tapered by 50 mg/day every 3 weeks plus RTX 1000 mg day 1 and 15, then after 6 months when CD19+ B cell count ≥5 cells/μl	41 (mean)	By 6 months 85% achieved remission (CR + PR). By 12 months, 54% achieved CR. 2 relapsed by 24 months. Treatment well tolerated.
Ruggenenti [41]	2015	Prospective nonrandomized	High	132	RTX 375 mg/m^2 weekly × 4	30.8	84 of 132 (63.6%) achieved remission (CR + PR), 43 (32.6%) achieved CR. Anti-PLA_2R antibody depletion preceded remission.
Ruggenenti [87]	2003	Prospective nonrandomized	Medium	8	RTX 375 mg/m^2 weekly × 4	Not specified	Significant reduction in proteinuria. Renal function stabilized. 2 achieved CR and 3 achieved PR.
Ruggenenti [88]	2012	Prospective nonrandomized	High	100	RTX 375 mg/m^2 weekly × 4	29 (median)	At end of follow-up, 65% achieved CR or PR. Median time to remission 7.1 months. Renal function improved in those who achieved CR.

Table 16.7 (Continued)

Author	Year	Type of study	Risk group	*n*	Treatment regimens	Median Follow-up (months)	Outcomes/comments
Fervenza [89]	2010	Prospective nonrandomized	Medium	20	RTX 375 mg/m^2 weekly × 4, repeated at 6 months	Not specified	Proteinuria reduced from 11.9 g/24 h to 4.2 and 2.0 g/24 h at 12 and 24 months, respectively. At 24 months, 4 of 18 achieved CR, 12 of 18 achieved PR, and 1 relapsed. Remission rates higher than fortnightly dosing.
Fervenza [90]	2008	Prospective nonrandomized	High	14	RTX 1000 mg on days 1 and 15, repeated at 6 months if proteinuria >3 g/24 h and CD9+ B cell >15 cells/μl	12	At 6 months, 4 achieved PR. At 12 months, 2 achieved CR and 6 PR.
Fervenza [91] (results from abstract)	2015	RCT	High	130	RTX 1000 mg on days 1 and 15, repeated at 6 months vs. CsA 3.5–5 mg/kg/day for 6 months	24	At 24 months, CR or PR in RTX arm was 62.5% vs. 20.6% in the CsA arm. Treatment failure higher in CsA group compared to RTX group (79.4% vs. 37.5%).
Rojas-Rivera [92]	2015	RCT	High		MTP 1 g IV days 1–3 then MTP p.o. 0.5 mg/kg/day for days 4–30 on months 1, 3, and 5 and cyclophosphamide PO 2.0 mg/kg/day for 30 days on months 2, 4, and 6 vs. tacrolimus 0.05 mg/kg/day for 6 months, then tapered to withdrawal by 9 months + RTX 1 g at day 180.		Awaited

CR, complete remission; CsA, cyclosporine; IV, intravenous; MTP, methylprednisolone; NIAT, nonimmunosuppressive antiproteinuric therapy; PO, per oral; PR, partial remission; RCT, randomized controlled trial; RTX, rituximab.

Table 16.8 Adrenocorticotrophic hormone treatment in idiopathic membranous nephropathy.

Author	Year	Level of Evidence	Risk Group	N	Treatment regimens	Median Follow-up	Outcomes
Berg [94]	1999	Prospective uncontrolled	Medium–high	14	ACTH 1 mg intramuscular. The dose of ACTH was increased from one injection every other week to three injections per week during a period of 8 weeks.	70 days	Urinary albumin excretion dropped from 4830 mg/day (3660–15877) to 1040 mg/day (630–3750). Serum creatinine went up from 135 μmol/l (98–314) to 110 μmol/l (98–210)
Ponticelli [96]	2006	RCT	Medium	32	Group A (16 patients) received methylprednisolone(1 g) administered IV on 3 consecutive days, and then orally 0.4 mg/kg for 27 days on months 1, 3, and 5. On months 2, 4, and 6, received either chlorambucil (0.2 mg/kg/day orally) or cyclophosphamide (2.5 mg/kg/day orally). Group B (16 patients) received tetracosactide (a synthetic analogue of ACTH), intramuscular injection of 1 mg between 7:00 and 9:00 a.m. Administration of ACTH was increased from 1 injection every other week to 2 injections per week for a total treatment period of 1 year.	22 months	CR or PR in group A was 93% (CR 5 and PR 10 patients) and 87% in group B achieved CR or PR (10 CR and 4 PR). There was no significant difference in either treatment group.
Hladunewich [97]	2014	RCT (nonblinded dose finding study)	Medium	20	Patients received either 40 or 80 units of ACTH. The dose of ACTH was increased from one injection every other week to two injections per week for total of 12 weeks	12 months	In both groups combined, the mean proteinuria improved significantly from 9.1 ± 3.4 g/day to 3.9 ± 4.2 g/day at 1 year of follow-up

ACTH, adrenocorticotrophic hormone; CR, complete remission; PR, partial remission; RCT, randomized controlled trial.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

controlled trial 200 patients with membranous nephropathy were treated every 2 weeks with two different intravenous dose regimens and compared to a placebo group over a total of 16 weeks [93]. In low certainty evidence, eculizumab did not have a detectable effect on proteinuria or renal function compared to placebo.

Adrenocorticotropic Hormone

Synthetic adrenocorticotropic hormone has been studied by various investigators as a treatment option for idiopathic membranous nephropathy [94–97]. These studies have been summarized in Table 16.8. However, these studies have small sample size with only short-term follow up. There is low-certainty evidence that adrenocorticotropic hormone has a significant effect on proteinuria.

Patients with severe renal insufficiency (serum creatinine of ≥3 mg/dl) are less likely to benefit from immunosuppression therapy, and the risk of treatment is significantly higher, so these patients should be considered for conservative therapy only and with plans made for transplantation in the future.

Disease and Treatment Summary

In conclusion, control of nephrotic syndrome, specifically with CR or PR, is strongly associated with renal survival and a slower rate of chronic kidney disease (CKD) progression. There are no standard or universal first-line specific therapeutic options for idiopathic membranous nephropathy. There is moderate to high certainty evidence that blood pressure lowering therapy aiming for a blood pressure 125/75 or below will retard CKD progression. There is low certainty evidence that statins, salt restriction, and prophylactic anticoagulation have a role in the treatment of membranous nephropathy.

In patients who are at low risk of progression, therapy focused on blood pressure lowering should suffice, although long-term follow-up is needed to ensure that there is no disease progression or worsening of proteinuria.

Patients at medium or high risk are candidates for additional immunosuppressive therapy. Patients with persistent nephrotic-range proteinuria are at increased risk for cardiovascular and thromboembolic complications. Proteinuria is an inducer of kidney injury and plays a major role in the development of progressive tubular injury, interstitial fibrosis, and subsequent loss in GFR. The higher the sustained level of proteinuria, the more likely the development of end-stage renal disease. Therefore, even if the main benefit of immunosuppressive therapy is to accelerate the induction of a remission, it may still have value in the long term. A treatment algorithm that combines the predictive factors and best evidence for immunosuppressive therapy is presented in Figure 16.1. Current first-line therapy is corticosteroids combined with cyclophosphamide or chlorambucil (which may be associated with a higher frequency of adverse events). Calcineurin

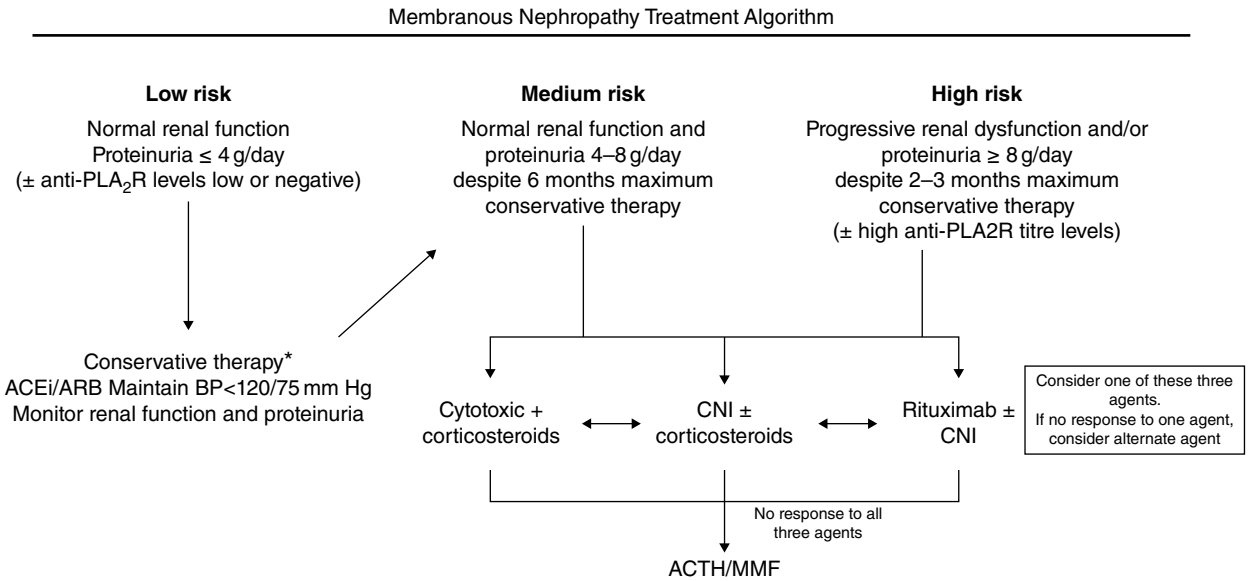

Figure 16.1 Membranous nephropathy treatment algorithm. ★Conservative treatment involves the use of ACEi ± ARB blocker to maintain blood pressure < 125/75 mmHg, lipid control with HMG-CoA reductase inhibitor, dietary protein restriction (0.6–0.8 g/kg ideal body weight/day), dietary NaCl intake (goal is 2–3 g Na) to optimize antiproteinuric effects of ACEi and ARBs, smoking cessation, and attempt to reduce obesity, if present. Abbreviations: anti-PLA_2R, phospholipase A_2 receptor antibody; ACEi, angiotensin converting enzyme inhibitor; ARB, angiotensin II receptor blocker; CNI, calcineurin inhibitor; ACTH, adrenocorticotrophic hormone; MMF, mycophenolate mofetil.

inhibitors combined with low-dose prednisone may be considered for patients who prefer or are intolerant of first-line therapy. Long-term therapy may be required due to the high incidence of relapse. Emerging data suggest rituximab may provide CR or PR at 24 months. Patients who do not respond well or relapse after a first course of immunosuppression therapy may benefit from a second course of immunosuppression [98].

Introduction

Immunoglobulin A nephropathy (IgAN) is the most common pattern of glomerulonephritis (GN) in all countries where renal biopsy is routinely practiced and is an important cause of end-stage kidney disease (ESKD) at all ages [1, 2]. IgAN is a mesangial proliferative glomerulonephritis characterized by the predominant deposition of IgA in the glomerular mesangium. The degree of histopathologic iewwwnjury is heterogeneous, and this is reflected in the varied progression and severity of clinical presentation seen in this disease [3]. Closely associated with IgAN is IgA vasculitis (IgAV) (also known as Henoch–Schönlein purpura), a small vessel systemic vasculitis characterized by small blood vessel deposition of IgA predominantly affecting the skin, joints, gut, and kidney. The nephritis of IgAV is also characterized by mesangial IgA deposition and may be histologically indistinguishable from IgAN [4].

In this chapter, we summarize the published studies according to their level of evidence and provide recommendations for the common clinical situations that confront the nephrologist treating patients with idiopathic IgAN (Figure 17.1). In each section we describe the results of therapeutic approaches to these clinical situations in adults with IgA nephropathy, followed by a pediatric perspective for which we review the results of similar therapeutic trials in children and adolescents. Some of these reports have been reviewed previously [6]. Whenever possible, the pediatric experience with each treatment will be compared with evidence-based conclusions drawn from adult studies. In this way, we will attempt to facilitate comparison between pediatric and adult recommendations for the management of patients with IgAN. Discussions of the treatment of IgAV or secondary forms of IgAN are not included in this chapter.

Epidemiology

No clinical presentation is pathognomonic of IgAN, including the archetypal young male with episodic visible hematuria following an upper respiratory tract infection. Also, although a number of abnormalities in circulating IgA and its production have been reported in IgAN patients, cohorts are heterogeneous with respect to these abnormalities, making their diagnostic utility poor [7]. Therefore, a diagnosis of IgAN currently requires a renal biopsy, which as described below also provides important prognostic information. This requirement for a renal biopsy means the true incidence and prevalence of IgAN are difficult to determine. Indeed, the prevalence of mesangial IgA deposits found at post mortem in unselected cases is surprisingly high: 4–16% [8, 9]. Reported prevalence rates for IgAN vary across the world, ranging from 5% in the Middle East [10] to 38% in Europe [11], and reaching 50% in China and Japan [12, 13]. Asian people who live in the United States have a fourfold higher incidence of IgAN compared to Caucasian Americans of European ancestry, and a sixfold higher prevalence than African-Americans while Northern Europeans with IgAN have a two to four times greater risk of progressing to end-stage renal disease (ESRD) compared to Southern Europeans [14]. There is also a disparity in gender prevalence of IgAN: in Europe and North America there is a 3 : 1 male-to-female distribution, while this ratio is 1 : 1 in East and South East Asia [15, 16].

Pathophysiology

Recurrence of IgAN after transplantation, and also the rare cases of resolution of IgA deposits in transplanted kidneys from donors with IgAN, supports the hypothesis that mesangial IgA is derived from a pathogenic IgA fraction within the circulating pool of serum IgA [7, 17, 18]. What defines this pathogenic IgA fraction is incompletely understood, but there is evidence for the importance of low-affinity, poorly *O*-galactosylated polymeric IgA1 molecules forming circulating IgA immune complexes with a propensity for both mesangial deposition and mesangial cell activation [19, 20]. The lack of a complete understanding of the pathogenesis of IgAN has resulted in there still being no treatment known to modify mesangial deposition of IgA. Available treatment options are mostly directed at downstream immune and inflammatory events in the glomerulus and the tubulo-interstitium that may lead to renal scarring. It is therefore likely that these are generic treatments with potential benefit in other chronic glomerular diseases.

Prognosis

Adult IgAN

The natural history of IgAN has now been well defined in a number of large series with prolonged follow-up [21]. Fewer than 10% of all patients with IgAN have complete resolution of urinary abnormalities [22] and episodes of visible hematuria become less frequent with time after diagnosis, although the majority of patients will still have persistent invisible hematuria. All patients have the potential for slowly progressive chronic kidney disease leading eventually to ESRD. Approximately 25–30% of any cohort will require renal replacement therapy within 20–25 years of presentation. From the first renal symptom, on average, 1.5% of patients with IgAN have been calculated to reach ESRD per year [23], but the observed risk varies with the diagnostic approach. Centers with a low threshold for renal biopsy for patients with mild urine abnormalities, particularly those in countries where urine screening programs are established, will likely diagnose IgAN in a larger number of patients with mild disease and good prognosis (length bias) and at an earlier stage in their disease (lead-time bias), thus favorably influencing the apparent prognosis for the cohort.

Rarely, acute kidney injury can complicate preexisting IgAN, and evaluation should include a further renal biopsy unless renal function improves rapidly with supportive measures. Acute kidney injury develops by two distinct mechanisms (Figure 17.2). There may be acute, severe immune and inflammatory injury producing crescent formation, or crescentic IgA nephropathy, which may be amenable to intensive immunosuppression. Alternatively, acute kidney injury can occasionally occur with mild glomerular injury when heavy glomerular hematuria leads to tubular occlusion and/or damage by red blood cells. This is a reversible phenomenon, and recovery of renal function occurs with supportive measures.

Pediatric IgAN

Children with progressive forms of IgAN will often not develop ESRD until they are adults [24, 25]. Thus, most pediatric trials must rely on surrogate measures, as discussed in the next section. Some reports of childhood IgAN have concluded that the risk of progressive renal failure is very low [26–28], whereas others have shown that a significant number of pediatric patients with IgAN will progress to ESRD [24, 25, 29]. It has been estimated that as many as 30% will progress to ESRD in the United States [25], but for Japanese children only 11–20% are expected to progress to ESRD [24, 28, 29]. However, similar to many adult studies, predictions are based on different selection criteria for renal biopsy candidates [28, 30]. In addition, when progressive disease occurs, it is often insidious, resulting in considerable difficulty in assessing outcomes over the short term. This also presents a significant obstacle when designing clinical trials to evaluate the effect of therapeutic interventions within a feasible time period (i.e. 2–5 years).

Prognostic Factors

Many studies have identified features at presentation that mark a poor prognosis (Table 17.1) [21]: proteinuria more than 1 g/24 h, raised serum creatinine, and hypertension. The severity of proteinuria has been shown to correlate with extent of glomerular lesions [31]. In one study, 98% of patients presenting with proteinuria of <1 g/24 h had at least a 15-year renal survival [32]. Another analysis identified those with proteinuria of more than 1 g/24 h and serum creatinine more than 1.7 mg/dl. The 7-year renal survival was 99% if both values were below this threshold, 87% if either one was above the cutoff, and 21% if both were above the cutoff [33]. Episodic visible hematuria does not entail a poor prognosis. It is likely that this observation reflects the variation in time between clinical presentation and diagnosis, which can hinder the accurate interpretation of the natural history.

Table 17.1 Prognostic markers at presentation.

Prognosis category	Clinical finding(s)	Histopathological findings
Worse prognosis	Increasing age Duration of preceding symptoms Severity of proteinuria Hypertension Renal impairment Increased body mass index Serum uric acid	*Light microscopy* Mesangial hypercellularity Endocapillary hypercellularity Segmental glomerulosclerosis Tubular atrophy/interstitial fibrosis Cellular/fibrocellular crescents *Immunofluorescence* Capillary loop IgA deposits *Ultrastructure* Capillary wall electron-dense deposits Mesangiolysis GBM abnormalities
Good prognosis	Recurrent visible hematuria	Minimal light microscopic abnormalities
No effect on prognosis	Gender Serum IgA level	Intensity of IgA deposits Codeposition of mesangial IgG, IgM, or C3

GBM, glomerular basement membrane.

The Oxford Classification of IgA Nephropathy

Renal biopsy provides important independent prognostic information about the renal outcome of patients with IgAN. The recently updated Oxford Classification of IgAN [34] identifies five morphological features that correlate strongly with clinical outcome, independent of known clinical risk factors at the time of diagnosis, including the presence of hypertension, reduced glomerular filtration rate (GFR), and degree of proteinuria as well as proteinuria and blood pressure (BP) at follow-up. These features are mesangial hypercellularity (M), endocapillary hypercellularity (E), segmental glomerulosclerosis (S), crescent formation (C), and tubular atrophy/interstitial fibrsosis (T). The presence of multiple pathological features (M, E, C, S, and/or T) in combination results in additive risk of kidney disease progression. The predictive value of these biopsy features is similar in both adults and children. Since its publication, the Oxford Classification of IgAN has been validated in different patient populations from North America, Europe, and Asia, and is now widely accepted as the histopathological scoring system of choice for IgAN [35–38].

The various prognostic factors described may be informative for groups of patients but do not have sufficient accuracy to predict the prognosis of an individual patient with complete confidence. More refined methods of assessing disease activity are required to define those patients in whom IgA deposition will lead to substantial and sustained glomerular injury. An approach incorporating information on blood pressure (BP), proteinuria, and estimated glomerular filtration rate (eGFR) at time of biopsy along with the Oxford MEST-C score has recently been developed by the International IgA Nephropathy Network (IIGANN) which allows individual risk stratification at the time of biopsy and is available at the QxMD website (https://qxmd.com/calculate/ calculator_499/international-igan-prediction-tool-adults).

Treatment

We have reviewed the English literature published on the treatment of IgAN since 1976. Despite the prevalence of IgAN, published randomized controlled trials (RCTs) are few in number, and even recent RCTs are not always sufficiently powered to provide definitive information on tested interventions. In part, this is because IgAN is a slowly progressive disease, making it necessary to study large numbers of patients for prolonged periods of time to determine the efficacy of any therapeutic intervention. Another consequence of the slowly progressive nature of IgAN is that for many of the trials now published, patient recruitment occurred at a time when the management of progressive glomerular disease was less clearly defined than it is now. These caveats are even more relevant for reports dealing with therapeutic interventions in children

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with IgAN. Although the most important outcome indicator for all patients with IgAN is based on deterioration of the GFR, the period from diagnosis to ESRD in patients with onset in childhood may be decades and may be highly heterogeneous. Thus, most studies of therapy for pediatric IgAN have relied on surrogate markers, such as deterioration in renal biopsy findings [39, 40] and/or decline in the amount of proteinuria or hematuria [40–42]. Significant deterioration in renal function (i.e. 40–50% reduction of GFR or doubling of serum creatinine concentration) is the surrogate end point most associated with progression to ESRD, although this occurs infrequently in patients participating in pediatric trials of IgAN [42].

All Patients with IgAN

Recommendations for Adults

All adult patients with IgAN should have a BP of <125/75 to 130/80 mmHg (strong recommendation, high level of evidence). The antihypertensive agents of choice should be angiotensin converting enzyme inhibitors (ACEi) and angiotensin II receptor blockers (ARB) (strong recommendation, high level of evidence). All normotensive patients with proteinuria of >1.0 g/l/1.73 m^2/day should be treated with the maximal tolerated dose of either an ACEi or ARB to reduce proteinuria as much as possible. Furthermore, all patients should have an individual assessment of their cardiovascular risk, particularly those with progressive chronic kidney disease, hypertension, and dyslipidemia, and treated accordingly (reviewed in Chapter 6).

Recommendations for Children

It is also important to maintain pediatric patients with IgAN in a normotensive range, utilizing age-, gender-, and height-appropriate norms for BP [43] (strong recommendation, high level of evidence). ACEi and ARB are the first choice for treatment of hypertension and/or proteinuria (strong recommendation, high level of evidence).

Evidence in Adults

In common with virtually all kidney diseases, hypertension is a risk factor for progression in IgAN and should be treated early in the course of the disease [21, 44]. There is, however, limited RCT evidence devoted specifically to IgAN concerning a target BP required to preserve renal function. In one 3-year RCT of 49 patients with IgAN, the

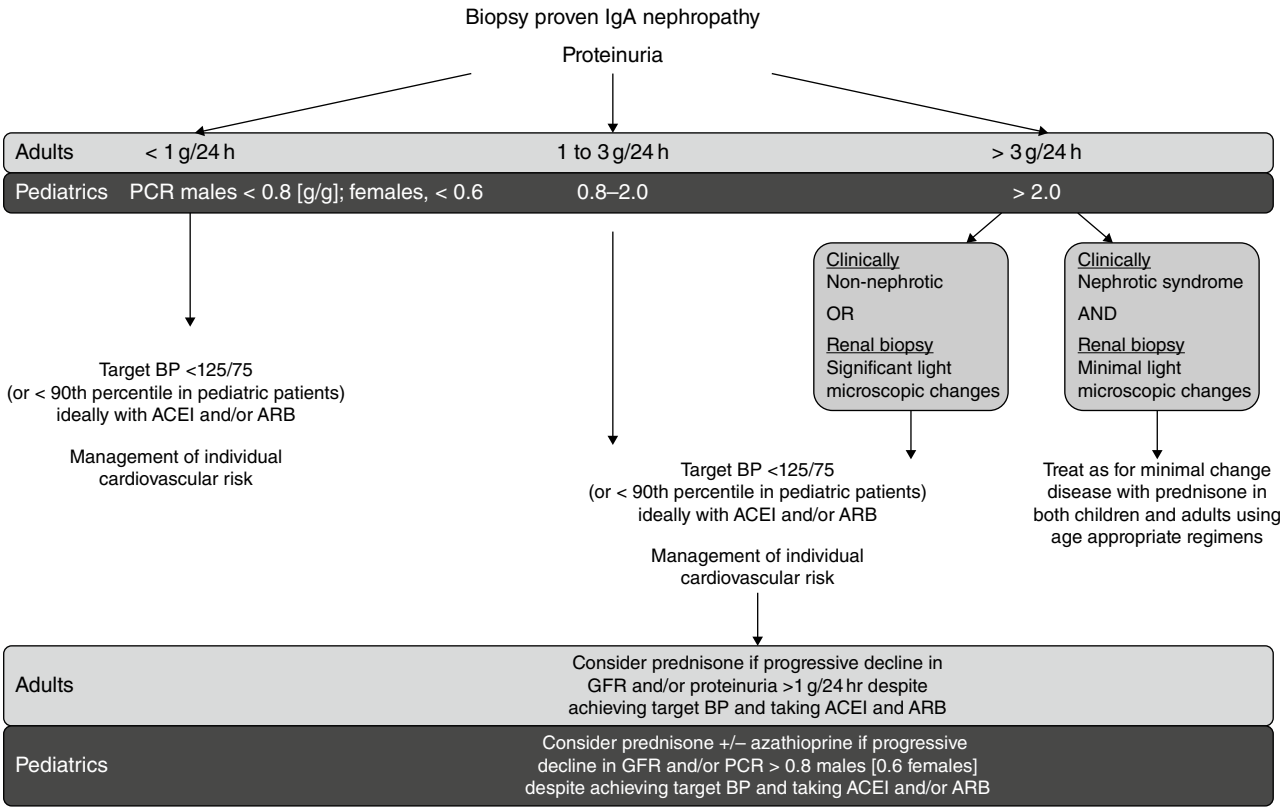

Figure 17.1 Flowchart for the management of IgA nephropathy.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

achieved mean BP of 129/70 mmHg stabilized GFR over 3 years, whereas patients with an achieved mean BP of 136/76 mmHg showed an average decline in GFR of 13 ml/min over 3 years [45]. As with other proteinuric glomerular diseases, the antiproteinuric effect of antihypertensive treatment appears to predict renoprotection, and so therapy should be titrated not only to target BP values but also to maximize reduction of proteinuria. There is increasing evidence that the antihypertensive strategy of choice should be maximal renin–angiotensin system (RAS) blockade, to both achieve a target BP of <125/75 to 130/80 mmHg and to minimize proteinuria [46] (Table 17.2). Retrospective data from the Toronto GN registry have shown that patients with IgAN treated with an ACEi to control BP had a lower rate of annual loss of renal function than similar patients treated with alternative antihypertensives [47]. This is supported by an RCT of 44 patients that demonstrated an additional benefit of an ACEi (enalapril) on progressive kidney disease in IgAN despite equivalent BP control [50]. This benefit was believed to have arisen from the additional reduction in proteinuria seen in the ACEi-treated group. Similarly, a more recent and larger RCT of 109 Asian patients showed benefit with an ARB (valsartan) both in proteinuria reduction and in retarding the rate of renal deterioration, although the investigators were unable to demonstrate a significant improvement in their primary end points of doubling of serum creatinine or ESRD at 2 years [51].

The safety of using ACEi in combination with an ARB is unclear [55, 56] and therefore should be avoided in IgAN.

Evidence in Children

A placebo-controlled RCT conducted in 23 centers in five European countries that evaluated benazepril (0.2 mg/kg/day) in 66 children and young adults <35 years of age provided evidence to support the use of ACEi in pediatric patients [54]. The patient cohort included 29 patients ≤18 years of age. Seventy-four percent of the patients had their initial renal abnormalities when they were ≤18 years old. The overall allocation of patients was 32 in the benazepril arm and 34 in the placebo arm. There was a significant benefit with benazepril in preventing progression of renal disease in these patients (defined as a reduction in GFR by 30% versus baseline or worsening of proteinuria to ≤3.5 g/l/1.73 m^2/day). Such progression was seen in 9/34 (26%) of the placebo group but only 1/32 (3%) of the benazepril group. Furthermore, at the end of the trial, the number of patients with proteinuria of <0.5 g/l/1.73 m^2/day in the benazepril group was significantly higher than the number in the placebo group (13/32 [40%] vs. 3/34 [9%]; $P = 0.0002$). This was evident in the groups of children (6/10 [60%] vs. 2/19 [10%]) and adults (7/12 [58%] vs. 1/15 [7%]) in this trial.

Patients with Recurrent Visible Hematuria

Recommendation for Adults and Children

Patients with recurrent visible hematuria require no specific additional intervention (strong recommendation, high level of evidence).

Table 17.2 Evidence for use of RAS blockade in IgAN[a].

Author [reference]	Design	*n*	Treatment	Follow-up (months)	Results
Cattran [47]	NRCT	115	ACEi	29	↑ GFR, ↓ proteinuria
Coppo [48]	NRCT	27	Captopril	26	↑ GFR, ↓ proteinuria

Evidence in Adults

Episodes of visible hematuria are self-limiting and can be provoked by a range of mucosal, most commonly respiratory, infections. There is no evidence supporting prophylactic use of antibiotics, even in the minority of patients in whom recurrent episodes are provoked by bacterial tonsillitis. Tonsillectomy is still favored as therapy in some regions of the world, notably Japan. Although several retrospective studies of the effectiveness of tonsillectomy have been published, most contain small numbers of patients, are nonrandomized, uncontrolled trials, and have generated conflicting data. In one Japanese study tonsillectomy was shown to be an independent factor in predicting remission in 329 patients followed for a minimum of 3 years [57]. A second retrospective study from Japan looked at the outcome in 118 patients followed over 20 years, of which 48 underwent tonsillectomy [58]. Benefit from the tonsillectomy only became apparent 10 years after initial diagnosis. The concomitant use of other treatment modalities and changing therapeutic goals during the follow-up period make these data difficult to interpret. A retrospective study from Germany of 55 patients in whom 16 had a tonsillectomy suggested no benefit of tonsillectomy at 10 years [59]. A retrospective study of 112 Chinese patients, of whom 54 underwent tonsillectomy, similarly showed no difference in renal survival at 130 months [60]. The only prospective RCT of tonsillectomy combined with steroids versus steroids alone has reported 12-month outcome data and while there was a small improvement in hematuria and proteinuria in the tonsillectomy group there was no difference in the rate of eGFR decline between the groups [61].

Evidence in Children

As for adults, there are no prospective clinical trials evaluating the role of tonsillectomy in children with IgAN. In 1996, Tomioka et al. reported that 13 of 15 children with IgAN who underwent tonsillectomy had improved urinalyses, with six of them going into remission [62]. More recently, changes in the levels of hematuria and proteinuria were assessed by Sanai et al. in eight children treated with "medication" combined with tonsillectomy compared to seven "control" children treated with "medication" [63]. These patients were a small subset of a larger patient cohort (ages 3–13 years) that included five children with Henoch–Schonlein purpura nephritis and eight with "other" types of glomerulonephritis. No details were given regarding the "medication" that was employed. The authors reported that both proteinuria and hematuria improved in five of eight patients in the tonsillectomy group compared to only one of the seven children with IgAN who received medication only. However, it is of interest that significant improvement also followed tonsillectomy in five of the eight children with other glomerulonephritis.

These limited data on the effect of tonsillectomy in children with IgAN are similar to the reports in adults. Most of the studies that have been reported in both groups are retrospective in nature, are based on unvalidated surrogate markers for outcome, and are confounded by co-interventions. There is no convincing evidence that tonsillectomy will prevent progressive renal disease in children or adults, and so this procedure should not be done (weak recommendation, low level of evidence).

Patients with Isolated Invisible Hematuria and Proteinuria of <1 g/24 h

Recommendation for Adults and Children

Adult patients with isolated invisible hematuria and proteinuria of <1 g/24 h require no specific additional intervention (strong recommendation). There are insufficient data to establish a specific evidence-based recommendation for children in this category, but we suggest that such patients require no additional therapy if their urinary protein (grams)/creatinine (grams) ratio is <0.6 (boys) or <0.8 (girls) (strong recommendation, high level of evidence).

Evidence

Available data suggest that most patients presenting with proteinuria of <1 g/24 h have at least a 15-year renal survival [32]. It is generally accepted that these patients require no additional treatment, although they should receive regular follow-up. It is, however, important to note that while a threshold for proteinuria of 1 g/24 h is commonly used to identify those at increased risk of progression (and therefore warranting treatment), this is an arbitrary value and the risk attributable to proteinuria is almost certainly a continuum. Interventions that may lower proteinuria further, and are therefore likely renoprotective, for example RAS blockade, have not been tested in this setting in either adults or children.

Patients with Rapidly Declining GFR

Recommendation for Adults

Unexplained acute kidney injury complicating preexistent IgAN requires evaluation with a kidney biopsy (Figure 17.2). Crescentic IgAN associated with active

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

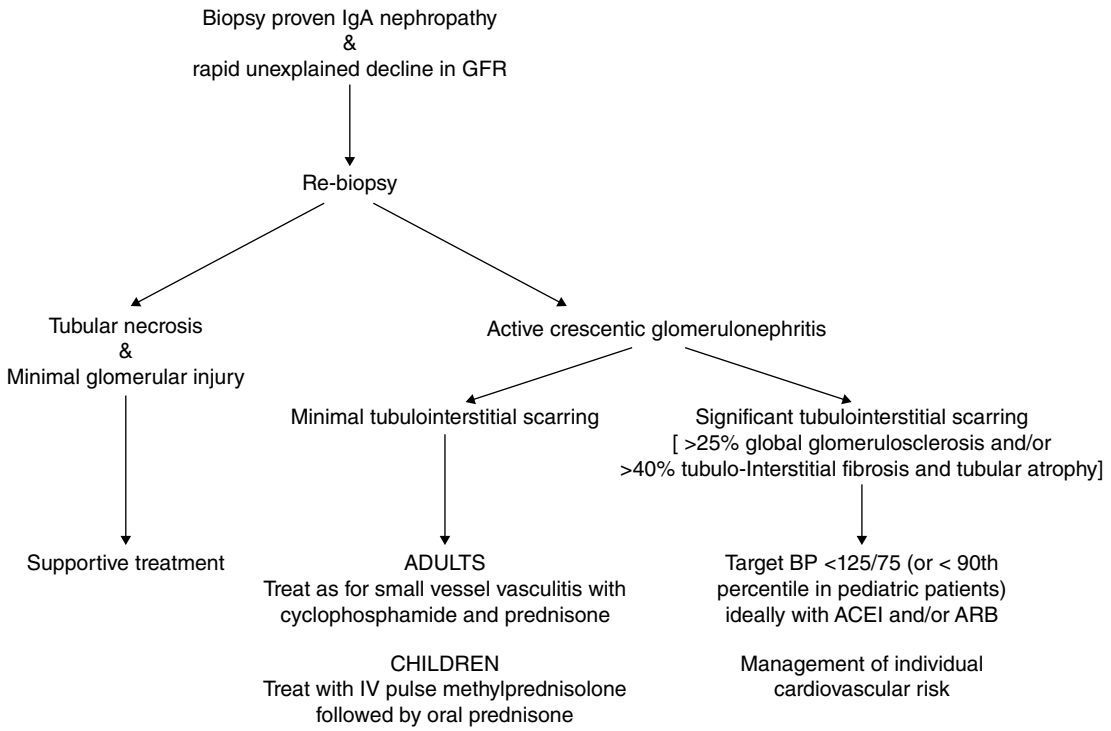

Figure 17.2 Flowchart for the evaluation and management of patients with previously diagnosed IgA nephropathy who present with a rapid unexplained decline in renal function.

glomerular inflammation and deteriorating renal function in the absence of significant chronic damage should be treated with induction therapy comprising cyclophosphamide and corticosteroids followed by maintenance therapy of azathioprine and corticosteroids at doses similar to those used for the treatment of anti-neutrophil cytoplasmic antibody-positive (ANCA) small vessel vasculitis (weak recommendation, very low level of evidence).

Recommendation for Children

Although there are no controlled trials of treatment regimens for children with crescentic IgAN, we recommend that pediatric patients with rapidly progressive disease and crescents in ≥50% of their glomeruli be treated with a 2-week course of intravenous (IV) methylprednisone pulses (six doses of 1 g/1.73 m^2 every other day), followed by 1 month of daily prednisone (1 mg/kg/day) and then alternate-day prednisone for 2–3 months (weak recommendation, very low level of evidence). Additional therapy with cyclophosphamide should be considered in patients who fail to respond to the pulse therapy (weak recommendation, very low level of evidence).

Evidence in Adults

Acute kidney injury may occur as the first presentation of IgAN with little preceding renal insult or may be superimposed on a background of preexistent disease with variable degrees of chronic glomerular and tubulo-interstitial scarring. Even if the diagnosis of IgAN has previously been established, evaluation should include renal biopsy to distinguish between acute kidney injury due to acute tubular necrosis, which should be self-limiting with supportive treatment, and crescentic IgAN, which may be amenable to intensive immunosuppression.

Crescentic IgAN has a less favorable prognosis, even with immunosuppressive therapy, than other forms of crescentic glomerulonephritis, such as ANCA-associated small vessel vasculitis; cumulative published cases suggest that renal survival in crescentic IgAN is only 50% at 1 year and 20% at 5 years [21, 64]. Evidence of chronic glomerular and tubulo-interstitial injury with scarring usually predicts a poor response to intensive immunosuppression. There is no published systematic definition of the degree of chronicity that predicts poor response to immunosuppressive treatment, but we do not recommend such an approach if a representative renal biopsy shows >40% tubulo-interstitial fibrosis and/or >25% global glomerulosclerosis.

Table 17.3 Evidence for management of crescentic IgAN with acute kidney injury[a].

Author [reference]	Design	*n*	Treatment	Follow-up (months)	Results
Lai [65]	NRCT	2	Plasma exchange	12	Unsustained slower ↓ GFR
Nicholls [66]	NRCT	13	Plasma exchange		Unsustained slower ↓ GFR
Roccatello [67]	NRCT	9	Plasma exchange, CP and steroids	60	Unsustained slower ↓ GFR
Roccatello [68]	NRCT	20	CP and steroids	60	Slower ↓ GFR
McIntyre [69]	NRCT	9	CP and steroids	17	↑ GFR, ↓ proteinuria
Tumlin [70]	NRCT	24	CP and steroids	36	Stabilized GFR, ↓ proteinuria

CP, cyclophosphamide; GFR, glomerular filtration rate; NRCT, nonrandomized controlled trial.
[a] Overall quality very low: inconsistent effects, nonrandomized, very small studies, surrogate outcomes.

A number of case series have been published that indicate good preservation of renal function when using treatment regimens similar to those recommended for renal vasculitis, usually with high-dose corticosteroids and cyclophosphamide, and in some cases plasma exchange (Table 17.3). However, all of these series are small nonrandomized studies, most using historical controls. There has still been no RCT of these treatments in crescentic IgAN, and response to treatment is not uniform. In addition, comparisons across studies are difficult because published reports use varying definitions of crescentic IgAN. Some include cases where crescents are seen, but others include acute injury where the glomerular tuft is not intense and renal function is not deteriorating. One report indicated that there is a subset of crescentic IgAN with circulating ANCA antibodies which respond well to immunosuppression [71].

Evidence in Children

As in adults, the prognosis for children with crescentic IgAN is also poor according to most reports [72]. However, in the largest pediatric experience reported to date, Niaudet et al. described a very aggressive and successful approach to 12 children aged 8–14 years with crescentic IgAN, 10 of whom had crescents in ≥50% of their glomeruli [73]. The patients received IV methylprednisone in a dose of 1 g/1.73 m^2 every other day, followed by 1 month of daily prednisone (1 mg/kg/day) and then alternate-day prednisone for 2–3 months. Three of the patients received a second course of pulse methylprednisone, whereas three others received cyclophosphamide. Although uncontrolled, the authors described very good results after a follow-up period of 1–9 years because none of the children progressed to ESRD, nine had improved histology on repeat biopsy, and six had recovered clinically, although one patient was still hypertensive.

Patients with Nephrotic Syndrome

Recommendation for Adults and Children

In patients presenting with nephrotic syndrome, preserved renal function, and minimal glomerular injury evident on light microscopy, a trial of high-dose corticosteroids using a regimen appropriate for minimal change disease in IgAN should be considered (strong recommendation, very low level of evidence). However, there is no evidence to support prolonged exposure to corticosteroids if there is not a prompt response, nor for their use in nephrotic syndrome in the presence of structural glomerular damage.

Evidence in Adults

In many patients with IgAN, nephrotic syndrome-range proteinuria is a manifestation of significant structural glomerular damage and progressive renal dysfunction. However, a small minority of both adults and children have nephrosis with minimal glomerular change on renal biopsy, although there are also IgA deposits, and proteinuria remits promptly in response to corticosteroids. In these patients, two common glomerular diseases may coincide: minimal change nephrotic syndrome and IgAN [74, 75]. The only RCT of corticosteroids in nephrotic IgAN confirmed this approach, since there was remission of proteinuria only in patients with minimal glomerular change on light microscopy [76]. More recent RCTs of corticosteroids in IgAN have excluded those with nephrotic-range proteinuria, so there is little evidence to inform treatment choices for nephrotic IgAN with significant histologic glomerular injury.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Evidence in Children

A number of reports have also described the association of mesangial IgA deposition in association with steroid-responsive nephrotic syndrome in children [77–79]. In at least two of the patients described in the SPNSG report, there was a temporal dissociation between the onset and course of nephrotic syndrome and the later development of clinical features of IgAN [77].

Patients with Slowly Progressive Renal Impairment

Recommendations for Adults

Tight BP control to a target of <125/75 mmHg and evaluation of individual cardiovascular risk are essential in this group of patients (strong recommendation, high level of evidence). In patients with persistent proteinuria (>1 g/24 h) despite tight BP control (<125/75 mmHg) and maximal RAS blockade (independent of BP), a 6-month treatment course of corticosteroids may reduce proteinuria and stabilize kidney function (weak recommendation, low level of evidence). Available evidence does not support a role for mycophenolate mofetil (MMF) in Caucasian patients (weak recommendation, very low level of evidence), although evidence from a single Chinese study suggests MMF may be useful as a steroid sparing agent in selected cases of IgAN in Chinese patients. We cannot recommend the use of cyclophosphamide (strong recommendation, low level of evidence), fish oil (weak recommendation, very low level of evidence), and other agents at the present time (Table 17.4).

Recommendations for Children

Based upon the limited evidence currently available, we are unable to make a specific recommendation regarding

Table 17.4 Treatment for IgA nephropathy.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Angiotensin converting enzyme inhibitors or angiotensin II receptor blockers	We suggest angiotensin converting enzyme inhibitors or angiotensin II receptor blockers be used to lower blood pressure to <125/75 to 130/80 and/or maximize reduction of proteinuria for patients with IgAN	*High* (decrease in eGFR and proteinuria)	Strong
Tonsillectomy	We do not suggest tonsillectomy to be considered routinely in patients with IgAN	*Low* (decrease in eGFR and proteinuria)	Weak
Corticosteroids	We suggest in patients with progressive decline in eGFR and/or persistent proteinuria (>1 g/24 h) despite tight BP control (<125/75 mmHg) and maximal RAS blockade, a 6-month treatment course of corticosteroids may reduce proteinuria and stabilize kidney function	*Low* (decrease in eGFR and proteinuria)	Weak
Cyclophosphamide and azathioprine	We suggest crescentic IgAN associated with active glomerular inflammation and deteriorating renal function in the absence of significant chronic damage should be treated with induction therapy comprising cyclophosphamide and corticosteroids followed by maintenance therapy of azathioprine and corticosteroids at doses similar to those used for the treatment of ANCA-positive small vessel vasculitis	*Low* (decrease in eGFR and proteinuria)	Weak
Mycophenolate mofetil	We do not suggest mycophenolate mofetil be used in patients with IgAN	*Very low* (decrease in eGFR and proteinuria)	Weak
Fish oil	We do not suggest that fish oil be used in patients with IgAN	*Very low* (decrease in eGFR and proteinuria)	Weak

eGFR, estimated glomerular filtration rate; IgAN, IgA nephropathy; BP, blood pressure; RAS, renin angiotensin system; ANCA, anti-neutrophil cytoplasmic antibody.
GRADE assessment of the certainty of the evidence [5]: High: this research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: this research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: this research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

the use of fish oil supplements for treatment of IgAN in the pediatric patient, although preliminary data from the North American IgA Nephropathy Trials indicate that such therapy may be efficacious in reducing proteinuria in such patients [77]. We recommend that a trial of alternate-day prednisone be considered in pediatric patients who have deterioration of GFR or persistent proteinuria (weak recommendation, very low level of evidence). If prednisone alone is unhelpful, we recommend therapy combining corticosteroids with azathioprine (weak recommendation, very low level of evidence)

Evidence in Adults and Children

Patients at risk of progressive renal dysfunction are typically those with hypertension, proteinuria of >1 g/24 h, reduced GFR at the time of diagnosis, and high Oxford scores in the diagnostic renal biopsy (M1, E1, S1, C1/2, and T1/2). Specific treatment strategies in this group of patients remain contentious. Progression is usually slow and therefore large studies with prolonged follow-up are necessary to evaluate new treatment strategies in these patients. Reported RCTs have tested interventions intended to slow immune and inflammatory events implicated in progressive IgAN, including corticosteroids, cyclophosphamide, and MMF. Because of the long duration required to identify with confidence the benefit of interventions, it is inevitable that recruitment into a number of these studies goes back 10 years or more, to a time when the generic approach to progressive glomerular disease was less well defined, so that BP targets and the use of RAS blockade are variable in these studies.

Immunosuppressive Treatments in Adults

The value of immunosuppressive treatment, in addition to best supportive therapy, in IgAN remains uncertain. The Supportive Versus Immunosuppressive Therapy for Progressive IgA Nephropathy (STOP-IgAN) trial was a multicenter, open-label, RCT in which immunosuppressive therapy added to comprehensive supportive therapy was compared with comprehensive supportive therapy alone in IgAN [80]. During a 6-month run-in period, patients received optimal comprehensive supportive care. Patients with persistent urinary protein excretion of >0.75 g/day were assigned randomly to continue comprehensive supportive care alone or comprehensive supportive care plus immunosuppressive therapy for 3 years. In the immunosuppression group, patients with an eGFR of 60 ml/min or greater received corticosteroid monotherapy for 6 months, and patients with an eGFR of 30–59 ml/min received cyclophosphamide for 3 months followed by azathioprine plus oral prednisolone. At 3 years there was no difference in either the number of patients who had a decrease in eGFR of at least 15 ml/min or the annual rate of decline in eGFR between the two groups. The glucocorticoid monotherapy arm produced a transient reduction in proteinuria in patients with relatively well-preserved GFR, but the reduction in proteinuria did not translate into protection against GFR decline. Adverse events (severe infections, impaired glucose tolerance, and weight gain of >5 kg in the first year of treatment) were more common in the immunosuppression group and one patient in the immunosuppression group died of sepsis.

Corticosteroids in Adults

The review of immunosuppressive treatments for IgAN by the Cochrane Renal Group identified six RCTs of sufficient quality to be included in their meta-analysis of corticosteroid treatment in IgAN (Table 17.5) [86]. This analysis suggests that corticosteroid therapy may be effective in reducing proteinuria (six trials, 263 patients) and reducing risk of ESRD (six trials, 341 patients), although the meta-analysis was unable to evaluate the influence of RAS blockade or achieved BP in the analysis. Follow-up in a large Italian study of corticosteroid treatment has now reached 10 years and the investigators report impressive benefit of treatment in reducing proteinuria and preventing ESRD [87]. However, the high-dose corticosteroid regimen, with pulse methylprednisone (1 g daily for 3 days at induction and beginning of months 2 and 4) and alternate-day oral prednisone (0.5 mg/kg) for 6 months, is regarded by many physicians as likely to carry considerable toxicity, even though none was reported by the investigators. Notably, RAS blockade was only used in a minority of patients in this study, although equally distributed among the participants, and achieved BP was not in line with current recommendations. Another RCT of corticosteroids (20 mg/day induction and 5 mg/day maintenance) from Japan in which BP control was tight even though RAS blockade was not used showed only a modest reduction in proteinuria with no protection of GFR [83]. It is unclear whether this lack of renoprotection was due to the lower dose of corticosteroid or a genuine lack of effect in patients managed to current BP targets. In a meta-analysis, consisting of nine studies and 536 patients, Lv et al. found that steroids therapy was associated with lower risk of developing kidney failure and reduction in proteinuria, but a 55% higher risk for adverse events [88].

Table 17.5 RCTs included in the Cochrane Renal Group meta-analysis evaluating the benefit of corticosteroids in IgAN[a].

Author [reference]	*n*	Treatment	Follow-up (months)	Results
Julian [81]	35	Pred, 60 mg/alt day (3/12) Controls: no treatment	6–24	Stabilized GFR, ↓ proteinuria
Kobayashi [82]	46	Pred, 40 mg/day (tapering over 7/12) Controls: no treatment	120	Stabilized GFR, ↓ proteinuria
Katafuchi [83]	90	Pred, 20 mg/day (tapering to 5 mg/day over 24/12) Controls: dipyridamole 150–300 mg/day	60	No effect on GFR decline, ↓ proteinuria
Lai [76]	34	Pred, 40–60 mg/day (halved at 2/12 for further 2/12) Controls: no treatment	38	Stabilized GFR, ↓ proteinuria
Pozzi [84]	86	MP, 1 g IV 3 times then 0.5 mg/kg/day for 6/12 Controls: no treatment	60	Stabilized GFR, ↓ proteinuria
Shoji [85]	21	Pred, 0.8 mg/kg/day (tapering to 10 mg alt day for 12/12) Controls: dipyridamole 300 mg/day (12/12)	13	Stabilized GFR, ↓ proteinuria

GFR, glomerular filtration rate; MP, methylprednisone; Pred, prednisone.
[a] Overall quality low: inconsistent effects, variable quality of RCT design and reporting, small studies, surrogate outcomes.

The Therapeutic Evaluation of Steroids in IgA Nephropathy Global (TESTING) study was a multicenter, double-blind placebo-controlled RCT in which the efficacy and safety of methylprednisolone (0.6–0.8 mg/kg/day, maximum 48 mg/day) was assessed in patients with IgAN [89]. At entry proteinuria was >1 g/24 h and eGFR of 20–120 ml/min after at least 3 months of BP control with RAS blockade. The study almost exclusively recruited form China and was terminated prematurely due to an excess of serious adverse events, mostly serious infections, including two deaths in the methylprednisolone group. While there did appear to be a potential renal benefit of oral methylprednisolone with a decrease in the primary composite outcome of ESRD, death resulting from kidney failure, or a 40% decrease in eGFR, a definitive conclusion could not be made because of early termination of the study. A low-dose TESTING study (ClinicalTrials.gov identifier NCT01560052) is now recruiting using half-dose methylprednisolone with co-trimoxazole prophylaxis and is expected to report in 2021/2.

Corticosteroids in Children

The short-term effects of prednisone on proteinuria and hematuria were examined by Welch et al. in a group of children with IgAN. Twenty patients were randomized to either placebo or prednisone (2 mg/kg/day, maximum 80 mg) for 2 weeks, followed by the same dose on alternate days for 10 weeks [90]. After a 12-week washout period, the treatments were reversed in each subject. No difference in the severity of hematuria was reported after treatment with prednisone compared to placebo. However, most of the subjects had only mild histologic changes, and the subjects in this study would not be expected to have progressive disease.

Waldo et al. compared the outcomes of 13 children with IgAN in Alabama followed for 4–10 years after they received alternate-day prednisone for 2 years with 15 children in Tennessee who received no steroid therapy [41]. All of the patients had either proteinuria of >1 g/m^2/day or renal biopsies showing more than a minimal degree of interstitial fibrosis, tubular atrophy, or glomerular sclerosis. None of the 13 treated patients progressed to ESRD, compared to five of 15 of the untreated patients ($P = 0.04$). At last follow-up, 12 of 13 treated patients had no hematuria and normal protein excretion ($P < 0.001$ compared with nontreated historic control patients).

Cyclophosphamide with/without Azathioprine in Adults

The use of cyclophosphamide in patients at very high risk of progression (ESRD predicted in all cases within 5 years) is supported by a single study. Patients received cyclophosphamide (1.5 mg/kg/day for 3 months) followed by azathioprine (1.5 mg/kg/day) in conjunction with high-dose prednisone (40 mg/day induction, 10 mg/day maintenance) and were followed for at least 2 years [91]. Notably, BP control and use of RAS blockade in this trial fell outside current recommendations. Previous RCTs of cyclophosphamide in less severe, slowly progressive IgAN have shown no consistent benefit [92], and this is supported by the STOP-IgAN trial and a Cochrane Renal Group meta-analysis, which failed to show any significant renal survival benefit from those RCTs incorporating cyclophosphamide,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cyclosporine, or other cytotoxic agents, although there was a significant reduction in daily proteinuria [80, 93]. These studies were, however, insufficiently powered to exclude any effect on progression with certainty.

Cyclophosphamide with/without Azathioprine in Children

The efficacy of a 1-year combined course of prednisone and azathioprine was evaluated in 10 children with IgAN by Andreoli and Bergstein [94]. Prednisone at 60 mg/m^2 (maximum 60 mg) daily for 8 weeks was followed by the same dose every other day for 10 months. Azathioprine (2–3 mg/kg/day) was given for 12 months. Proteinuria decreased significantly after treatment and serial renal biopsies showed that the activity score improved, but the chronicity score was unchanged. The level of microscopic hematuria also improved.

In 1994, Murakami et al. evaluated the efficacy of a 6-month course of prednisolone at 10–15 mg on alternate days, cyclophosphamide at 1 mg/kg/day, and dipyridamole at 5 mg/kg/day in 17 patients who had proteinuria of >1 g/m^2/day plus histologic risk factors for progressive disease compared to 21 patients with similar features who received the same regimen plus warfarin for 3 months [95]. The dipyridamole therapy was subsequently continued in all patients until the patient had ≤1 g/m^2/day proteinuria. Both groups of patients showed significant improvement in proteinuria but the chronic histology indices on post therapy biopsies (14 patients) showed persistent signs of chronic disease, as with Andreoli and Bergstein [94]. Addionally, follow-up studies showed rebound deterioration of proteinuria after 5–6 years.

In 1999, Yoshikawa et al. reported an RCT evaluating 2 years of therapy in two groups of children: group 1 prednisone, azathioprine, heparin, warfarin, and dipyridamole; group 2 heparin, warfarin, and dipyridamole [40]. The prednisone dose was 2 mg/kg/day (maximum 80 mg) for 4 weeks, reduced over 8 weeks, then maintained at 1 mg/kg every other day for 21 months. The azathioprine dose was 2 mg/kg/day. Although there was no significant change in GFR in either group, group 1 patients had a significant reduction of proteinuria but those in group 2 did not. There was also a significant decrease in glomerular IgA staining in follow-up biopsies in group 1 patients but not in group 2. These follow-up biopsies showed progression of glomerular sclerosis in control patients but not in those receiving prednisone and azathioprine. More recently, in 2006, Yoshikawa et al. described the results of a second RCT that compared the effects of combination therapy using prednisone, azathioprine, warfarin, and dipyridamole in 40 children versus prednisone alone in 40 children over 24 months [96]. Both treatment regimens were associated with remarkable improvement in proteinuria. The percentage of glomeruli showing sclerotic changes was unchanged from baseline in the patients receiving combination therapy but significantly higher in those receiving only prednisone. However, the use of ACEi/ARB was prohibited in this trial, hence it is not clear whether such aggressive immunosuppressive therapy would be the first choice of therapy in clinical practice.

MMF and Mizoribine in Adults and Children

MMF has been used in six major trials for IgAN (Table 17.6). Two studies reported no benefit from MMF (2 g/day) in Caucasian patients either at risk of progression (hypertensive and/or proteinuria of >1 g/24 h and/or reduced GFR within 5 years of diagnosis) [97] or with more advanced

Table 17.6 Evidence for the use of MMF in IgAN[a].

Author [reference]	Design	*n*	MMF treatment	Follow-up (months)	Results
Maes [97]	RCT	34	2 g/day for 36/12	36	No effect on GFR decline, no effect on proteinuria
Chen [98]	RCT	93	1–1.5 g/day for 6/12 1 g/day for 6/12 0.75 g/day for 6/12	18	No effect on GFR decline, ↓ proteinuria
Tang [99]	RCT	40	2 g/day for 6/12	18	No effect on GFR decline, ↓ proteinuria
Frisch [100]	RCT	32	2 g/day for 12/12	24	No effect on GFR decline, no effect on proteinuria
Hogg [101]	RCT	44	25-36 mg/kg/day for 12/12	6 (early termination)	No effect on proteinuria
Hou [102]	RCT	176	1.5 g/day	12	No effect on proteinuria

GFR, glomerular filtration rate; RCT, randomized controlled trial.

disease (mean serum creatinine at entry, 2.6 mg/dl) [100]. Both of these studies achieved rigorous BP control with use of an ACEi. In two separate studies in Chinese patients with less advanced renal impairment, MMF (1–2 g/day) did reduce proteinuria over an 18-month follow-up period, but neither study demonstrated a change in rate of renal decline [98, 99]. Again, both studies achieved tight BP control with ACE inhibition. A more recent study examined the use of MMF versus placebo in Caucasian adults and children in addition to lisinopril/losartan plus highly purified omega-3 fatty acid. The trial was terminated early because of a lack of benefit [101]. In a Chinese study, MMF and low-dose prednisolone (0.4–0.6 mg/kg per day) was compared with full dose prednisolone (0.8–1 mg/kg per day). Both regimens had equal efficacy in terms of remission rates at 6 and 12 months [102]. However, the MMF and steroid group suffered significantly fewer adverse events, suggesting MMF could be used as a steroid sparing agent in Chinese patients with IgAN.

A retrospective study in Japan showed that mizoribine, which blocks purine synthesis in a manner similar to MMF, resulted in a significant reduction in proteinuria when given to 20 pediatric patients in combination with prednisone, warfarin, and dipyridamole [103]. This was significantly better than the reduction in proteinuria seen in 21 historic control patients who were given only prednisone, warfarin, and dipyridamole, or in 20 historic control patients who also received IV pulses of methylprednisone. Follow-up renal biopsies in the mizoribine-treated patients showed no progression of chronic lesions, whereas the other two sets of patients had a significant increase in the chronicity index. A recent pilot study using mizoribine, again in combination with prednisone, warfarin, and dipyridamole, confirmed the efficacy and safety of this regimen in treating children with IgAN [104].

Fish Oil in Adults

A number of studies have evaluated the role of fish oils (eicos-apentanoic acid and docosahexanoic acid) in IgAN (Table 17.7). An RCT of 106 patients with proteinuria of >1 g/24 h and impaired renal function at enrollment (60% also hypertensive) found those treated with fish oil had a slower rate of decline in GFR at both 2 and 5 years [107, 108]. This effect appeared independent of the dose used [109]. These results have not been replicated in other RCTs studying similar patient cohorts [42, 105, 106]. A meta-analysis (three trials, 175 patients [105–107]) failed to detect a benefit of fish oils on renal outcome in IgAN [110]. Furthermore, a recent RCT showed no benefit following 2 years of treatment with fish oil compared to placebo [42], although a subsequent post hoc analysis of the data in the study revealed a dose-dependent decrease in proteinuria in the fish oil group [108]. In a Cochrane meta-analysis, consisting of four studies with 256 participants, there was no overall benefit of fish oil, as compared to placebo or no treatment, on renal outcomes, including change in serum creatinine, creatinine clearance, and decrease in proteinuria [111].

Rituximab

The role of rituximab in the treatment of patients with IgA nephropathy was evaluated in an open-label randomized study of 34 patients. Patients were randomly assigned to receive two doses of rituximab 1 g administered 2 weeks apart and an identical course 6 months later, or no rituximab. Despite successful depletion of CD19+ B cells, there were no differences in the change in proteinuria or change in renal function from baseline between the two groups [112].

Table 17.7 Evidence for the use of fish oil in IgAN[a].

Author [reference]	Design	*n*	EPA + DHA daily doses (g)	Follow-up (months)	Results
Bennett [105]	RCT	37	1.8 + 1.2	24	No effect on GFR decline
Pettersson [106]	RCT	32	3.3 + 1.8	6	↓ GFR, no effect on proteinuria
Donadio [107, 108]	RCT	106	1.8 + 1.2	24 and 60	Slower ↓ GFR
Donadio [109]	RCT	73	3.8 + 2.9 1.9 + 1.5	24	No difference between high- and low-dose EPA–DHA
Hogg [42]	RCT	96	1.88 + 1.48	24	No effect on GFR decline, ↓ proteinuria

DHA, docosahexanoic acid; EPA, eicosapentanoic acid; GFR, glomerular filtration rate; RCT, randomized controlled trial.
[a] Overall quality low: inconsistent effects, variable quality of RCT design and reporting, small studies, surrogate outcomes.

Other Therapies

Warfarin, urokinase, antiplatelet agents, phenytoin, sodium cromoglycate, dietary gluten restriction, and a low-antigen content diet have all been assessed for the treatment of IgAN and have not been shown to affect renal outcomes [92].

The use of newer immunosuppressive agents, such as the targeted release formulation of budesonide (ClinicalTrials.gov identifier NCT03643965), fostamatinib (ClinicalTrials.gov identifier NCT02112838), sparsentan, OMS721 (ClinicalTrials.gov identifier NCT03608033), LNP023 (ClinicalTrials.gov identifier NCT03373461), blisibimod (ClinicalTrials.gov identifier NCT02062684), and atacicept (ClinicalTrials.gov identifier NCT02808429), while of potential interest for this group of patients, should be considered experimental therapies at this point.

Membranoproliferative Glomerulonephritis

Fabrizio Fabrizi[1] *and Piergiorgio Messa*[1,2]

[1] *Division of Nephrology, Maggiore Hospital and IRCCS Foundation, Milano, Italy*
[2] *University School of Medicine, Milano, Italy*

Introduction

The term membranoproliferative glomerulonephritis (MPGN) refers to a morphological pattern of injury common to a heterogeneous group of diseases; it is also known as "mesangiocapillary glomerulonephritis" or "lobular glomerulonephritis." Light microscopy examination shows glomerular injury which consists of increased mesangial matrix accompanied by an increase in the cellularity of the mesangium and capillary-wall remodeling. These changes result in lobular accentuation of the glomerular tufts.

Based on the results provided by electron microscopy, MPGN has been conventionally categorized as primary (idiopathic) type I, type II, or type III. The most common form of MPGN is MPGN I, which is characterized by subendothelial deposits (often presumed to be immune complexes); MPGN type III has both subendothelial and subepithelial deposits. MPGN type II has dense deposits in the glomerular basement membrane ("dense deposit disease") [1].

A more recent classification is based on the composition of the deposits, as highlighted by immunofluorescence staining [2–4]. This classification results from an enhanced understanding of the role of complement in the pathogenesis of MPGN, and treatments targeting specific diseases are under way. This chapter reviews the most important advances regarding pathogenesis, prognosis, and current therapeutic options for MPGN and some additional MPGN-associated conditions.

MPGN: Histology

The morphological pattern of MPGN includes a marked and diffuse thickening of the glomerular capillary walls. The thickening can be more prominent in some glomeruli and in some capillary loops than in others. Periodic acid Schiff and silver methenamine stains show that the thickened glomerular capillary walls sometimes have two basement membranes with a clear nonargyrophylic region between them. The double contour is termed duplication of the glomerular basement membrane; interposition of mesangial cells or trapping of circulating cells between various layers of basement membrane commonly occurs. In some capillaries, the duplication of the glomerular basement membrane results in multiple laminations. The thickening of the capillary walls, the mesangial expansion (increase in matrix and cellularity in mesangium), and the occurrence of subendothelial deposits lower the glomerular capillary lumen. These abnormalities are most often diffuse and generalized, and lead to a simplification of the architecture of the glomeruli and an accentuation of the lobulation of the glomerular capillaries. Extracapillary crescent formation can complicate the histological picture in approximately 10% of patients. These are frequently small and focal crescents. Morphological changes in the tubules and interstitium typically reflect the changes noted in the glomeruli. Arterial and arterioles are affected in cases with renal failure and long-standing hypertension. The strong association between MPGN and hypocomplementemia has been highlighted by West and coworkers in

1965 and led to the adoption of the term "hypocomplementemic persistent glomerulonephritis" for this subset of glomerular disorders [5].

MPGN: Novel Classification and Pathophysiology

According to the novel classification, three types of MPGN have been suggested: (i) immune-complex-mediated MPGN, (ii) complement-mediated MPGN, and (iii) nonimmune-complex mediated/noncomplement mediated MPGN [2–4] (Figure 18.1).

Patients with immune-complex-mediated MPGN (IC-MPGN) typically show at kidney biopsy immunoglobulin and complement on immunofluorescence staining. Immune-complex mediated MPGN is further subdivided depending on the Ig structure (i.e. monoclonal IgG heavy chain or polyclonal IgG, as in lupus nephritis). When an autoimmune disease such as lupus is the underlying disorder, MPGN is characterized by a "full house" pattern of immunoglobulin deposition including IgG, IgM, IgA, C1q, C3, and kappa/lambda chains [6]. Immune-complex-mediated MPGN includes most of those cases formerly considered MPGN type I and some cases of MPGN type III (Burkholder type). The absence of marked immunoglobulin staining on immunofluorescence microscopy distinguishes MPGN due to alternative-pathway dysfunction from immune-complex-mediated MPGN. Indeed, complement-mediated MPGN is typically immunoglobulin-negative but complement-positive on immunofluorescence studies; it is associated with dysregulation of the alternative pathway of complement. On the basis of electron microscopy, complement-mediated MPGN or $C3_3$ glomerulopathy (C3G) may be classified into dense-deposit disease (DDD) and C3 glomerular disease (C3GN). Cases of the former MPGN type II (DDD) and some cases of MPGN type III (Strife and Anders type) are included in the subset of complement-mediated MPGN.

An additional category is nonimmune-complex mediated/noncomplement-mediated MPGN. Glomerular lesions consistent with MPGN are very infrequent and confined to a few patients of chronic thrombotic microangiopathies, de novo chronic transplant nephropathy, radiation nephritis, or drug-associated thrombotic angiopathy. In these cases, immunofluorescence is typically negative for immunoglobulins and complement, and electron-dense deposits are not detected by electron microscopy (Figure 18.1).

Immune-complex-mediated MPGN

Immune-complex-mediated MPGN is typically a consequence of the deposition of immune complexes in the glomeruli owing to persistent antigenemia, with antigen-antibody immune complexes forming as a result of chronic infections, elevated levels of circulating immune complexes due to autoimmune diseases, or paraproteinemias due to monoclonal gammopathies. Then, the immune complexes activate the classical complement pathway and this is clinically reflected in a normal or mildly decreased serum C_3 concentration and a low C_4 level. The most frequent underlying disorders linked with immune-complex MPGN are infections and these include hepatitis B [7] or C virus (with or without cryoglobulinemia) [8, 9], bacterial, or protozoal agents (Table 18.1). In addition, autoimmune disorders involved in the pathogenesis of MPGN are

rheumathoid arthritis and systemic lupus erythematosus. Additional causes of MPGN are monoclonal gammopathies (mostly of uncertain significance) and malignancies (renal cell carcinoma, non-Hodgkin lymphoma) [10–14].

The diagnosis of idiopathic MPGN is made after all of the secondary causes are excluded; idiopathic MPGN is considered now a rare entity and the majority of cases of immune-complex-mediated MPGN are secondary to the etiologies reported above.

HCV-associated Immune-complex-mediated MPGN

Hepatitis C virus (HCV) may instigate mixed cryoglobulinemia and the most significant accompanying kidney lesion is type I MPGN, usually occurring in the context of type II mixed cryoglobulinemia. Patients with type II MC show monoclonal IgM *k* (or IgG or IgA) having rheumatoid factor (RF) activity and polyclonal Ig (mainly IgG). After the identification of HCV, it has been recognized as the cause of 80–90% of mixed cryoglobulinemia. In the absence of an identified etiologic factor (<5% of all mixed cryoglobulinemia), cryoglobulinemic vasculitis is defined as essential or idiopathic. The most common symptoms of MC syndrome are weakness, arthralgias, and purpura, also called Meltzer's triad. The dermatologic manifestations of MC can vary from simple cutaneous palpable purpura to complex confluent lesions (Figure 18.2), including ulceration of the skin.

Although extrarenal signs of mixed cryoglobulinemic vasculitis usually precede the kidney manifestations, often by years, in 29% of cases kidney and extrarenal involvement are concurrent. Kidney involvement in mixed cryoglobulinemia occurs in 8–58% of patients, and in a minority of cases kidney disease can be the first manifestation of MC. More than half the patients have proteinuria and/or hematuria only. A "nephritic" syndrome is diagnosed in around 20% of cases. Hypertension is common and may be severe, affecting >50% of patients at the time of diagnosis. In 10% of patients, acute oliguric kidney failure is the first indicator of kidney disease. Often both nephrotic proteinuria and active urinary sediment with elevated serum creatinine are present simultaneously. Of particular importance is the development of kidney disease because patients with cryoglobulinemic nephritis have a poor prognosis, mainly because of a high incidence of infections, end-stage liver and cardiovascular diseases.

Roccatello et al. [8] evaluated 146 patients with cryoglobulinemic nephritis, of whom 87% ($n = 127$) were HCV positive, and noted type II cryoglobulins (IgG/IgM-*k*) in

Figure 18.2 Confluent purpura (right inferior limb: distal portion thigh and proximal leg) in HCV-related MPGN.

74.4% of cases; the rest had type III cryoglobulins. The most common histologic pattern was diffuse MPGN (83%). Survival at 10 years was only 30%, with cardiovascular disease the cause of death in >60% of patients. Additional causes of death included infections (10%), liver failure (19%), and neoplasia (3%). Another survey by Tarantino et al. ($n = 105$ patients) gave different results, with deaths caused by infections (21%) and liver failure (19%) nearly as common as those caused by cardiovascular diseases (29%) [15]. Differences in antibiotics or immunosuppressive agents could explain these differences.

Complement-mediated MPGN or C3 Glomerulopathy

C3G encompasses glomerular diseases associated with persistent activation of the alternative complement pathway [3, 16, 17]. Kidney biopsy findings are characterized by the occurrence of glomerular deposits, mostly composed of C3, and no staining for immunoglobulins or for components of the classical pathway of complement activation.

The complement system includes three pathways, the classical, lectin and alternative pathways, and patients with C3G have abnormal control of the alternative pathway of complement (Figure 18.3). The most important protein in the circulation that controls the alternative pathway is complement factor H (CFH); mice engineered to lack CFH have undetectable circulating C3 because their C3 is persistently consumed by an uncontrolled complement activation (alternative pathway) [18].

It has been recently discovered that mutations in genes encoding proteins of the alternative complement pathway (AP) occur in more than 50% of patients with atypical hemolytic uremic syndrome (aHUS) and in approximately 20% of patients with MPGN [16]. Complement gene abnormalities associated with aHUS most commonly result in complement dysregulation restricted to the cell surface, whereas complement activation in the fluid phase is more common in most genetic cases of MPGN [16]. These acquisitions have highlighted the role of genetic variations in the complement system in determining predisposition to glomerular injury. Hyperactivation of the alternative pathway of the complement system as observed in deposit dense disease (DDD) or C3 glomerulonephritis (GN) has been often associated with multiple mutations in inhibitors of the alternative pathway, including factor H, factor I, CD46 (membrane cofactor protein [MCP]), and the factor–H-related protein family (CFHR, 2, 3, 4, and 5). CFHRs are a group of closely related proteins controlling the activity of factor H; it appears now that CFHRs are able to antagonize the CFH action. Many patients with C3G show failure of CFH to control the activation of the alternative pathway in the circulation, thus they have low levels of serum C3 due to exaggerated consumption.

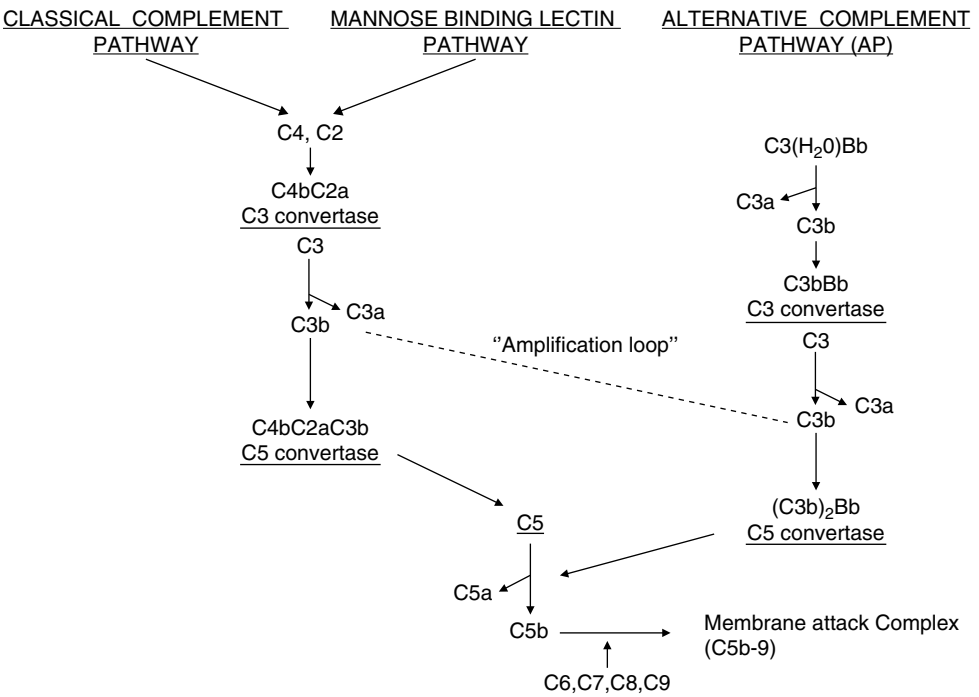

Figure 18.3 Complement cascade (the three complement pathways).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

An increased activation of the AP has been also linked with the occurrence of auto-antibodies against various components of the complement system: anti-CFH, anti--CFB (anti-complement factor B), anti-C4, or anti-C3b. These antibodies activate the alternative pathway either by stabilizing C3 convertase (such as C3 nephritic factor, C3NF) or its components against CFH. C3NFs are a group of autoantibodies that bind to the AP C3 convertase (C3bBb), increasing both convertase activity and the duration of the active forms, making it more stable (from minutes to hours) [16, 17]. These autoantibodies can be detected by using C3 convertase stabilizing activities, semiquantitative hemolytic assays, by measuring autoantibody levels. There are various types of C3NFs, including both IgM and IgG, which can be classified by either being heat sensitive and properdin dependent or heat stable and properdin independent. The clinical significance of C3Nefs remains unclear. More than 80% of patients with dense-deposit disease (DDD) and 40–50% with C3 glomerulonephritis (C3GN) have C3NFs; however, their association with disease outcome gave conflicting results. Alternatively, autoantibody can block the activity of pathway inhibitors (such as antifactor H autoantibody) [17]. A familial type of C3 glomerulopathy is CFHR5 nephropathy, where the mutation is a duplication of the first two exons of the CFHR5 gene [19].

The most recent view is that the dysregulation of the AP may be familiar or triggered by external factors. A genetic or acquired defect in complement regulatory proteins if severe enough may lead to the disease process. On the other hand, a genetic mutation with incomplete penetrance might need an environmental trigger to start with the disease. The most common environmental triggers are infections, surgery, autoimmune disease flares, vaccinations, pregnancy, and postpartum state. Thus, genetic mutations affecting the regulatory proteins of the AP (CFH, I, membrane co-factor protein, CFH related proteins, among others) and triggers result in the clinical manifestations of DDD and C3GN.

C3G, Dense Deposit Disease, and C3GN

DDD is characterized by osmiophilic deposits that replace the glomerular basement membrane and also occur in the mesangium; C3G without the characteristic appearances of DDD is called C3 glomerulonephritis (C3GN). C3GN has frequently mesangial, subendothelial, and sometimes subepithelial and intramembranous deposits. It has been suggested that DDD and C3GN are part of a continuum. Histological features intermediate between DDD and C3GN have been reported: some capillary loops show intramembranous dense deposits and others have subendothelial and subepithelial deposits on electron microscopy. Patients with DDD have dark, ribbon-like osmiophilic deposits within the glomerular basement membrane. DDD is typically a disease of children and C3 is frequently depressed (79% in DDD vs. 48% in C3 GN). DDD is frequently associated with extrarenal abnormalities such as partial lypodystrophy or drusen, which is similar to age-related macular degeneration. Ocular drusen are yellow deposits under the retina and are made of lipids and fatty proteins. Drusen likely do not cause age-related macular degeneration; however, patients with ocular drusen are at risk of developing age-related macular degeneration. A few patients with DDD have partial lipodystrophy (APL) which is characterized by symmetric loss of adipose tissue from upper portions of the trunk, face, and arms.

The most common pathological lesion in C3GN is MPGN, but other patients of glomerular damage have been reported, including mesangio-proliferative GN, diffuse endocapillary GN, focal segmental glomerulosclerosis, and crescentic GN [20].

There is a paucity of data regarding the natural history and outcome of C3 glomerulopathy. It is an infrequent renal disorder and its classification has been recently updated. The outcome of C3 glomerulopathy has been retrospectively addressed in a large ($n = 111$) cohort of patients, 87 with C3GN and 24 with DDD [21]. Complement-associated gene variants and auto-antibodies were detected in 24% and 35% of patients, respectively. Over an average observation period of 72 months, remission occurred in 38% of patients with C_3GN and 25% of patients with DDD. Progression to end-stage renal disease (ESRD) was frequent, and no differences between C3GN (39%) and DDD (42%) were found. Multivariate analysis showed that eGFR at diagnosis and tubular atrophy/interstitial fibrosis were the strongest predictors for progression to ESRD. Medjeral-Thomas and coworkers in a European cohort of 80 patients with C3 glomerulopathy (21 with DDD and 59 with C3GN) observed that patients with DDD were younger, more likely to have low serum C3 levels, and more likely to have crescentic GN than patients with C3GN [22]. Median follow-up, censored for ESRD development, in the remaining cohort ($n = 70$) was 28 months (interquartile range 7–84) without any significant difference in median follow-up duration between subgroups. At last follow-up, 20 patients progressed to ESRD (47% of patients with DDD and 23% of patients with C3GN). Cumulative renal survival did not, however, differ between groups by Kaplan–Meier survival analysis. Age > 16 years ($P < 0.04$), DDD subtype ($P < 0.03$), and crescentic GN ($P < 0.01$) were independent predictors of ESRD within the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. entire cohort. DDD recurs very frequently after renal transplant; it has been calculated that approximately 45% of patients lose their allograft within 5 years after transplant due to the recurrence of the disease.

MPGN: Clinical Presentation and Natural History

The clinical manifestations of patients with MPGN are highly variable and similar to those reported in other types of glomerular diseases. Patients can show microscopic hematuria with or without mild proteinuria. Proteinuria in the nephrotic range or even full brown nephrotic syndrome with or without hypertension and low glomerular filtration rate (GFR) may occur. It may also present with macroscopic hematuria with or without a fast worsening of the renal function (particularly when crescents are present at histology). The discovery of hypocomplementemia (reduced levels of C3 and/or C4 or lowered C/H50) is a frequent feature which characterizes most MPGN forms in comparison with the other idiopathic glomerular diseases (minimal change disease, focal and segmental glomerulosclerosis, membranous nephropathy, and IgA nephropathy seldom, if ever, display hypocomplementemia).

Clinical factors which are associated with a progressive course leading to ESRD include persistence of nephrotic-range proteinuria (> 3 g/g of creatinine in a spot urine sample in an adult), the presence of arterial hypertension (AH) (blood pressure > 140/90 mmHg), and raised serum creatinine at baseline. In addition, marked hematuria (> 500 000 erythrocytes/ml of urine not centrifuged) is strongly associated with the presence of crescents, which confer a less favorable prognosis. Patients with MPGN who have intact kidneys at baseline and show persistent non-nephrotic proteinuria seldom progress to ESRD.

Kidney biopsy can provide some pathological features at the time of diagnosis which play a role in the outcome. An unfavorable course of MPGN is often associated with some kidney changes, including extensive crescent disease (>50% involvement of glomeruli), extensive glomerulosclerosis, tubulo-interstitial fibrosis, and tubular atrophy. Such findings often are strongly associated with an elevation of serum creatinine levels.

A contemporary analysis of the natural history of MPGN (unmodified by any specific therapy) and all of its varieties is extraordinarily difficult, and multiple reasons exist for this. The overall long-term renal survival (5 and 10 years after diagnosis) for untreated idiopathic MPGN can be reconstructed from reports in the literature. Some factors that limit the accuracy of these predictions include the following: (i) lead-time bias for patients discovered during screening; (ii) lack of stratification of patients into HCV-positive or negative cases; (iii) inclusion of patients treated with various regimens in observational studies of prognosis; (iv) lack of information concerning the degree of blood pressure control and the use of ace-inhibitors or angiotensin receptor blockers; (v) lack of detailed information on concomitant renal lesions affecting outcomes (e.g. crescentic involvement); and (vi) failure to stratify patients according to the presence and persistence of complement regulatory dysfunction, thrombotic microangiopathy, or monoclonal immunoglobulin deposition disease. For the last, the recent changes in the classification of MPGN with the identification of some additional MPGN-associated conditions are an additional impediment.

The analysis of the long-term renal survival (5- and 10-year after diagnosis) for idiopathic and untreated MPGN can be in part reconstructed from the medical literature. Placebo or untreated arms of the reported randomized controlled trials (RCTs) of specific therapies can give detailed information on this point. For example, in the open-label RCT of therapy for MPGN in children and adults reported by Cattran et al. in 1985, the control group ($n = 32$), who received no specific therapy, displayed a 2-year kidney survival of 85% in MPGN type I and 90% in MPGN type II. All of these patients had an initial creatinine clearance of <80 ml/min/1.73 m^2 and proteinuria of >2 g/day at baseline [23]. Of note, 8 of 32 control patients in this study obtained a spontaneous clinical remission. In the randomized, placebo-controlled trial of treatment of MPGN reported by Tarshish et al. the actuarial renal survival in the placebo group ($n = 40$) was only 12% at 130 months, and a progressive decline of renal function was noted in about 60% of the placebo group [24]. In the study by Tarshish and coworkers 52% had MPGN type I, 17% had MPGN type II, and 30% had MPGN type III or other types of MPGN. Donadio et al. carried out a randomized, double-blind placebo-controlled trial of therapy for MPGN type I. The average decline in GFR was 19.6 ml/min/year/1.73 m^2 in the placebo group [25]. A total of 9 of 19 patients in the placebo group developed ESRD after 33 months. The authors suggested that the poor outcome observed in the placebo group could be related to the long duration of disease prior to entry into the randomized trial.

Evidence coming from observational studies can also give some insight into the natural history of MPGN. In the study by Chan et al. 27 (59%) of 46 patients with MPGN (including 20% with hepatitis B surface infection) developed or died of ESRD within a follow-up period averaging 60 months, with no difference in outcome between treated ($n = 19$) and untreated ($n = 27$) patients [26]. Cansick et al. assessed the long-term outcome of 53 children with MPGN (58% type I, 26% type II, and 16% type III and others).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The median follow-up was 3.3 years (range, 0–17 years). Twenty-nine of the 53 children were treated with corticosteroids with an uncontrolled design. Overall renal survival including the treated patients and patients without nephrotic syndrome was 92% at 5 years and 83% at 10 years. In the group of patients with nephrotic syndrome at discovery, the mean renal survival was 8.9 years compared to 13.6 years when nephrotic syndrome was absent [27].

In summary, it is difficult on the grounds of the current medical literature to establish a consistent pattern of long-term outcome for patients with MPGN who did not receive therapy. Overall renal survival of MPGN type I patients among treated and untreated patients averages about 60% at 10 years (range 50–80%), with adults having a less favorable outcome. Concomitant hepatitis B or C virus infection likely confers a worse prognosis.

Treatment

Idiopathic Immune-complex MPGN

As mentioned above, the term idiopathic MPGN in adults or children refers to cases of MPGN with an unknown cause. The Kidney Disease Improving Global Outcomes recommends making the diagnosis of idiopathic MPGN only after exclusion of any other identifiable cause [28]; the histological pattern of type I MPGN is most typical among patients with idiopathic MPGN. Also, the MPGN histological pattern is characterized by various clinical pictures. It appears that idiopathic MPGN is more frequent in less-developed countries, where infectious diseases are more common than among developed world. The management of secondary MPGN requires treatment of the primary disease, often in combination with immunosuppression.

The evidence regarding the treatment of idiopathic MPGN is not robust for numerous reasons. A few RCTs have been published, but all these studies were conducted a long time ago and do not conform to modern-day standards of excellence. Thus, many early reports of treatment of idiopathic MPGN probably included cases now categorized as secondary MPGN. Only six RCTs (involving fewer than 270 patients with MPGN) have been reported for MPGN to date (Table 18.2) [23–25, 29–33].

In short, the evidence currently coming from RCTs is weak (very low to low level), as already emphasized by others [34, 35]. For patients with *mild disease*, i.e. hematuria and low-level proteinuria (<500 mg/day), and normal or nearly normal kidney function, RAS inhibition with angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin II receptor blockers (ARBs) should be made. In patients with *nephrotic syndrome* and intact kidney function, oral steroids (prednisone, 1 mg/kg/day of body weight) should be given for 12–16 weeks. Tapering of steroids should last for 6–8 months, but should be faster in patients with resistant disease. Cyclophoshamide should be considered according to the clinical response to steroids. In cases of *deterioration of kidney function*, oral steroids (according to the aforementioned dosage scheme) should be tried. If there is no response, oral cyclophosphamide (1–2 mg/kg body weight adjusted to eGFR) for 4–6 months or rituximab (RTX) (1 g × 2 on day 1 and 15) should be considered. In patients with *rapidly progressive glomerulonephritis*, with or without nephrotic syndrome, rescue therapy with intravenous steroids (methyprednisolone, 0.5–1 g/day for three consecutive days) has been suggested, followed by oral prednisone (1 mg/kg/day body weight) and cyclophosphamide.

Therapies based on ACEIs and ARBs are safe and have some efficacy in proteinuric patients. Some case series have been recently published regarding the treatment of idiopathic MPGN with alternative drugs, such as mycophenolate mofetil (MMF) (Table 18.3) [36–42], calcineurin inhibitors [43, 44], and monoclonal antibody (rituximab and imatinib) (Table 18.4) [45–50]. These drugs have been able to give some benefit to patients with idiopathic MPGN but we need RCTs on this point. Several questions remain unanswered, including dose and duration of therapy with these drugs, their role (first-line therapies or not), and their safety profile.

HBV- or HCV-associated MPGN

Patients with hepatitis B virus (HBV)-associated MPGN should receive antiviral therapy with nucleos(t)ide analogs (NUCs) and/or immunosuppressive therapy, according to the clinical presentation of the disease (Figure 18.4). Many patients with HCV-associated MPGN also have mixed cryoglobulinemia and they may also have overt chronic liver disease. All patients presenting with MPGN type I are now routinely tested for anti-HCV antibody (and HBsAg) and often are also examined for HCV RNA by reverse polymerase chain reaction. Thus, it should not be difficult to make a differential diagnosis between idiopathic forms of MPGN and those secondary to HCV or HBV.

The discovery of HCV and a better understanding of the mechanisms of disease has provided the opportunity to control HCV-induced glomerular disease (including MPGN) using targeted approaches: (i) antiviral therapy, supported by the notion that HCV infection stimulates the synthesis of immune complexes and the ensuing glomerular disease; (ii) B-cell depletion therapy targeting B cells that produce cryoglobulins; and (iii) nonspecific immunosuppressive therapy targeting inflammatory cells at the glomerular level.

MMF, mycophenolate mofetil; MPGN, membranoproliferative glomerulonephritis; SCr, serum creatinine.

The information in the literature regarding the management of HCV-associated MPGN is limited; the incidence of the disease is probably low even if epidemiological studies on this point are lacking. No prospective RCTs to establish evidence-based recommendations to treat MPGN associated with HCV exist. We urgently need this evidence as renal disease is now considered a major cause of morbidity and mortality in mixed cryoglobulinemic vasculitis induced by HCV.

Several clinical studies regarding the antiviral therapy of HCV-associated glomerular disease (including HCV-related MPGN) have been published, some based on IFN [51–53] and others that adopted direct-acting antiviral agents (DAAs) [54, 55]. The evidence generated from these studies suggests that the advent of interferon-free antiviral therapy based on DAAs represents a real advance even in so far "difficult-to-treat" settings such as HCV-induced MPGN

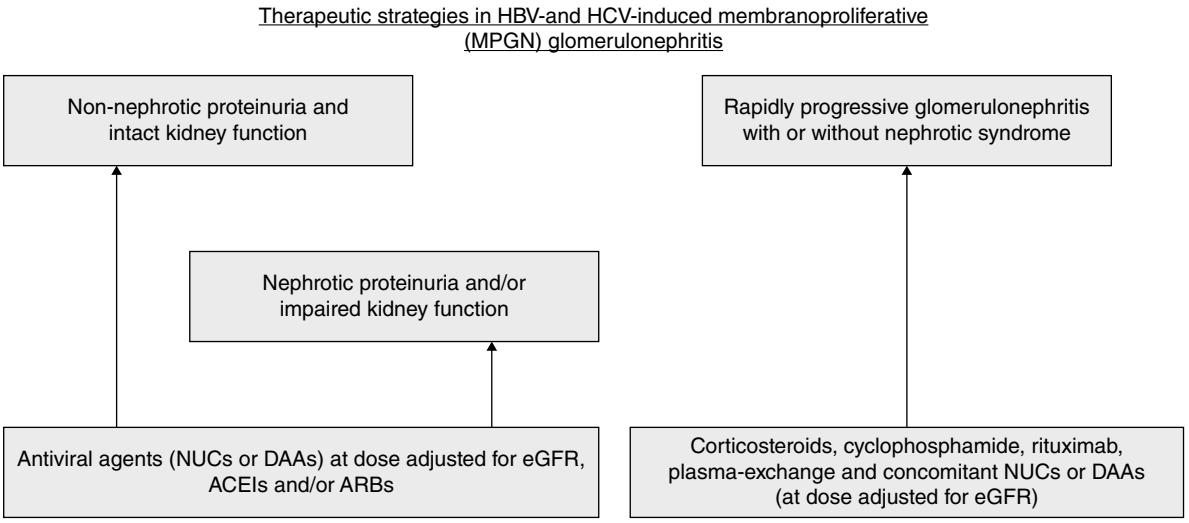

Figure 18.4 Treatment of HBV- and HCV-associated MPGN according to the clinical presentation.

(and other HCV-induced glomerular diseases). These studies have an observational and uncontrolled design; in addition, the size is small. The extensive use of DAAs for the antiviral therapy of HCV in the adult general population will make the frequency of HCV-associated MPGN even more uncommon in the near future.

Some studies regarded the treatment of HCV-associated glomerular disease (including many cases of HCV-associated MPGN); others assessed the antiviral treatment of HCV-associated cryoglobulinemic disease, but the details concerning the cryoglobulinemic glomerulonephritis (including cryoglobulinemic MPGN) were not reported clearly [56]. Of note, the sustained viral response (i.e. the clearance of HCV RNA from serum which persists at least 3 months after completing antiviral therapy with DAAs) is often accompanied by improvement of glomerular abnormalities (reduction of proteinuria, haematuria, and serum creatinine) and this effect has been achieved in the absence of concomitant immunosuppressive therapies. However, clinical improvement after antiviral agents is sometimes incomplete and this is in keeping with the notion that circulating cryoglobulins may be an independent risk factor for clinical nonresponse to antiviral treatments. In addition, remote onset of glomerular disease may be another explanation. In other cases, glomerular and/or cryoglobulinemic disease relapsed over a long follow-up despite sustained virological response (SVR) and it is well known that cryoglobulinemic vasculitis shows an own course, regardless of the presence of trigger agents such as HCV (or HBV). However, the absence of HCV RNA from serum allows the adoption of immunosuppressive therapies with benefits for glomerular changes and no concern on replication of HCV (Figure 18.3).

At the present time the cumulative evidence from the published studies is not satisfactory; clinical studies or anecdotal reports have suggested that IFN-based regimens were provided with low efficacy and high toxicity in patients with HCV-related GN (including HCV-associated MPGN) compared to those with intact kidneys. The evidence from some observational studies reported that the treatment of HCV-associated glomerular disease (including HCV-associated MPGN) with DAAs has given a frequency of SVR of 95–100%, much greater than that obtained with IFN-based therapy (35–50%) [54–56].

As mentioned in these recent series, there were some clinical nonresponders or relapsers despite SVR and this highlights the role of immunosuppressive agents in the management of HCV-associated MPGN (and other HCV-related glomerular diseases). Only preliminary data exist on the immunosuppressive agents, i.e. micophenolate mofetil [57, 58], rituximab [59], or immunomodulatory therapy (low-dose ribavirin) [60] for HCV-related glomerular disease.

C3 Glomerulopathy

The optimal treatment for C3G remains unclear and various approaches have been suggested, at least from a theoretical point of view. C3G was grouped with other forms of MPGN and this hampered the opportunity to make specific recommendations for C3G.

As with any GN, blockade of the RAS remains part of therapy with lipid-lowering therapy.

Patients with mutations involving deficiency of regulatory proteins of the alternative complement pathway may benefit from replacement of factors with plasma therapy.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Patients might need lifelong plasma therapy. In contrast, plasma therapy is ineffective in patients with mutations of the membrane cofactor protein (MCP, also known as CD46) since it is a membrane-bound protein and replenishing plasma with this protein would not offer protection to the endothelial cells. In patients with gain of function mutations in complement activating proteins (such as factor B or mutant C3 convertase resistant to CFH), plasma therapy may be detrimental since it provides additional substance to activate AP.

Plasma exchange replenishes plasma with deficient proteins, removing autoantibodies or mutant proteins that activate the AP. The response to PE remains short lived and rebound complement activation is noted within 48 hours.

Theoretically, immunosuppressive therapy (based on corticosteroids, MMF, and rituximab) should reduce or eliminate autoantibody production. However, the effectiveness of this approach appears unclear and no RCTs supporting this approach have been made; most of the evidence concerning RTX is based on a few case reports [61–65] (Table 18.5). Treatment of active disease with MMF and corticosteroids has shown promise in two retrospective case series [66–67], but was not found to be effective in a third report regarding patients with more severe baseline kidney disease [68]. A high recurrence of the original disease after solid organ transplant has been noted in patients who are already immunosuppressed [69].

The advances regarding the current classification have coincided with the availability of the first complement inhibitor, eculizumab (EZ), which is a humanized monoclonal antibody directed against C5. EZ binds to the C5 complement protein and inhibits its cleavage into pro-inflammatory and pro-thrombotic C5a and C5b. This binding prevents the generation of the pro-thrombotic and cytolytic terminal complex (C5b-9, membrane attack complex [MAC]). Successful blockade of C5 in C3GN should prevent C5a formation, resulting in lower infiltration of leukocytes. A major side effect of EZ therapy is recurrent meningococcal infections (incidence less than 1%); patients are mandated to receive the meningococcal vaccination in advance to therapy to reduce infection risk.

A small prospective study and a limited number of case series or case reports have shown some efficacy of eculizumab in this disease (Table 18.6) [70–79]. These case reports are clearly subject to publication bias (studies providing positive results are selected for reporting). The introduction of EZ has changed the natural history of aHUS; studies addressing the activity of EZ in patients with C3G have given disparate results, especially compared with results of EZ in patients with aHUS. It appears that treatment with EZ in patients with C3G is beneficial in patients with mild/advanced renal damage, and is able to lower not only proteinuria but also to improve kidney function. It is clear that treatment with EZ requires further assessment in patients with C3G, and prospective studies are those we urgently need. Appropriate candidates to therapy with EZ are patients with C3G who have a relatively short duration of the disease, have shown active inflammatory kidney abnormalities (crescents and endocapillary proliferation), and have reported a recent increase in serum creatinine level and/or proteinuria [79]. The evidence based on pathology is limited and suggests that EZ lowers endo-capillary proliferation and inflammatory cell infiltration in some patients. These findings are in accordance with animal data which showed that anti-C5 therapy effectively targeted the inflammatory

component of C3 glomerulopathy [80]. The current approach to C3G is mostly based on case studies and expert opinion; trial data are currently lacking. Long-term use of EZ is required in this disease due to the inherent risk of recurrence but this hampered by the cost burden (use of EZ for 1 year has been associated with an approximate cost of US$600 000).

The pathophysiology of C3G remains unclear and is probably more complex than that of aHUS. The levels of complement dysregulation at the site of the C3 and C5 convertase have great variability and this could explain the heterogeneity in response to EZ therapy in patients with C3G. Patients with C3G who show important activation of C5 convertase will benefit from therapy with EZ; on the contrary, patients with C3G who have significant dysregulation at the level of C3 convertase will not show dramatic benefit.

Some clinical trials using targeted complement inhibition with novel agents (i.e. compstatin, which is a C3 inhibitory peptide) are under way and promise to change more radically than EZ the management of C3G.

Summary

Recent advances have been made in the last decade regarding the understanding of the multiple pathogenetic pathways of MPGN. This has given us the possibility to expand the therapeutic armamentarium against MPGN. However, at this time there is insufficient high-quality evidence regarding effective and safe therapies for MPGN. Idiopathic or primary immune-complex MPGN is clearly an uncommon condition and an extensive evaluation is required to exclude the etiologies reported above. The low frequency of MPGN could at least partially explain the paucity of controlled trials on this issue.

Adults with idiopathic immune-complex MPGN showing *nephrotic syndrome* and *progressive decline of kidney*

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

function should receive an oral course of cyclophosphamide, or MMF, or oral/intravenous corticosteroids. The initial therapy should be limited to less than 6 months (evidence level, 2C).

The management of C3 glomerulopathy is not based on RCTs as the diseases (C3GN and DDD) are very uncommon. Only small case series and case reports have been made. In patients with C3 glomerulopathy who present *mild disease*, i.e. haematuria, low-grade proteinuria (<0.5 g/day), and intact kidney function, management should include RAS blockade with ACEIs and ARBs (evidence level, 2D). Patients with C3G and *moderate or severe renal disease* (greater levels of proteinuria, nephrotic proteinuria, and/or kidney dysfunction) should receive treatment according to the underlying etiology. Plasma exchange, rituximab, steroids, and eculizumab should be considered in patients with C3G where antibody-stimulating AP have been identified (evidence level, 2C). Treatment with EZ allows targeted complement inhibition and has considerably improved the prognosis of some patients with C3G; however, the C5 blockade does not seem to significantly alter the course of the disease in many cases. The therapeutic regimen consisted of 900 mg EZ, given intravenously, weekly for 4 consecutive weeks, and then 1200 mg/2 weeks for 12 months [68]. We need prospective trials or cohort studies to assess the efficacy of EZ and its superiority over conventional approaches (i.e. cyclophosphamide, corticosteroids, and MMF). In patients with C3G due to genetic defects, fresh frozen plasma is indicated to replace the insufficient plasma concentration of CFH or any other related protein. Patients with C3G and *rapidly progressive GN* should receive rescue therapy (pulses of intravenous corticosteroids and oral cyclophosphamide or MMF). Methylprednisolone pulses (0.5–1 g/day) for 3 days followed by oral prednisone (1 mg/kg/day body weight and slow tapering over 2–3 months) and cyclophosphamide. This approach is not specifically targeted to DDD or C3GN (evidence level, 2D).

Patients with HCV-induced MPGN showing *stable kidney function* and/or *non-nephrotic proteinuria* should receive initially antiviral therapy with DAAs. (evidence level, 1B) Patient with HCV-induced MPGN showing *cryoglobulinemic flare*, *nephrotic syndrome*, or *progressive kidney failure* should receive antiviral therapy with DAAs and concomitant immunosuppressive therapy (and/or plasma-exchange) (evidence level, 1B). Rituximab should be considered the first-line immunosuppressive agent in patients with HCV-related MPGN, even in those who do not respond to antiviral therapy (evidence level, 1B).

Autosomal Dominant Polycystic Kidney Disease

Gopala Rangan[1,2], Annette Wong[1,2], Alexandra Munt[1,2], Irene Sangadi[1,2], Sayan Saravanabavan[1,2], and Jennifer Zhang[1,2]

[2] *Michael Stern Laboratory for Polycystic Kidney Disease, Westmead Institute for Medical Research, University of Sydney, Sydney, Australia*

Introduction

Autosomal dominant polycystic kidney disease (ADPKD) is a progressive chronic kidney disease (CKD) that in ~90% of cases has four features: (i) autosomal dominant pattern of inheritance in first-degree relatives; (ii) mutation in one of the causative genes (*PKD1, PKD2* or others); (iii) variable expressivity but complete age-dependent penetrance of multiple renal cysts that fulfill the Pei-Ravine ultrasound criteria; and (iv) variable systemic complications (extra-renal cysts in solid organs, vascular aneurysms, connective tissue defects, such as hernia) [1–11] (Table 19.1).

Epidemiology

Incidence and Prevalence of ADPKD in the General Population

ADPKD occurs uniformly throughout the world. Disease mutations occurred early in modern human evolution. Determining the prevalence of ADPKD is difficult as the condition is clinically silent in up to 50% of patients. The Danish and Olmstead cohort studies (which included autopsy specimens) performed in the 1950s and 1980s, respectively, showed that the lifetime risk in the general population was 1:1000, with an annualized incidence of 2.75 per 100 000 person-years [12, 13]. More recent studies performed in selected geographic areas in the 2010s suggested a lower prevalence (4.76 per 10 000, Modena, Italy [14], 3.96 per 10 000 European Union [15], 5.73 per 10 000, southwest Germany [16]). An analysis performed in 2018 showed that the frequency of high-confidence mutations in *PKD1/PKD2* was 9.3 cases per 10 000 cases in two large population sequencing databases [17]. Taken together, these data indicate that the true incidence of ADPKD in the general population is probably 1:1000 but that the overall incidence of symptomatic ADPKD leading to end-stage kidney disease (ESKD) is approximately 1:2500.

Pathophysiology

ADPKD is due to heterozygous germ-line mutations in *PKD1* (85% of cases, located on chromosome 16p13.3, 46 exon-length), *PKD2* (15%, located on chromosome 4q21, 15 exon-length), or rarely additional genes (<1:1000, such as *GANAB* or *DNAJB11*). Approximately 10% of patients have no mutation detected in either *PKD1* or *PKD2* (no mutation detected). The mutations are inherited in an autosomal dominant manner but occasionally may involve other complex genetic mechanisms (e.g. mosaicism or bi-allelic transmission of *PKD1*). *PKD1* and *PKD2* encode two cellular membrane proteins: polycystin-1 and polycystin-2, respectively. The formation of the kidney cysts starts in early life due to random postnatal reductions in *PKD1* or *PKD2* dose in the principal cells of the collecting duct, as a result of loss of heterozygosity (LOH, "second hits") or other poorly defined stochastic factors. In cohort studies, mutations in *PKD1* are associated with more severe renal disease than *PKD2*, as defined by an earlier onset of ESKD (50–55 vs. 75–80 years old) and twice the number of renal cysts. The clinical phenotype of ADPKD has high intra- and interfamilial heterogeneity due to environmental (epigenetic) mechanisms and modifying genes [1].

Table 19.1 Treatment of ADPKD.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Diagnosis	We recommend confirming diagnosis using the Pei-Ravine ultrasound criteria.	High	Strong
	We recommend genetic testing in selected clinical circumstances and in consultation with a clinical geneticist.	High	Strong [5]
Assessment of renal prognosis	We recommend evaluating factors associated with high risk for ESKD in an individual patient to guide patient education, frequency of clinical follow-up, and treatment.	Moderate	Strong
Genetic counseling	We suggest referral to a clinical geneticist and genetic counselor if detailed advice on family planning and pre-implantation genetic diagnosis is sought by patients and/or if genetic testing is being considered to inform diagnosis.	Low	Weak [5]
Screening at-risk of ADPKD	We recommend screening all first-degree adults at risk of ADPKD with renal ultrasound.	High	Strong
	We suggest that parents be informed of the advantages/disadvantages of screening by renal ultrasound for ADPKD in children <18 years old who are at risk (50%) of ADPKD.	Low	Weak
Fluid intake	We suggest consuming fluids as advised by the treating physician.	Low	Weak [6]
Blood pressure lowering	All patients with ADPKD should receive either an ACEI or ARB for first-line pharmacological treatment of hypertension (>130/80 mmHg) and the stepwise use of a α/β cardio-selective blocker, dihydropyridine calcium channel blocker or a diuretic either as second-line agents or in combination with first-line drugs.	High	Strong [7]
Disease-modifying treatments	We do not recommend the use of somatostatin analogs or target of rapamycin complex 1 inhibitors, and to use shared decision-making regarding the use of vasopressin receptor antagonists in patients with "rapid progression" as defined by a historical decline in the eGFR.	High	Weak [7]
Chronic kidney pain	We suggest that chronic pain is evaluated during clinic visits and that management should be stepwise, involving nonpharmacological and pharmacological treatments, and minimally invasive and invasive therapies.	Low	Weak [8]
Kidney cyst infection	We suggest that suspected renal cyst infection is treated with empirical antibiotic therapy and renal cyst aspiration if refractory to treatment.	Low	Weak
Kidney cyst hemorrhage	We suggest that renal cyst hemorrhage be treated with bed rest and analgesia as first-line treatment, followed by minimally invasive or invasive therapies if bleeding is refractory.	Low	Weak
End-stage kidney disease	We recommend that patients with ESKD be considered for kidney transplantation and evaluated for need for nephrectomy prior to transplantation.	High	High [9]
Polycystic liver disease	We suggest that severe polycystic liver disease (total liver volume >1800 ml/m) is managed by a multidisciplinary team (hepatologist, hepatobiliary surgeon, interventional radiologist, nephrologist).	Low	Weak [10]
Intracranial aneurysm	We recommend that MR angiography or CT (circle of Willis angiography) be used for screening and detection of ICAs in asymptomatic individuals at high risk for an ICA (i.e. a positive family history of SAH/unruptured ICA in at least one first-degree relative with ADPKD or previous SAH/ICA).	Moderate	Weak [11]
	We recommend urgent intracranial imaging in patients who experience a sudden onset of severe headache or neurological symptoms of concern.	Very low	Weak [11]
	We recommend referral to a neurosurgeon if an ICA is detected, and suggest treatment in centers which have expertise in endovascular coiling and microsurgery.	Very low	Weak [11]

GRADE assessment of the certainty of the evidence [12]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

ACEI, angiotensin converting enzyme inhibitor; ADPKD, autosomal dominant polycystic kidney disease; ARB, angiotensin receptor blocker; CT, computed tomography; eGFR, estimated glomerular filtration rate; ESKD, end-stage renal disease ICA, intracranial aneurysm; MR, magnetic resonance; SAH, subarachnoid hemorrhage.

The growth of kidney cysts is slow, exponential, and has interindividual variability (~2–10% per year) leading to kidney enlargement by mid-life (mean 1 kg/kidney vs. 0.2 kg/kidney in health). The expanding kidney cysts compress and destroy normal kidney tissue, causing chronic pain, hypertension, and renal impairment. The growth of renal cysts is mediated by chloride-driven fluid secretion (via the cystic fibrosis transmembrane regulator [CFTR] chloride channel) and proliferation (via multiple signal transduction pathways, including TORC1). in vitro arginine vasopressin (AVP) increases intracellular cyclic adenosine monophosphate (cAMP), CFTR-mediated trans-epithelial fluid secretion, and proliferation of cyst-forming renal epithelial (Madin–Darby canine kidney cells [MDCK] cells), implicating it as an important nongenetic factor in exacerbating renal cyst growth during the postnatal period. Thus, disease-modifying treatments to inhibit proliferation (e.g. sirolimus, a TORC1 inhibitor; metformin, an AMP-activated protein kinase [AMPK] inhibitor), "kidney cyst-specific growth factors" (e.g. vasopressin), and other pathways have been investigated in clinical trials [1].

Diagnosis

Renal Ultrasound in Patients with a Positive Family History

We recommend confirming the diagnosis with renal ultrasound using the Pei-Ravine ultrasound criteria in all patients at risk of ADPKD (positive family history of autosomal dominant pattern of inheritance in first-degree family members) (high certainty, strong recommendation) [18, 19]. Renal ultrasound is the preferred imaging modality as it is safe, reliable, inexpensive, and easily accessible. The Pei-Ravine criteria use kidney cyst number according to age (Table 19.2). If the cyst number fails to meet Pei-Ravine criteria ("indeterminate"), a follow-up ultrasound in 1–2 years is suggested [19].

Renal Ultrasound in the Absence of a Family History

In the absence of a positive family history, there are no evidenced-based ultrasound criteria to make a diagnosis of ADPKD but expert opinion is that at least 10 renal cysts in each kidney are required [19–23]. In this situation or if the ultrasound is indeterminate, other supporting evidence from the history, physical examination, and ultrasound features (such as the presence of hepatic cysts and increased kidney size) might provide evidence to support the diagnosis [19].

Genetic Testing

We do not recommend universal genetic testing in all patients with ADPKD using current technologies (high certainty of evidence, strong recommendation) [20] because (i) the results are inconclusive or negative in 10% of patients with typical ADPKD or as high as 50% with a clinical phenotype that is atypical [21]; (ii) genetic testing is 10 times more expensive than kidney ultrasound [18–21]; and (iii) genotyping does not correlate with phenotypic severity. We recommend restricting the use of genetic testing use to specific clinical situations in consultation with a clinical geneticist (high certainty, strong

Table 19.2 Pei-Ravine's criteria for the diagnosis of ADPKD by renal ultrasound[a] [18,19].

Age in years	Positive family history (genotype unknown)	Number of kidney cysts needed to *make* the diagnosis of ADPKD	Number of kidney cysts to *exclude* the diagnosis of ADPKD
15–29	Yes	≥3 (unilateral or bilateral); *PPV = 100%, sensitivity = 81.7%*	Normal ultrasound does not exclude diagnosis
<40	Yes	≥3 (unilateral or bilateral); *PPV = 100%, sensitivity = 82–96%*	Normal ultrasound does not exclude diagnosis
40–59	Yes	≥4 (at least two in each kidney); *PPV = 100%, sensitivity = 90%*	*<2; NPV = 100%, specificity = 98.2%*
≥60	Yes	≥8 (at least four in each kidney); *PPV = 100%, sensitivity = 100%*	<2
Any age[b]	No	≥10 cysts in each kidney with renal enlargement ± hepatic cysts	N/A

AKPKD, autosomal dominant polycystic kidney disease; NPV, negative predictive value; PPV, positive predictive value.
[a] Criteria based on expert opinion.
[b] Criteria based on the use of conventional 3–5 MHz ultrasound probe with cyst size typically being above 1 cm in diameter. CT, MRI, and more sensitive ultrasound probes detect smaller cysts and therefore the above criteria are not applicable to these imaging modalities.

recommendation): (i) the exclusion of disease in potential living related kidney donors under the age of 40 years old (as a normal renal ultrasound and computed tomography [CT] scan does not exclude ADPKD in this setting) (Table 19.3); (ii) during pre-implantation genetic diagnosis [24]; and/or (iii) in the evaluation of a patient with an atypical clinical phenotype (i.e. negative family history, equivocal renal imaging, and unusual clinical phenotype, especially in syndromic forms or early-onset disease) [20].

Method of Genetic Testing in ADPKD The gold-standard for genetic testing in ADPKD has been long-range polymerase chain reaction (LR-PCR) amplification followed by Sanger sequencing of all exons. However, this method is labor-intensive and is being superseded by next-generation sequencing (whole-genome sequencing, targeted exome sequencing) [20].

Table 19.4 Risk factors associated with high risk for ESKD.

Clinical factors
Age >35 years old
Family history of ESKD
Age of at least one family member with ESKD <55 years old (suggest mutation in PKD1) (vs. >70 in PKD2)
Onset of hypertension<35 years old
Episode of hematuria <30 years old
Laboratory investigators
Albuminuria
Renal function
• Baseline serum creatinine>92 μmol/l
• Stage 2 CKD by 30 years old, stage 3 by 50 years old or stage 4/5 or ESKD by 55 years old
• Annual rate of decline in eGFR >5 ml/min in 1 year or >2.5 ml/min/year over 5 years
Imaging
Renal length on ultrasound >16.5 cm

CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; ESKD, end-stage kidney disease; PKD1, polycystic kidney disease gene-1; PKD2, polycystic kidney disease gene-2.

Prognosis

We recommend evaluating factors associated with high risk for ESKD in an individual patient to guide patient education, frequency of clinical follow-up, and treatment (Table 19.4) (moderate certainty of evidence, strong recommendation). However, the certainty of estimating risk in an individual is low because (i) there is wide clinical heterogeneity in the severity of kidney disease (even within the same family); (ii) the accuracy of current methods to estimate the risk of development of ESKD are poor and based on a limited prospective cohort studies; (iii) disease-specific imaging biomarkers (Ht-TKV by magnetic resonance imaging [MRI]) used in research are not available in clinical practice and statistical prediction models (Mayo Subclassification for TKV) are in the early stages of development and not validated; and (iv) many novel molecular biomarkers (e.g. urinary monocyte chemoattractant protein-1, copeptin) are under investigation, but none has superseded standard methods of clinical history, estimated glomerular filtration rate (eGFR), and imaging.

Clinical History

- *Age:* Patients older than 35 years old at presentation have a 1.7-fold increased risk of developing CKD stage 3A (sensitivity 0.60 and specificity 0.66) [25].
- *Family history:* A three-generation family pedigree is recommended in all ADPKD patients: (i) confirm the autosomal dominant pattern of inheritance; (ii) determine

Table 19.3 Summary of diagnostic tests in ADPKD.

Test	What does it measure?	Comments
Pei-Ravine ultrasound criteria	• Determines the number of renal cysts based on age in a population at 50% risk of having ADPKD • Validated by genetic testing • Simple and cost-effective • May be indeterminate in up to 10% of cases	• Applies only if there is a family history of ADPKD in a first-degree relative • Criteria in the absence of family history are based on expert opinion • Negative ultrasound excludes ADPKD only after the age of 40 (important to recall this fact during live-kidney donor assessment involving family members)
Genetic test	• Provides direct information of the mutation type (*PKD1* vs. *PKD2* vs. no mutation detected or other genes) • May be indeterminate in up to 10–50% of cases depending on the clinical history	• Diagnostic accuracy in enriched populations is 90% but may decline to 50% in atypical or real-world cases • Analysis is expensive, complex, and time-consuming but likely to be more useful as workflow and technological improvements are reported

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the history of ESKD in the family (and age of onset in family members); (iii) identify other family members who are at-risk for ADPKD; and (iv) screen for a family history of intracranial aneurysms (ICAs). Specifically, a family history of onset ESKD ≤58 years or >68 years predicts a mutation in *PKD1* (PPV 100%, sensitivity 75%) or *PKD2* (PPV 100%, sensitivity 78%), respectively [26].

- *Clinical events:* The onset of hypertension or a urological event (episode of cyst hemorrhage, cyst infection, and/or acute flank pain) below 35 years of age is associated with a truncating mutation in *PKD1* and with a worse renal prognosis [27,28].
- *Perinatal history:* Higher birth weight is protective, with every kilogram at birth deferring the age of ESKD onset by 1.7 years [29] (Table 19.5).

Table 19.5 Clinical value of methods used to predict renal prognosis in individual patients.

Prognostic test	Bias	Precision	Benefits	Harms and cost	Value
Clinical information (Age, age of ESKD in family, birth weight)	High	High	Information easy to obtain but has low sensitivity and specificity	Low in harm and cost	Low-moderate
Tests					
Genetic testing (Sanger)	High	High	Identifies the causative mutation (PKD1 PKD2/NMD) but not useful for determining prognosis in an individual patient	Low in harm but very high in cost	Low
Single measurement of total kidney volume at baseline corrected by height	Moderate	High	Estimates the number of kidney cysts and is a disease-specific marker that can identify early risk for ESKD	Not all patients able to do MRI, moderate in cost, and not validated in all population groups (e.g. by ethnicity, country)	Moderate
Single measurement of renal length by ultrasound at baseline	Moderate	Moderate	Estimates the number of kidney cysts and is a disease-specific marker that can identify early risk for ESKD	Low in cost but not validated in all population groups (e.g. by ethnicity, country)	Moderate–high
Serial measurement of Ht-TKV by MRI	Moderate	High	Measures actual rate of kidney cyst growth	Intervals to measure standard; not all patients suitable for MRI, moderate in cost and not validated in all groups	Low
Single eGFR at baseline	Low	Moderate	Estimates GFR but not a disease-specific marker and does not reflect number of functioning nephrons due to glomerular hyperfiltration	Low in harm and cost	High
Serial eGFR changes	Moderate	Low	Estimates the rate of change in eGFR but insensitive in early stage of disease	Useful for late stage of disease and not validated	Low in stage 1 CKD and moderate-high in CKD stages 2–4
Statistical prediction models					
Mayo subclass (Irazabal) class at baseline	Moderate	High	Estimates the rate of kidney cyst growth based on Ht-TKV and age at the time of the test, and therefore subclassifies groups	Not all patients able to do MRI, moderate in cost and not validated in all populations and for ESKD	Moderate
PRO-PKD score	Moderate	High	Composite score based on clinical events and genetic testing	Genetic testing not performed and not validated in all populations	Low

Investigations

Laboratory and imaging tests. The performance characteristics of tests for renal function (serum creatinine and urea; urine albumin to creatinine ratio) and kidney volume (Ht-TKV by MRI and renal length by ultrasound) to estimate the 8-year risk of developing CKD stage 3a are shown in Table 19.6 [25]. These data are derived from longitudinal follow-up of a prospective cohort of 241 ADPKD patients who had an initial creatinine clearance >70 ml/min aged between 15 and 45 years [25]. In this cohort 30.7% of patients reached the study CKD3A during follow-up period. These data indicate that baseline serum creatinine has similar performance characteristics to kidney size (as determined either by MRI or ultrasound) [30].

eGFR and serum creatinine: The precision of eGFR is strongly correlated with measured glomerular filtration rate (GFR) and predicts the subsequent decline in renal function [31, 32]. The decline in renal function is estimated by the rate of change in eGFR using the CKD-EPI formula in serial measurements. ADPKD patients typically display decades of stable or mildly abnormal GFR until mid to late adulthood [32]. Once abnormal and compared to other forms of CKD, the decline in renal function can be rapid (up to 3–4 ml/min/1.73 m^2) per year depending on kidney enlargement [32].

Lack of validity to define "rapid progressor." The availability of tolvaptan in some regions has forced the use of decline in eGFR to define patients with "rapid" rates of progression [33]. The latter has been defined as the presence of eGFR <90 ml/min/1.73 m^2 with either (i) decline in eGFR of >5 ml/min/1.73 m^2 in 1 year; or (ii) decline in eGFR of >2.5 ml/min/1.73 m^2 per year over 5 years [33]. However, the clinical rationale and effectiveness of this definition to categorize patients in this manner is not supported by long-term outcome data. Alternatively, Blanchette [34] (in a retrospective observational cohort analysis; $n = 8018$), defined rapid progression as if one or more of the following were present: hypertension <35 years old, hematuria <30 year, albuminuria; stage 2 CKD by age 30; stage 3 by age 50, and/or stage 4/5 or ESKD by 55 year (50% vs. 75% 5-year renal survival).

Imaging: Total kidney volume (TKV) by MRI is a disease-specific biomarker useful for evaluating progression in clinical trials of patients with preserved renal function. In contrast, in clinical practice, the value of TKV over annual eGFR measurement in predicting renal prognosis is uncertain. Current evidence is limited to a single longitudinal cohort study where baseline height corrected-TKV>650 ml/m only marginally outperformed the baseline serum creatinine (97 μmmol/L) in predicting CKD stage 3A over 8 years (Table 19.6) [30]. However, as MRI is not reimbursed in many countries, longitudinal kidney length on ultrasound provides a simple parameter that can be used in clinical practice. In this regard, in the same cohort study a kidney length greater than 16.5 cm on renal ultrasound had a similar performance to Ht-TKV in predicting the development of 8-year risk of CKD stage 3A (Table 19.6) [30].

Statistical Prediction Models

Currently two models have been developed: (i) the Irazabal (Mayo) subclassification [35] and the PRO-PKD score [28] (Tables 19.7 and 19.8). The Mayo subclassification might be useful for prognostic enrichment in clinical trials. However, in clinical practice, barriers exist to applying both of these

Table 19.7 Irazabal (Mayo) subclassification [35].

Scoring method (Ht-TKV divided by age − 150 ml) × 100		
Mayo subclass	**Estimated kidney growth rates/ year (%)**	**Risk for ESKD**
A	<1.5	Low
B	1.5–3.0	Intermediate
C	3.0–4.5	Intermediate
D	4.5%–6.0	High
E	>6.0	High

ESKD, Ht-TKV

models as (i) the tests incorporated in the models (Ht-TKV for Mayo subclassification and genetic testing for PRO-PKD) are not part of routine clinical practice; and (ii) the models have not been validated prospectively for the development of ESKD or in real-world populations.

Treatment

Figure 19.1 provides an overview of the management approach in a patient with ADPKD. The key goals of care in ADPKD are to preserve quality of life (QoL) and normal life expectancy by (i) reducing the lifetime risk of ESKD; (ii) preventing and/or minimizing cardiovascular disease; and (iii) treating and managing extrarenal disease manifestations. The management of ADPKD should be "patient-centered" (i.e. care in which patients and their families are active partners in decision-making by being provided with clear and accurate knowledge regarding their situation) and "personalized" (i.e. "a disciplined approach to delivering care that responds to patients' circumstances, capabilities, and preferences").

Genetic and Psychosocial Care

The provision of coordinated genetic, medical, and psychosocial care should be the overarching goal of care [27]. Due to the systemic nature of disease manifestations, multidisciplinary care is typical for most patients with ADPKD and is tailored according to local health services, but the optimal model of delivery is not known.

Genetic Care

- *Genetic counseling:* As there is high intra- and interindividual variability in ADPKD, it is important that all patients receive education that is individualized to suit their circumstances. The counseling should include a discussion on the mode of inheritance (as well as communicating this to at-risk family members); the role, indication, and interpretation of diagnostic testing; information regarding the natural history, prognosis, and treatment; and options regarding family planning and prenatal testing options (including preimplantation genetic diagnosis). Referral to specialized genetic services and a genetic counselor can be offered to enhance the care, especially if molecular genetic testing is considered and/or family planning anticipated (such as preimplantation genetic diagnosis low certainty, weak recommendation). Patients should be informed about patient support organizations for PKD as well as centers where clinical trials in PKD or other novel treatments are being conducted.
- *Screening of adults and children at-risk of ADPKD:* Screening of first-degree adult relatives is recommended [36]. Renal ultrasound is the first-line screening test, and patients should receive the appropriate counseling regarding the advantages and disadvantages prior to performing predictive testing (high certainty, strong recommendation) (Table 19.9). The optimal approach for screening asymptomatic at-risk children (<18 years of age) is unknown but the decision should be individualized and considered with parental discussion (low certainty, weak recommendation) [37]. The historical view has been to defer screening children until adulthood but this view must be challenged [37, 38] due to the following emerging evidence: (i) at least one renal cyst may be detected in up to 80% of children who are at-risk of ADPKD [39]; (ii) hypertension is present in up to one-third of children [39] and a systematic review showed that ~8% reduced have renal function

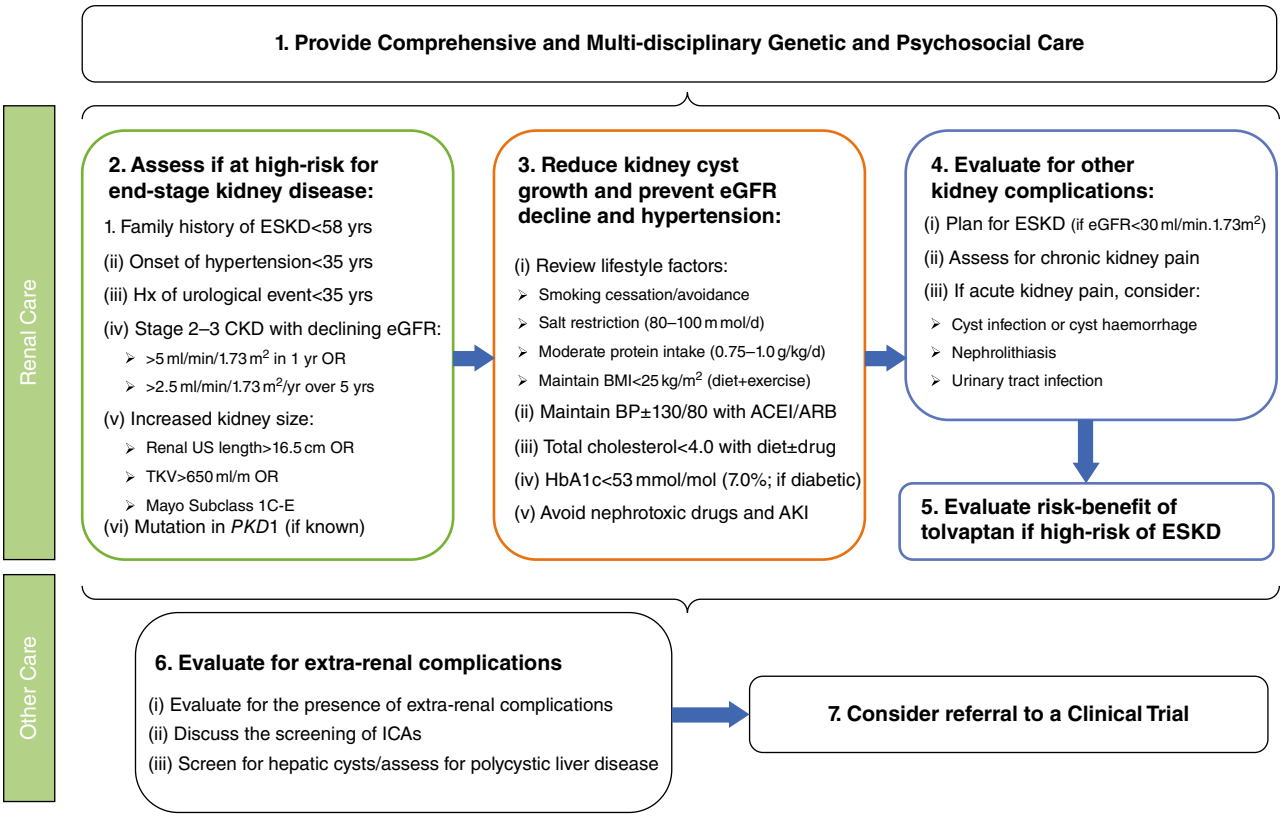

Figure 19.1 Overview of the treatment of ADPKD. *Source:* Adapted and modified from Rangan et al. [1].

Table 19.9 Benefits and disadvantages of screening adults at-risk for ADPKD.

Benefits of screening adults at-risk for ADPKD	Disadvantages of screening adults at-risk for ADPKD
Reduces uncertainty and anxiety	False negative result requiring re-testing
Diagnosis permits early treatment of complications	Financial discrimination
Permits decisions regarding lifestyle and employment	Employment discrimination
Permits discussions on reproductive options	Changes in social and family interactions
Allows family members to be informed	Psychological impact of diagnosis
Identify potential unaffected living-related kidney donors	

[40]; and (iii) subclinical manifestations of ADPKD begins in childhood, and early detection and treatment may slow renal cyst growth [41] with the potential to eliminate the lifetime risk of ESKD and other extrarenal manifestations in high-risk families [22] [24].

- *Family planning and preimplantation genetic diagnosis (PGD):* Couples with ADPKD should be informed of the pattern of inheritance and risks during pregnancy. The perinatal risks of pregnancy to a mother with ADPKD are dependent on the level of kidney dysfunction and/or hypertension. Young families with ADPKD are increasingly interested in PGD. In a survey of 96 UK patients with ADPKD, the majority (>95%) were concerned about the risk of genetic transmission [42] and most (>80%) would consider using PGD [42]. PGD involves in vitro fertilization as well as genetic testing and therefore id a costly procedure, but it is considered an option by patients with ADPKD with a family history of severe disease [24]. The application of PGD requires expert genetic counseling given the large phenotypic variability in ADPKD and complexities in genetic testing. Patients should be referred to specialist centers with previous experience and expertise in in vitro fertilization and molecular diagnostics [24]. The long-term outcome of PGD in ADPKD is unknown and will be informed by an ongoing observational cohort study underway in China (ESPERANCE trial; NCT02948179).

Acute and Chronic Psychological Care

The prevalence of psychological issues (anxiety, depression, denial, anger) in ADPKD is higher than in to the general population [27, 43]. Acute psychological symptoms

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

are worst at the time of diagnosis when it comes as a "shock" to patients (some patients describe being told the diagnosis as a receiving a "bomb") [27, 43, 44]. The origins of emotional distress in ADPKD are complex but include the hereditary nature of the disease (with patients calling it an "evil heritage" and experiencing guilt from transmitting the disease to future generations), the uncertainty of future prognosis regarding the kidney disease, chronic pain and lack of effective treatment options, worry about financial factors (future employment status and eligibility for life insurance), impact on family planning, and the changes in body image due to kidney and liver enlargement [45–47]. Psychological factors may negatively influence treatment adherence due to a sense of helplessness and denial. The evidence for psychological care in ADPKD is of low certainty but strongly recommended and includes (i) performing an initial evaluation using screening questions; (ii) determining the severity; and (iii) initiating appropriate management [48, 49]. The goal of care is to recognize and minimize psychological morbidity, and foster patient empowerment and self-motivation [50].

First-line Treatments to Prevent and/or Minimize Renal and Cardiovascular Disease

All patients with ADPKD should receive first-line (or primary) treatment (dietary salt minimization, optimal caloric energy intake) [51], treatment of hypertension with either angiotensin converting enzyme (ACE) or angiotensin receptor blocker (ARB), and avoidance of acute renal injury by minimizing exposure to nephrotoxins (low certainty evidence, strong recommendation). In patients with low to moderate risk of renal disease progression (which may be up to 50-75% of patients) first-line interventions may curtail the lifetime development of ESKD and cardiovascular morbidity if effectively implemented in young adults soon after diagnosis [52].

Diet Modification

Dietary salt restriction: In the HALT-PKD trial, each 18 mEq increase in averaged urinary sodium excretion was associated with a 0.43% per year rise in ht-TKV in patients with eGFR>60 ml/min/1.73 m^2 and with a faster decline in renal function (−0.09 ml/min/1.73 m^2) in patients with eGFR between 25 and 60 ml/min/1.73 m^2 [53]. In addition, in a small randomized controlled trial (RCT) ($n = 34$) of 2 weeks in duration in ADPKD patients with eGFR>60 ml/min/1.73 m^2, an ~30% reduction in urinary sodium intake (as determined by 24-hour urine sodium from ~3 to ~2 g/day) together with an ~40% increase in fluid intake caused a small but signification reduction in serum copeptin (~1 pmol/l) (a surrogate marker of AVP) [54].

Dietary protein intake: A subgroup analysis of ADPKD patients ($n = 141$, Study A; GFR between 25 and 55 ml/min1/1.73 m^2) in the Modification of Renal Disease study showed that a low protein diet (≤0.6 g protein/kg/day) compared to usual protein intake (1.3 g protein/kg/day) did not alter the decline in renal function (5.9 ml/min/year) [55]. Current evidence does not support any specific dietary protein intake for patients with ADPKD beyond standard recommendations in CKD (no recommendation).

Fluid Intake

We suggest consuming fluids whenever and in whatever volume desired or as advised by the treating physician (low certainty of evidence, weak recommendation). The volume of fluid that patients with ADPKD "should" drink is a topical question that has been asked by both nephrologists and patients. It has been hypothesized that maintaining a fluid intake of ~3 l per day may reduce the progression of renal cyst growth in ADPKD by suppressing AVP release [56]. However, there is no high-level evidence to support this as a clinical recommendation [6]. Furthermore, the volume of fluid required to suppress AVP is also likely to vary because it is dependent on the amount of dietary solute intake that a patient consumes [56]. To date, the evidence for the hypothesis is limited and based on short-term studies (less than 2 months in duration) which show that it is possible to reduce serum copeptin at consumption volumes that were tolerable to patients. However, the long-term efficacy (on renal function decline and renal cyst growth), safety, and feasibility of this approach are not known. The only available long-term data in humans is a small nonrandomized observational cohort study ($n = 33$) which showed that the progression of TKV or decline in eGFR in patients who drank 2.5–3.0 l per day was not different to those who consumed lower amounts over a 1-year period [57]. This study was nonrandomized, of insufficient duration and power as well as being an observation cohort design, therefore further data are needed [6]. Caffeine intake is not contraindicated in ADPKD patients (strong recommendation, low certainty evidence) [6].

Blood Pressure Control, Vascular Dysfunction, and Cardiovascular Disease

Blood pressure lowering: Angiotensin converting enzyme inhibitors or angiotensin II receptor blockers are preferred first-line agents for blood pressure control in (high certainty evidence, strong recommendation) [7]. There is limited evidence to guide second-line treatment choice (alone if intolerant to angiotensin converting enzyme inhibitor or in combination) but the stepwise use of a cardioselective blocker dihydropyridine calcium channel blocker, and/or

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

or a diuretic is suggested [2]. The KDIGO Controversy Conference on ADPKD suggested a target blood pressure (BP) of ≤130/80 mmHg in patients with macroalbuminuria (≥25 mg/mmol in males and ≥35 mg/mmol in females) or ≤140/90 mmHg if no macroalbuminuria for ADPKD patients [3]. The HALT-PKD trial showed that a target BP of 95/60 to 110/75 mmHg (vs. 120/70 to 130/80) was associated with a small (1.1% per year) but significant reduction in TKV in young ADPKD patients (15–49 years old with eGFR>1.73 m^2) over an 8-year period. This was associated with a 16% increase in dizziness and light-headedness in the low BP target group. Based on this data, the KHA-CARI ADPKD Guidelines suggest a BP target of at least ≤130/80 mmHg, and that a lower target BP could be considered in selected patients [2, 7].

Cardiac manifestations: The prevalence of cardiac valvular abnormalities (especially mitral valve prolapse/incompetence) and cardiomyopathy are increased in ADPKD [58, 59]. The incidence of left ventricular hypertrophy and valvular calcification increases as renal function declines [59]. However, echocardiography is not recommended unless physical examination is abnormal [2].

Intracranial aneurysms

- *Screening:* We recommend that magnetic resonance angiography or CT (circle of Willis angiography) is used for the screening of ICAs in asymptomatic individuals at high risk for an ICA (moderate certainty of evidence, weak recommendation). However, the decision to perform universal/systematic screening (i.e. to screen everyone with ADPKD at diagnosis) or to perform targeted screening for of those with risk factors (i.e. screen those at high-risk, family history of SAH, presence of neurological symptoms, prior to major surgical procedures) is controversial [60], and this likely explains the higher than expected screening rate in ADPKD patients (~30% undergo screening for ICAs within 2 years of diagnosis of ADPKD) [61]. In this regard, a recent cohort analysis of French patients suggested that screening should be systematic rather than targeted [62]. Interestingly, clinical practice guidelines led by nephrologists recommend performing targeted screening for ICAs whereas professionals from the stroke community favor a universal approach [11, 63]. In counseling patients, the risks and benefits of screening should be carefully discussed, noting that when positive, small aneurysms of the anterior circulation have a low risk of rupture [64]. Overall, complications related to the treatment of unruptured aneurysms may be as high as 15.6% [64]. Cerebral CT angiogram with low-dose contrast or cerebral magnetic resonance angiography is the standard screening method [11].
- *Repeat screening*: Follow-up interval screening is recommended only in patients with a family history of ICA or subarachnoid hemorrhage, or those with previous ICA or rupture, at intervals between 2 and 5 years, or according to risk factors such as hypertension, smoking, "high-risk" occupation or prior to major elective surgery [3]. The incidence of de novo aneurysms is 1.4% patient/year [64]. Repeat interval screening in low-risk asymptomatic patients with a negative initial scan is not recommended (low certainty of evidence, weak recommendation) [3].

Serum cholesterol and lipid-lowering drugs: We suggest lipid-lowering drugs are prescribed to prevent cardiovascular death based on evidence recommendations in CKD rather than to specifically reduce kidney cyst growth (low certainty of evidence, weak recommendation). In a study of 110 pediatric ADPKD patients (8–22 years), pravastatin mildly attenuated the increase in TKV over 3 years (21% vs. 30% from baseline, $P = 0.02$) independent of serum cholesterol [41], but this was not confirmed in a post hoc analysis of the HALT trial [65].

Physical Activity

Patients should be educated that the risk of renal cyst hemorrhage is increased if the kidney volume is high (e.g. if the longitudinal length is >15–16 cm) and these patients should preferably avoid high-risk contact sports (e.g. boxing, rugby, American football) (low certainty, weak recommendation).

Avoidance of Acute Kidney Injury

ADPKD patients should avoid or minimize their exposure to nephrotoxins (NSAIDs, aminoglycosides, radiocontrast) or procedures that increase the risk of acute kidney injury as it may increase the risk of renal cyst growth (low certainty of evidence, strong recommendation) [66] (Table 19.10).

Disease-modifying Treatments to Prevent and/or Minimize Renal Disease

Disease-modifying treatments may be defined as those for use in selected patients at high risk for ESKD (possibly ~25% of patients) and/or who exhibit features of rapid progression (e.g. "rapid progressor" or other prognostic factors) despite receiving maximal first-line management. The high likelihood of adverse events and/or low uncertainty of evidence are reasons for their exclusion as first-line treatments.

Vasopressin receptor antagonists in patients at high risk for progression of ESKD: The current evidence based on two RCTs does not support the routine use vasopressin

receptor antagonists in ADPKD and to use shared decision-making with patients if there is "rapid progression" as defined by a historical decline in the eGFR. [23, 67]. Tolvaptan is a specific vasopressin receptor antagonist that inhibits the binding of AVP at the V_2 receptor (a G_S-protein-coupled receptor) of the cortical collecting duct. In two RCTs, treatment with tolvaptan reduced the rate of decline in eGFR by approximately 1ml/min/1.73m^2/year compared to placebo [23, 67], but the limitations of this data should be considered: (i) the effect size on eGFR was small and apparent only after discontinuation, suggesting a role for hemodynamic and other cofounding factors [68]; and (ii) the long-term effect of tolvaptan on preventing ESKD is assumed and evidence is lacking [68]. In addition, mechanistic questions remain: (i) preclinical studies in *pck* rats suggest that both increased water intake and vasopressin receptor antagonist could have similar efficacy on reducing the kidney to body weight ratio by ~30% [69, 70]; and (ii) in vitro studies support a direct role for inhibition of AVP on renal cyst growth, but it is not known if human renal cysts express V_2 receptor.

The main adverse effects of tolvaptan are aquaresis (mean 5–7 l per day at maximal dose) and 5% of patients may develop reversible drug-induced liver injury. Thus, patients receiving tolvaptan must have liver function tests monitored every 1-3 months while on therapy (low certainty of evidence, strong recommendation).

Somatostatin analogs (octreotide, lanreotide): Somatostatin is a neuropeptide produced by gastrointestinal-derived delta-cells that attenuates intestinal motility, absorption, and proliferation [71, 72]. In humans, the ALADIN study (an RCT of 75 patients) showed that oectroetide reduced the increase in TKV at 1 year but not at 3 years compared to no treatment [71, 72]. The DIPAK-1 study which was a 2.5-year RCT comparing lanreotide + standard care (120 mg SC 4 weekly, $n = 153$) with standard care. The results showed that lanreotide did not alter the decline in eGFR (−3.56 vs. −3.46 ml/min/1.73 m^2 per year) but reduced the rate of increase in TKV (4.2% vs. 5.6%) [71, 72]. These data as well as the high risk of gastrointestinal side-effects do not support the use of somatostatin analogs in ADPKD.

TORC1 inhibitors (everolimus, sirolimus): Animal studies conclusively demonstrated that TORC1 inhibitors suppress the proliferation of cystic epithelial cells and reduce renal cyst growth. However, two clinical trials did not confirm the same efficacy in humans [73]. This disparity could be explained by: patient dropouts due to side effects (mouth ulcers), insufficient drug delivered to target tissue, and trial design, as therapy was initiated when kidneys had reached their near-maximal volume [73].

Kidney Pain

Chronic pain (>4–6 weeks in duration): The optimal management of chronic kidney pain is not certain [8]. Mild diffuse discomfort in the loin, abdomen, or lower back, present on most days, is common and reported by 60% of patients with "large" kidneys due to their physical effect in the abdominal cavity and pressure on the lower lumbar spine. In a cross-sectional analysis of the HALT study cohort ($n = 1043$) back pain was reported in ~50% of patients and was unrelated to kidney volume when the eGFR was greater than 60 ml/min/1.73 m^2 (unless the Ht-TKV exceeded 1000 ml/m) whereas patients with eGFR<60 were more likely to report abdominal fullness and pain that was disabling. The DIPAK cohort analysis ($n = 309$) showed that up to 30% of patients have associated gastrointestinal symptoms (such as heartburn, nausea, vomiting, and early satiety) due to combined kidney and liver volume. In a systematic review of patient perspectives on living with ADPKD, renal pain was described as volatile and incapacitating, which disrupted daily living and impaired ability to establish long-term life goals [47]. Hence, screening for chronic pain should be routine during all clinic visits. There is no high-level evidence to recommend the optimal approach for managing chronic pain. However, in refractory cases, a stepwise approach consisting of nonpharmacological (behavioral modification, physiotherapy, ice/heating pads,) and pharmacological (three-step analgesic ladder) treatments followed by minimally invasive (nerve block) and invasive (cyst aspiration, cyst fenestration, nephrectomy/hepatectomy) therapies is suggested (low certainty of evidence, weak recommendation) [74, 75]. A nonrandomized single-center study showed that a multidisciplinary sequential protocol involving nerve block can relieve pain in up to 80% of patients ($n = 60$) with chronic refractory pain [76].

Acute pain: The incidence of acute pain in ADPKD is less common than chronic pain, and data from the TEMPO 3:4 study suggested an average incidence of seven episodes per 100 years. The sudden onset of acute pain requires evaluation with history, physical examination, and renal imaging (generally by CT). The differential diagnosis includes:

- *Kidney cyst hemorrhage and rupture*: We suggest that renal cyst hemorrhage be treated with bed rest and analgesia as first-line treatment, followed by minimally invasive or invasive therapies if bleeding is refractory (low certainty of evidence, weak recommendation). Kidney cyst hemorrhage is characterized by sudden onset of sharp localized and unilateral abdominal pain either secondary to contact sports, blunt trauma or may be spontaneous (as cysts are surrounded by neoangiogenesis). In most cases (~80%) cyst hemorrhage bleed into the urinary collecting system causes macroscopic hematuria, and less commonly bleeding is retroperitoneal. The risk of cyst hemorrhage increases with kidney size, especially when kidney length exceeds 15 cm [77]. Bleeding into the collecting system tends to self-resolve, with symptomatic episodes lasting 3–5 days, and management entails bed rest, increased fluid intake, and analgesia. Rarely, selective renal artery embolization is required if retroperitoneal bleeding is refractory or catheter irrigation is required if there is ureteric clot obstruction [78].
- *Nephrolithiasis*: Kidney stones occur in ~30% of ADPKD patients (2-fold higher than the general population) and are usually composed of uric acid or calcium oxalate [79]. They occur because of reduced citrate excretion (an inhibitor of stone formation) and altered tubular urine flow. Clinical features resemble classical renal colic with or without macroscopic hematuria and urological management is the same as in the general population [79].
- *Infection*: Urinary tract infections (UTIs) (upper: pyelonephritis; lower: cystitis, urethritis) occur at least once in ~30–50% of ADPKD patients. The characteristic features are an acute onset of unilateral renal pain, associated with fever, chills, and rigors, and/or macroscopic hematuria with a positive urine culture and pyuria (mostly gram-negative enteric organisms). The mechanisms and management of ADPKD-associated UTI are the same as for the general population. By comparison, an infected cyst (either kidney or hepatic) has a subacute onset, nonspecific symptoms, low-grade fever, and evidence of systemic inflammation (elevated white cell count, C-reactive protein). The urine culture is negative and there may be acute tenderness corresponding to the location of the infected cyst. Features on a CT scan that favor cyst infection (vs. hemorrhage) include increase in cyst wall thickness or rarely the presence of gas within a cyst. There are no evidence-based guidelines for the optimal management of cyst infection. Microbiological confirmation can be difficult, as the urine culture is often negative. Occasionally, CT-guided aspiration of an infected cyst is required if antibiotic refractory. Positron emission tomography can be used as second-line investigation if the diagnosis is uncertain but has low specificity and is expensive. Suspected cyst infection should be treated with lipid- and cyst-permeable antibiotics (e.g. norfloxacin or co-trimoxazole) for an extended duration (4–8 weeks). A systematic review found that risk factors for failure of initial therapy (~39%) were large cysts (diameter >5 cm), ESKD, and atypical organisms [80]. Safety data from the DIPAK trial show that lanreotide is associated with higher risk of hepatic cyst infection for reasons not understood.
- *Effect of tolvaptan on acute pain episodes:* A post hoc analysis of the TEMPO 3:4 study showed that tolvaptan use was associated with a reduced incidence kidney pain events when compared to placebo (10.1% vs. 16.8%, $P < 0.001$) [67]. This effect is largely due to a decrease in acute pain secondary to urinary tract infection, kidney stones, and hematuria, and it is not known if prescribed water intake could also be similar.

Management of Extrarenal Complications

The frequency of extrarenal manifestations is shown in Table 19.11. Psychological morbidity (as discussed earlier) followed by the cardiovascular and gastrointestinal systems are the most commonly affected extra-renal areas. Patients with ADPKD were historically suspected to have an increased incidence of malignancy, but data to support this hypothesis is inconsistent.

Hepatic Cysts and Polycystic Liver Disease

Liver cysts and hepatomegaly occur in up to 80% of patients, but generally remain asymptomatic, with normal liver function tests in ~95% of patients [1, 10]. Approximately 5% of patients develop severe polycystic liver disease (PLD, defined as a height-corrected liver volume >1800 ml/m) predominantly (~80%) in females. The increased risk in females is associated with a history of multiple pregnancies and exposure to hormone replacement therapy, suggesting a causative link to estrogen exposure. In these cases, we suggest that severe PLD be managed by a multidisciplinary team (hepatologist, hepatobiliary surgeon, interventional radiologist, nephrologist; low certainty of evidence, weak recommendation). Short-term clinical trials suggest that somatostatin analogs (octreotide, lanreotide, pasiretoide) reduce symptoms of PLD with a small effect on reducing hepatic cyst growth rate, but long-term outcomes are not known. Rarely, liver transplantation (due to abdominal distension and portal hypertension) is required in severe PKD [1, 10].

Table 19.11 Frequency of extrarenal manifestations of ADPKD.

	Frequency of patients
Psychological issues	
Anxiety, depression, anger and denial	High
Cardiovascular system	
Cardiac valve abnormalities (mitral valve prolapse)	25%
Hypertension	80–100%
Left ventricular hypertrophy	20–40%
Gastrointestinal system	
Liver cysts	94% >35 years old
Diverticular disease	50–83% in ESKD patients
Hernia	45%
Pancreatic cysts	9–26%
Splenic cysts	2.7%
Choledochal cysts	Rare
Common bile duct dilation	40%
Neurological	
Intracranial aneurysms	9–12%
Arachnoid cysts	8–12%
Spinal meningeal cysts	1.7%
Other organ complications	
Seminal vesicle cysts	40%
Bronchiectasis	37%
Thyroid cysts	Not clearly defined
Risk of malignancy	Controversial, not defined

Management of ESKD in ADPKD

Late-stage 4–5 CKD should be managed as for other types of CKD [9]. Either peritoneal dialysis or hemodialysis are appropriate treatment options to manage ESKD. A recent meta-analysis ($n = 14\,673$) showed that peritoneal dialysis-related complications (technique failure, peritonitis, hernia) in ADPKD patients were similar to those in non-ADPKD patients [81]. As for other types of CKD, kidney transplantation is the preferred modality for the management of ESKD and patients should be evaluated for need for nephrectomy prior to transplantation (high certainty of evidence, strong recommendation). Transplantation may be associated with a ~2-fold increased risk for developing new-onset diabetes compared to other causes of CKD [9].

Conclusion

At present there is minimal evidence that treatment with disease-modifying agents (such as vasopressin receptor antagonists) improves outcomes in ADPKD due to uncertainty regarding efficacy, absence of patient-centered endpoints, and the high risk of significant risk adverse events. On the other hand, it is possible that first-line treatments (as described in this chapter), if instituted consistently in early life, could reduce lifetime risk of ESKD in moderate- to low-risk patients. For high-risk patients, numerous clinical trials are in development and understanding of disease pathogenesis and diagnostics is proceeding at an exponential rate. Furthermore, previously neglected areas of treatment, such as optimal genetic and psychosocial care, ICAs, and polycystic liver disease, are also gaining much deserved attention. The challenge for basic and clinical researchers will be to discover, select, and recommend the most promising interventions that have acceptable side effects (given that they might need to be taken for decades) using the most efficient methods in clinical trial design.

Urinary Tract Infection

Suetonia C. Palmer[1] *and Giovanni F.M. Strippoli*[2]

[1] *Department of Medicine, University of Otago Christchurch, Christchurch, New Zealand*
[2] *Department of Emergency and Organ Transplantation University of Bari Bari, Italy and School of Public Health University of Sydney Sydney, NSW, Australia*

Introduction

Urinary tract infection is one of the most common bacterial infections around the globe, and is an important cause of morbidity, hospitalization, and antibiotic resistance. Urinary tract infection can be upper or lower; lower urinary tract infection refers to infection of the bladder (or cystitis). Asymptomatic bacteriuria refers to the presence of $>10^5$ colony-forming units in the urine without physical signs of infection. Uncomplicated lower urinary tract infection is usually a self-limiting illness. Symptom duration is reduced by treatment with antibiotics to which the infective pathogen is sensitive. Urinary tract infections occur due to predominantly bowel-related organisms, most commonly *Escherichia coli*, while other common bacterial etiologies include *Staphylococcus* and less frequently *Enterobacteriaceae* (*Proteus mirabilis* and *Klebsiella* spp.). Lower urinary tract infection is frequently identified by specific urinary tract symptoms combined with urine dipstick testing, with or without subsequent microbiological confirmation. Older adults and children may present with atypical symptoms. Children often present with fever and other symptoms such as lethargy, vomiting, and poor feeding.

In this chapter, we summarize the evidence and provide recommendations for the treatment and prevention of uncomplicated lower urinary tract infection in nonpregnant women and in children and men (Table 20.1). We describe the evidence for therapeutic approaches to asymptomatic bacteriuria. Discussions of the treatment of complicated urinary tract infection in all adults and children (including upper tract infection), and uncomplicated urinary tract infection in pregnant women are not included in this chapter.

Epidemiology

Infection of the lower urinary tract accounts for between 1% and 3% of all ambulatory assessments in the United Kingdom and approximately 0.5% of visits in the United States [2, 3]. Urinary tract infection leads to 10–20% of antibiotic prescriptions in ambulatory care [4]. The diagnosis of a urinary tract infection is suggested by the presence of typical urinary symptoms. Confirmation of uropathogenic bacterial species at >100 colony-forming units/ml in the urine indicates infection when symptoms are present. Leucocyte esterase or nitrite positivity on dipstick is highly sensitive in detecting pyuria but may not accurately rule out infection [5]. If the dipstick is negative in the presence of symptoms, urinary culture is appropriate to evaluate further for the diagnosis. Lower urinary tract infections mostly occur through migration of gut-related bacteria into the bladder via the urethra [6]. *E. coli* is the most likely causative organism, occurring in 70–95% of cases, with *Staphylococcus saprophyticus* occurring in about 5–10% of cases and occasionally *Enterobacteriaceae* spp. such as *Proteus* and *Enterobacteriaceae* [7]. Asymptomatic bacteriuria is considered present when there are no urinary symptoms and $>10^5$ colony-forming units of pathogenic bacterial species are detected in the urine.

Urinary tract infections are more common in boys before the age of 6 months, occur at similar rates for boys and girls at 2 years (8%), occur in 1.7% of girls and boys at 7 years, and in 11% and 4% of girls and boys by 16 years [8]. Women are approximately 30 times more likely to experience lower urinary tract infection than men, with almost half of women experiencing one or more infections during their lifetime [9]. The risk is markedly increased after the onset of sexual

Table 20.1 Treatment for uncomplicated urinary tract infections.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Uncomplicated lower urinary tract infection in women			
Antibiotics	We suggest that lower urinary tract infection is treated with nitrofurantoin or trimethoprim/sulfamethoxazole as first-line therapy. Other drug classes may have similar effects (beta-lactams), although resistance may be higher. Fluoroquinolones have no advantage over other antibiotic groups and may increase resistance. We suggest that 3 days of antibiotic therapy is similar to 5–10 days for achieving symptomatic cure for uncomplicated urinary tract infection while longer treatment can be used for bacterial cure in patients for whom this is important.	*High* (symptomatic relief); *moderate* (bacterial cure)	Strong
Recurrent lower urinary tract infection in women			
Antibiotics	We suggest that continuous antibiotic prophylaxis (trimethoprim/sulfamethoxazole, nitrofurantoin, cephalosporin) be used to prevent lower urinary tract infection although the effect is limited to the active antibiotic intake period, the optimal duration is uncertain, and side effects are common.	*Low* (recurrent urinary tract infections)	Weak
Cranberries	We do not suggest cranberries be used to prevent urinary tract infections.	*High* (recurrent urinary tract infections)	Strong
Probiotics	We do not suggest probiotics be used to prevent urinary tract infections.	*Low* (recurrent urinary tract infections)	Weak
Lower urinary tract infection in children and adolescents			
Antibiotics	We suggest children older than 3 months with lower urinary tract infection be treated with trimethoprim/sulfamethoxazole, trimethoprim, or nitrofurantoin as first line. We suggest that 3 days of antibiotic therapy is similar to 5–10 days for achieving symptomatic cure for uncomplicated urinary tract infection while longer treatment can be used for bacterial cure in patients for whom this is important.	*Low* (symptomatic relief, bacterial cure)	Weak
Prevention	We do not suggest long-term antibiotics be used in children with one or more previous urinary tract infections, except in young infants or children with renal abnormalities. We do not suggest that cranberries or probiotics be used to prevent recurrent infection.	*Moderate* (recurrent urinary tract infection, antibiotic resistance)	Moderate
Uncomplicated lower urinary tract infection in men			
Antibiotics	We suggest that lower urinary tract infection in men is treated with nitrofurantoin as first-line therapy. Other drug classes may have similar effects (trimethoprim/sulfamethoxazole, beta-lactams).	*Very low* (symptom and bacterial cure)	Weak
Asymptomatic bacteriuria			
Antibiotics	We do not suggest that antibiotics be used to treat asymptomatic bacteriuria. Screening for asymptomatic bacteriuria in nonpregnant adults and in children is not recommended.	*Moderate* (development of urinary tract infection, side effects)	Moderate

GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

activity. Recurrent urinary tract infections are those that occur after appropriate treatment of a previous infection and are usually due to reinfection rather than relapse. One-quarter of women experience a further infection within 6 months of a sentinal urinary tract infection [10].

Pathophysiology

Urinary tract infection occurs due to the migration of uropathic bowel-related organisms (predominantly *E. coli*) that colonize the periurethral opening and which subsequently

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ascend to the bladder [6]. The bacteria then bind directly to epithelial cells (facet cells) in the bladder wall, which then may internalize the adherent organisms [11]. Uropathogenic bacteria may neutralize intracellular lysosomes and enter the bladder epithelial cell cytoplasm. Subsequently, bacteria form clonal intracellular bacterial communities within facet cells and evade innate immune responses when encased within a biofilm [12]. Protein secretion and induction of host gene expression can alter the immune response to bladder wall bacterial invasion and replication. *E. coli* or other bacteria may develop resistance to neutrophil action through morphological changes and reinvade surrounding and previously unexposed bladder wall epithelial cells.

Prognosis

Adult Urinary Tract Infection

Uncomplicated urinary tract infection is associated with a good prognosis in the long term. Among women with an infection sensitive to antibiotics, severe symptoms are expected to last for approximately 3 days, although they may continue for an additional 1.5 days in women with an antimicrobial-resistant organism and somewhat longer overall if antibiotics are not prescribed [13]. Patients may wait almost 5 days before seeking a medical consultation for symptoms which have a moderate impact on activities of daily life, with minimal ongoing impact on usual activities at 10 days [14]. Recurrence of urinary traction infection is most commonly reinfection with the same organism. Following a first urinary tract infection, approximately 25% of women will have a culture-confirmed recurrence within 6 months and 2.7% may have a second recurrence within that time frame [15, 16]. Asymptomatic urinary tract infection is associated with increased risk of urinary tract infection with symptoms, although antimicrobial therapy does not reduce this risk [17].

Pediatric Urinary Tract Infection

In a systematic review, it was reported that between 3% and 15% of children have demonstrable renal parenchymal changes at 1–2 years after a first urinary tract infection [18]. However, it is likely that most children have no cortical renal defects (>80%) and are unlikely to develop new renal damage despite recurrent infection, while the remainder have focal structural abnormalities that may represent congenital or acquired injury [18, 19].

Treatment

Several Cochrane systematic reviews of interventions for treatment and prevention of uncomplicated urinary tract infection have been published. These reviews focus on antibiotic therapy and some nonantibiotic interventions, including cranberries and probiotics as prophylaxis. Most studies of urinary tract infection treatment have used symptomatic cure, bacteriological cure (short-term and long-term), isolation of resistant pathogens, time to symptom resolution, days of work loss, and adverse events, particularly rash and gastrointestinal effects, as critical outcomes. Evidence is most available for nonpregnant women, with a small number of trials involving children, and a paucity of data for outcomes in men with urinary tract infection. Some men (<10%) have been included in trials of women with infection. Trials have evaluated duration of antibiotic therapy, route of administration including oral versus intravenous, and the long-term use of antibiotics to prevent urinary tract infection. There is a limited evidentiary base for evaluation of nonpharmacological interventions.

Treatment of Urinary Tract Infection

Recommendations for Adults

Adult patients with uncomplicated urinary tract infection should receive oral nitrofurantoin or trimethoprim/sulfamethoxazole for 3 days (strong recommendation, high level of evidence). Antibiotic therapy may be reasonably delayed by 48 hours in adults without an indication for immediate treatment (moderate recommendation; moderate level of evidence). Beta-lactam therapy is likely to be equivalent to other first-line antibiotic classes, although local organism resistance may lead to a lower preference of this treatment option. Fluoroquinolones are effective but associated with higher risks of antibiotic resistance. A longer duration of antibiotic treatment (5–10 days) is recommended for women for whom bacteriological eradication might be important (planning pregnancy, recurrent, and painful lower urinary tract infections) and for all men.

Recommendations for Children

Children with uncomplicated urinary tract infection should receive oral antibiotics for 3 days (weak recommendation, low level of evidence). Appropriate antibiotic choices include trimethoprim/sulfamethoxazole, trimethoprim, nitrofurantoin, amoxycillin/clavulanate, or a cephalosporin. Short treatment courses (3 days) have been shown to be as effective as longer duration of therapy (5–10 days).

Evidence in Adults

The different antimicrobial treatments for acute uncomplicated lower urinary tract infection have been evaluated in 21 randomized controlled trials involving over 6000

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

participants [20]. Trimethoprim-sulfamethoxazole is as effective as fluoroquinolones, beta-lactam drugs, and nitrofurantoin based on short-term and long-term resolution of symptoms. Rash is more commonly experienced with trimethoprim/sulfamethoxazole compared to nitrofurantoin and fluoroquinolones. Due to higher resistance to beta-lactams in some areas, first-line therapy decisions might include consideration of the potential for adverse events, local microbial patterns, and patient preferences. In a single randomized trial in 300 nonpregnant women, five different management approaches (empirical antibiotics, delayed antibiotics [48 hours], targeted antibiotics based on a symptom score, a dipstick result, or a positive result on a mid-stream urine analysis) achieved similar symptom control. Antibiotic therapy based on dipstick results or delayed prescribing may reduce antibiotic use [21]. In evidence from 32 trials (9605 participants), there was no difference between 3-day and a 5–10-day antibiotic regimen, although the bacteriological failure rate may be higher with 3-day therapy [22]. Adverse events were not surprisingly more common in the 5–10-day treatment groups. Evidence in men is largely derived from trials involving men as a small proportion of the study population and is very uncertain.

Evidence in Children

Sixteen randomized controlled trials involving 1116 children were included in a Cochrane systematic review of antibiotics for treatment children with lower urinary tract infection [23]. The methodological quality of most studies resulted in high or unclear risk of bias for many aspects of trial conduct. This resulted in lower certainty in the evidence and a weak recommendation. A lack of data reduced confidence in understanding whether different classes of antibiotics have different effects, based on outcomes such as persistent bacteriuria, recurrence, or reinfection. There was no evidence that a longer course of treatment (10 days) had different effects than a single dose, except for a higher rate of initial bacterial eradication. Children and young people in the included studies were aged between 2 weeks and 19 years.

Prevention of Urinary Tract Infection

Recommendations for Adults

We suggest in women with two or more documented urinary tract infections in the previous 12 months that continuous antibiotic prophylaxis (trimethoprim/sulfamethoxazole, nitrofurantoin, cephalosporin) might be used to prevent lower urinary tract infection although the effect is limited to the active antibiotic intake period, the optimal duration of treatment is uncertain, and side effects are common (weak recommendation, low certainty evidence). Adults do not benefit from cranberries or probiotics to prevent urinary tract infections.

Recommendations for Children

Children do require antibiotic treatment to prevention urinary tract infection (moderate recommendation, moderate certainty evidence).

Evidence in Adults

In 10 trials involving 430 women, microbiological and clinical recurrence were reduced during the active prophylaxis phase of therapy for 6–12 months duration. In general, the methodological quality of the contributing trials was poor, reducing certainty in the results. In two studies, there was no detectable difference between prophylactic antibiotic use and placebo after completion of antibiotic therapy [24]. In older women with recurrent urinary tract infection, three small trials compared antibiotics with vaginal estrogen therapy, probiotics, or D-mannose powder, antibiotic therapy similarly reduced microbiologically confirmed urinary tract infection episodes during treatment, but there was no apparent effect at 3 months after treatment cessation, although microbiological resistance may have been increased [25].

Cranberries release proanthocyanidins that prevent *E. coli* adherence to bladder wall epithelia [26]. In a Cochrane review published in 2008, it appeared that cranberries might decrease symptomatic urinary tract infections in women, and especially those with recurrent infections [27]. In an updated review that included 24 studies (4473 participants), cranberries did not prevent symptomatic urinary tract infection in women with recurrent infection, older women, children, pregnant women, or those with urinary tract abnormalities [28]. Participants experienced a high drop-out rate, indicating that cranberry juice may not be acceptable over the longer term. In nine studies (735 participants) at high risk of bias involving women and girls with recurrent urinary tract infection, there was no evidence that probiotics prevented symptomatic urinary tract infection [29].

Evidence in Children

A Cochrane review published in 2019 included 16 studies involving 2036 children at often high risk of methodological bias [30]. When analysis was limited to higher quality studies, there was evidence that antibiotics led to a modest reduction in symptomatic recurrence in children with and without vesico-ureteric reflux. Prophylactic antibiotics possibly increased microbiological resistance. There was no evidence in two Cochrane reviews that cranberries or probiotics prevented urinary tract infection in children [28, 29].

Treatment of Asymptomatic Bacteriuria

Nonpregnant adults and children with asymptomatic bacteriuria and a normal or noninstrumented urinary tract do not require antibiotic therapy. Nonpregnant adults do not benefit from screening for asymptomatic bacteriuria.

Evidence in Adults

In a Cochrane view that included nine studies and 1614 participants, antibiotic therapy of asymptomatic bacteriuria had no detectable effect on symptomatic urinary tract infection or complications [31]. Studies were generally of high or moderate methodological quality. Antibiotics increase the likelihood of bacteriological cure, at the expense of increased adverse events. Limited data were available for understanding the impact of antibiotic therapy on microbial resistance. In data from a randomized controlled trial and a prospective cohort study, there was no evidence that screening for asymptomatic bacteriuria is effective [32].

Evidence in Children

There is insufficient evidence to be certain whether antibiotic therapy benefits children in the long term. The impact on kidney injury or harmful effects of providing treatment are uncertain [33].

Patient Perspectives

In qualitative analysis, women with symptomatic urinary tract infection preferred to avoid antibiotic therapy and would consider nonantibiotic-based approaches. Prior experiences of antibiotics led to a greater acceptance of this approach, while a "delayed antibiotic" strategy was preferred by most women but was viewed as lack of validation for symptoms and being taken seriously by some [34].

Introduction

Environmental nephrotoxins include materials found predominantly in the workplace [1–3] (Table 21a.1). Many of these chemicals have no biological value for the treatment of diseases and are toxic to many tissues and cells. The clinically important industrial nephrotoxins include lead, mercury, cadmium, silica, a variety of (sometimes poorly defined) organic hydrocarbons (aliphatic, aromatic, and halogenated), uranium, chromium, and arsenic [4]. Most of these nephrotoxins cause biological exposure through inhalation and ingestion of contaminated food and drinks. Although low concentrations of heavy metals are present in the environment naturally, there is a greater exposure to these nephrotoxins in industrial and developed countries. For many of these nephrotoxins [5], it should be recognized that there are no randomized controlled trials for the management of kidney diseases caused by these environmental agents. The cornerstone of treatment is prevention and limiting further exposure (Table 21a.2).

Heavy Metals

Lead

Acute lead poisoning continues to rise in most developed countries and in particular in socio-economically deprived communities [6]. Acute lead poisoning causing abdominal pain, anemia, and encephalopathy may occur days or weeks after exposure to lead. Blood lead levels exceeding 70 μg/dl (current mean blood lead in the USA is <2 μg/dl) are associated with acute lead toxicity [7]. Acute childhood lead poisoning usually occurred because of the ingestion of lead-based paint in deteriorated housing. Fanconi syndrome (aminoaciduria and phosphaturia) has been reported in children with acute lead toxicity. This finding is consistent with transient proximal tubular reabsorptive defects [8]. Fanconi syndrome is regularly reproducible in experimental animals exposed to sufficiently high doses of lead. Lead-induced Fanconi syndrome is reversible with chelating therapy ($CaNa_2$–EDTA) and removal from exposure [9].

In acute lead toxicity states, there is a clear relationship between plasma level and toxic exposure. The diagnosis and treatment are much more difficult in the long-term, low-dose exposure of lead in adults. In addition, many comorbid conditions might mask the signs and symptoms of chronic lead toxicity [5, 10]. Chronic lead exposure is also associated with hypertension, gout, and tubulointerstitial nephritis, which is histologically indistinguishable from hypertensive nephrosclerosis. In the past, lead nephropathy was identified in lead workers or those working with moonshiner (illegal use of distilled liquor) after chronic exposure [2]. Blood lead in these workers was often above 40 μg/dl, which is the exposure limit promulgated in the federal occupational lead standard. It was widely assumed that blood lead levels of 60 μg/dl or higher, sustained for many years, were required to induce lead nephropathy. However, recent epidemiologic evidence using blood and bone lead measurements (by noninvasive in vivo K X-ray fluorescence) indicate that the adverse effects of lead on blood pressure and kidney function occur at much lower levels than previously recognized. Ninety-five percent of lead in the body is retained in bone, with a biological half-life approximating two decades, whereas

[b] Often in clinically complex settings with multicausal renal damage.

blood lead has a biological half-life of about 30 days [11]. Therefore, bone lead reflects cumulative lead absorption, whereas blood lead primarily reflects recent exposure.

Blood lead and bone lead predict blood pressure even when both are within the range traditionally considered "normal." Epidemiologic evidence that low-level lead absorption (blood lead of <10 μg/dl) has deleterious effects on blood pressure and renal function was obtained from National Health and Nutrition Evaluation Survey III, 1988–1994. Analysis of data on over 15 000 Americans showed that hypertensive people had significantly higher blood lead levels (4.21 vs. 3.30 μg/dl) than people without hypertension [11, 12]. Two large, cross-sectional studies also reported a significant association between low-level lead exposure and serum creatinine [7, 12]. The adverse effects of low-level lead exposure on renal function are further supported by longitudinal observations. Because lead does not accumulate in patients with kidney failure of non-lead etiology, these observations point to low-level lead exposure as a contributor to hypertension and kidney disease.

Bone lead levels were found to be significant predictors of hypertension in community-exposed men [13]. The mean blood lead level in these men was 6 μg/dl. Similarly, bone lead levels were found to be a significant predictor of hypertension in nurses [14]. A study in pregnant women

Solvents	Supportive measures and avodiance

$CaNa_2$–EDTA, calcium ethylenediaminetetraacetic acid.

with a geometric mean blood lead level of 1.9 μg/dl found increases in bone lead were associated with an increased risk of pregnancy hypertension [15]. Increases in both diastolic and systolic blood pressures in pregnant women were significantly associated with blood lead, and the major portion of the effect was found with blood lead levels under 5 μg/dl. These observations on adverse effects at blood lead levels below 10 μg/dl in diverse groups indicate that, even at levels traditionally considered acceptable, important adverse health effects occur.

Treatment of lead-induced hypertension and kidney failure with calcium ethylenediaminetetraacetic acid ($CaNa_2$–EDTA; also called calcium disodium versenate or edetate calcium disodium) may improve the glomerular filtration rate (GFR) or reduce the rate of progression of kidney failure. However, there is no clinical data to support the reversibility of established interstitial nephritis after treatment with $CaNa_2$–EDTA [16, 17]. It is reasonable to do an EDTA lead mobilization study and 24-hour urine collection in patients with unknown causes of hypertension, gout, and potential exposure to lead. Therapeutic benefits have been noted in patients with acute kidney injury from much lower levels of lead exposure. Lin et al. [11] treated patients with chronic kidney disease (CKD) from lead exposure (mean creatinine 2.1 mg/dl, mean blood lead 5.3 μg/dl) with $CaNa_2$–EDTA, 4–13 g intravenously, over 2 years. The treated group had a modest improvement in GFR averaging 3.4 ml/min, whereas untreated controls had a decrease in GFR of 1.0 ml/min during this period. The same laboratory demonstrated that low levels of lead absorption correlate significantly with the rate of progression of kidney failure in type 2 diabetics and that $CaNa_2$–EDTA therapy, averaging 7 g over 3 months, significantly reduced the rate of progression of kidney failure compared to untreated diabetic controls. These results suggest that reducing even very low levels of lead may improve GFR in a variety of nonlead-related kidney diseases. Moreover, if the beneficial effect of $CaNa_2$–EDTA is, in fact, due to the removal of lead from the body, these observations indicate that there is no threshold for the deleterious effects of lead on kidneys [18].

However, the mechanism of the beneficial effect of $CaNa_2$–EDTA on the kidneys is not clear. Improvement and management of comorbid conditions may play an important role in the improvement of hypertension and reduced GFR. Prevention remains the most effective method of treatment of lead poisoning. Chelation transiently increases the rate of removal of lead, causing the urinary excretion of up to several milligrams of lead in heavily exposed individuals within a few days. If, on the other hand, excessive exposure is terminated, the expected urinary excretion of 100–200 μg of lead/day will achieve a negative balance of 35–70 mg/year. Because a lifetime of occupational exposure can result in bone lead stores of 500 mg or more, a course of chelation therapy (e.g. 1–2 g $CaNa_2$–EDTA) eliminates only about 0.2–0.4% of the body burden, whereas terminating exposure reduces bone stores by about 10% per year. Although it is not feasible to eliminate all lead intake, similar calculations for individuals with low-level exposure indicate that, in the long term, prevention is more effective than chelation in lowering the body lead stores. In summary, chelation therapy is justified in cases of symptomatic lead poisoning or when the blood lead exceeds about 70 μg/dl, but when no symptom end point is clearly defined, chelation for blood lead of <70 μg/dl is not usually justified [8].

Mercury

Exposure to mercury can be through inhalation, oral, or dermal. Mercury is a natural element with atomic weight of 200.6. There are many form of organic and inorganic mercury in the pharmaceutical industry. Mercury is unique in that it exists as a liquid at room temperature. Inorganic mercury mostly accumulates in the kidney while organic mercury mostly accumulates in the central nervous system. A number of studies have suggested that patients/animals with reduced renal function are at greater risk of mercury renal toxicity [19]. The salt of mercury thimerosal is still used in vaccines as a preservative. The toxicity of mercury depends on both its chemical form and the route of absorption. Although preferentially accumulated in the kidney, neurologic disease, but not kidney disease, regularly follows exposure to elemental mercury. Once in the

environment, elemental mercury undergoes biotransformation to both organic and inorganic salts, which are absorbed by living organisms and thus enter the food chain. Mercury at the cellular level accumulates at proximal tubular cells via OAT-1 and 3. Mercury may alter the function and structure of nephrons. After exposure to a toxic dose of mercury exposure, mitochondrial swelling and dilation of the endoplasmic reticulum of proximal tubular cell can be identified [20].

In addition to diuresis and acute tubular necrosis, mercury has been sporadically reported to cause nephrotic syndrome in what has usually been considered an idiosyncratic response. Observations in rats may provide a framework for understanding mercury-induced glomerular disease in humans. In 1971, Bariety et al. [21] reported that multiple subcutaneous injections of $HgCl_2$ in specific rat strains, in doses too small to produce tubular necrosis, induced membranous nephropathy. Kidney disease characterized by glomerular deposition of immune complexes and heavy proteinuria developed in about 2 months. Subsequent studies showed that the immune response is actually biphasic; immune complex deposition is preceded by antiglomerular basement membrane antibody and complement deposition. The response to mercury in the rat is under precise genetic control. As little as 0.05 mg/kg of body weight will elicit immunologically mediated glomerular disease in selected strains. As in humans, mercury-induced glomerular disease in rats is self-limited [22].

There are no randomized clinical trials for the treatment of acute tubular necrosis or nephrotic syndrome due to mercury. Chelation therapy has been employed for excessive mercury exposure, often defined as more than 5 μg Hg/dl in blood or 50 μg Hg/l in urine, but evidence for the effectiveness of chelation therapy is lacking. Traditional use of BAL (British antilewisite, dimercaprol) for chelating mercury is currently being replaced by its soluble congeners, dimercaptopropane sulfonic acid (unithiol or Dimaval) and succimer (dimercaptosuccinic acid, Chemet). Dimercaptopropane sulfonic acid is the chelator of choice for inorganic mercury intoxication, whereas succimer is the agent of choice for organic mercury [22]. Case reports suggest that in the presence of severe kidney failure the mercury-chelate complex can be removed by hemodialysis or hemofiltration.

Cadmium

Cadmium (Cd) is an environmentally prevalent heavy metal and pollutant that is known to have multiple adverse effects on the human body and is most commonly found in batteries, plastics, pigments, and fertilizers [23]. Given its role in fertilizers, Cd can accumulate in both plants and animals. As a result, diet becomes the primary route of exposure among the nonsmoking population [24]. However, in the smoking population, inhalation is the primary route of exposure as tobacco plants accumulate Cd in high concentrations. Verdugo et al. investigated the concentration of Cd in cigarettes and found that 1–2 μg of Cd were present in each cigarette, of which 5% is absorbed by the lungs [25–27].

Once Cd is absorbed systemically, it accumulates in multiple organs, including bone and liver, like other heavy metals, but also in the kidney. As much as 50% of the total body stores are found in the kidney, which explains the significant renal adverse effects associated with Cd [28, 29]. Cadmium deposition in the bone results in a long half-life, requiring decades for complete elimination. Complete elimination, however, is difficult because of the chronic low-dose exposure that may initially go unnoticed until large burdens accumulate.

While renal handling of Cd is complex and not fully understood, it is known that Cd has a high affinity for sulfhydrl moieties, and is suspected to be transported along with organic anions/cations and amino acids or oligopepties [30]. Additionally Cd utilizes other metal transports such as divalent metal transporter (DMT1) and zinc transporters such as ZIP8 and ZIP14 to cross cell membranes. Despite these routes, it is suspected that most Cd enters the proximal tubular epithelial cells after being transformed to Cd-metallothionein [MT] by the liver. Cd-MT is a nontoxic byproduct that usually accumulates in the liver, but may be released through Cd-induced hepatocellular necrosis, resulting in serum Cd-MT, which is subsequently absorbed by the proximal tubular epithelium via endocytosis [30, 31]. Once in the kidney, Cd disassociates from MT in the lysosomes where it may lead to renal adverse effects. Accumulation of Cd in the kidney typically causes polyuria, reduced GFR, and Fanconi syndrome [28].

Thought rarely tested, cadmium monitoring can be done through urine and or blood assays. Serum levels are helpful for acute exposures (within the last month), whereas urinary sampling is utilized when chronic exposure is suspected. Given that most people are exposed chronically at low dose, urinary excretion of Cd is a more reliable indicator, especially when it comes to renal and total body burden [23, 32]. Monitoring for kidney damage typically involves nonspecific signs including urinary biomarkers, β2-microglobulin, *N*-acetyl-β-D-glucosamidase (NAG), kidney injury moleculre-1 (KIM-1), and cystatin C [28], the latter being a more reliable biomarker for Cd-induced damage [33]. Prolonged Cd exposure typically manifests as proximal tubular microvilli damage, resulting in reduced transporters and reabsorption. If severe enough, Fanconi syndrome may be diagnosed, which is characterized by aminoaciduria, glucosuria, hypercalciuria, and hyperphosphaturia. While kidney damage has

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

multiple negative downstream effects, nonrenal adverse events occur such as decreased synthesis of activated vitamin D (1,25-dihydroxycholecalciferol) and liver damage.

Multiple epidemiological studies have documented a dose-related correlation to renal insufficiency, but given the high incidence and prevalence of CKD in the world, one must have a high clinical suspicion to diagnose Cd-induced CKD. This most typically occurs in places with high incidence of Cd in the environment such as Sri Lanka [34]. As CKD develops and GFR declines, there is a reduced capacity to clear the nephrotoxin, exacerbating preexisting renal disease [35–38].

Excretion occurs very slowly given the distribution and deposition in the bone, but risk factors such as age, gender, and diabetes decrease excretion. One study reported decreased urinary Cd was associated with diabetic rats compared to nondiabetic rats [4]. Although not fully understood, some studies have shown decreased insulin expression in Cd exposure, but this is confounded because both Cd and diabetes cause renal disease, which has been shown to decrease excretion. Interestingly, studies assessing the differential burdens of Cd between men and women found women to have greater burdens compared to men. Further investigation revealed that both blood and urinary Cd levels correlate with age and iron stores. On average women tend to have lower iron stores than men and as a result of the lower iron stores, they upregulate DMT1 in an attempt to absorb more iron. This also facilitates Cd uptake through the same transporter, ultimately predisposing those with low iron to increased Cd uptake [39–41].

Once cadmium has been detected in the body at toxic levels, treatment is primarily through chelation therapy with succimer or EDTA. Further research still has to be done, but other metals such as zinc and magnesium have been shown to limit renal toxicity. While the mechanism of action is likely multifactorial, it has been shown to prevent enzyme alteration as well as saturate metal transporters. This hinders the further uptake of Cd into both the cell and the body. While no agents are particularly effective for removing Cd from the liver, zinc has been shown to help transform Cd to the nontoxic form (Cd-MT) and reduce cellular apoptosis induced by Cd [42–44]. Overall, to diagnose Cd toxicity, one must have a high suspicion for it as exposure is commonly low dose and chronic. Despite limited interventions, diagnosing cadmium toxicity enables environmental assessment in an attempt to reduce exposure and limit further damage.

Itai-Itai Disease

In Japan, a painful bone disease associated with pseudofractures due to cadmium-induced renal calcium wasting was recognized in the 1950s. Attributed to local contamination of food staples by river water polluted with industrial effluents, the syndrome, known as itai-itai or "ouch-ouch" disease, primarily afflicted postmenopausal, multiparous women. Sustained deficiencies in iron, zinc, calcium, and vitamin D rendered these women particularly vulnerable to cadmium toxicity [45]. Women with itai-itai disease tended to have reduced GFR, anemia, lymphopenia, and hypotension as well as osteomalacia. They exhibited a waddling gait, short stature, anemia, glycosuria, and elevated serum alkaline phosphatase levels. Hypertension was absent. β2-microglobulin excretion exceeded the normal maximum (1 mg/g of creatinine) by 100-fold, and GFR was substantially reduced in the most severely affected individuals. Long-term follow-up studies showed that excessive urinary excretion of the low-molecular-weight protein β2-microglobulin predicts the later development of kidney failure in patients with itai-itai disease and that kidney damage progresses even after exposure has ceased. Succimer is effective for chelation in acute cadmium poisoning [22]. No agent has been found to be effective for mobilizing hepatic or renal stores of cadmium [2, 46].

Silicon

Silicon is a semimetal found as the dioxide (SiO_2, silicon dioxide) in 28% of the earth's crust. It has been reported to induce interstitial nephritis by direct deposition of crystalline material in the renal parenchyma [47] and by immunologic mechanisms acting as an adjuvant to stimulate the immune response [48]. Tubular proteinuria is found in workers exposed to silica dust. The odds of a sandblaster developing end-stage renal disease is 3.8 compared to matched controls. In the accelerated form of silicosis known as silicoproteinosis, silicon dust appears to be indirectly responsible for rapidly progressive, immune complex-mediated focal glomerulosclerosis [49]. In addition to severe pulmonary disease, these patients develop an overwhelming autoimmune response that frequently includes lupus erythematosus [23] or rheumatoid arthritis (Caplan's syndrome). Glomerular disease, sometimes in association with silica-induced systemic sclerosis, systemic lupus erythematosus, and small vessel vasculitis, has also been described as a result of exposure to silica dust independent of silicosis [24]. Antineutrophil cytoplasmic antibody (c-ANCA)-positive Wegener's granulomatosis has been associated with exposure to silica dust as well as to silica-containing compounds, such as grain dust. No specific therapies have been reported for silica-induced glomerular disease other than those in current use for immunologically medicated glomerular disease [3].

Solvent Nephropathy

Halogenated hydrocarbons have often been implicated in the induction of acute tubular necrosis or Fanconi syndrome in both humans and experimental animals. Low-level occupational absorption by inhalation of volatile hydrocarbons or absorption through the skin may also induce tubular proteinuria, which does not necessarily signify the presence of clinical kidney failure.

At least 40 case-control studies have examined the relationship between glomerulonephritis and exposure to organic solvents. A number of these studies concluded that patients with chronic glomerulonephritis had been exposed to organic solvents (aliphatic and aromatic) more frequently than patients with other diseases. Initially, solvent nephropathy was associated with antiglomerular basement membrane antibody-mediated glomerulonephritis and pulmonary hemorrhage, i.e. Goodpasture's syndrome, but later reports of solvent nephropathy have included many different types of glomerulonephritis [50].

The etiologic role of solvents remains controversial because the dose and exact chemical composition of industrial solvents are usually unknown. Moreover, of the thousands of workers exposed, very few develop immunologically mediated glomerular disease. The genetic and environmental factors that make specific individuals susceptible to solvent nephropathy have not been delineated. The experimental mercury-induced immunologically mediated glomerular disease in rodents described above may provide a model for understanding solvent nephropathy in humans. No specific therapies have been recommended for solvent nephropathy. Avoidance of exposure to volatile hydrocarbons and their derivatives remains an essential preventive approach.

Toxic Nephropathies: Nonsteroidal Anti-inflammatory Drugs

Joseph B. Pryor[1], William M. Bennett[2], and Ali Olyaei[3]

Introduction

Nonsteroidal anti-inflammatory drugs (NSAIDs) are one of the most commonly prescribed groups of drugs for the treatment of pain and inflammation. It is estimated that, worldwide, more than 30 million people take NSAIDs daily [1]. The precise incidence of renal disease related to NSAIDs is difficult to estimate due to the heterogeneity of the population. In general, approximately 1–3% of the patients taking NSAIDS may manifest one or more kind of renal injury from acute or chronic use of NSAIDS [2]. Thus, the widespread use of NSAIDs means that renal complications are observed relatively frequently in clinical practice. Complications include hypertension, edema, salt and water retention, acute tubular necrosis, acute interstitial nephritis, hyperkalemia, as well as acute and chronic kidney failure [3]. In addition, NSAIDs may worsen preexisting hypertension, heart failure, and electrolyte imbalance and cause acceleration and progression of kidney disease [4, 5].

In addition to renal side effects, NSAIDs also have significant gastrointestinal complications such as ulcers and bleeding. Furthermore, the use of NSAIDS at higher doses is associated with increased risk of cardiac events, such as myocardial infarctions, acute coronary syndromes, and strokes.

Two different iso-enzymes of cyclooxygenase (1 and 2) have been identified. Both enzymes play an important role in platelet aggregation, gastrointestinal integrity, and cardiovascular health [6]. It has been hypothesized that nonselective NSAIDs inhibit both constitutive cyclooxygenase 1 (COX-1) and inducible COX-2, the rate-limiting enzymes that are involved in the production of prostaglandins and thromboxane A2, while selective COX-2 inhibitors only inhibit inducible COX-2. Originally, three COX-2-selective NSAIDs, namely celecoxib, rofecoxib, and valdecoxib, were approved. They were designed with the hope of exhibiting anti-inflammatory properties while lacking the deleterious effects on homeostatic functions mediated by COX-1 activation such as gastrointestinal ulcers and bleeding; however, increased myocardial infarctions and ischemic strokes were reported with all agents when used at higher than recommended dosage compared to placebo or other NSAIDs [7]. In the Vigor study, a 79% greater risk of death or serious cardiovascular events was found in one treatment group compared with the other, rofecoxib ($P = 0.007$) [8], and increased cardiovascular events in patients who underwent coronary artery bypass surgery and received valdecoxib [9]. This led to their withdrawal from the market in 2004 and 2005, respectively. Recently, the results of the PRECISION study were published [10]. Among patients requiring a moderate dose of daily NSAID treatment, the incidence of cardiovascular disease, cardiovascular death, nonfatal myocardial infarction, and nonfatal stroke for celecoxib [200 mg daily] was noninferior to ibuprofen and naproxen. However, the incidence of renal events was significantly lower with celecoxib versus ibuprofen.

Low-dose aspirin irreversibly inhibits platelet COX-1, thereby blocking the synthesis of thromboxane A_2, a prothrombotic factor, and has little effect on endothelial COX-2 derived prostacyclin [11]. Prostacyclin inhibits platelet aggregation and leads to vasodilatation. Due to its selectivity, low-dose aspirin is the drug of choice for the prevention of thrombotic events, even in patients with

underlying kidney disease, without the risk of jeopardizing prostaglandin-dependent kidney function. By contrast, higher doses of aspirin can inhibit COX-2-derived prostacyclin production. Prostacyclin is mainly COX-2 derived and is inhibited by both nonselective NSAIDs and COX-2-selective NSAIDs. Therefore, a potential cardiovascular risk is seen with nonselective NSAIDs as well as COX-2-selective drugs [12–14].

Actions of Renal Prostaglandins

Both COX-1 and COX-2 are expressed extensively in the kidney. COX-2 activities have been identified mostly in the macula densa and medulla while COX-1 works in the glomerulus and both cortical and medullary collective ducts [15, 16]. The kidney produces the vasodilator prostaglandins PGE_2, $PGF_2\alpha$, and PGI_2 as well as vasoconstrictive thromboxane A_2. These autocoids, synthesized and metabolized by the kidney, autoregulate renal blood flow, renin release, tubular ion transport, and water metabolism [17, 18]. PGI_2, which is mainly present in the afferent arteriole and glomerulus, plays a major role in controlling glomerular hemodynamics [19]. In contrast, PGE_2, which is predominantly produced in the collecting tubule and within the interstitium, regulates medullary hemodynamics [18].

Effects on COX-2 NSAIDs on Renal Prostaglandins

All NSAIDS, nonselective or selective, prevent prostaglandin synthesis in the kidneys. The urinary excretion of PGE_2 and 6-keto-$PGF1_a$, the stable metabolite of PGI_2, reflects the renal synthesis of PGE_2 and PGI_2, respectively. In healthy older adults, rofecoxib reduces baseline urinary 6-keto-$PGF_1\alpha$ by 47%, comparable to the 53% reduction induced by indomethacin [20]. In another study, rofecoxib reduced urinary PGE_2 and 6-keto-PGF1α excretion in healthy volunteers by approximately 40–50%, similar to that induced by meloxicam or diclofenac [21]. This inhibition has a profound effect on hemodynamic compensatory mechanism in the kidneys.

Furthermore, excretion of urinary 6-keto-$PGF_1\alpha$ was comparable in response to celecoxib and traditional NSAIDs [22]. In a trial of healthy elderly volunteers consuming normal amounts of sodium, multiple doses of twice-daily celecoxib reduced PGE_2 and 6-keto-PGF1α excretion to the same degree as naproxen, by approximately 65 and 80%, respectively [23]. These data suggest that the COX-2 isoform plays an important role in renal prostaglandin biosynthesis. It is thus likely that COX-2 inhibitors will impact renal function just as nonselective NSAIDs do.

Maintenance of Renal Blood Flow and Glomerular Filtration Rate

NSAIDs produce negligible effects on the renal hemodynamics of most young and healthy euvolemic subjects [24, 25]. However, in hemodynamic compromised subjects, NSAIDS are associated with number of renal syndromes. Prostaglandins maintain renal blood flow and glomerular filtration rate despite vasoconstrictor stimuli, such as leukotrienes, thromboxane A_2, angiotensin II, vasopressin, endothelin, and catecholamines. Though vasoconstrictive, catecholamines stimulate local prostaglandin production, resulting in a feedback loop between vasoconstrictors and vasodilatory prostaglandins [26–28]. $PGF_2\alpha$-like peroxidation products also have major vasoconstrictive effects [29]. Thus, in patients with underlying ischemic or inflammatory renal injury, the addition of a nonselective or COX-2-selective NSAID not only decreases the production of vasodilatory prostaglandins but also results in the nonenzymatic formation of vasoconstrictor metabolites of arachidonic acid, further jeopardizing renal blood flow and glomerular filtration. However, in the presence of salt depletion, an ineffective circulating plasma volume, or under conditions characterized by high circulating levels of vasoconstrictor hormones, NSAIDs may be nephrotoxic. Such conditions include cirrhosis, hypovolemia, cardiac disease, renal disease, septic shock, advanced age, diuretic use, diabetes mellitus, and following surgery [30].

In elderly, salt-replete subjects, both indomethacin and rofecoxib decreased sodium excretion, but only indomethacin reduced the glomerular filtration rate [20]. Celecoxib, like rofecoxib, affects renal function in selected groups of subjects. Whelton et al. compared celecoxib with naproxen in 29 healthy elderly subjects in a single-blind, randomized, crossover study [31]. Subjects were given either celecoxib at 200 mg twice daily for 5 days followed by celecoxib at 400 mg twice daily for the next 5 days or they received naproxen at 500 mg twice daily for 10 days. After a 7-day washout, subjects were crossed over to the other regimen. Glomerular filtration rate fell more with naproxen than with celecoxib, although urinary excretion of prostaglandin E_2, 6-keto-PGF1α, and sodium was comparable. In another study involving salt-depleted elderly subjects, rofecoxib and indomethacin induced a comparable reduction of glomerular filtration rate [32]. These studies illustrate that COX-2 inhibitors and nonselective NSAIDs have similar effects on renal hemodynamics.

Postoperative Use of NSAIDs

Lee and coworker in a meta-analysis of 19 trials ($n = 1024$) demonstrated that the postoperative use of NSAIDs in adults with normal preoperative renal function resulted in

SCr, serum creatinine.

a 16 ml/min fall in creatinine clearance (95% confidence interval [CI] 5–28) and a fall in potassium excretion of 38 mmol/day (95% CI 19–56) on the first day after surgery compared with placebo [33]. No cases of postoperative acute kidney failure requiring dialysis were reported. The conclusions were that NSAIDs caused a clinically unimportant reduction in kidney function in the early postoperative period in patients with normal kidney function and that these drugs should not be withheld in such patients. Others have reported, however, an overall incidence of postoperative renal insufficiency of 18% after major surgery, with a subsequent hospital mortality rate of 13% [34]. In general, NSAIDs should be withheld from patients at risk for kidney injury or patients with preexisting kidney disease pre- and postoperative because of concerns about their effects on renal function [3] (Table 21b.1).

Renal Dysfunction in COX-2 Trials

In one study, renal adverse events were reported in 24.3% of 144 patients receiving celecoxib and in 30.8% of 143 patients receiving diclofenac and omeprazole. Kidney failure (defined as a rise in serum creatinine to above 200 μmol/l) was seen in 5.6 and 6.3% of patients, respectively [35]. Overall, renal adverse events were more common in patients with renal impairment (celecoxib 51.4%, diclofenac plus omeprazole 40.7%). In another study, adverse effects related to kidney function occurred in about 1% of naproxen- and rofecoxib-treated patients [8]. In a review of randomized clinical trials lasting 2 weeks or more involving celecoxib, a rise in serum creatinine was seen in 0.7% of patients treated with celecoxib and in 1.2% of patients treated with diclofenac ($P < 0.05$) [36]. In a meta-analysis of data from company clinical trial reports, there was no difference in the incidence of renal adverse events (defined as an increase in serum creatinine >1.3 times the upper limit of normal) in 15 319 patients treated with celecoxib (0.3%) or other NSAIDs (0.5%) (relative risk [RR] 0.78, 95% CI 0.48–1.3) [37]. In summary, from these trials, there are no differences in renal side effects between COX-2-selective inhibitors and nonselective inhibitors. In the PRESION study, the serum creatinine level of ≥2.0 mg/dl (177 μmol/l), an increase of verified serum creatinine level of ≥0.7 mg/dl (62 μmol/l) from baseline or doubling of the baseline serum creatinine, or hyperkalemia (defined as >6 mmol/dl) with ≥50% elevation in serum creatinine and initiation of hemodialysis or peritoneal dialysis were comparable between naproxen and celecoxib while much higher for ibuprofen (0.5% vs. 0.9% $P = 0.004$) [10]

Renin Release and Potassium Homeostasis

PGE_2, PGI_2, and arachidonic acid are potent stimuli of renin release [15]. Both nonselective and COX-2-selective NSAIDs can inhibit renin secretion and under some circumstances lead to hyporeninemia and hypoaldosteronism with attendant hyperkalemia. This is particularly common in patients with preexisting renal impairment [38–40]. Inhibition of prostaglandin synthesis can also lead to hyperkalemia by decreasing distal tubular flow rate and sodium delivery, both of which limit potassium secretion [41, 42].

Natriuresis and Diuresis

Renal prostaglandins are natriuretic and diuretic. They inhibit sodium and chloride reabsorption in the proximal and distal nephrons as well as in the loop of Henle [43, 44]. In addition, renal prostaglandins reduce the renal corticomedullary solute gradient and antagonize the action of vasopressin in vivo [45]. Although prostaglandins acutely influence salt and water excretion, they do not regulate it under normal conditions.

Clinical Syndromes Associated with Nonselective and COX-2-Selective NSAIDs

Acute Renal Impairment and Acute Tubular Necrosis

Under circumstances where there is poor renal perfusion with high renin levels, nonselective and COX-2-selective NSAIDs can reduce glomerular filtration rate, resulting in acute kidney failure. This complication has been reported with most NSAIDs but only rarely with aspirin. Kidney failure has also been described after administration of topical and intramuscular NSAIDs [46–48].

A multicenter study in France examined the incidence and subsequent outcome of patients with drug-induced acute kidney failure [49]. Of the 398 patients with acute kidney failure, 147 (36.9%) had taken NSAIDs. One-third of them required dialysis, and 71.4% recovered or regained previous renal function. A renal biopsy obtained in 25 patients with NSAID-associated kidney failure disclosed acute tubular necrosis and acute interstitial nephritis in 21 patients and either minimal change nephropathy or chronic renal damage in four. A nested case–control study using the United Kingdom General Practice Research Database reported that current users had an RR of developing acute kidney failure of 3.2 (95% CI 1.8–5.8) compared with non-NSAID users [50]. This increased risk was higher in patients with heart failure, hypertension, or diabetes. Thus, although renal side effects from NSAID use are relatively rare, renal damage can be irreversible and the outcome can be fatal. Renal function usually improves upon drug withdrawal, although in some cases permanent renal damage may occur [51].

Acute kidney failure and hyperkalemia have been observed after the administration of COX-2-selective inhibitors to patients with risk factors for NSAID-induced acute renal insufficiency, including underlying chronic renal impairment and volume depletion [52]. Acute kidney failure was also reported in a patient with a kidney transplant 4 weeks after starting rofecoxib [53].

Acute Tubulo-Interstitial Nephritis

NSAIDs of different classes have been associated with acute tubulo-interstitial nephritis and kidney failure [2, 51, 54, 55]. Acute allergic tubulo-interstitial nephritis due to NSAIDs is much less common than hemodynamic kidney failure. The patients are often elderly and may have taken the offending agent for months or years before the development of acute interstitial nephritis. Clinical evidence of an allergic reaction, such as fever, rash, arthralgia, eosinophilia, or eosinophiluria, is uncommon. Of note, proteinuria, often in the nephrotic range, may occasionally appear, especially in fenoprofen-induced tubulo-interstitial nephritis [54, 56, 57]. Cases of interstitial nephritis have been reported with both celecoxib and rofecoxib [58–64]. In two cases, interstitial nephritis was associated with glomerulopathies, one case with minimal change disease [62] and the other one with membranous nephropathy [58]. Thus, there is little evidence that suggests a major difference between NSAIDs and COX-2 inhibitors in the incidence of acute interstitial nephritis.

NSAID-induced acute tubulo-interstitial nephritis is formally diagnosed by renal biopsy. A patchy acute tubular damage coexists with tubulo-interstitial infiltrate predominantly of T-lymphocytes and, to a lesser extent, monocytes/macrophages, B lymphocytes, plasma cells, and eosinophils [57, 65]. Rarely, a granulomatous interstitial nephritis is seen [66]. Immunofluorescence microscopy is usually negative or nonspecific. The predominance of T-lymphocytes in the interstitial infiltrate has been taken to indicate that T-lymphocyte activation mediates this syndrome, rather than a humoral mechanism, as seen in other forms of drug-induced acute interstitial nephritis [56, 57]. Inhibition of renal COX has also been incriminated in the genesis of NSAID-induced acute tubulo-interstitial nephritis. The resulting stimulation of the lipoxygenase pathway of arachidonic acid metabolism produces leukotrienes, which are potent chemotactic factors for lymphocytes. Recovery of renal function may be only partial [65], and chronic interstitial fibrosis may progress to chronic renal failure [67]. Prednisolone has been successfully used in anecdotal reports, but there is no conclusive evidence that corticosteroids hasten the resolution of the renal lesion [2].

Glomerulonephritis

Membranous nephropathy with nephrotic syndrome may occur as an idiosyncratic reaction to various classes of NSAIDs [68–70]. The temporal association with the intake of NSAIDs, the prompt and complete recovery after drug discontinuation, and the absence of recurrent disease may help distinguish NSAID-associated membranous nephropathy from the idiopathic form [71]. As with NSAIDs, glomerulopathies with the nephrotic syndrome can occur with COX-2 inhibitors [63]. Membranous nephropathy with acute interstitial nephritis secondary to celecoxib has been described [58].

Renal Papillary Necrosis

Renal papillary necrosis has been infrequently reported in patients treated with ibuprofen, indomethacin, phenylbutazone, fenoprofen, or mefenamic acid [51, 67, 72–74] or with paracetamol [75, 76]. One case of celecoxib-related renal papillary necrosis has been reported [77].

Chronic Kidney Disease

Sandler et al. evaluated the risk for chronic kidney disease associated with regular use of nonaspirin NSAIDs in 554 patients with newly diagnosed chronic renal dysfunction [5].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

They found a twofold-increased risk for chronic kidney disease in patients with a history of previous daily use of NSAIDs (adjusted odds ratio [OR] 2.1, 95% CI 1.1–4.1). The increased risk was predominantly limited to men older than 65 years, for whom the OR was 10.0 (95% CI 1.2–82.7) after adjusting for use of other analgesics. The NSAID-associated risk was also greater among those with a history of conditions that might indicate an enhanced susceptibility to the effects of NSAIDs, including previous myocardial infarction, congestive heart failure, heavy alcohol consumption (as a surrogate for cirrhosis), or diuretic use. These observations were confirmed in a case-control study of 716 patients with end-stage renal failure and 361 controls [6]. In this study, a high cumulative intake of NSAIDs (>5000 tablets) was associated with a 4.5-fold excess risk of end-stage renal failure, although the CI was wide (1.0–19.5) and, curiously, this excess risk was not seen when an average annual intake of NSAIDs was examined. Other studies of NSAID usage in hospitalized patients [78, 79] and also cohort studies, however, did not show this association [80, 81]. The reasons for these discrepant findings are unclear. On balance, it seems likely that chronic NSAID use may be associated with a slightly increased risk for the development of chronic kidney failure. Some patients with chronic kidney failure rely on prostaglandin-mediated vasodilatation to maintain renal blood flow [82–84]. Addition of NSAIDs may cause further deterioration of renal function [49, 82, 84, 85].

Salt and Water Retention

NSAID therapy may aggravate the sodium retention induced by renal hypoperfusion in heart failure, cirrhosis, or nephrotic syndrome [3]. Hyponatremia may occur if water retention is disproportionate to sodium retention [86], especially when thiazide diuretics are given simultaneously [2].

Hypertension

Two large meta-analyses encompassing more than 90 studies have demonstrated that NSAIDs may increase blood pressure, especially in previously hypertensive patients [87, 88]. NSAIDs elevate supine mean blood pressure by 5 mmHg [88], a rise known to increase hypertension-related morbidity and mortality [89]. This complication is of importance in the elderly, who are frequently prescribed NSAIDs for musculoskeletal disorders and also have a high prevalence of other chronic disorders, including hypertension.

Whelton et al. performed a post hoc analysis on the renal safety of celecoxib, incorporating more than 50 clinical studies with more than 13 000 subjects [23]. The most common events, peripheral edema (2.1%), hypertension (0.8%), and exacerbation of preexisting hypertension (0.6%), were not dose or time-related. Their incidence and profile were similar to those of nonselective NSAIDs. A similar post hoc analysis of rofecoxib revealed peripheral edema in 3.8% of patients [90].

Whelton et al. also compared the effects of celecoxib at 200 mg and rofecoxib at 25 mg over a 6-week period in 810 hypertensive patients with osteoarthritis, aged over 65 years [91]. Edema developed in nearly twice as many rofecoxib-treated than celecoxib treated patients (9.5% vs. 4.9%, $P = 0.014$). Systolic blood pressure increased significantly in 17% of rofecoxib-treated patients, compared with 11% of celecoxib-treated patients ($P = 0.032$). In conclusion, celecoxib induces edema less frequently and results in smaller rises in blood pressure than rofecoxib. A meta-analysis of COX-2 inhibitors and their effects on blood pressure showed that they were associated with a nonsignificant higher risk of causing hypertension compared with placebo (RR 1.61, 95% CI 0.91–2.84) or nonselective NSAIDs (RR 1.25, 95% CI 0.87–1.78) [92]. Thus, both NSAIDs and COX-2 inhibitors can raise blood pressure, especially in hypertensive, elderly patients, and there is no substantial evidence to suggest that COX-2 inhibitors are safer in this respect.

Pavlicevic et al., in a prospective clinical study, investigated 88 hypertensive patients being treated with lisinopril/hydrochlorothiazide and amlodipine. The effects of addition of ibuprofen, acetaminophen, or piroxicam were recorded over a 3-month period. A significant systolic blood pressure increase of 7.7–9.9% ($P < 0.001$) was reported when ibuprofen and piroxicam were also given with lisinopril/hydrochlorothiazide and NSAIDs [93].

Hyperkalemia and Hyporeninemic Hypoaldosteronism

NSAIDs may cause hyperkalemia, and this is seen more commonly in patients with chronic kidney failure, diabetes mellitus, and type IV tubular acidosis through previously outlined mechanisms [39, 94]. Increases in potassium levels are also expected to occur with COX-2 inhibitors. Indeed, rofecoxib raises serum potassium levels by more than 0.8 mM, with a similar incidence as NSAIDs [95]. In a retrospective cohort study of 202 patients using propensity scores methods the incidence of hyperkalemia was compared between nonselective NSAIDS versus COX-2 selective NSAIDs. Compared to

patients prescribed nonselective NSAIDs, those prescribed a selective COX-2 inhibitor had a higher risk of serum potassium increase greater than 5 mEq/l (OR 2.56, 95%CI 1.03–6.36). The use of NSAIDs in particular COX-2 inhibitors should be avoided in patients at risk for hyperkalemia and in patients taking other drugs known to decrease renal potassium excretion, such as potassium-sparing diuretics, angiotensin-converting enzyme inhibitors, and β-blockers.

Therapeutic Use of NSAIDs in Nephrotic Syndrome

NSAIDs reduce proteinuria in patients with nephrotic syndrome [40, 96], probably by reducing renal blood flow and glomerular filtration rate [97]. The occurrence of irreversible kidney failure in patients with a nephrotic syndrome treated with NSAIDs [55] suggests great caution for the use of these drugs in this clinical setting.

Conclusions

The increasing use of NSAIDs both by prescription and over the counter has increased the prevalence of nephrotoxicity. A history of NSAID use should be sought in all patients with unexplained impairment of renal function and/or proteinuria. In patients with volume depletion or decreased organ perfusion, the use of NSAIDs should be avoided. NSAIDs should not be prescribed in patients with chronic renal impairment or with a functioning kidney transplant. Patients with an NSAID-induced, interstitial nephritis or papillary necrosis should not be given NSAIDs again. In some individuals who have developed NSAID-induced acute kidney failure and who have recovered kidney function, NSAIDs may be reintroduced if clinically necessary, provided that the risk factors for enhanced susceptibility have been corrected and that renal function is closely monitored. COX-2-selective inhibitor use requires the same cautions as with traditional NSAIDs.

Hypertension

Swapnil Hiremath

Department of Medicine, University of Ottawa, Ottawa, Canada

Introduction

The kidneys are inextricably interwoven with high blood pressure (BP). In his second paper published in 1836, while describing the natural course of nephritis, Richard Bright mentions the observation of a hard pulse along with a detailed description of the accompanying headache, loss of vision, seizures, and dyspnoea [1]. These cardiovascular changes were then thought to be secondary to the kidney disease, though it is reported that Bright acknowledged the possibility of reverse causation. He did suggest that the "altered quality" of the blood in renal disease affected the peripheral vasculature in such a way that an increased force was necessary for propelling the blood, a remarkably accurate observation. In 1856, Ludwig Traube reasoned that a shrunken kidney will first decrease the amount of liquid which is removed from the arterial system as urinary secretion, as a result of which the pressure of the arterial system ("Aortenspannung") must increase, as good a description of renal parenchymal hypertension as one could have done at the time [1]. BP measurement became more feasible in the late nineteenth century, and in 1874 Mahomed described high arterial pressure which was present before albuminuria in patients with Bright's disease, and advanced the view that high BP could be leading to contracted kidneys [1]. Thus, right from the beginning, hypertension as a cause, or a consequence of kidney disease has been a matter of contention.

Why Treat Hypertension?

Hypertension is called the silent killer in the lay media precisely because it is asymptomatic for the vast majority. As portrayed in the prevention paradox also, the majority of the adverse outcomes may indeed occur in the low to intermediate risk, asymptomatic individuals [2]. Whether it is labeled as a disease or a condition, the global burden of hypertension is high, estimated at 20 526 per 100 000, with significant associated attributable mortality and disability [3]. Thus, treatment of hypertension, i.e. lowering of BP, would be to prevent adverse clinical outcomes. For patients with chronic kidney disease (CKD), these could be either cardiovascular or renal outcomes. Though BP is often bandied about as the most important risk factor for worsening kidney function, the evidence for lowering BP and decreasing progression of kidney disease is rather limited. It is true that at very high levels of BP there exists an association of BP and kidney outcomes. However, in the modern era where the decisions are more to do with whether systolic BP should be lowered to <140, <130 or even to <120, the outcomes that matter are mostly the cardiovascular rather than renal. The relationship of BP with cardiovascular (CV) outcomes is stronger than for progression of kidney disease. Hence, unsurprisingly, lowering of stroke and heart failure drives most of the CV outcome reduction with intensive BP lowering, and prevention of end stage kidney disease (ESKD) is not one of them [4].

Blood Pressure Measurement

An underappreciated aspect of the management of hypertension is proper BP measurement. Inaccurate measurement will result in inappropriate treatment. While the research gold standard of BP measurement is intra-arterial continuous BP monitoring, several practical alternatives are suitable for use in clinical practice. A "casual" measurement performed in a noisy atmosphere using improper

technique and with inadequate rest is perfectly useless and should be abandoned [5]. At the other end, we have 24-hour ambulatory blood pressure monitoring (ABPM) which provides multiple measurements throughout the day and night, thus providing an assessment of the overall BP load, diurnal pattern, and an assessment of out of office BP values. However, it is not available in all jurisdictions, and cost as well as logistics may hinder universal adoption. A properly done resting office measurement can go a long way, but manual methods are notoriously unreliable, with human error, poor technique, terminal digit preference, and such issues being an unsurmountable barrier despite educational efforts [6]. Automated oscillometric blood pressure (AOBP) offers a suitable compromise, especially newer devices which can specify a period of rest before initiating measurement and with repeat measurements providing an average of two to five readings [7, 8]. Comparative data suggests AOBP use decreases the misdiagnosis of white coat hypertension and, more importantly, it approximates proper resting BP measurement (as is done in clinical trials) more than a casual measurement [7]. Recent hypertension trials, including Heart Outcomes Prevention Evaluation – 3 (HOPE-3), Action to Control Cardiovascular Risk in Diabetes (ACCORD) and the Systolic Blood Pressure Intervention Trial (SPRINT) all used a form of AOBP, and further validation of AOBP with clinical outcomes should be considered hence unnecessary [9–11]. Nevertheless, AOBP should not be construed as a replacement for ABPM. The ABPM can allow for diagnosis of masked hypertension, nocturnal dipping pattern, and provide an assessment of variability.

Another out-of-office technique is home BP measurement. Modern home BP devices use an oscillometric technique, and are cheap and easy to use. They offer similar advantages to the ABPM method, in providing multiple measures for an overall BP load, potentially minimizing white coat effect and picking up masked effect. Caveats of home BP measurement include the accuracy of these devices, as multiple studies have reported a large proportion of home BP monitors being inaccurate [12, 13]. Lastly, they do not provide a picture of nocturnal pattern and variability as ABPM does. They do, however, empower patients, and have been reported to result in improved BP control, potentially by overcoming therapeutic inertia [14].

Wearable BP devices are the next frontier, with one device being approved recently in the United States. Potentially, these will provide richer data about BP and empower patients immensely. Certain caveats about their accuracy and the ability to deal with the sheer amount of information and possible resultant false alarms will have to be worked out before widespread adoption [15].

To summarize, out-of-office measurement, preferably with ABPM followed by home BP measurement, is the preferred way of diagnosing and following up hypertension management. Office measurement with AOBP is a reasonable alternative when this option is not routinely available. Table 22.1 provides highlights of different BP measurement techniques.

Table 22.1 Different BP measurement methods and their advantages and disadvantages.

Technique	Advantages	Disadvantages	Comments
Casual	Easy	Rarely done correctly Misdiagnosis of true BP	Should be abandoned
AOBP	Eliminates many human errors Can specify rest period Multiple measurements Minimizes white coat effect	More time required Workflow may be slowed Cannot diagnose masked hypertension or diurnal pattern	Used in recent trials Devices vary with respect to period of rest, number of measurements
ABPM	Diagnose white coat and masked effect Assess BP variability Assess nocturnal BP pattern Assess overall BP load	Cost Inconvenience	"Gold standard" Strong association with outcomes Outcome trial with ABPM-based strategy ongoing
Home	Inexpensive Easy Can diagnose white coat and masked effect Empowers self-management	Accuracy variable Cannot assess nocturnal pattern	

AOBP, automated oscillometric blood pressure; ABPM, ambulatory blood pressure monitoring; BP, blood pressure.

Blood Pressure Variability

A brief note about BP variability is necessary given its reported association with clinical outcomes. Though we still do not know enough about the causes and the cure, we do know more about the consequences of high BP variability. Variability is variably defined based on the time frame. Short-term variability refers to that seen on a 24-hour ABPM whereas long-term refers to visit-to-visit variability. Numerically, variability is often defined on the basis of a large standard deviation or a coefficient of variation that reflects an overall dispersion of the values around the mean, but not specifically the order of these dispersed values. The average real variability represents a potentially more reliable representation of true variation [16]. Long-term variability refers to visit-to-visit variation, as measured on the basis of office or out-of-office measurements. An increased short-term, as well as long-term, variability is associated with a correspondingly increased risk of cardiovascular events. Specifically in CKD, visit-to-visit variability has been reported to be associated with a 20% higher relative risk of death and a 90% higher risk of hemorrhagic stroke (though with no association for ischemic stroke, heart failure or ESKD) [17]. Similarly, CKD itself has been associated with short-term variability, with the caveat that the absolute variability may seem higher in CKD purely because individuals with CKD are more likely to have higher BPs [18]. Certain extreme cases are caused by autonomic dysfunction; however in the vast majority we still do not have a good mechanistic explanation of this phenomenon. Additionally, a search for strategies that could potentially mitigate this variability and whether these will also reduce the higher risk of adverse outcomes is fertile ground for clinical research.

Nocturnal Pattern

The normal pattern of BP has a diurnal variation with lower BP at night and a fall of about 15% being commonly observed [19]. The absence of this nocturnal dipping is defined as an average nocturnal systolic BP being 10% or more lower than the daytime average. This absence of nocturnal dipping (i.e. being a "nondipper") is associated with an increased risk of cardiovascular events and mortality in the general population. In the CKD literature, the effects are less clear, since nondipping is also associated with other comorbid conditions (e.g. diabetes, proteinuria) which are themselves also associated with poor outcomes, thus making causation somewhat confounded [20]. An exception is a study from Italy, which did take proteinuria and comorbidities into account and reported an increased hazard of death and ESKD amongst nondippers compared to dippers [21].

The prevalence of nondipper status is quite high in CKD, with reports estimating it at 60–80%. Mechanistically, absence of nocturnal dipping is thought to be caused by heightened sympathetic activity, increased sodium sensitivity and volume status, and disturbances of the sleep activity cycle. These factors are all clearly more common in CKD patients, thus the finding of increased nondipping is not surprising. More important is whether nondipping status can be corrected and whether this correction decreases the adverse risk profile observed in these patients.

One group has reported success with nighttime dosing of BP medications in CKD patients, which lowered nocturnal BP sufficiently to restore normal dipping pattern in an additional 30% of the patients compared to controls, but also resulted in an improved survival [22]. Interpretation of these fantastic results (which reported a hazard ratio of 0.28 for major adverse cardiovascular events [MACEs]) from the Monitorización Ambulatoria de la Presión Arterial y Eventos Cardiovasculares, i.e. the Ambulatory Blood Pressure Monitoring and Cardiovascular Events (MAPEC) study, should be tempered with the lack of effect on nocturnal BP seen in two other trials [23]. Moreover, the reduction in MACE outcomes reported in the MAPEC study with bedtime dosing (but not additional BP lowering medications) is higher than the reduction reported in the HOPE study with ramipril compared to placebo (hazard ratio [HR] 0.28 in MAPEC and HR 0.78 in HOPE) [20]. Nevertheless, bedtime dosing is a simple and inexpensive intervention that could be applied to most BP lowering drugs with the exception of diuretics.

Since sleep apnea is associated with nondipping status, correction of sleep apnea with a device such as continuous positive airway pressure (CPAP) could presumably lower nocturnal BP. From a meta-analysis of four randomized controlled trials (RCTs), the effect of CPAP therapy was quite small on nighttime BP, with a mean reduction of 1.9 mmHg in systolic BP and 1.5 mmHg in diastolic BP, insufficient to significantly alter dipping status [24]. Not surprisingly, CPAP therapy has also failed to show a benefit overall for MACE or mortality, though other benefits, especially on sleep quality and quality of life, do exist [25].

Masked Hypertension

Masked hypertension deserves a separate mention since it follows, as a corollary of improper BP measurement, that it is underrecognized and potentially undertreated. Masked effect, in general, refers to an out-of-office BP measurement that is *higher* than the office measurement. Masked hypertension refers to the phenomenon when BP may be normal (or controlled) in the office, but elevated out of office. An additional wrinkle is whether this masked hypertension is present, but controlled, or uncontrolled. See Table 22.2 for a breakdown of the somewhat bewildering terminology. The

Table 22.2 Different facets of masked hypertension with a proposed labelling scheme.

Possible label	Normotension	Masked effect	Masked, untreated hypertension	Masked uncontrolled hypertension	Masked controlled hypertension
Office BP	Normal	Normal	Normal	Normal	Normal
Out-of-office BP	≤10 mmHg of office BP	>10 mmHg of office BP	>10 mmHg of office BP	>10 mmHg of office BP	>10 mmHg of office BP
Out-of-office BP controlled?	Yes	Yes	No	No	No
On treatment?	No	No	No	Yes	Yes
Possible label	Normotension	Masked effect	Masked, untreated hypertension	Masked uncontrolled hypertension	Masked controlled hypertension

BP, blood pressure.

exact biological explanation for this phenomenon is not satisfactorily elucidated yet, though observational studies suggest associations with age, sex, increased sympathetic activity, and certain personality types [26].

This phenomenon matters in CKD because the prevalence of masked hypertension in CKD is higher than in the general population. Most reports peg the prevalence at about 20–30% with slightly higher numbers (43–50%) reported in two cohorts with a high proportion of African-American individuals [21, 27–33]. More important than mere prevalence numbers is whether masked hypertension is associated with adverse outcomes. Masked hypertension is indeed associated with surrogate outcomes such as increased left ventricular mass index and proteinuria, and also with a higher risk of cardiovascular outcomes (see Table 22.3 for a summary of the reported literature). Perhaps even more clinically relevant is whether treatment of masked hypertension mitigates the risk of these adverse outcomes or just represents a more aggressive phenotype with the masked hypertension being an epiphenomenon? An ongoing randomized trial, the MASTER trial (MASked-unconTrolled hypERtension Management Based on Office BP or on Out-of-office, Ambulatory BP Measurement; NCT02804074) might fill some of these lacunae, randomizing 1240 patients to an office versus ABPM guided strategy. The sample size is powered for surrogate outcomes (albuminuria and left ventricular mass index) and not hard clinical outcomes, nevertheless it will be helpful to validate the practice of diagnosing and treating masked hypertension.

Treatment of Hypertension in CKD

Nonpharmacological Measures

Nonpharmacological measures that have been reported to be efficacious in hypertension include changes in diet (less sodium, more potassium, and other dietary interventions), more exercise and weight loss, and lower alcohol intake. These are well-established interventions on the basis of RCTs and systematic reviews of RCTs, mostly in the general population. Most of these can be extrapolated to the CKD population, with a few considerations, as summarized in Table 22.4 [34, 35].

Sodium: A good systematic review from the World Health Organization (WHO) reports a reduction in BP of about 3.4 mmHg in systolic BP and 1.5 mmHg in diastolic BP in trials of reducing sodium intake [36]. The mean reduction of sodium intake in these trials was an impressive 1.7 g/day (45% from baseline). Though these trials were in the general population, one could presume that the contribution of sodium intake to hypertension would be even higher in the CKD population. One small RCT from Australia of 20 patients did report a significant decrease in BP with sodium restriction, of −10/4 mmHg, in patients with CKD (glomerular filtration rate [GFR] 15–59 ml/min) [37]. Another small crossover RCT of 58 patients with stage 3 or 4 CKD also reported a decrease of 10.7 mmHg in 24-hour ABPM, accompanying a 57 mmol decrease in 24-hour urinary sodium and a mean weight loss of 2.3 kg [38].

Potassium: Another WHO systematic review highlighted the evidence that increasing potassium intake (whether by diet or by using a supplement) also resulted in lower BP, on the order of −3.5 mmHg in systolic BP and −2.0 mmHg in diastolic BP [39]. Increasing potassium intake, needless to say, should be done more carefully and extrapolating to CKD, especially advanced CKD, where there might be a limit to the tubular potassium excretion, may not be wise. An ongoing RCT of a potassium supplement (40 mmol of potassium chloride, potassium citrate or placebo) in 400 patients with advanced CKD (GFR 15–44 ml/min) will provide more data on the efficacy and safety of potassium in the CKD population [40].

Table 22.4 Major nonpharmacological measures in management of hypertension in CKD.

Intervention	Expected BP decrease	Evidence in CKD?	Comments
Sodium reduction	−3.4/1.5 mmHg	Yes	Small RCTs in CKD suggest greater BP lowering (~10 mmHg)
Potassium increase	−3.5/2.0 mmHg	No	Risk of hyperkalemia Await ongoing RCTs
Alcohol reduction	−5.5/4.0 mmHg	No	Little reason to doubt heterogeneity in CKD
Exercise	−4.6/2.6 mmHg	Yes	Small trials, adherence, effectiveness unknown
DASH diet	−11.4/5.5 mmHg	No	Small feeding RCT of $n = 11$ Observational data suggests benefit

BP, blood pressure; CKD, chronic kidney disease; DASH, Dietary Approach to Stop Hypertension; RCTs, randomized clinical trials.

DASH diet: The Dietary Approach to Stop Hypertension (DASH) trial demonstrated a robust reduction in systolic BP of 11.4 mmHg and diastolic BP of 5.5 mmHg [41]. The DASH diet consists of eating vegetables, fruits, and whole grains, including fat-free or low-fat dairy products, fish, poultry, beans, nuts, and vegetable oils, limiting foods that are high in saturated fat, such as fatty meats, full-fat dairy products, and tropical oils such as coconut, palm kernel, and palm oils, and limiting sugar-sweetened beverages and sweets. Of interest in CKD, the DASH diet provides approximately 4700 mg potassium corresponding to about 120 mmol/day. A small feeding trial of 11 patients with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

CKD did not demonstrate a significant increase in serum potassium (+0.15 ± 0.28 mmol/l) [42]. Longer-term data are not available. Observational data suggest an association between following the DASH pattern of diet and slower decline of kidney function [43], but there are no RCTs which support such an effect. Caution should be exercised in recommending the DASH diet in patients who may have high normal potassium or being concomitantly started on other agents such as renin angiotensin system (RAS) blockade.

Alcohol: Despite robust epidemiological data supporting the association of higher alcohol intake and BP, most public health messages do not mention temperance as a means of lowering BP. These data are actually now bolstered with high-quality trials which show that reduction of alcohol intake results in a lowering of BP, with an overall effect of −5.5/−4 mmHg for systolic and diastolic BP [44]. Moreover, this meta-analysis also demonstrated a dose–response effect, with the strongest effect seen in those who drank more than six drinks and no significant reduction in BP seen from further reduction in those who drank two or fewer drinks per day.

Exercise: Evidence from the general population supports a recommendation to exercise in an effort to decrease BP. Specifically, a systematic review of 21 trials reported that a supervised program of aerobic exercise of 30–60 minutes, five times per week, can reduce systolic BP by a pooled estimate of 4.6 mmHg and diastolic BP by 2.6 mmHg [45]. In addition, we do have data in CKD patients from a systematic review which reported the effects of exercise (including cardiovascular training, mixed cardiovascular and resistance training, resistance-only training, and yoga) [46]. The review reports a similar overall reduction in BP (mean difference, 6.1 mmHg in systolic from nine trials and 2.3 mmHg in diastolic from 11 trials) as the previous review conducted in the general population. However, in subgroup analyses, the effects were significant in the pooled analysis of trials when exercise training was supervised (and was not significant in trials when it was unsupervised) and in trials with high-intensity exercise training (and not significant in trials with low-intensity exercise). Lastly, emerging data also suggest that the beneficial effect of exercise on BP is not restricted to aerobic, but also to dynamic resistance and isometric static exercise [47, 48].

Stop Interfering substances: Interfering substances which can increase BP include prescription drugs such as nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, erythropoiesis-stimulating agents, antidepressants, methylphenidate, and over-the-counter remedies such as cough/cold/allergy preparations, appetite suppressants, licorice and drugs such as cocaine.

Efficacy and Effectiveness in Nonpharmacological Interventions

Several caveats should be taken into account when considering nonpharmacological interventions for management of hypertension in CKD. Indeed, patients often favor lifestyle modifications and shy away from starting BP lowering medications, demonstrating pill disutility, sometimes of an extreme nature [49]. In situations when the observed BP is ~5 mmHg higher than the target, and in a motivated patient, it is indeed reasonable to focus on lifestyle changes and review at the next visit. However, effects seen in RCTs are likely to be an overestimate of the effects one might see in real clinical practice. RCTs of diet in the hypertension literature are feeding trials (and are not trials of counseling) and as mentioned in the exercise section, the exercise interventions that have the most effect are supervised interventions [50]. A healthier diet is more expensive (estimated at ~US $1.5 daily) [51]. Access to resources and care, attention to adherence, and physician–patient interaction are all additional determinants of true effectiveness. A neglected area, which is especially important for complex interventions such as lifestyle change, is poor health literacy, which is especially common in CKD [52–54]. In the setting of poor health literacy, pharmacological therapy may be considered preferable to these complex and often costly lifestyle changes.

Level and Drug Choice

Over the last few decades, the research has shifted from whether high BP should be lowered at all, to how should it be lowered, and now to how low should it be lowered [55, 56]. With respect to first-line drug to use in hypertension, the seminal trial in the primary care population was the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT), which reported that a thiazide-like diuretic (i.e. chlorthalidone) was superior to alpha-adrenergic antagonists (doxazosin) and just as good as an angiotensin converting enzyme inhibitor (ACE-I, lisinopril) or a calcium channel blocker (CCB, amlodipine) [57]. This and other evidence have lead to the acceptance of one of the so-called A-C-D drugs (i.e. ACEi or angiotensin receptor blocker [ARB], a CCB, or a diuretic) as the choice for first-line BP lowering drug, as well as being the first three drug classes that should be used for BP lowering. These drugs are also the ones to be preferably combined when one drug is not enough, as is common in CKD.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

With respect to the level of BP control, BP control down to 140/90 has been widely accepted. Beyond that, to what is labeled as "intensive BP lowering", to systolic BP levels of <120 or <130, is still a matter of contentious debate, and is discussed below.

Pharmacotherapy

Nonpharmacological measures are insufficient for BP lowering in most CKD patients, most of whom need pharmacotherapy not just for BP lowering, but in addition for specific indications such as the antiproteinuric effect or more specifically for CV protection. A large cohort study suggests that about 60% of CKD patients receive three or more antihypertensive medications, thus making the discussion of the specific BP lowering class somewhat redundant [58]. The discussion below summarizes some of the evidence of the specific medications, while acknowledging that combination therapy with most of the first-line drugs will be the most common scenario.

Renin Angiotensin System Blockade

RAS blockade, consisting of either ACEi or angiotensin receptor blockade (ARB), has become a mainstay of hypertension management in CKD. ACEi blocks the conversion of angiotensin I to angiotensin II, a potent vasoconstrictor, and ARBs block the angiotensin II receptors. The downstream reduction in aldosterone secretion and sodium reabsorption, coupled with a decrease in angiotensin II medicated vasoconstriction, underlies their BP lowering effect. Extensive trial data demonstrate the benefit in CV outcome reduction with these agents. However, a careful examination of how much of their effect is independent of BP lowering reveals a slightly complicated story. Briefly, when compared against placebo, RAS blockade is indeed superior in preventing CV outcomes and prolonging survival. However, when compared against active comparators, i.e. other BP lowering drugs, then there is no significant difference for hard clinical outcomes in patients with heart disease, or with diabetes, or with nonproteinuric CKD. The major factor in all these systematic reviews is the inclusion of ALLHAT, which did not report a benefit to using lisinopril over chlorthalidone and, being a large trial, carries a lot of weight in the meta-analysis [59]. The only exception, where RAS blockade is clearly superior to other BP lowering drugs, is in the setting of proteinuric diabetic nephropathy. RAS blockade has an additional effect on the intraglomerular pressure by dilatation of the efferent arteriole, reducing proteinuria and explaining this additional beneficial effect. However, one might consider this as an academic question, since most CKD patients do require more than one agent, and RAS blockade being part of that armamentarium is eminently sensible.

What is not sensible is the use of an ACEi and an ARB in combination. In patients at high CV risk, and in patients with proteinuric diabetic nephropathy, the use of these in combination did not demonstrate any benefit in CV or kidney outcomes [60, 61]. Moreover, there was an excess risk of hyperkalemia and acute kidney injury, and since then dual RAS blockade has not been recommended for use in management of hypertension. Lastly, the direct renin inhibitor aliskiren might have similar effects as ACEi or ARB. However, the major clinical trials were all conducted in combination with either an ACEi or an ARB, and as with ACEi–ARB combination, these did not demonstrate any benefit and increased risk of adverse events [62]. Monotherapy with aliskiren might have similar effects as ACEi or ARB monotherapy, but this has not been proven and hence aliskiren use may be relegated to the rare occasion when RAS blockade is desirable, but both drugs are not tolerated.

Thiazide and Thiazide-like Diuretics

Thiazide diuretics are the oldest class of BP lowering drugs which are still first-line agents. They act on the NaCl transporter in the distal convoluted tubule and acutely do cause natriuresis. With chronic therapy, however, extracellular volume comes back to baseline but peripheral resistance falls, from an unknown mechanism, but thought to be related to the initial natriuresis. The main thiazide diuretics are hydrochlorothiazide (HCTZ), Bendroflumethiazide, and chlorothiazide. The thiazide-like diuretics, namely indapamide and chlorthalidone, are somewhat longer acting, have greater effect on nocturnal BP, and are more potent compared to HCTZ, the most commonly used thiazide [63]. Moreover, in the RCTs that demonstrate a benefit with diuretics, either chlorthalidone or indapamide have been used [10, 57, 64]. Even in SPRINT, chlorthalidone was preferentially used in the formulary. Some other RCTs in which HCTZ has been used have failed to report beneficial CV effects [9, 65]. However, no head-to-head trial of HCTZ compared to chlorthalidone exists, though one is ongoing [66]. Additionally the increased potency of thiazide-like diuretics can result in more adverse events related to electrolyte imbalances in particular [67]. For relevance to CKD, thiazide diuretics were not thought to be effective in severe CKD (GFR < 30). This has been challenged in a recent pilot trial with chlorthalidone and more data is awaited [68].

Calcium Channel Blockers

CCBs bind to the alpha-1 subunit of L-type calcium channels, lowering cytosolic calcium and resulting in vascular smooth muscle relaxation and consequent vasodilatation. The nondihydropyridine CCBs (diltiazem and verapamil) also have an additional negative chronotropic effect on the heart. Because of their additional drug interactions (inhibition of the cytochrome p450 3A4 system) and drug interactions, these are used less often compared to the dihydropyridine CCBs, namely nifedipine, amlodipine, and others. These drugs are mostly hepatically metabolized and do not require dose adjustment, have few metabolic adverse effects, and work throughout the spectrum of CKD.

Second-line Drugs

Spironolactone, doxazosin, and bisoprolol all significantly reduced BP compared to placebo, as add-on to the A-C-D combination in patients with resistant hypertension [69]. The highest BP lowering effect was with spironolactone, and this would be the appropriate fourth agent to use in this setting. The trial, however, excluded patients with GFR <45 ml/min, and the efficacy of spironolactone for BP lowering is not well established in severe CKD. A small observational study does suggest it has BP lowering effects below a GFR <45, albeit with the additional unsurprising risk of hyperkalemia [70]. A follow-up of the same Prevention And Treatment of Hypertension With Algorithm-based therapy (PATHWAY) trial also suggested that the efficacy of amiloride may be similar to spironolactone [71]. Eplerenone is another mineralocorticoid antagonist which does not have the androgenic side effects of spironolactone. Alpha- and beta-adrenergic antagonists are the next preferred agents, based on the PATHWAY-2 trial [69]. These suggestions are based on BP lowering and not on clinical outcome data.

Centrally acting alpha-agonists (clonidine and guanfacine) and direct vasodilators (minoxidil and hydralazine) are also potent in BP lowering and reserved for use after exhausting all above options. Clonidine is available in some countries as a transdermal patch, which can be applied once a week (especially useful for hemodialysis patients). Though hydralazine has some evidence (though not in the CKD setting), it requires three to four times a day dosing and minoxidil is preferable for BP lowering.

Newer Agents

Sodium-glucose transporter inhibitors (SGLT2i), which are perceived as hypoglycemic agents, also have natriuretic and BP lowering effects. A meta-analysis reports a lowering of BP by −3.8/−1.8 mmHg with these agents, which also have clinical outcome data in the form of heart failure and CV event reductions [72, 73]. The neprilsyn inhibitor, sacubutril/valsartan, has been reported to improve survival in patients with congestive heart failure [74]. It has been shown to be safe in a recent trial in CKD patients (GFR 20–60) and reduced BP more than irbesartan by about 5 mmHg [75]. Other classes of drugs which show promise in BP lowering and are under investigation include aldosterone synthase inhibitors, ACE-2 activators, aminopeptidase inhibitors, angiotensin Ii vaccines, and endothelin antagonists [76].

Combination Choice

Mechanistic considerations and empiric data, along with pharmacokinetic considerations and adverse effects, are the factors that go into decisions about drug combinations. From a physiological perspective as well as reviewing trial data, combining RAS blockade with either CCB or diuretics makes sense. Conversely, combining a beta-blocker with RAS blockade does not, given that renin release would already be reduced by the beta-blocker. Similarly, combining a CCB with a diuretic has no specific synergistic advantages (and often the diuretic has been mistakenly added to manage CCB-induced leg edema, better treated with a lower dose of the CCB and addition of RAS blockade). For patients with CKD, given the primacy of RAS blockade, combining them with either a diuretic or a CCB makes eminent sense, followed by addition of the third agent. Since the publication of the PATHWAY study, as well as observational data supporting the relatively high prevalence of hyperaldosteronism in this population, a mineralocorticoid antagonist is the ideal fourth agent [69]. Beta-blockers, alpha adrenergic antagonists and vasodilators and central sympatholytic agents come next. Little trial evidence for clinical outcomes exist for these drugs, hence their relegation here. It is not unusual for their use to be common in later stages of CKD, when fears of worsening creatinine have lead to discontinuation of RAS blockade and/or diuretics.

Device Therapy

Device therapy has shown some promising results in recent years, but it is far from being ready for clinical use yet. It is nevertheless important to review the most promising interventions and any potential role they might have for management of hypertension in CKD patients.

Sympathetic renal nerve ablation has the most data among all device-based interventions. We have known that lumbar sympathectomy is extremely effective in

lowering BP since Adson's first case report decreasing the BP from 250/180 to 170/120 after ventral rhizotomy [77]. However, this procedure was almost always followed by impressive side effects, such as loss of sensation, paralytic ileus, problems with ejaculation, and loss of sweating and the occasional mortality [78]. With the advent of safe BP lowering drugs, sympathectomy went rapidly out of favor. This was the state of affairs until a few years ago, when an intrepid group reported on the role of renal sympathetic nerves in resistant hypertension, followed by the successful demonstration of percutaneous renal denervation using a catheter with a dramatic BP fall [79, 80]. The initial excitement following the first few clinical trials came crashing down to Earth after the release of the Symplicity HTN-3 trial [81]. This was the first sham controlled and double-blind RCT, performed in patients with resistant hypertension, and showed no difference in BP (~14 mmHg decrease in both groups). However, subsequent soul-searching and an awareness of the problems inherent in studying patients with resistant hypertension (with high variance and varying adherence) lead to the design of different RCTs [82]. The resultant RCTs, this time in patients with mild hypertension, reported a decrease of about 5–6 mmHg and this seems to be the true average BP lowering effect of renal denervation [83, 84]. Safety in the short term seems good, though the absence of a renal sympathetic afferent system has been associated rarely with shock and acute kidney injury [85]. Do these results mean renal denervation could help CKD patients? Most CKD patients do require more than one BP lowering medication, so the advantages of reducing pill burden by one (considering the average effect of −5 mmHg) is small. Second, while increased sympathetic activity might indeed have a larger role to play in hypertension in advanced CKD, there is no data on clinical outcomes. Small case series do report that denervation is technically feasible in CKD patients, so the benefits will have to be carefully weighed if denervation becomes widely available [86, 87].

The other device therapies under development include baroreceptor activation and the arteriovenous fistula creation. Baroreceptor activation therapy in theory modulates "deranged sympathovagal balance" but in practice the clinical trial did not meet safety or efficacy endpoints, though further refinements are ongoing [88]. Central iliac arteriovenous anastomosis creation has been reported in a small open-label trial, in which ipsilateral venous stenosis developed in a third of the patients (along with significant BP reductions) [89]. Lack of blinding, lack of data on clinical outcomes, and serious long-term safety concerns suggest this is the least promising of all device-based BP lowering interventions.

Patient Populations

Intensive BP Lowering

RCTs of BP lowering have traditionally been conducted in carefully defined populations based on demographics or comorbidities, e.g. the elderly (Systolic Hypertension in the Elderly Program [SHEP] and Hypertension in the Very Elderly Trial [HYVET]) [64, 90], diabetes (ACCORD) [11], African-American with kidney disease (AASK) [91] and so on. These groups are not homogenous when it comes to CV risk, which is the main purpose of treating hypertension. Hence the benefits (and risks) of BP lowering will vary even within these populations based on their underlying CV risk. On the other hand, stratifying populations based on the underlying CV risk may represent a cleaner view on the risks and benefits of BP lowering, especially of intensive BP lowering. Indeed, a meta-analysis from the BP Treatment Trialists Collaboration does show that there is no heterogeneity on relative risk reduction between trials with and without CKD or diabetes [92]. The common denominator for understanding treatment benefit is the underlying baseline CV risk. As shown in Figure 22.1 from an individual patient level meta-analysis, the absolute risk benefit with BP lowering increases with higher level of baseline CV risk [93]. One proposed scheme to think about stratifying patient population while thinking about intensive BP lowering is shown in Figure 22.2 [56]. Needless to say, intensive BP lowering requires careful assessment of the risk of adverse events, such as electrolyte imbalances and orthostatic hypotension.

Nondiabetic CKD

Four major RCTs have been conducted in nondiabetic CKD with BP lowering targets, as summarized in Table 22.5 [10, 91, 94–96]. As can be seen, the earlier trials were not powered for CV outcomes, nor for all-cause mortality. In one of the trials, the separation between arms of the BP was also minimal. The largest and most consequent RCT in this area is hence the Systolic Blood Pressure Intervention Trial (SPRINT) [10]. In the main trial, there was no significant interaction between the patients with CKD and those without CKD, which is the proper method to assess if patients with CKD are different in their response to intensive BP lowering. In addition, the detailed analysis of the CKD subgroup published subsequently confirms the benefit of intensive BP lowering for all-cause mortality [94]. A subsequent systematic review, including data from 18 RCTs and 15 924 participants confirms these findings, reporting 14% relative risk reduction in mortality with intensive BP lowering

(with an achieved systolic BP fall from a mean of 148 to 132 mmHg) [97]. Indeed, the risk of adverse events, mostly electrolyte disorders, do also go up as a consequence of adding potent antihypertensive agents, but this risk should be weighed against the benefit of not dying.

Diabetic CKD

There are no trials which specifically included patients with diabetes and CKD, and targeted a certain BP level intervention. From the general population with diabetes, the most relevant trial is Action to Control Cardiovascular Risk in Diabetes Blood Pressure (ACCORD) [11]. In this randomized trial, 4773 patients with diabetes and at high CV risk were randomized to two BP targets: systolic BP <140 mmHg versus systolic BP <120 mmHg. The overall primary composite outcome was not significantly different between the two groups, with a hazard ratio of 0.88 (95% confidence interval [CI] 0.73–1.06). Of all the specific events included, stroke (which arguably has the strongest link with BP) was significantly lower with the intensive BP target (HR 0.59, 95% CI 0.39–0.89). There was much consternation about the slightly greater number of deaths with intensive BP lowering (150 versus 144, HR 1.07, 95 CI 0.85–1.35). Intriguingly, this has lead to many different post hoc analyses, with two major schools of thought being that either ACCORD was underpowered (the observed event rate was about half as expected) or the other showing an effect modification [98]. ACCORD had a factorial design, with the other intervention being intensive blood glucose lowering, which was found to be harmful compared to standard glucose control [99]. In a post hoc analysis of ACCORD published a decade after the original publication, a significant interaction ($P = 0.03$) was reported, such that in the group receiving standard glucose lowering, intensive BP lowering decreased mortality, whereas in the intensive glycemic control group, intensive BP lowering increased mortality [100]. Thus it is indeed possible that intensive BP lowering not only confers a benefit in stroke reduction, but may not increase mortality if done in conjunction with standard, but not intensive, glycemic lowering.

Another approach, using a Bayesian analytic model of conducting a meta-analysis of *achieved* BP suggests intensive BP lowering is associated with a 10% reduction in all-cause mortality, a 17% increase in stroke, but with a 20% increase in serious adverse effects [101]. Specifically, it also suggests that these benefits were seen with an achieved BP of 130–135 mmHg, with further reductions only providing additional benefit in stroke reduction. These and other meta-analytic approaches either rely on baseline BP or achieved BP for grouping trials and arms [102–104]. They also include RCTs of BP lowering agents (e.g. olmesartan or lisinopril-losartan combination) compared with placebo, where the achieved BP would be higher with placebo, but where the interventions are no longer used as tested in these RCTS (e.g. dual blockade) [60]. To finish this discussion, the most recent meta-analysis of these reports on the CV effect of a standardized decrease of 10 mmHg on outcomes [4]. Overall, they report a benefit of 10 mmHg BP lowering on CV outcomes (including stroke and heart failure) and on all-cause mortality in diabetes, with little heterogeneity between trials in patients with and without diabetes (see Figure 22.3).

These analyses, needless to say, are from the general population, and not in CKD, where we must necessarily extrapolate the evidence. Should we expect outcomes to be different in patients with diabetes and CKD compared to those without CKD? From a mechanistic perspective, patients with diabetes and CKD are possibly different, but from an empiric point of view, no interaction has been reported yet from epidemiological studies.

Advanced CKD

Little evidence exists about BP management in advanced CKD, once the GFR is less than 20 in particular, since these patients have been excluded from the large trials that guide practice. The outcomes of interest are indeed different in these patients, since the specter of dialysis looms much larger. Intensive BP lowering does cause a decrease in GFR, which in some patients might tip them over to dialysis.

Table 22.5 Details of the four major trials targeting BP thresholds in nondiabetic CKD.

Trial	Population	Outcomes: renal, CV and mortality
Klahr et al. (MDRD) [95]	$n = 840$ *Inclusion:* Age 18–70 years CrCl <70 ml/min MAP <125 mmHg *Exclusion:* Diabetes, Proteinuria >10 g/day Chronic medical conditions Body weight <80% or >160% standard body weight	*Decline in GFR* 10.7 (9.113.9) ml/min/3 years in usual BP arm 12.3 (10.6–14.0) ml/min/3 years in low BP arm *ESRD or death* RR 0.85 (0.60–1.22)
Wright et al. (AASK) [91]	$n = 1096$ *Inclusion:* Age 18–70 years GFR 20–65 ml/min *Exclusion:* Diabetes Clinical evidence of heart failure Proteinuria (urine PCR > 2.5 g/g) Serious systemic illness	*% risk reduction for GFR slope + ESRD* −2 (95% CI −31 to +20) *CV* 2.9% (lower BP) versus 3.4 % (usual BP) *Mortality* 1.6% (lower BP) vs. 1.9% (usual BP)
Rugenenti et al. (REIN-2) [96]	$n = 338$ *Inclusion:* Age 18–70 years Proteinuria 1–3 g/day and CrCl <45 ml/min OR Proteinuria >3 g/day and CrCl >70 ml/min *Exclusion:* Diabetes Overt heart failure (NYHA III or IV) Recent (<6 months) MI or CVA	*Decline in GFR* 0.22 ml/min/mo in intensified BP arm versus 0.24 ml/min/mo in usual BP arm ($P = 0.62$) *CV* 37 (22%) in intensified arm versus 25 (15%) in usual arm[a] *Mortality* 2 (1.2%) in intensified versus 3 (1.8%) in usual arm

Adverse effects from drugs required to lower BP, namely electrolyte disorders, are also more common in advanced CKD. This would specifically also apply to the use of RAS blockade. An ongoing trial in which 410 patients with progressive stage 4 or 5 CKD have been randomized to continue or stop ACEi/ARB will answer this question [105]. However, if the benefit of intensive BP lowering (i.e. a decrease in all-cause mortality and cardiovascular events) reported in the general population and milder stages of CKD applies to this population also, one has to consider this against the real risk of needing to start dialysis from worsening GFR. This trade-off requires shared decision making and open discussion about preferences and patient important outcomes. Additionally, initiation of dialysis should not be on the basis of GFR alone, which also might help some of the decision-making process [106].

Dialysis

The foremost question in dialysis populations is that of BP measurement. In hemodialysis (HD) though many BP measurements are taken during a session, many of those measurements do not necessarily provide a proper assessment of the overall BP load. Nevertheless, hypertension is very common in dialysis patients, with an estimated prevalence of 70–80% or higher, irrespective of whether predialysis BP or interdialytic measures using ABPM are used [107, 108].

Peritoneal Dialysis

BP measurement in peritoneal dialysis (PD) is less of a quagmire compared to HD, though we do not have any RCTs to guide us regarding the BP level which would best reduce CV outcomes and mortality in this population. Unlike some early estimates, hypertension is quite common in PD, and the overall prevalence is similar to that in HD [109]. High BP also has similar associations with CV outcomes, however, residual renal function and technique failure are additional important outcomes to consider. The circadian pattern of BP in PD is different than in HD which is not surprising given the nature of and timing of salt and fluid removal between the two modalities [110]. Given their benefit in preserving kidney function in nondialysis CKD, one should not be surprised that RAS blockade would be useful in this setting to preserve residual function as well [111]. Additional intriguing data suggests that spironolactone may be useful in this setting since it not only reduces BP, but increases potassium levels, which is useful since hypokalemia is quite common in PD patients [112]. With respect to volume management, body impedance analysis guided volume management resulted in a modest 2.7 mmHg drop in systolic BP with no impact on clinical outcomes [113]. The use of icodextrin-containing solutions is a useful method for better volume management and has been reported to lower BP in a few RCTs, without impairing residual function or having the deleterious effect of high glucose solutions [114, 115]. Reducing dialysate sodium to levels lower than what are commercially available is also an intriguing approach so far only tried in phase two trials [116, 117].

Hemodialysis

Which BP Measurement to Use?

Though predialysis and postdialysis BP measurements are considered most often, they are least useful given events around dialysis initiation, which may cause a physiological increase in BP. Interdialytic ABPM measurements, which can be done over the 44-hour interdialytic interval, provide a more accurate assessment of the BP load as well as the

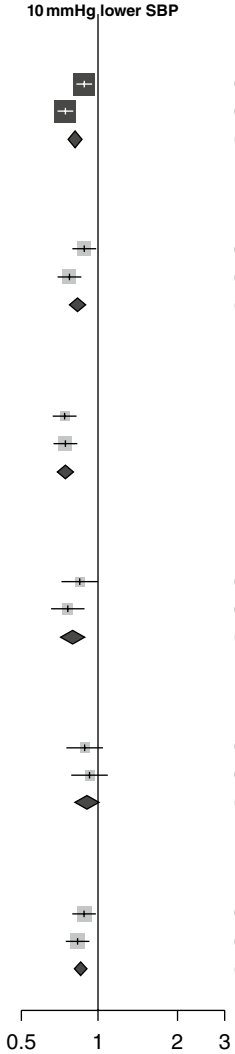

Figure 22.3 Standardized effect of a 10 mmHg reduction in systolic blood pressure (SBP) on the relative risk (RR) of major cardiovascular events, coronary heart disease, stroke, heart failure, renal failure, and all-cause mortality stratified by subgroups in which all (DM) or none (No DM) of the participants had diabetes mellitus at baseline. *Source:* From Ettehad et al. [4], used with permission. © 2016, Elsevier.

circadian pattern. Similar data exist about home BP, and these out-of-office measures are also more reproducible and have a stronger association with CV outcomes.

Early studies on BP and outcomes in hemodialysis reported a U-shaped curve of BP and survival in hemodialysis, and most concerning has been that the nadir of the U was reported at about systolic BP 160 mmHg, much higher than conventional thinking about BP targets and thresholds [118]. Although almost all other biological variables have a U-shaped relationship with clinical outcomes, the precise optimal BP being 160–180 mmHg would be a huge change from the ~120–140 in nondialysis populations. The former has indeed been reported, but those reports are from cross-sectional data and moreover rely on predialysis BP measurements. Cross-sectional data is notorious for susceptibility to selection bias and especially in HD populations is even more susceptible to reverse epidemiology [119]. Patients with heart failure, cancer, and patients in the last few months of their life have lower BP, and will also be more likely to die, independent of the BP. This leads to spurious associations which have been widely reported. In contrast, a meta-analysis of RCTs in dialysis patients shows a reduction of CV events with BP lowering [120]. Similarly, a linear relationship between BP and CV outcomes up to a systolic BP of 110–120 mmHg was reported when out-of-office BP measurement was used rather than predialysis BP [120, 121].

Nonpharmacological Measures

Minimizing dietary sodium intake: The focus of communication with patients on dialysis is often on fluid intake, a thoroughly useless and futile waste of time and energy. Sodium intake drives fluid intake, and efforts to reduce sodium intake are likely to have a greater effect on BP in the dialysis population given the outsize contribution of sodium to BP in this population. Data supporting this is mostly from observational literature and, as before, the effectiveness of counseling on change in behavior is unknown.

Maximizing dialytic sodium removal: This can be achieved by adequate ultrafiltration by probing the dry weight, especially in patients with high BP even without any signs of overt volume overload, and by considering longer or more frequent dialysis in those who do not tolerate ultrafiltration. There is RCT-level evidence for the former as well as for the latter. These data, however, demonstrate efficacy in the form of a change in BP, but not on consequent clinical outcomes [122]. Longer and more frequent dialysis does not improve quality of life or longevity, and may have deleterious effects on vascular access and residual renal function, which are important considerations [123–126]. The last mechanism of maximizing sodium removal is by altering dialysis sodium. Observational data provide mixed evidence in this regard. The clinical trial data do suggest that lowering or individualizing dialysate sodium to patient serum sodium is an efficacious method of lowering BP [127–129] (see Table 22.6). Given the association of hemodynamic stability and lower cramps (both patient important outcomes) with higher dialysate sodium, higher quality data from an ongoing cluster RCT may help resolve this dilemma (Randomized Evaluation of Sodium Dialysate Levels on Vascular Events [RESOLVE] NCT 02823821).

Pharmacotherapy

From the limited trial evidence available, discussed below, the use of beta-blockers as initial agents, followed by RAS blockade and CCBs is a reasonable approach to be considered.

A few RCTs have been conducted of BP lowering drugs compared to placebo in HD patients. The results are decidedly mixed, owing potentially to small sample sizes, co-interventions, and open label designs. Two small RCTs suggest a benefit of beta-blocker use in improving survival. For RAS blockade, one RCT of fosinopril failed to show a benefit for CV outcomes ($P = 0.06$), and two small open label RCTs of different ARBs seemed to show a benefit on CV outcomes [130, 131]. The most rigorous of the RAS blockade trials is the most recent, which was open label, but had an adequate sample size and where the target BP was similar in both groups, and did not report any difference between the two arms for CV outcomes or for all-cause mortality [132]. Lastly, one RCT of amlodipine, which enrolled fewer patients and reported fewer events than expected, still reported a CV outcome benefit [133]. However, achieved systolic BP was about 10 mmHg lower in the amlodipine group, hence it is hard to separate the BP effect from the drug effect. Thus, to summarize, there are clear uncertainties about the benefits of these individual classes of drugs in HD patients. The existing data do seem sufficient to elevate beta-blockers, along with RAS blockade and CCBs, to the first line of therapy when needed to control BP. These data also suggest that BP lowering with pharmacotherapy overall is beneficial in decreasing CV events.

Some additional consideration is necessary to consider pharmacokinetic aspects, including the effect of dialyzability. Recent research has revealed that with modern high

Table 22.6 Clinical trials of changing dialytic sodium and blood pressure.

Study	Population	Design	Interventions	Results
De Paula et al. [127]	$n = 27$ Non diabetes and not prone to hypotension	Non randomized, prospective, crossover study 3 weeks each	Dialysate sodium 138 mmol/l or set to patients serum sodium	Individualized dialysate sodium decreased weight gain (− 0.6 kg) BP similar between two arms
Munoz Mendoza [128]	$n = 15$ In-center nocturnal hemodialysis	Prospective, crossover trial 12 weeks each (three phases)	Dialysate sodium 140 versus 136/134 versus 140	Lower dialysate sodium with lower weight gain (0.6 kg) BP change −8.3 mmHg (±14.9)
Inrig [158]	$n = 16$ Patients with history of intradialytic hypertension	Prospective, crossover trial 3 weeks each	Dialysate sodium set at serum sodium +5 or −5 mmol/l	Lower dialysate sodium lowered BP (mean −9.5 mmHg, 95% CI −13.4, −6.4 mmHg)

BP, blood pressure.

flux dialysers, drugs such as bisoprolol, earlier thought to be nondialyzable, are indeed removed by dialysis [134]. On the other hand, despite atenolol being dialyzed out, it did show greater efficacy compared to lisinopril in one of the few RCTs in this area [135]. Thus it is not clear that dialyzability, or the lack thereof, matters in terms of efficacy in CV outcome reduction [136, 137]. However, the prolonged half-life of certain drugs can be used for more convenient dosing schedules, especially when there is a concern of nonadherence, and direct observed therapy can be provided with three times a week dosing in the dialysis unit [138].

An additional note is warranted about the utility of mineralocorticoid antagonists, namely spironolactone and eplerenone, which have had resurgence in resistant hypertension as well as in ESKD. Two trials suggest a fantastic benefit of these in lowering CV events and mortality, but both trials had a relatively small sample size to demonstrate such an outsize benefit [139, 140]. Another pilot/feasibility study of 100 patients did not demonstrate any difference, but did show a higher risk of hyperkalemia, borne out in a subsequent systematic review [141, 142]. Given these aspects, prudence would dictate awaiting the results of two large RCTs ongoing in this area (Aldosterone bloCkade for Health Improvement EValuation in End-stage Renal Disease [ACHIEVE] NCT03020303 and ALdosterone Antagonist Chronic HEModialysis Interventional Survival Trial [ALCHEMIST] NCT01848639).

Transplantation

In kidney transplant populations, additional contributors to hypertension include primarily the effect of immunosuppressive medications, but additionally the effect of the donor: recipient kidney volume mismatch, acute and chronic rejection, and transplant renal artery stenosis (often at anastomotic site) [143]. The steroid effect on BP is well known, and calcineurin inhibitors (CNIs) also increase BP by calcium channel mediated vasoconstriction, renal sodium retention, and in the long run by worsening kidney function. Specifically in the kidney transplant population, higher BP is associated with poorer patient survival, but also with more graft failure on the basis of observational data [144, 145].

With respect to treatment of hypertension, no trials have examined targets of BP lowering in these populations and guidelines have most often followed nontransplant CKD data. Given the role of immunosuppression, minimizing steroids and/or the CNI dose can assist in BP lowering, apart from the other nonpharmacological options discussed above. For specific pharmacotherapy, there do exist a few RCTs. The first line of agents, i.e. CCBs, RAS blockade, and even thiazide-like diuretics, are potent in lowering BP in this population [146, 147]. For outcomes, the strongest data support the use of CCBs as BP lowering drugs, as reported in this systematic review, and reduced graft loss (relative risk 0.75, 95% CI 0.57–0.99) [148]. For RAS blockade, the evidence is decidedly mixed when it comes to graft or patient survival. Overall, when combining ACE-inhibitors and ARBs as a class, there is no benefit seen against placebo or active comparators in this meta-analysis [149]. Intriguingly, the few ARB trials seem to report better graft survival than the ACEi RCTs, which may be a chance finding or worthy of further dissection or a larger replication [150, 151]. Other BP lowering drugs have little data on clinical outcomes and their use should be guided based on the BP lowering effect desired, adverse effects, and pharmacokinetics.

Guidelines and Variability

There is little agreement when it comes to the level of BP lowering in the plethora of existing international and national guidelines, even when it comes to the CKD subpopulation [152–154]. Despite a seeming overabundance of clinical trials, the same evidence is rated and weighed differently, resulting in this difference of opinion. Points that are common to all guidelines are that the systolic BP goal is <140 mmHg and the diastolic BP goal is <90 mmHg. The differences mostly arise with respect to how much lower should the BP target be and in whom should the BP be lowered further. Given that CKD itself is a robust risk factor for adverse CV outcomes, it would be sensible for intensive BP targets to be applied to this population. Previously mentioned caveats of identifying patients at high risk of adverse events and discussing risks and benefits and shared decision making, especially those of weighing outcomes which matter to the individual patients, do apply. The Kidney Disease Improving Global Outcomes (KDIGO) taskforce is also reviewing the data and will presumably come to a conclusion that may be acceptable to all in the coming months.

Research Needs

The discussion above highlights several lacunae in the evidence for management of hypertension in CKD patients.

- What are optimal BP targets in patients with diabetes and CKD?
- Is there a benefit with intensive BP lowering in patients with severe CKD (GFR < 20)?

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. - What BP target should be used in PD patients? HD patients?
- Which outcomes are important for patients and what is the role of shared decision making for intensive BP lowering in CKD?
- What strategies can be used for improving adherence to BP lowering drugs?
- What are effective strategies for delivering nonpharmacological therapies for BP lowering?

Renovascular Disease

Jörg Radermacher

Department of Nephrology, Johannes Wesling Klinikum Minden, UK-RUB, Minden, Germany

Introduction

End-stage renal disease requiring renal replacement therapy puts a major economic burden on the healthcare system. Atherosclerotic renovascular disease has been found in about 12–31% of patients >45 years old with end-stage renal disease [1, 2], constitutes the fastest-growing group of these patients [3], and is associated with a mean survival time of 25–34 months [4]. In unselected patients with hypertension, the prevalence of renal artery stenosis (RAS) is only about 1–5% [5]. In certain patient populations, such as those with severe hypertension, refractory hypertension, aortic aneurysm [6], or coronary artery disease [7], the prevalence is as high as 20–40% [8, 9].

Patients with RAS of >50–70% renal artery diameter were frequently advised to undergo correction of the stenosis. The reason for treatment usually was difficult-to-control hypertension. However, nowadays kidney failure should also be present, since patients with both hypertension and impaired renal function benefit the most from angioplasty. Identifying patients whose blood pressure and/or renal function will improve postintervention remains difficult. Retrospective studies have shown a lack of improvement in blood pressure and renal function despite correction of the stenosis in 20–46% of patients [10–16].

Because angioplasty and surgery can lead to complications like cholesterol embolism, persistent acute kidney failure, and even patient death, these procedures should only be performed in patients with a high likelihood of benefit. Possible reasons for a lack of treatment effect are correction of trivial stenoses (<60%), lack of a clinical problem (not difficult to control hypertension, not severely impaired or declining renal function) underlying renoparenchymatous disease, technical failure, cholesterol embolism, or radiocontrast toxicity. These aspects will be discussed.

Terminology

The term renovascular hypertension is reserved for those patients with improvement, or rarely even normalization, of blood pressure after intervention. The term renovascular azotemia is used for those patients who have improved renal function. Frequently, the term ischemic nephropathy is used, but this term does not distinguish whether a patient is going to be a responder. RAS and renovascular hypertension are frequently used as synonyms in the literature [17]. However, the term RAS should be reserved for an anatomical description, whereas renovascular hypertension and renovascular azotemia describe the functional relevance of the stenosis.

Pathophysiology of RAS

RAS leads to renal ischemia, causing the release of renin from the juxtaglomerular cells of the kidney and resulting in the conversion of angiotensin I to angiotensin II, subsequent release of aldosterone from the adrenal gland, vasoconstriction, and sodium and water retention. The long-term consequences are the buildup of extracellular matrix and collagen IV via angiotensin II-induced increased expression of transforming growth factor β and interstitial platelet-derived growth factor, resulting in irreversible parenchymal damage [18–20] also in the nonaffected kidney. The challenge of treatment of atherosclerotic RAS is to intervene at a stage before major parenchymal damage has occurred.

Should we still Diagnose and Correct RAS?

At present there are 10 randomized controlled trials [15, 21–29] (Table 23.1), a metaanalysis [31], and a Cochrane analysis [30], none of which has shown a benefit of angioplasty compared to optimal medical treatment (OMT) alone. Some experts suggest we should stop looking for the presence of RAS because a benefit of correction of RAS has not been shown.

However, relevant patient groups have not been included in those studies. The second-largest ASTRAL trial [25] only included patients for whom the treating doctor was unsure whether angioplasty would be of help. The largest and most recent CORAL trial [27] included mostly patients without clinical problems (no severe hypertension, no declining renal function). Even if angioplasty were always futile – which it is not as will be shown – the diagnosis of RAS would still have to be made. All recent studies found a 50% less than expected event rate in the control group and attributed that to the OMT consisting of ASS, statins, and antihypertensives, including a RAS-inhibitor. Treating patients with OMT is class 1A advice in all guidelines and not looking for the presence of RAS would deny patients this treatment.

The Salford group included 72 patients in the ASTRAL trial and reported their outcome on a further 467 patients with >50% RAS who were not included in ASTRAL [33]. Thirty-seven patients had flash pulmonary edema but only 66% received angioplasty. The hazard ratio for death in the angioplasty group was 0.4 (0.2–0.9). Thirty-one patients had refractory hypertension and declining renal function. The hazard ratio for death in those patients receiving angioplasty was 0.15 (0.02–0.9) and the HR for a cardiovascular event was 0.23 (0.1–0.6). Vassallo et al. showed similar findings in 131 patients with ≥70% stenosis and clinical problems compared to 144 patients with the same degree of stenosis but without the clinical problem [34]. Median follow-up time was 58 months. Revascularitzation was associated with a 50% reduced risk of progression to end-stage kidney disease and cardiovascular events in patients with rapidly deteriorating renal function. Furthermore, patients with bilateral RAS and patients with proteinuria <1 g also had significantly better renal and cardiovascular outcomes post revascularization compared to controls.

Grey et al. reported findings on 39/207 patients with flash pulmonary edema or recurrent episodes of congestive heart failure. After angioplasty blood pressure and renal function improved significantly, and hospitalization for heart failure was reduced from 2.4 to 0.3 episodes per year before and after angioplasty [35].

This shows that correction of RAS may still be considered in patients with RAS and a relevant clinical problem.

A recent S2K guideline on diseases of the renal artery (https://www.awmf.org/uploads/tx_szleitlinien/004-008l_S2k_Erkrankungen-der-Nierenarterien_2020-01_01.pdf) describes case scenarios where angioplasty (usually stent assisted) should be avoided or can still be considered (Table 23.2) [32].

Patients who should be Screened for RAS

Because RAS is present in only about 1% of unselected patients with hypertension, general screening is not advisable. The clinical signs suggesting renovascular disease include an abdominal bruit, difficult-to-control hypertension (requiring three or more antihypertensive agents), accelerated hypertension or hypertension that was previously well-controlled, worsening of renal function 4–31 days after introduction of angiotensin converting enzyme inhibitor (ACEi) or angiontensin II receptor blocker treatment [10], severe atherosclerosis in other vascular beds, otherwise unexplained chronic kidney disease, hypertension associated with sudden and repeated left heart failure or pulmonary edema, the onset of hypertension before the age of 30 years in nonobese and 15 years in all patients (from fibromuscular renal artery disease) or after the age of 55 years (from atherosclerotic renal artery disease), and differences in the sizes of the two kidneys. It is important to identify these clinical clues because the prevalence of RAS increases to 39% among these patients [40]. Once RAS is suspected, a screening test is used to confirm its presence.

Screening Methods for RAS

Screening tests should be inexpensive, accurate (i.e. with a low rate of technical failure and high sensitivity and specificity), and noninvasive. This excludes angiography, although angiography is still considered the reference standard for detection and quantification of stenosis. A high interobserver variability for stenosis quantification has been shown ($\kappa < 0.4$) [41]. One study found a systolic pressure gradient of ≥30 mmHg in 13 of 22 renal arteries in which arteriography had shown only minor degrees of stenoses (<50%) [42], a pressure gradient generally associated with a reduction of the glomerular filtration rate (GFR) [43]. Angiography may also cause atheromatous embolization of the kidneys or renal impairment due to radiocontrast nephrotoxicity.

Spiral computed tomography angiography (CTA) and magnetic resonance angiography are noninvasive imaging

Table 23.2 Treatment of atherosclerotic renovascular disease [30–32].

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
No angioplasty	No angioplasty in unilateral or bilateral asymptomatic stenosis	High	Medium [32]
No angioplasty	No angioplasty in patients with proteinuria >1 g/day, biopsy proven severe renal disease or resistive index >0.80	Moderate	Weak [32]
Angioplasty	Angioplasty can be considered in patients with both refractory hypertension and rapidly declining renal function (also with unilateral stenosis)	Low	Weak [32]
Angioplasty	Angioplasty can be considered in patients with flash pulmonary edema or recurring cardiac decompensation even in unilateral stenosis	Low	Medium [32, 35, 36]
Nicotin	Nicotine use must be stopped	High	Strong [32]
Statin	All patients with RAS should be treated with a statin to a goal of LDL < 70 mg/dl	Moderate	Medium [32, 37, 38]
Diet	Follow a healthy diet (salt restriction, moderation of alcohol consumption, high consumption of vegetables and fruits) and reduce weight and perform regular physical exercise	Moderate	Medium [32, 36]
Goal blood pressure	Blood pressure should be lowered to <140/90 mmHg	High	Strong [32]
RAS inhibitor	A RAS inhibitor should be given to all patients with unilateral RAS	Moderate	Medium [32, 39]
RAS inhibitor	A RAS inhibitor can be given to patients with bilateral RAS with tight control of s-creatinine and potassium	Low	Weak [32]
Aspirin	Acetylsalicylic Acid should be given	High	Strong [32, 36]
HbA1c	In patients with RAS and diabetes HbA1c should be ≤7.5%	Moderate	Medium [32]

techniques that have high sensitivity and specificity (>95%) for detecting RAS [44–47], although a more recent study did not find the same level of accuracy when these methods were applied in everyday practice [47]. The latter study reported a sensitivity of 64% and a specificity of 92% for CTA and 62% and 84%, respectively, for magnetic resonance angiography. These techniques are also limited by their high costs and, in the case of spiral CT, the use of contrast agents. Magnetic resonance is not suitable for patients with claustrophobia and certain types of metallic implants. Measurement of the concentrations of renin in the renal veins have been used to predict the potential success of surgical revascularization. False-negative and false-positive results are common with this technique, and it is therefore not recommended as a reliable screening test for RAS. In theory, the accuracy of renal vein renins is enhanced by using an ACEi (captopril test), which attenuates the vasoconstrictive effect of angiotensin II on the efferent arteriole and reduces filtration on the side of the stenosis [44]. The reported sensitivity and specificity after 25–50 mg of captopril, however, are also low [48].

Captopril scintigraphy (25–50 mg of oral captopril given 12 hours before isotope) can detect RAS with high sensitivity and acceptable specificity, and has also been shown to be of value in identifying patients whose blood pressure will improve after correcting the stenotic lesion [49]. This test, however, has not been shown to predict an improvement in renal function after correction of RAS and it cannot locate the stenosis or determine its severity [44]. Furthermore, the sensitivity of this test is reduced to 80% in patients with renal insufficiency (GFR of <50 ml/min) or in patients with bilateral stenoses or a stenosis in a single functioning kidney [44, 50]. It is particularly important to identify significant stenoses in these patients because the major rationale for performing surgery or angioplasty is to preserve renal function.

In experienced hands Doppler ultrasonography is highly sensitive and specific for detecting RAS, and it is rapid and inexpensive [51]. Two main approaches are used to detect a significant RAS of 50–70% [51]. The first (direct) approach looks at flow acceleration at the site of the stenosis. This approach has good sensitivity and specificity for detecting stenoses of ≥50%. Obesity, excessive bowel gas, or poor blood flow in the main renal artery can, however, interfere with direct visualization of the renal arteries [51]. The second (indirect) approach looks at poststenotic flow phenomena (tardus and parvus). This approach can be used in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. nearly all patients but will only detect severe stenoses of >60%. A combination of both approaches is the most suitable technique for accurate detection of RAS in almost all patients. In patients with normal or impaired renal function, we reported no technical failure with this combination method and showed high sensitivity (96.7%) and specificity (98.0%) for detecting RAS of ≥50% compared with angiography [51]. The value of Doppler ultrasonography to reliably detect stenoses of 50% and more has been shown in the majority of more recent studies (Table 23.3) and screening for RAS with Doppler ultrasound is favored by most guidelines [36].

In summary, the best screening test is probably the test performed most frequently at an individual facility. In patients with a GFR of <50 ml/min, CTA (due to radiocontrast toxicity) and captopril scintigraphy (due to low sensitivity) should be avoided.

Quantification of Stenosis and Estimation of Functional Relevance

Other than detecting the presence of stenosis, Doppler ultrasonography can also be used to estimate the severity of RAS with reliable estimates up to 70% diameter reduction. A good correlation compared to intravascular ultrasound has been shown ($R = 0.97$) [65]. An RI difference >0.05 (parvus phenomenon) suggests stenosis of at least 60% and an acceleration time >70 ms (tardus phenomenon) suggests a stenosis >65% [66].

There is general agreement [67] that a diameter stenosis of <50% causes neither high blood pressure nor impairment of renal function. For this reason, intervention should not be performed for these low-degree stenoses. Stenoses <60% progress slowly and almost never proceed directly to occlusion [68]. A policy of watchful waiting (e.g. ultrasonographic follow-up of stenoses) is reasonable. Stenoses of >65–80% are considered to be hemodynamically relevant [69, 70]. Stenoses in most studies have been graded by angiography. Simon et al. found hypersecretion of renin, suggesting functional relevance, in stenoses of >80% diameter reduction [70]. Unfortunately, data on the improvement of blood pressure or renal function after correction of stenosis are lacking. Giroux retrospectively evaluated the degree of stenosis in patients who did or did not have improved blood pressure after correction of RAS. They found tighter stenoses in patients that did benefit (79 ± 9% vs. 74 ± 9%, $P < 0.05$), but the differences were small [69]. Future studies should quantify stenoses using noninvasive Doppler ultrasound, intravascular ultrasound, or a pressure gradient measured by pressure wire (an expensive method) or catheter.

Exclusion of Renoparenchymatous Disease

Possibly the main reason for a lack of treatment benefit despite successful correction of RAS is preexisting renoparenchymatous disease. The two most frequent diseases coexisting with or even causing RAS are long-term hypertension and diabetes leading to hypertensive nephrosclerosis and diabetic glomerulosclerosis [71]. Renal biopsy can predict treatment failure but is usually not indicated in these disease entities [72]. Some readily available clinical and angiographic clues as predictors of treatment success have been suggested [73, 74] (Table 23.4). However, none of these parameters is sufficiently sensitive or specific, and contradicting data have been published for many of these. Rapidly deteriorating renal function in the presence of RAS has been associated with a favorable response after angioplasty [81]; however, follow-up data on renal function are frequently not available. Some screening methods have been evaluated regarding prediction of treatment success: measurement of renal vein renin, captopril scintigraphy, magnetic resonance tomography, and Doppler ultrasonography. Because a hemodynamically relevant RAS should cause increased renin production, renal vein renin measurements have been considered the reference standard for predicting the functional relevance of stenoses. The diagnostic accuracy of this test is, however, disappointing, and the requirement for invasive venous angiography and radiocontrast agents have made this method almost obsolete. Renal scintigraphy without captopril also has only low diagnostic accuracy, but captopril scintigraphy is an established method to predict a treatment effect. Captopril causes a further fall in GFR in the stenosed kidney. The positive predictive value for blood pressure improvement of a positive captopril scintigraphy is reported to be 92%; however, sensitivity drops to 80% in patients with impaired renal function [50]. This could be due to dependence of renal filtration on vasoconstriction of the efferent arteriole in patients with advanced renoparenchymatous disease, which is impaired after ACEi treatment. A further drawback of captopril scintigraphy is the requirement for meticulous patient preparation in order to obtain reliable results. Patient preparation includes controlled hydration, controlled sodium diet, and removal of diuretics and ACEi 4–14 days before the investigation [50, 82]. van Jaarsveld et al. did not find a predictive value of captopril scintigraphy for improvement of blood pressure in their study [15].

Gadolinium-assisted magnetic resonance imaging after ACEi treatment has been used to quantify renal filtration and has provided predictive results comparable to captopril scintigraphy [83]. The study protocol was later refined [84].

Table 23.4 Predictors of a lack of effect of successful correction of RAS related to blood pressure and/or renal function.

	Studies [reference] that found the parameter to be:	
Patient characteristic	**Predictive**	**Not predictive**
Advanced age, >65 years	[15, 16, 75, 76]	[69, 77, 78]
Male gender	[75]	[69, 77, 78]
Severe atherosclerosis	[16, 69, 78]	
Proteinuria >1 g/day	[16, 79]	
Severely impaired renal function (GFR <40 ml/min)	[16, 78]	[69, 76, 77]
No sudden appearance of hypertension or sudden worsening of previously well-controlled hypertension	[15]	[16]
Duration of hypertension >10 years	[69, 75]	[76]
Diastolic blood pressure <80 mmHg	[69, 75, 76]	[77]
Systolic blood pressure <160 mmHg	[77]	[76]
Diabetes mellitus	[69]	[16, 78]
Nonsmoker	[16, 69]	
Degree of stenosis <70%	[69]	[15, 77]
Resistance index >0.80	[16]	[80]

Prospective studies on this fascinating technique as a predictor for renovascular hypertension or azotemia are lacking at present, however.

In two studies with low patient numbers, an increased intrarenal resistance index value measured by Doppler ultrasonography was associated with a rapid loss of renal function [85] and a lack of blood pressure improvement [86], despite correction of RAS. A prospective study found that a resistance index of >0.8 in the intrarenal segmental arteries had a sensitivity and specificity of >90% for predicting renal function deterioration and a lack of blood pressure improvement [16] (Figure 23.1).

Improving Short- and Long-term Results of Correction of RAS

Ten-year patency rates are still only available for surgically corrected renal artery stenoses, although outcomes may be better after surgery compared to angioplasty [87]. However, angioplasty has become the method of choice because it is less invasive and has a lower mortality rate. Only when an aortic aneurysm or other severe aortic disease requires simultaneous treatment should surgery be the preferred method. Ostial stenoses should always be treated with angioplasty plus stenting; stenoses located >1 cm distally to the aorta or stenoses due to fibromuscular dysplasia can be treated with angioplasty alone [88]. A randomized controlled study reported better initial patency rates (88% vs. 57%) and lower restenosis rates (14% vs. 48%) 6 months after stent-assisted angioplasty compared to angioplasty alone in ostial stenoses [89]. However, the same study failed to show superiority of stenting regarding blood pressure or renal function improvement. Newer studies report primary patency rates in the range from 94 to 100% [69, 77, 90], but long-term results are less favorable. Restenosis, de novo stenosis, or thrombosis rates in the range of 10% per year have been reported both in stent-treated patients and patients who had angioplasty alone [16, 69, 77, 81, 90–93] Revascularization success should therefore be monitored by ultrasonography at 3 months, 6 months, and yearly intervals thereafter. Newer technologies using sirolimus-coated stents are being evaluated [94].

Cholesterol Embolism and Radiocontrast Toxicity

Cholesterol embolism in the renal arterial bed or the aorta is always a dramatic event. It can lead to progressive loss of renal function despite patency of the renal artery. At present, there is no reliable method to detect cholesterol embolism. Renal biopsy is invasive and may miss the site of embolism due to sampling error. Blood eosinophilia, hypocomplementemia or the "blue toe" suggest cholesterol embolism but are not sufficiently sensitive or specific to allow the diagnosis of renal cholesterol embolism. Dejani et al. found blood eosinophilia of >5% in seven of 20 patients older than 55 years with impaired renal function (serum creatinine >2 mg/dl) treated by renal angioplasty [95]. The feasibility of renal protection devices catching cholesterol crystals and other debris has been shown but has not been tested in randomized controlled trials [96].

A further frequent complication associated with renal angiography and renal arterial stenting is radiocontrast toxicity. Treatment of RAS may be of greatest benefit in patients with impaired renal function, and these patients are most sensitive to radiocontrast toxicity. Controlled hydration with NaCl at 1 ml/kg/h for 12 hours prior to and after angioplasty is considered standard prophylactic therapy. A randomized controlled trial has shown the superiority of this regimen, compared with additional mannitol or furosemide treatment [97]. Prehydration with sodium bicarbonate (154 mmol plus 900 ml 5% glucose solution) instead of saline alone may further lessen the risk. However, these data have not been confirmed in subsequent studies [98]. Acetylcysteine (600–1200 mg twice a day) has been shown to have an additive

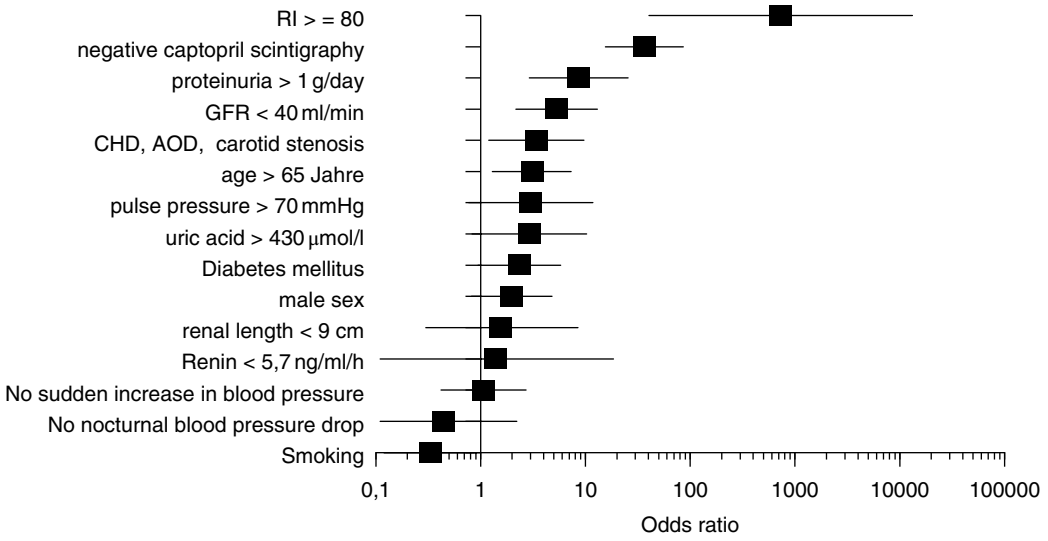

Figure 23.1 Odds ratios for various factors to predict deterioration of renal function. Squares depict odds ratios; lines depict 95% confidence intervals. RI, resistance index; CHD, coronary heart disease; AOD, atheroocclusive disease of the legs.

protective effect compared with hydration alone for preservation of renal function and prevention of acute kidney failure in several randomized controlled trials [99, 100], but a recent meta-analysis including 19 randomized trials failed to show such a protective effect [101].

The newer nonionic radiocontrast agents have lessened the risk of toxicity but have not abolished it [102]. Furthermore, the isoosmolar radiocontrast agent iodixanol has been associated with significantly less contrast nephropathy than the low-osmolar agent iohexol [103]. These results have not been confirmed in other studies. Hemodialysis during or directly after application of radiocontrast agents does not prevent radiocontrast toxicity, but hemofiltration may have a beneficial effect [104]. Here also, confirmatory studies have not been performed, and this method of treatment is invasive and expensive. Calcium channel blockers, ANP [105], dopamine [106], and endothelin receptor antagonist [107] have been proven useless to prevent radiocontrast toxicity. Theophylline may have a protective effect, but its effects are not additive compared to hydration treatment alone [108].

Conclusions

Patients should only be screened for the presence of RAS when the likelihood that they have RAS is sufficiently high. A good screening method is Doppler ultrasonography. If local experience favors CT or MRI these methods can also be applied. Only patients with a high likelihood for improvement should be treated with angioplasty. Randomized trials have failed to show a significant superiority of angioplasty compared to OMT alone. However, these studies included patients because they had anatomical RAS and not because they had RAS and a significant associated clinical problem. Future technical improvements regarding prevention of cholesterol embolism and radiocontrast toxicity may increase the proportion of patients who benefit from stenosis correction. Based on current data, stenoses of >60% can be treated with angioplasty if there is both uncontrolled hypertension and declining renal function, or if the patient suffers from flash pulmonary edema or recurring congestive heart failure.

Diabetic Nephropathy vs. Diabetic Kidney Disease

Diabetic nephropathy classically refers to the renal microvascular pathology that occurs in patients with type 2 diabetes mellitus (DM) resulting in glomerular hyperfiltration, moderately increased urine protein, and severely increased urine protein, and followed by a reduction in glomerular filtration rate (GFR). It is generally accompanied by hypertension and other evidence of microvascular pathology, including retinopathy and neuropathy. It is characterized histologically by thickening of the glomerular and tubular basement membranes, mesangial expansion, and nodular sclerosis (Kimmelstiel–Wilson lesions). Although a recognized entity for 50 years [1], a pathological classification, dominantly based on glomerular pathology, has only been developed in the last decade [2] (Table 24.1). The classification also notes the presence of tubulointerstitial lesions, vascular lesions, and nondiabetic glomerular lesions which may be present to a variable degree in classic diabetic nephropathy [2] (Table 24.2).

It is now recognized that individuals, particularly those with type 2 DM and chronic kidney disease (CKD), do not uniformly present with the clinical features and trajectory of biochemical abnormalities outlined above, nor with the glomerular histological features listed in Table 24.1. Hence modern nomenclature has favored the term diabetic kidney disease (DKD) over diabetic nephropathy as this is more representative of the coexistent obesity-induced, vascular, and hypertensive kidney injury that is likely to be over-represented in patients with type 2 DM.

Incidence and Prevalence of Diabetic Kidney Disease

Diabetes is recognized as the world's fastest growing noncommunicable chronic disease. In 2003 the International Diabetes Federation (IDF) estimated that 194 million adults (aged 20–79 years) were living with diabetes and projected that this number would increase to 333 million people by 2025. However, in 2017 the IDF estimated 425 million people were living with diabetes and this number is expected to increase to 629 million by 2045 [3] (Figure 24.1).

In the 2017 report from the IDF [3], the highest prevalence is in China with 114 million people, followed by India with 73 million, and the USA with 30 million. The estimated worldwide expenditure on diabetes in 2017 was US $ 727 billion. Alarmingly, rates of childhood diabetes are increasing, being highest in the USA. Contrary to expectation, approximately one-third of the world population living with diabetes resides in nonurban environments and thus is arguably less likely to be strongly influenced by a Western diet. The vast majority of cases are due to type 2 DM, but the incidence of type 1 DM is also increasing, with a marked variation in the incidence and prevalence of type 1 DM across the globe that is currently unexplained.

The increasing prevalence of type 2 DM is driving the increased prevalence of kidney failure, with kidney failure 10 times more likely to occur in people with diabetes than in the remainder of the population [4]. The IDF estimate DKD is estimated to be responsible for between 12% and 55% of cases of kidney failure worldwide [3]. The proportion of kidney failure attributable to diabetes, hypertension, or a combination of

Table 24.1 Glomerular classification of DKD.

Class	Description	Inclusion criteria
I	Mild or nonspecific LM changes and EM proven GBM thickening	Biopsy does not meet any of the criteria mentioned below for classes II, III, or IV
		GBM >395 nm in female and >430 nm in male individuals 9 years of age and older
IIa	Mild mesangial expansion**	Biopsy does not meet criteria for class III or IV
		Mild mesangial expansion in >25% of the observed mesangium
IIb	Severe mesangial expansion	Biopsy does not meet criteria for class III or IV
		Severe mesangial expansion in >25% of the observed mesangium
III	Nodular sclerosis (Kimmelstiel–Wilson lesion)	Biopsy does not meet criteria for class IV
		At least one convincing Kimmelstiel–Wilson lesion
IV	Advanced diabetic glomerulosclerosis	Global glomerular sclerosis in >50% of glomeruli
		Lesions from classes I through III

DKD: diabetic kidney disease
LM: light microscopy
EM: electron microscopy
GBM: glomerular baseline membrane
IFTA: interstitial fibrosis tubular atrophy
**The difference between mild and severe mesangial expansion is based on whether the expanded mesangial area is smaller or larger than the mean area of a capillary lumen

Table 24.2 Interstitial and vascular lesions of DKD* [2].

Lesion	Criteria	Score
Interstitial lesions		
IFTA	No IFTA	0
	<25%	1
	25–50%	2
	>50%	3
Interstitial inflammation	Absent	0
	Infiltration only in relation to IFTA	1
	Infiltration in areas without IFTA	2
Vascular lesions		
Arteriolar hyalinosis	Absent	0
	At least one area of arteriolar hyalinosis	1
	More than one area of arteriolar hyalinosis	2
Presence of large vessels	–	Yes/no
Arteriosclerosis (score worst artery)	No intimal thickening	0
	Intimal thickening less than thickness of media	1
	Intimal thickening greater than thickness of media	2

DKD: diabetic kidney disease
IFTA: renal interstitial fibrosis and tubular atrophy

both in the majority of countries where data are available is approximately 80%. As hypertension and diabetes are inextricably linked, ascertainment bias as to the cause of kidney failure may contribute to this variation. It is estimated that patients with CKD not requiring dialysis have 50% higher health costs compared to patients with diabetes but no CKD. In Australia, patients with CKD are 20 times more likely to die of a cardiovascular event than to reach kidney failure [5].

Pathogenesis of Diabetic Kidney Disease

The pathogenesis of DKD is complex, with multiple interacting and redundant pathways contributing to progressive kidney pathology. Mediators that are responsible for DKD (classically seen in younger patients with type 1 DM) overlap with additional factors more prevalent in patients with type 2 DM, including hypertension, macrovascular disease, and infection to result in a complex pathogenesis of kidney disease in patients with DM. With some significant exceptions, particularly regarding glycemic control, the majority of evidence to improve outcomes in DKD is based on trials in patients with type 2 DM and associated DKD.

Hyperglycemia is considered a key driver of DKD [6, 7]. It is directly or indirectly responsible for both metabolic abnormalities and altered intrarenal hemodynamics that contribute collectively to DKD. Intracellular hyperglycemia contributes to activation of the polyol pathway [8], hyperuricemia [9], dyslipidemia [10], the production of advanced glycation end products (AGEs), and interaction with receptors such as the receptor for advanced glycation end products (RAGE) leading to oxidative stress [11]. As a result, fibrosis, thrombosis, DNA damage, cellular dysfunction, vascular leakage, angiogenesis, inflammation, and decreased oxidative stress defense mechanisms are initiated, resulting in tubulointerstitial fibrosis [12, 13].

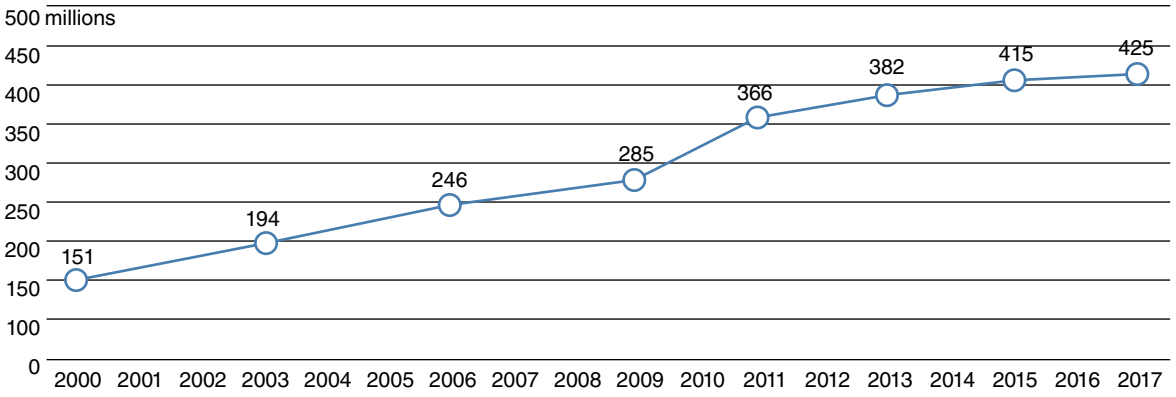

Figure 24.1 Estimates of the number of adults (aged 20–79 years) living with diabetes worldwide. *Source:* Based on Ogurtsova et al. [3].

Somewhat paradoxically DKD is associated with reduced mitochondrial superoxide production. A basal level of mitochondrial superoxide level is required to maintain adenosine monophosphate kinase (AMPK) activation and phosphorylation of endothelial nitric oxide to promote vascular dilatation under physiological circumstances. Reduced AMPK activity stimulates inflammatory transcription factors, including nuclear factor kappa B (NFκβ), and proinflammatory and profibrotic molecules in a paracrine manner from multiple renal cells. Under hyperglycemic conditions there is a reduction in mitochondrial superoxide generation, oxidative phosphorylation, and mitochondrial adenosine triphosphate (ATP) generation in the kidney and abnormalities in cellular bioenergetics occur [14, 15].

Vascular and glomerular lesions contribute to hypoxia, which further exacerbates oxidative stress in both the glomerulus and tubules [13, 16]. Hypoxia-inducible factors (HIFs) are induced with downstream transcription of genes such as vascular endothelial growth factor (VEGF) and erythropoietin to improve tissue oxygenation. However, there is experimental evidence that hyperglycemia may interfere with the stability of HIF and facilitate tissue fibrosis [17, 18].

These diverse mediators collectively lead to downstream activation of hormones and proinflammatory mediators [19] and profibrotic cascades. It is increasingly recognized that inflammation and fibrosis are inextricably linked in all forms of CKD, including DKD [20–23]. It is also now evident that as well as the adaptive immune system being activated in CKD, the innate immune system is also upregulated [24–28]. These responses are initiated by several classes of pattern recognition receptors (PRRs) in response to immune activators such as pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs). The latter are heterogenous molecules, derived from injured cells and components of the extracellular matrix (ECM), such as hyaluronan, biglycan, and fibronectin. DAMPs trigger innate immunity by activating Toll-like receptors, purinergic receptors, or the NLRP3 inflammasome, leading to necroptosis increased interferon gamma and downstream chemoattractants, macrophage chemoattractant protein-1 (MCP-1), and CCl10 [28–34]. Necroinflammation, an autoamplification loop between tubular cell death and interstitial inflammation, leads to the exacerbation of kidney injury [35, 36]. Although not yet specifically reported in DKD it is likely that common mechanisms are in play across the spectrum of CKD. Recent evidence suggests DAMPs also contribute to epithelial-mesenchymal transition of tubular cells to myofibroblast differentiation and proliferation. Furthermore, tubular cells also play an active role in progressive kidney injury via emerging mechanisms associated with a partial epithelial-mesenchymal transition and cell-cycle arrest at both G1/S and G2/M checkpoints [37].

It is clear that inflammation plays a major role in the pathogenesis of CKD. Inflammation occurs as a result of cellular injury, mediated by macrophages and lymphocytes [38–40]. The transcription factor nuclear factor kappa B (NF-κB) is responsible for upregulating genes involved in inflammatory processes within macrophages and tubular cells. Amplification of pro-inflammatory and pro-fibrotic cytokines, such as transforming growth factor β (TGF-β), platelet derived growth factor (PDGF), and fibroblast growth factor 2 (FGF-2), then occurs that causes migration and proliferation of resident fibroblasts. Such fibroblasts are differentiated, and along with tubular and glomerular cells ECM production is enhanced [41–43]. Resident and invading cells then secrete various chemokines, including MCP-1, IL-6, and tumor necrosis factor α (TNFα), that lead to further macrophage accumulation, perpetuating the development of fibrosis [44]. TGF-β, VEGFs, insulin-like

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

growth factors (IGFs), and lipid mediators also contribute to inflammation and fibrosis [45].

As stated above, multiple transcription factors and cytokines are involved in expansion of the ECM, but TGFβ1 is considered the "master regulator" of kidney fibrosis in DKD. TGF-β1 is a well-characterized key mediator in the pathogenesis of tubulointerstitial fibrosis due to its direct and indirect effect on various cells types [46–49].

The direct action of TGF-β1 can initiate the transition of tubular and endothelial cells to a fibroblastic phenotype as described above and proliferation, migration, and synthesis of profibrotic proteins, such as collagens and fibronectin [50–56]. TGF-β1 can also induce an indirect fibrotic response via accelerating apoptosis of resident healthy cells and promoting resident and infiltrating cells to increase ECM deposition [57–59].

Hyperglycemia also causes release of vasoactive mediators, such as IGF-1, glucagon, nitric oxide (NO), VEGF, and prostaglandins, resulting in afferent arteriolar vasodilation. Additionally, both hyperglycaemia and insulin resistance result in dysregulation of the renin-angiotensin-aldosterone and endothelin [60] systems that act both systemically and specifically on the efferent arteriole. This results in peripheral and intraglomerular hypertension, leading to kidney impairment. [61]. Upregulation of proximal tubular sodium reabsorption occurs due to increased expression of sodium-glucose linked transport-2 and increased sodium-hydrogen exchange leading to a low sodium concentration at the macula densa and inhibition of tubuloglomerular feedback, thus resulting in single nephron glomerular hyperfiltration [62].

Shear stress as well as podocyte apoptosis driven by angiotensin II and endothelin, reduction in the slit diaphragm proteins nephrin and podocin, and glycation of the glomerular basement membrane with associated loss of negative charge results in albuminuria [63–65].

More recently, additional pathways have been identified as contributing to cellular dysfunction that predisposes to or accelerates the development of DKD. Both hyperglycemia and hyperinsulinemia trigger abnormalities in cell bioenergetics [66] that ultimately lead to inefficient use of metabolic substrates that contribute to tissue hypoxia. Additional dysregulated metabolic pathways, include upregulation of the mammalian target of rapamycin (mTOR), which drives suboptimal use of metabolic substrates, resulting in both cytosolic and mitochondrial derived dysregulated oxidative stress and dysfunctional autophagy and mitophagy [66–71].

Fatty acid beta-oxidation is the catabolic process by which fatty acid molecules are broken down in the cytosol and in the mitochondria to generate acetyl-CoA, which enters the citric acid cycle to produce ATP. The cellular mechanisms to ensure orchestrated fatty acid uptake, oxidation, and synthesis are tightly regulated to avoid excessive intracellular lipid accumulation. The transcription factors, peroxisome proliferator-activated receptors (PPARs), and PPARδ coactivator-1a (PGC1A) regulate the expression of proteins involved in fatty acid uptake and oxidation. In the setting of CKD lower expression of genes responsible for fatty acid oxidation, PPARs, and PGC1A is observed suggesting that lipid metabolism is impaired. Human proximal tubular studies have demonstrated that TGF-β is intrinsically involved in blocking fatty acid oxidation pathways, mediated by PGC1A [72].

Genetic and epigenetic modifications of both genes and histones induced by hyperglycemia, hypoxia, and as a consequence of proinflammatory and profibrotic pathways are increasingly recognized to influence the phenotype of individuals that directly or indirectly influences the development of diabetes and the propensity to develop DKD. Gene methylation or acetylation induced by hyperglycemia significantly influences the likelihood of gene expression or repression involved in the development of DKD. Similarly, hyperglycemia modifies the expression of noncoding mRNA including microRNA, long noncoding RNA, and small RNA, which collectively modify the expression of coding genes and therefore the phenotype of the individual with DM [73–80]. Increasingly it is recognized that epigenetic modifications, particularly of mitochondrial DNA, may be maternally transmitted from mother to offspring and hence predispose to population shifts in the propensity to chronic disease.

A schematic view of the key processes involved in the development of progressive kidney disease is summarized in Figure 24.2.

Screening and Diagnosis of Diabetic Kidney Disease

Moderately increased urine protein is an independent risk factor for the development of CKD and GFR loss [81, 82], as well as cardiovascular (CV) morbidities and mortality [83–86]. Most guidelines recommend annual screening for moderately increased urine protein in individuals with DM [87–90]. Screening should begin 5 years after the onset of type 1 DM and at the diagnosis of type 2 DM because of the inability to establish the onset of type 2 DM with certainty. Annual assessments of both albuminuria and of kidney function are commonly used screening tools [88]. Although a 24 hour urine collection was originally accepted as the gold standard for urinary albumin measurement, it is inconvenient to most patients and accuracy is flawed by inadequate

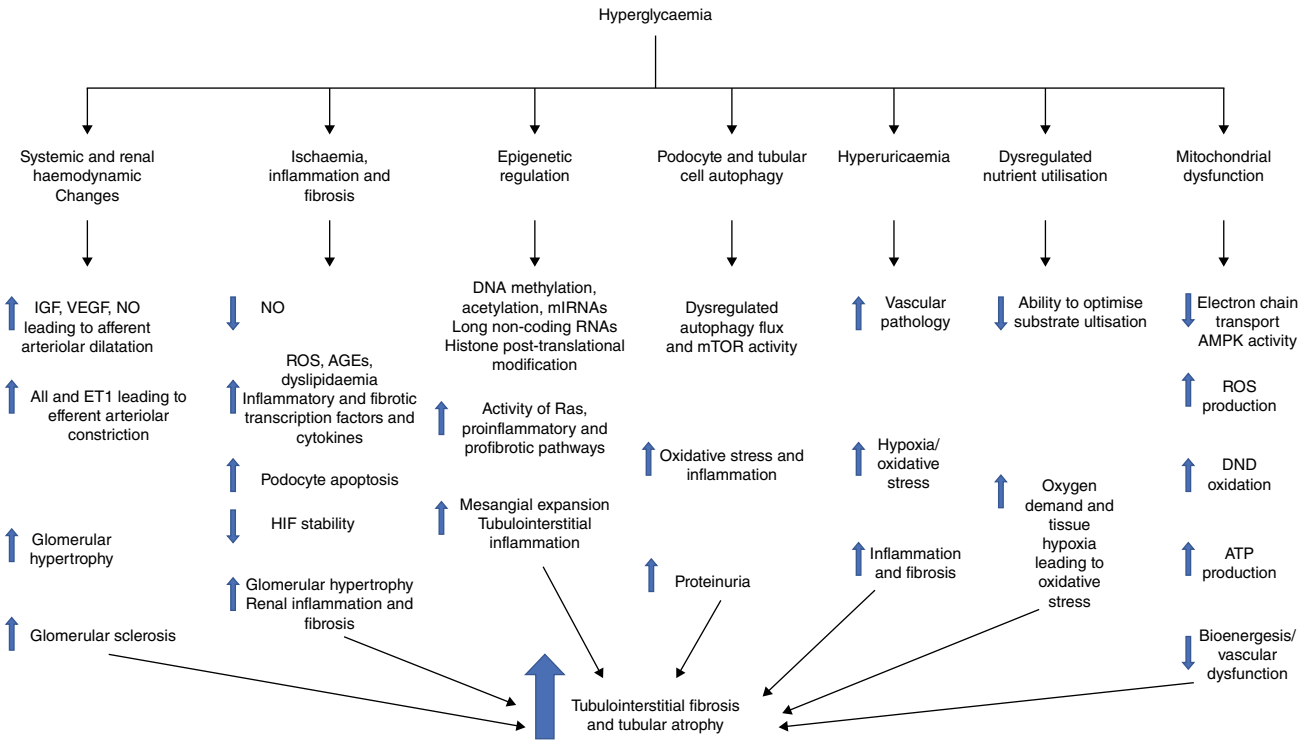

Figure 24.2 Schematic of the processes leading to tubulointerstitial fibrosis and tubular atrophy in DKD.
IGF: insulin-like growth factor
VEGF: vascular endothelial growth factor
NO: nitric oxide
ET1: endothelin-1
ROS: reactive oxygene species
AGEs: advanced glycation end products
miRNAs: microRNA
HIF: hypoxia inducible factor
ATP: adenosine triphosphate
DNA: deoxyribonucleic acid
RNA: ribonucleic acid

collection. Early-morning (or indeed random) urine assessment of the albumin-to-creatinine ratio (uACR) is now commonly used as a screening tool for the detection of DKD [88]. The random measurement of uACR has an inherent day-to-day variability (30–40%) [91], and may be elevated by factors independent of kidney disease, including strenuous exercise within 24 hours of measurement, urinary tract infection, menstruation, heart failure, marked hyperglycemia, and drugs, e.g. nonsteroidal anti-inflammatory drugs (NSAIDs). Therefore, an elevated uACR should be confirmed in the absence of urinary tract infection with two additional early-void specimens collected 3–6 months apart (Figure 24.3).

Although 24-hour collections are not commonly performed for the screening of DKD, they are useful when there is doubt about the accuracy of an estimated glomerular filtration rate (eGFR) (e.g. in populations where eGFR has not been validated such as where muscle mass is low) or when uACRs vary widely. Occasionally, 24-hour urine collections are also used

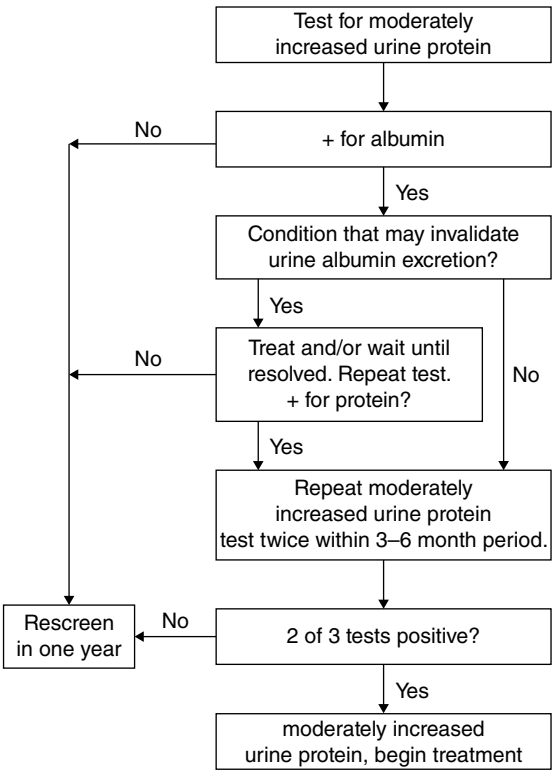

Figure 24.3 Screening for moderately increased urine protein recommended by American Diabetic Association (ADA) [89].

to estimate daily dietary sodium and protein intake in individuals with DKD and refractory edema or hypertension.

The evidence for the utility of eGFR alone as a screening test for CKD in diabetes is unclear. The eGFR can be calculated using either the Modification of Diet in Renal Disease (MDRD) equation [92] or the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula [93]. Both equations perform well when the GFR is <60 ml/min/1.73 m^2 [92], but the CKD-EPI is more accurate at higher levels of kidney function [93]. Many patients with diabetes and classical "diabetic nephropathy" may have high-normal GFRs, particularly in the early stages of DKD. Therefore, progressive CKD is best determined by the slope of sequential eGFR measurements, rather than a single estimate. As alluded to above, other markers of kidney damage (e.g. albuminuria) are additionally required to detect early stages of CKD. The eGFR is useful for assessing progressive changes in kidney function but should not be used in situations where kidney function is changing rapidly, such as acute kidney injury (AKI) that can be observed in infection, hypotension or volume depletion.

Up to 52% of Japanese [94] and 55% of Australians [95] with type 2 DM had an eGFR of less than 60 ml/min and no evidence of moderately increased urine protein. In an Italian multicenter study 57% of patients with type 2 DM had an eGFR of less than 60 ml/min and normoalbuminuria, and had a significant risk of cardiovascular disease (CVD), although this was lower than if albuminuria and kidney impairment coexisted [96]. Porrini et al. have summarized the incidence of normoalbuminuric DKD to vary between 14% and 57% [97]. Hence CKD in patients with DM is likely to have multiple etiologies, including classical DKD. Despite this, an increase in urinary albumin, a decrease in eGFR or both in individuals with DM should reflect a diagnosis of DKD. In patients with DM, CKD should be attributed to diabetes if: i) severely increased proteinuria (previously known as macroalbuminuria) in the prescence of other microvascular complications ii) moderately increase proteinuria (previously known as microalbuminuria is present with either diabetic retinopathy, or in patients with type 1 DM of at least 10 years' duration. Other causes of CKD should be considered if any of the features listed in Table 24.3 is present. A kidney biopsy may be warranted in some cases for confirmation of diagnosis.

Table 24.3 Features indicative of a potential alternative diagnosis other than DKD.

- Absence of diabetic retinopathy
- Low or rapidly decreasing GFR
- Rapidly increasing proteinuria or nephrotic syndrome
- Refractory hypertension
- Presence of active urinary sediment, e.g. persistent microscopic hematuria
- Signs or symptoms of other systemic disease
- >30% reduction in GFR within 2–3 months after initiation of an ACE inhibitor or ARB

DKD: diabetic kidney disease
GFR: glomerular filtration rate
ACE: angiotensin-converting enzyme
ARB: angiotensin II receptor blockers

Prevention, Treatment, and Follow-up of Diabetic Kidney Disease

Lifestyle and Multifaceted Approach to Prevent and Treat DKD

Lifestyle interventions such as reduced salt intake, weight loss, physical exercise, and supplementation with polyunsaturated fats have been shown to improve glycemic control, lower blood pressure (BP), reduce albuminuria, and change metabolic risk profiles in the general population as well as in individuals with diabetes and CKD [98–101]. However, there is no evidence that lifestyle modifications reduce the risk of DKD or slow its progression. Dietary sodium restriction has been shown to reduce BP and albuminuria, and enhance the response to RAAS inhibition [102–104]. However, optimal dietary sodium intake in DKD remains controversial, with observational studies showing a benefit [105] or conversely a detrimental effect on wellbeing and mortality [104, 106, 107]. In reality, multiple risk factors are managed concurrently in patients with diabetes and kidney disease. In the STENO study, 80 Danish patients of European descent with type 2 DM and moderately increased urine protein were randomly assigned to receive conventional treatment in accordance with national guidelines and another 80 to receive intensive treatment, with a stepwise implementation of behavior modification and pharmacologic therapy that targeted hyperglycemia, hypertension (RAAS blockade), dyslipidemia, and moderately increased urine protein, along with secondary prevention of CVD with aspirin. The outcomes were first reported in 2003 with a mean follow-up of 7.8 years [108, 109]. Patients receiving intensive therapy had a significantly lower risk of CVD (hazard ratio [HR] 0.47, 95% confidence interval [CI] 0.24–0.73), nephropathy (HR 0.39, 95% CI 0.17–0.87), retinopathy (HR 0.42, 95% CI 0.21–0.86), and autonomic neuropathy (HR 0.37, 95% CI 0.18–0.79) compared to those receiving a standard approach. Patients in the intensive arm showed a mean decrease in albuminuria and lower incidence of progression from moderately to severely increased urine protein (but not for the development of kidney failure) [109] and a reduction in the composite outcome of CVD events or death by about 50% when compared to the group treated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with standard therapy. After 7.8 years, the study continued as an observational follow-up with all patients receiving treatment as for the original intensive-therapy group, and recently reported a 21.2 years follow-up ($n = 22$ conventional group, $n = 42$ intensive group) that shows a median of 7.9 years of gain of life mainly driven by time free from incident CVD [110]. Median time before first CV event after randomization was 8.1 years longer in the intensive-therapy group ($P = 0.001$). Microvascular complications were study predefined tertiary endpoints. Progression of retinopathy was decreased by 33%, autonomic neuropathy was decreased by 41%, and progression to diabetic nephropathy (severely increased urine protein) was reduced by 48% in the intensive-therapy group when compared to the conventional groups. Ten patients in the conventional-therapy groups versus five patients in the intensive-therapy group progressed to kidney failure ($P = 0.061$). The nonfatal endpoints and causes of death were adjudicated by an external endpoint committee blinded for treatment allocation.

The Look AHEAD (Action for Health in Diabetes) multicentre trial is the largest randomized trial to date evaluating the efficacy of a physical activity and dietary control intervention (targeting a ≥7% weight loss) in older obese adults with type 2 DM. The study randomly assigned 5145 obese participants with type 2 DM to either intensive lifestyle intervention ($n = 2570$) or standard diabetes support and education ($n = 2575$). Intensive lifestyle intervention was designed to achieve and maintain weight loss through reduced caloric consumption and increased physical activity (a minimum of 175 min/week of unsupervised exercise). Major CV event rates were not significantly different in the two groups, which resulted in early termination of the study. After a median of 8.0 years of follow-up, the study demonstrated slower progression of CKD in the intensive lifestyle intervention group than patients in the comparator group. The incident CKD rate was 0.91 cases per 100 person-years in the standard group and 0.63 per 100 person-years in the intensive lifestyle group (difference 0.27 cases per 100 person-years, HR 0.69, 95% CI 0.55–0.87, $P = 0.0016$) [111]. The Intensive lifestyle intervention group achieved significantly greater and more sustained improvements secondary outcomes, including weight loss, improved cardiorespiratory fitness, improved glycemic control, BP, and lipids with fewer medications, as well as decreased rate of sleep apnea, retinopathy, depression, sexual dysfunction, urinary incontinence, and knee pain, plus better physical mobility maintenance and quality of life, with lower overall healthcare costs. There were no safety signals suggestive of kidney-related adverse events.

These studies are limited by the difficulty in attributing which facets of the intervention are associated with reduced risk. Despite the low-level evidence that studies using a multipronged approach to risk-factor management provide, the importance of addressing multiple risk factors needs to be considered for renoprotection but also for benefits on mortality and cardiovascular events, which are more likely to occur in patients with DKD than is kidney failure [112–114]. The Kidney Disease Improving Global Outcomes (KDIGO) Guideline 2020 [115] recommended moderately intensity exercise in people with diabetes and CKD. Recently, a new study by Cohen et al [116] compared bariatric surgery (laparoscopic surgery) versus standard care (non-surgery intervention) in 100 patients with type 2 DM and CKD stages G1-G3, during a follow-up of 2 years. The study reported zero events for mortality (both all-cause and cardiovascular) and no cardiovascular events. However, bariatric surgery improved remission of albuminuria (<30 mg/g) in participants who received bariatric surgery compared to standard of care (Relative risk (RR) 1.44 , 95%CI 1.03, 2.02).

Glycemic Control

Tight sugar control is critical, and hyperglycemia can cause organ complications. Therefore, optimal glycemic control is integral to the management of DKD. Regardless of the underlying treatment, glycated hemoglobin HbA1c: glycated haemoglobin levels >7.0% (53 mmol/mol) are associated with a significantly increased risk of both microvascular and CV complications [7, 117,118]. These studies show a curvilinear relationship between HbA1c and diabetes complications, with no apparent threshold of benefit, although the absolute reduction in risk was much at lower HbA1c levels. Most of the evidence comes from studies of intensive glycemic control in people with type 1 and 2 DM and early CKD. The evidence for the risks and benefits of intensive glycemic control is scant for more advanced stages of CKD, including individuals receiving dialysis or kidney transplant recipients.

The Diabetes Control and Complications Trial (DCCT) in type 1 DM [6], the Kumamoto trial [119], and the United Kingdom Prospective Diabetes Study (UKPDS) [117,120] in patients with type 2 DM confirmed that improved glycemic control significantly reduced the risk of microvascular complications, but had no significant effect on CV outcomes. Subsequent observational long-term follow-up after termination of both the DCCT and UKPDS studies showed a persistence of significant microvascular benefits and also demonstrated the emergence of a beneficial effect on CV outcomes attributed to intensive glycemic control. In the DCCT cohort, there was a significant reduction in CV outcomes (42%), nonfatal myocardial infarct (MI), stroke, and CV death (57%) as well as all-cause mortality (33%) in previously intensively treated participants compared with those who were previously in the standard arm [121–123]. Similarly, there was a significant reduction in MI (15–33%) and all-cause mortality (13–27%) in the UKPDS cohort in participants who

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

had been originally randomized to intensive treatment [124].

The Action to Control Cardiovascular Risk in Diabetes (ACCORD), Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE), and Veterans Affairs Diabetes Trial (VADT) are three major trials that examined the effect of intensive glycemic control on people with long-standing type 2 DM. The ACCORD trial randomly assigned 10 251 participants with type 2 DM who had either an established CVD history or multiple risk factors for CVD to intensive therapy targeting an HbA1c <6.0% (42.1 mmol/mol) or standard therapy targeting an HbA1c level of 7.0–7.9% (53–62.8 mmol/mol) [125]. The mean age of participants was 62 years and the mean duration of diabetes was 10 years. A difference in HbA1c was rapidly obtained and maintained throughout the trial at 6.4% (46.4 mmol/mol) and 7.5% (58.5 mmol/mol) in the intensive and standard therapy groups, respectively. The primary composite major CV outcomes (nonfatal MI, nonfatal stroke, or death from CV causes) were not different between two arms (HR 0.90, $P = 0.16$). The glycemic control portion of the trial was prematurely terminated after 3.5 years due to higher mortality in the intensively treated arm. Intensive glycemic control arm showed a 32% reduction in the development of incident of severely increased urine protein (2.7% vs. 3.9%) and a 21% reduction in the development of incident of moderately increased urine protein (12.5% vs. 15.3%) [125, 126]. However, an observational follow-up of the surviving participants in the ACCORDION study ($n = 8601$) over a median of 8.8 years showed a neutral long-term effect of intensive glucose control on the composite CV outcome and all-cause mortality (HR 1.01, CI 0.92–1.10) [127]. In the same follow-up study, intensive glycemic control significantly reduced the development of severely increased urine protein (HR 0.68, CI 0.59–0.77) but had no impact on doubling of serum creatinine or need of dialysis [128].

The ADVANCE study was a 2×2 factorial designed randomized control trial randomly assigning 11 140 participants to standard (targeting HbA1c based on local guidelines) or intensive glucose control therapy aimed at reducing HbA1c to ≤6.5% (47.5 mmol/mol) [23]. Participants were ≥55 years of age with a history of major CV or microvascular disease or at least one other risk factor for CVD. The mean duration of diabetes was 8 years. After a 5-year follow-up, the mean achieved HbA1c was 6.5% (47.5%) in the intensive group and 7.3% (56.3 mmol/mol) in the standard group. The primary outcome was a composite of microvascular events (nephropathy and retinopathy) and CV disease defined by major adverse CV events. There was a significant reduction in the incidence of major microvascular events in the intensive arm, largely driven by a 21% relative reduction in nephropathy, including new or worsening nephropathy and kidney failure. The number of participants needed to treat over 5 years to prevent one kidney failure event ranged from 410 in the overall study to 41 participants with severely increased urine protein at baseline. Thus, improved glucose control improved major kidney outcomes in patients with type 2 DM [129]. However, the small number of kidney failure events observed during the trial limited the strength of the conclusion [129]. There was no reduction in major CV events or all-cause mortality in the intensive glucose lowering either during the in-trial period or observational follow-up of a median 5.4 years [130]. In the post-trial observational follow-up ADVANCE-ON study, there was a significant reduction in the risk of kidney failure with intensive glucose lowering that was observed during the in-trial period (7 vs. 20 events, HR 0.35, 95% CI 0.15–0.83, $P = 0.02$) that persisted after a total of 9.9 years of follow-up (29 vs. 53, HR 0.54, 95% CI 0.34–0.85, $P < 0.01$) [129, 130]. The patients who appear to benefit most from intensive glycemic control are those with preserved kidney function (early stages of CKD) and those with better blood pressure control at baseline (systolic BP <140 mmHg). This also shows that CKD stages at baseline did not affect the impact of intensive glucose lowering on mortality or major cardiovascular events [131].

Neither study demonstrated a reduction in CV events or mortality with intensive glycemic control. This raises the question of whether optimal HbA1c may differ for microvascular/renoprotection versus cardiovascular events. In addition, the safety of intensive glucose control in the presence of CKD has been questioned, with the ACCORD trial [132] reporting that its intensive glucose lowering strategy increased the risk of cardiovascular and all-cause death among participants with CKD, but not in those with normal kidney function.

A smaller VADT study randomly assigned 1791 United States military veterans with a mean duration of diabetes of 12 years and poor glycemic control (≥7.5% or 58.5 mmol/l) to either standard or intensive glucose lowering therapy, which aimed for an overall reduction in HbA1c levels by 1.5% [133]. The mean duration of diabetes was 12 years and the HbA1c levels achieved in the intensive and standard therapy groups were 6.9% (51.9 mmol/mol) and 8.4% (68.3 mmol/mol), respectively. During a median follow-up of 5.6 years, there was a nonsignificant reduction in the primary outcome (first occurrence of a major CV event), but the progression to albuminuria was significantly reduced in the intensive-treated group 17% vs. 35% standard-treated group after 2 years ($P = 0.05$). During an observational median follow-up of 9.8 years, the intensive-treated group had a significantly lower risk of the primary outcome (MI, stroke, new or worsening congestive heart failure [CHF], amputation for ischemic gangrene, or CV-related death) than did the standard therapy group (HR 0.83, $P = 0.04$), with an absolute reduction in risk of 8.6 major CV events

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. per 1000 person-years [134]. There were no differences in kidney failure between groups in the VADT [133] or VADT-F [134], its long-term follow-up study.

Data from a meta-analysis from 58 160 patients in 13 randomized controlled trials suggest that people with type 2 DM who receive intensive glucose-lowering therapy have a reduced risk of the composite major adverse cardiovascular events (MACE) and MI, with no significant effect on the risk of total mortality, cardiac death, stroke, and CHF [135]. A further meta-analysis examined intensive versus standard glycemic control in 27 391 adult patiants with type 2 DM and CKD from four randomized controlled trials (RCTs) and found the pooled odds ratio (OR) for the doubling of serum creatinine and need of dialysis were not statistically significant, i.e. 0.98, 95% CI 0.81–1.19, and 0.84, 95% CI 0.69–1.02, respectively. The pooled OR for the outcome of death from kidney failure was 0.62, 95% CI 0.39–0.98 [136].

Hypoglycemia is more common as lower HbA1c levels are targeted, and people with CKD are at an increased risk of hypoglycemia [137, 138]. In the ACCORD study, hypoglycemia in the intensively treated group was associated with an increase in mortality [125]. The frequency of severe hypoglycemia in these trials was two to three times higher in the intensive therapy groups and a higher mortality was reported in participants with one or more episodes of severe hypoglycemia in the ACCORD [30], ADVANCE [31], and VADT trials [25], irrespective of the different treatment arms in which individual participants were allocated. Therefore, it has been suggested that tight glycemic control with a target HbA1c of 6.0% may not be ideal for older/frail individuals or those with longer duration of diabetes, advanced coronary artery disease (CAD), and a known history of severe hypoglycemia. It also highlights individualized glycemic control targeting, with patient education, and monitoring for hypoglycemic episodes should be an important component of management plans in patients with DKD.

Monitoring of glycemic control in DKD can be problematic. HbA1c is most commonly used but is influenced by shortened red blood cells (RBCs) survival in patients with DKD in the uremic millieu [139, 140], use of erythropoietin, carbamylation of hemoglobin [141], and mechanical destruction of RBCs on dialysis. Thus, clinicians may often need to rely more on random or continuous home blood glucose monitoring, which raises practical and cost challenges. Alternatives to HbA1c such as fructosamine, glycated albumin, and 1,5-anhydroglucitol (1,5-AG) have been proposed. These biomarkers have been shown to reflect glycemic control in CKD and also post-prandial glucose fluctuations. Serum 1,5-AG may be useful for estimating within-day glucose variations. However, each has its inherent limitations [142] and no relationship to the development or limiting the progression of DKD has been demonstrated. Evidence from adequately powered clinical trials is required to determine whether any of these monitoring tools provide superior to HbA1c in patients with DKD.

Pharmacotherapy for Glucose Lowering in DKD

Slowing the progression of DKD has been the subject of both primary and secondary endpoints in studies of patients with DM. Initial studies were primarily targeted to lower blood glucose and/or blood pressure. Subsequently, specific studies were undertaken to assess the benefit of interrupting the renin angiotensin system in patients with DKD, with or without tight glycemic control. Collectively these studies have established that current best practice includes interruption of the renin angiotensin system to slow progression of kidney disease [143, 144].

The requirement of the Food and Drug Administration (FDA) to undertake cardiovascular endpoints in drugs being brought to market for glycemic control has increased our knowledge of potential kidney benefits in the diabetic population when specific interventions are used to improve glycemic control. Although currently available data reflect secondary endpoints, studies adequately powered to demonstrate kidney benefits of agents primarily developed for glycemic control are underway. More recently therapies have been trialed to interrupt specific pathways considered to be of key importance in the development of DKD.

Sodium-Glucose Linked Co-transport-2 Inhibitors

The combined sodium-glucose linked co-transport-1 and -2 (SGLT1 and 2) inhibitor phlorizin was initially isolated from the bark of apple trees in 1835. It was recognized soon after that the compound caused glycosuria, polyuria, and weight loss. However, interest in inhibiting tubular reabsorption of glucose as a potential treatment for DM did not emerge till the 1970s with discovery of the location of SGLT transporters in the kidney. Phlorizin was not pursued as a treatment for hyperglycemia due to poor oral absorption and concurrent blockade of SGLT1, resulting in diarrhea and gastrointestinal side effects due to inhibition of intestinal glucose and galactose absorption. As SGLT2 is responsible for more than 90% of glucose reabsorption in the proximal tubule of the kidney, specific SGLT2 inhibitors were developed. Clinical trials initially focused on the efficacy of glycemic control in patients with type 2 DM. Given the glucose-lowering effects are dependent on glomerular filtration delivering glucose to the tubular lumen, where the SGLT2 transporters are situated, initial studies did not include patients with more than mild degrees of kidney impairment. Two

large cardiovascular (CV) endpoint trials have been reported to date in patients with type 2 DM at high risk for future cardiovascular events. Both the EMPA-REG [145] and CANVAS/CANVAS R trials [146] showed an impressive reduction in important cardiovascular endpoints, but importantly secondary analyses of kidney endpoints in both studies showed a significant and remarkably similar benefit on kidney-specific outcomes in this high-risk population. Specifically, of the 7020 patients studied in EMPA-Reg, approximately 1800 had eGFR <45 ml/min, 750 had severely increased urine protein, and 80% were on renin-angiotensin system blockers. Overall the study demonstrated a 39% reduction in new-onset or worsening of existing nephropathy (HR 0.61, 95%CI 0.53–0.7), a 46% reduction in the composite outcome of doubling of serum creatinine, initiation of kidney replacement therapy, and death due to kidney disease in the empagliflozin group (HR 0.61, 95% CI 0.53–0.7). The impact of empagliflozin on the primary endpoint was not diminished in patients with CKD compared to those without it (MACE HR 0.88, CV death HR 0.78, heart failure HR 0.59, all-cause mortality HR 0.80, no signal of MI, stroke) [147].

Similarly, in the CANVAS study the composite outcome of sustained doubling of serum creatinine, kidney failure, and death from kidney causes occurred less frequently in the canagliflozin group compared with the placebo group (HR 0.53, 95% CI 0.33–0.84), with consistent findings across prespecified patient subgroups. Annual eGFR decline was slower (slope difference between groups 1·2 ml/min/1.73 m^2 per year, 95% CI 1.0–1.4) and mean uACR was 18% lower (95% CI 16–20) in participants treated with canagliflozin than in those treated with placebo [148].

The DECLARE-TIMI58 study compared dapagliflozin with placebo in >17 000 individuals with type 2 DM and variable risk for CVD. The outcomes were reported in a scientific session at the American Heart Association (AHA) meeting in November 2018 and indicate that dapagliflozin is noninferior but not superior for reducing MACE in patients with this cohort. The composite rate of cardiovascular death or hospitalization for heart failure was 17% lower for patients receiving dapagliflozin compared with those who received placebo (4.9% vs. 5.8%). Kidney events and predefined composite outcomes (defined as new kidney failure, eGFR decrease by at least 40% to less than 60 m/min/1.73 m^2, or death from kidney or CVD) were 23% lower in the dapagliflozin group (4.3% vs. 5.6%, $P < 0.05$, compared to placebo) [149].

The mechanism of action benefit for this class of drug for both cardiac and kidney outcomes has been widely discussed and potential mechanisms are detailed in Figure 24.4.

Clearly these results are derived from secondary endpoints of studies primarily powered to determine CV outcomes. The CREDENCE study was designed to determine the efficacy and safety of canagliflozin versus placebo at preventing clinically important kidney and cardiovascular outcomes in patients with diabetes and established kidney disease [151]. CREDENCE randomized 4401 adults with type 2 DM, eGFR ≥30 to <90 ml/min/1.73 m^2, and severely increased urine

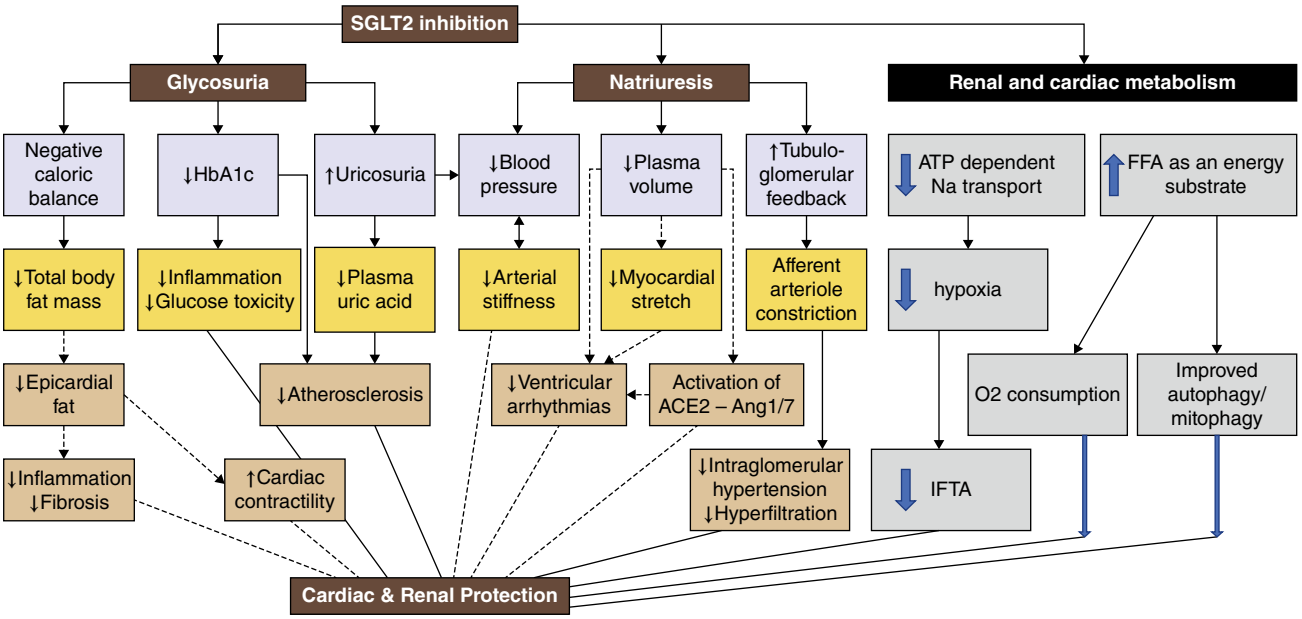

Figure 24.4 Proposed mechanisms of benefit for cardiovascular and kidney outcomes with the use of SGLT2 inhibitors. *Source:* Adapted from Rajasekeran et al. [150].

protein (uACR >300 to ≤5000 mg/g) with a median follow-up of 2.62 years. The CREDENCE study was terminated early on the advice of the Data Safety Monitoring Committee because of the magnitude of efficacy in the intervention arm, which found a 30% lower risk of the primary composite endpoint is kidney failure, doubling of serum creatinine, and kidney or CV death in the canagliflozin arm compared to standard of care (HR 0.70, 95% CI 0.59, 0.82) [151].

Because the mechanism of benefit of SGLT2 inhibitors appears to be somewhat independent of glycemic control, several studies have been developed and undertaken to assess whether these drugs have renoprotective benefits in patients with type 1 DM and in patients with non-DKD. DAPA-CKD study [152], compared dapagliglozin 10 mg with placebo in 4304 participants with CKD with or without diabetes. The study found a decrease in the primary composite outcome of sustained decline in eGFR at least 50%, kidney failure, kidney-related or CV mortality in both participants with type 2 DM (HR 0.64, 95% CI 0.52,0.79) and those without diabetes (HR 0.50, 95% CI 0.35, 0.72). Further studies are also planned in the CKD population without diabetes (EMPA- Kidney, http://ClinicalTrials.gov, Identifier NCT03594110). A Cochrane systematic review which is undergoing an update [153] reported that SGLT2 inhibitors decrease all-cause mortality (17 studies, 31523 participants; HR 0.88, 95% CI 0.82 to 0.95; $I^2 = 0\%$, *high certainty evidence*), cardiovascular mortality (12 studies, 46442 participants; HR 0.90, 95% CI 0.83 to 0.98; $I^2 = 0\%$, *high certainty evidence*), major adverse cardiovascular events 3-point (MACE-3P) (10 studies, 40866 participants; HR 0.88, 95% CI 0.82 to 0.95; $I^2 = 28\%$, *high certainty evidence*), acute kidney injury (AKI) (8 studies, 24187 participants; HR 0.76, 95% CI 0.66 to 0.89; $I^2 = 0\%$, *high certainty evidence*), and kidney composite outcome (8 studies, 34788 participants; HR 0.60, 95% CI 0.52 to 0.70; $I^2 = 46\%$, *high certainty evidence*), compared to placebo. SGLT2 inhibitors probably increase diabetic ketoacidosis (9 studies, 31442 participants; HR 2.22, 95% CI 1.18 to 4.16; $I^2 = 6\%$, *moderate certainty evidence*) and genital infection (13 studies, 14843 participants; HR 2.6, 95% CI 2.02 to 3.34; $I^2 = 0\%$, *moderate certainty evidence*) compared to placebo (Table 24.4).

Glucagon-like Peptide-1 Receptor Agonists

Glucagon-like peptide-1 (GLP-1) agonists have been shown in experimental models to reduce albuminuria, decrease mesangial expansion and glomerular basement membrane

Table 24.4 SGLT2 versus placebo in people with type 2 diabetes mellitus and chronic kidney disease

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of Participants(No. of studies)	Quality of the evidence(GRADE)	Conclusions
All-cause mortality Mean follow-up: 37 months	HR 0.88 (0.82 to 0.95)	10 fewer per 1,000(from 16 fewer to 4 fewer)	31523 (17 studies)	High	SGLT2 inhibitors decrease all-cause mortality
Cardiovascular mortality Mean follow-up: 26 months	HR 0.90 (0.83 to 0.98)	7 fewer per 1,000(from 12 fewer to 1 fewer)	46442 (12 studies)	High	SGLT2 inhibitors decrease cardiovascular mortality
MACE-3P Mean follow-up: 31 months	HR 0.88 (0.82 to 0.95)	15 fewer per 1,000(from 23 fewer to 6 fewer)	40866 (10 studies)	High	SGLT2 inhibitors decrease MACE-3P
Kidney composite outcome Mean follow-up: 33 months	HR 0.60 (0.52 to 0.70)	39 fewer per 1,000(from 48 fewer to 29 fewer)	34788 (8 studies)	High	SGLT2 inhibitors decrease kidney composite outcome
AKI Mean follow-up: 30 months	HR 0.76 (0.66 to 0.89)	11 fewer per 1,000(from 15 fewer to 5 fewer)	24187 (8 studies)	High	SGLT2 inhibitors decrease AKI
Diabetic ketoacidosis Mean follow-up: 28 months	HR 2.22 (1.18 to 4.16)	37 more per 1,000(from 5 more to 92 more)	31442 (9 studies)	Moderate	SGLT2 inhibitors probably increases diabetic ketoacidosis
Genital infection Mean follow-up: 18 months	HR 2.6 (2.02 to 3.34)	14 more per 1,000(from 9 more to 21 more)	14843 (13 studies)	Moderate	SGLT2 inhibitors probably increases genital infections

AKI = Acute kidney injury; CI = Confidence interval; HR = Hazard ratio; MACE-3P = Major adverse cardiovascular events 3-point; SGLT2 = Sodium-glucose cotransporter-2

thickness, confer endothelial protection, and restore podocyte function. The main factors mediating renoprotection include inhibition of protein kinase B signaling, inhibition of NAD(P)H oxidative signaling, increased cAMP and protein kinase A, and reduction in inflammatory cell infiltration and ICAM-1 expression [154, 155]. GLP-1 receptor agonists have also been shown to normalize glomerular hyperfiltration in diabetes through inhibition of atrial natriuretic peptide, which limits afferent arteriolar vasodilation, and inhibition of endothelin, which limits efferent arteriolar vasoconstriction [156]. These positive effects have been replicated in clinical trials with lira- [155], sema- [156], and dula-glutides and lixisenatide all demonstrating a reduction in albuminuria; liraglutide and duraglutide have shown a reduction in the decline of eGFR. Both CV and kidney benefits persist in patients with an eGFR of <60 ml/min.

The secondary kidney outcomes of the LEADER study were reported in 2017 [157]. Of the 9340 patients randomized 20.7% had an eGFR of between 30 and 59 ml/min (stage 3 CKD), 26.3% had moderately increased urine protein, and 10.5% had macroproteinuria. The kidney outcome, i.e. a composite of new-onset persistent severely increased urine protein, persistent doubling of the serum creatinine level, kidney failure, or death due to kidney disease, occurred in fewer participants in the liraglutide group than in the placebo group (268 of 4668 patients vs. 337 of 4672, HR 0.78, 95% CI 0.67–0.92, $P = 0.003$). This result was driven primarily by the new onset of persistent severely increased urine protein, which occurred in fewer participants in the liraglutide group than in the placebo group (161 vs. 215 patients, HR 0.74, 95% CI 0.60– 0.91, $P = 0.004$). Liraglutide administration was associated with a significant reduction in albuminuria, with nearly 25% lower likelihood of development of severely increased urine protein, and with the uACR approximately 20% lower among treated people, regardless of the baseline level of eGFR. No significant effect on eGFR was found with liraglutide, although both those receiving and not receiving the drug showed a decline in eGFR from approximately 75 to 65 ml/min/1.73 m^2 over the 48-month period of observation. In subgroup analyses presented at the EASD in October 2018, it was demonstrated that the cardiovascular benefit was more significant in patients with an eGFR between 30 and 60 ml/min/1.73m^2 compared to those with higher levels of eGFR [158].

Similarly, in the Trial to Evaluate Cardiovascular and Other Long-term Outcomes with Semaglutide in Subjects with Type 2 Diabetes trial (SUSTAIN-6), persistent severely increased urine protein developed among 2.7% of those receiving semaglutide, but among 4.9% of those receiving placebo. Fewer subjects treated with semaglutide overall reached the composite endpoint of severely increased urine protein, doubling of serum creatinine to reach an eGFR of less than 45 ml/min/m^2 or persistent renal replacement therapy. Overall the HR of developing new or worsening nephropathy was 0.64 (CI 0.46–0.88, $P < 0.005$) [159].

The ELIXA trial investigated the effects of lixisenatide in acute coronary syndrome (ACS) [160]. Although no benefit was observed in CV outcomes, secondary analyses demonstrated a reduction in severely increased urine protein in the lixisenatide-treated patients ($P < 0.01$) with a modest reduction in moderately increased urine protein ($P < 0.05$) [161]. Despite no benefit in eGFR being observed with lixisenatide treatment in the overall population, in the subgroup with an eGFR of between 30 and 59 ml/min/1.73m^2 a slowing in the rate of decline in eGFR was observed [157].

AWARD-7 assessed the effect of dulaglutide versus insulin glargine in a study population enriched with DKD (mean eGFR 38 ml/min/1.73 m^2). A slowing in the rate of decline of GFR, measured by cystatin C and a reduction in albuminuria, was observed in patients treated with either 1.5 or 1.75 mg of dulaglutide/day. The benefit for dulaglutide was more pronounced in patients with severely increased urine protein compared to those with moderately increased urine protein. These benefits were independent of glycemic control. A greater weight loss and lower incidence of hyperglycemia were also observed in the dulaglutide-treated patients [162]. A Cochrane systematic review which is undergoing an update [153]reported that GLP-1 agonists decrease all-cause mortality (6 studies, 3363 participants; HR 0.76, 95% CI 0.62 to 0.93; $I^2 = 0\%$, *high certainty evidence*), cardiovascular mortality (4 studies, 3138 participants; RR 0.70, 95% CI 0.54 to 0.92; $I^2 = 0\%$, *high certainty evidence)*, probably decrease MACE-3P (6 studies, 31245 participants; HR 0.83, 95% CI 0.75 to 0.93; $I^2 = 55\%$, *moderate certainty evidence*), decrease kidney composite outcome (2 studies, 4357 participants; HR 0.83, 95% CI 0.74 to 0.93; $I^2 = 0\%$, *high certainty evidence*), and probably make little or no difference on AKI (2 studies, 2482 participants; HR 0.83, 95% CI 0.62 to 1.11; $I^2 = 0\%$, *moderate certainty evidence*) compared to placebo or standard care (Table 24.5).

Dipeptidyl Peptidase 4 Inhibitors

Dipeptidyl peptidase (DPP) inhibitors are increasingly used in the CKD population to achieve optimal glycemic control. DPP-4 is involved in the development of kidney fibrosis process via catalytic-dependent or -independent mechanisms [163]. DPP-4 exhibits several important biological functions that predict that inhibition of DPP-4

Table 24.5 GLP-1 versus placebo/standard care in people with type 2 diabetes mellitus and chronic kidney disease

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of Participants (No. of studies)	Quality of the evidence(GRADE)	Conclusions
All-cause mortality Mean follow-up: 5 months	HR 0.76 (0.62 to 0.93)	28 fewer per 1,000(from 45 fewer to 8 fewer)	3363 (6 studies)	High	GLP-1 agonists decrease all-cause mortality
Cardiovascular mortality Mean follow-up: 20 months	RR 0.70 (0.54 to 0.92)	25 fewer per 1,000(from 38 fewer to 7 fewer)	3138 (4 studies)	High	GLP-1 agonists decrease cardiovascular mortality
MACE-3P Mean follow-up: 44 months	HR 0.83 (0.75 to 0.93)	42 fewer per 1,000(from 62 fewer to 17 fewer)	31245 (6 studies)	Moderate	GLP-1 agonists probably decrease MACE-3P
Kidney composite outcome Mean follow-up: 4.6 years	HR 0.83 (0.74-0.93)	12 fewer per 1,000(from 22 fewer to 0 fewer)	4357 (2 studies)	High	GLP-1 agonists decrease kidney composite outcome
AKI Mean follow-up: 26 months	HR 0.83 (0.62 to 1.11)	1 fewer per 1,000(from 3 fewer to 1 more)	2482 (2 studies)	Moderate	GLP-1 agonists probably make little or no difference on AKI

AKI = Acute kidney injury; CI = Confidence interval; GLP-1 = glucagon-like peptide 1 receptor; HR = Hazard ratio; MACE-3P = Major adverse cardiovascular events 3-point; RR = Relative risk

should reduce inflammation and fibrosis. More than 30 potential substrates for DPP-4 have been identified, including GLP-1, glucose-dependent insulinotropic peptide (GIP), high mobility group protein 1 (HMGB1), brain natriuretic peptide, neuropeptide Y, and meprin [163–169]. DPP-4 and integrin-β1 interactions induce profibrotic cellular signaling and endothelial mesenchymal transition [170]. DPP4 inhibitors have experimentally been shown to be renoprotective, with in vitro and animal data suggestive of inhibition of inflammatory and fibrotic responses that would otherwise drive kidney injury [171–174]. DPP-4 inhibition induces miR-29, a key antifibrotic miR, integrin β1, and IFN-γ. Suppression of IFN-γ results in the induction of FGF 1, which induces miR-let-7. Increased levels of miR-let-7 suppress the expression of TGFbR1, resulting in the auto amplification of miR-29s [163].

Many preclinical studies have confirmed the potential renoprotective effects of DPP-4 inhibitors in multiple kidney injury models, including diabetic [175–178] and non-diabetic models of nephropathy [179–182]. Thus far, no clinical trial has revealed beneficial effects of DPP-4 inhibitors on kidney hard outcomes.

Smaller and retrospective clinical studies demonstrated a benefit in favor of DPP4 inhibitors reducing albuminuria [183], but cardiovascular endpoint studies where kidney outcomes have been reported have shown no benefit compared to that of placebo for saxagliptin (SAVOR-TIMI) [184], sitagliptin (TECOS) [185], alogliptin (EXAMINE) [186], or linagliptin. The CARMELINA trial compared DPP-4 inhibitor linagliptin against placebo for cardiovascular safety as specified by the FDA. The CARMELINA trial is unique as 60% of the participants had CKD, with patients enrolled down to an eGFR of 15 ml/min/1.73 m^2. Linagliptin did not increase the risk of CV events or heart failure and hence was deemed safe in individuals with DKD. Although linagliptin showed a significant reduced risk for progression to albuminuria (HR 0.86, 95% CI 0.78–0.96, $P < 0.0034$), it had no impact on the composite kidney endpoint of a sustained >40% reduction in eGFR, kidney failure, or death due to kidney disease (HR 1.04, 95% CI 0.89–1.22) [187]. A Cochrane systematic review which is undergoing an update [153] reported that DPP-4 inhibitors make little or no difference on all-cause mortality (9 studies, 11509 participants; HR 0.92, 95% CI 0.80 to 1.05; $I^2 = 0\%$, *high certainty evidence*), cardiovascular mortality (4 studies, 7569 participants; HR 0.98, 95% CI 0.83 to 1.15; $I^2 = 0\%$, *high certainty evidence*), MACE-3P (4 studies, 14441 participants; HR 1.00, 95% CI 0.92 to 1.10; $I^2 = 0\%$, *high certainty evidence*), kidney composite outcome (2 studies, 9555 participants; HR 1.08, 95% CI 0.89 to 1.31; $I^2 = 33\%$, *high certainty evidence*), and may make little or no difference on AKI (2 studies, 7112 participants; RR 0.95, 95% CI 0.73 to 1.24; $I^2 = 0\%$, *low certainty evidence*) compared to placebo (Table 24.6).

Metformin

Metformin is a widely used and effective hypoglycemic drug that remains the first line of treatment for individuals with type 2 DM. The mechanisms underlying improved glycemic control are complex and not fully understood. Metformin reduces hepatic gluconeogenesis and increases peripheral glucose sensitivity. Although not tested in clinical trials, experimental evidence suggests it may limit kidney disease via both AMP-activated protein kinase (AMPK)-dependent and AMPK-independent mechanisms and by inhibition of mitochondrial respiration [188]. Current guidelines recommend metformin monotherapy should be started when a diagnosis of type 2 DM is made (in different jurisdictions a failure of lifestyle interventions also needs to be demonstrated), unless there are contraindications [189, 190]. This recommendation is based on its efficacy in lowering HbA1c, its safety profile, affordability, negligible risk of hypoglycemia, and lack of weight gain. Compared to sulfonylureas, metformin monotherapy has comparable HbA1c-lowering effects, glycemic durability [191], lower risks of hypoglycemia [192], less weight gain [192, 193], and in observational studies a lower CV risk [193]. In the UKPDS, metformin was shown to confer CV benefit in newly diagnosed overweight included individuals with type 2 DM [194]. However, conflicting evidence from a meta-analysis of metformin trials has been presented [195, 196]. Metformin has well-documented gastrointestinal side effects. Hence, it is recommended to commence on low dose with gradual dose escalation based on tolerability. Metformin is associated with vitamin B12 deficiency and periodic testing of vitamin B12 levels should be considered, especially in those with anemia or peripheral neuropathy [197]. Combination glucose-lowering therapy is often recommended by guidelines with insulin, DPP-4 inhibitors, GLP-1 receptor agonists or SGLT2 inhibitors over other antihyperglycemic agents as these combinations are associated with less hypoglycemia and weight gain provided there are no contraindications or barriers to affordability or access [189, 190].

Adding metformin to insulin therapy may reduce insulin requirements and improve metabolic control in patients with type 1 DM. Evidence suggests the use of metformin, in addition to insulin therapy in type 1 DM, results in reduced insulin requirements [198], weight reduction [199], improvement in lipid profiles [200] but no improvement in glycemic control or CV outcomes [198, 200].

Metformin can lead to rises in serum lactate due to conversion of glucose to lactate by the intestinal mucosa and reduced uptake of lactate in the liver [201–203]. The molecular weight (MW) of metformin is 129.16 g/mol [204] (MW of creatinine is 113.12 g/mol). Metformin is nonprotein-bound and is primarily eliminated unchanged by the kidneys and therefore CKD is associated with higher drug levels that could increase the risk of lactic acidosis [205, 206]. However, significant lactic acidosis associated with metformin use is rare. A small

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nonplacebo-controlled study involving 35 patients on automated peritoneal dialysis with insulin-dependent type 2 DM, receiving 0.5–1 g daily dose of metforminm, found no incidence of lactic acidosis, although a higher number of individuals receiving metformin had plasma lactate levels >2 mmol/l [204]. The FDA recently revised the label for metformin to reflect its safety in patients with eGFR ≥30 ml/min/1.73 m^2 [207].

In a meta-analysis of 347 comparative trials and cohort studies there was no evidence to suggest the use of metformin in CKD stage 3b or higher enhances the risk for lactic acidosis. In fact, no cases of lactic acidosis were identified in 70 490 patient-years of metformin use [208]. Individual studies have reported crude incidences of 3.3–10.4 cases per 100 000 patient-years [209–212], which is comparable to rates of lactic acidosis in individuals with type 2 DM taking nonmetformin agents [210, 213]. In the only randomized control trial, Rachmani et al. randomly assigned 393 patients with type 2 DM with a serum creatinine of 130–200 μmol/l to continue or stop metformin [214]. The authors demonstrated a close correlation between serum creatinine and lactate levels ($r = 0.78$, $P < 0.001$), which was not shown in other studies [215, 216]. Hung et al. reported metformin use in 3254 patients with advanced CKD approaching kidney failure (creatinine >530 μmol/l) was not associated with a significantly greater risk of metabolic acidosis (adjusted HR 1.30, 95% CI 0.88–1.93) [217]. Richy et al. examined the Datalinkage records of 77 601 patients in UK treated with metformin for type 2 DM between 2007 and 2012 [211], and found no difference in the incidence of lactic acidosis in patients with more advanced CKD compared to those with normal kidney function. Eppenga et al. investigated a larger cohort of 223 968 patients with type 2 DM prescribed metformin between 2004 and 2012 [212], and reported no difference in incidence of lactic acidosis between metformin or nonmetformin users if eGFR ≥60 ml/min, but the risk was significantly higher for metformin users with an eGFR <60 ml/min (adjusted HR 6.37, 95% CI 1.48–27.5). Interestingly, the risk of lactic acidosis of those with eGFR 30–44 ml/min was comparable to those with an eGFR of 45–59 ml/min.

The existing evidence is largely extrapolated from studies involving participants with normal or mildly impaired kidney function. There is a lack of objective outcome data to guide the use of metformin in the CKD population itself and further studies are needed. For the CKD population, the question is not whether to start metformin but whether to continue. In patients who have been well maintained on metformin, particularly those who are overweight, the evidence supporting its routine withdrawal upon reaching an eGFR of 30 ml/min is equivocal [218–220].

Sulfonylureas

Sulfonylureas bind ATP-dependent K+ channels on cell membranes of the pancreatic beta cells which, through increasing intracellular calcium, leads to increased insulin secretion [221]. Sulfonylurea use in CKD requires careful attention to dosing to avoid hypoglycemia [222, 223]. However, if a sulfonylurea is to be added to metformin, gliclazide should be considered as first choice as it is associated with a lower risk of hypoglycemia [222, 224]. Glyburide is extensively metabolized in the liver into several active metabolites that are excreted by the kidney and is not recommended for use in CKD. Glipizide is metabolized by the liver into several inactive metabolites, and its clearance and elimination half-life are not affected by a reduction in eGFR, thus dose adjustments in patients with CKD are not necessary. Although glimepiride is associated with less hypoglycemia when compared with glyburide, it has similar rates of hypoglycemia when compared to other sulfonylureas. No studies have demonstrated a kidney benefit for the use of sulfonylureas, with conflicting data on CV events and mortality. A network meta-analyses of 14 464 patients concluded that gliclazide and glimepiride were associated with a lower risk of all-cause and cardiovascular-related mortality compared with glibenclamide [225]. A prospective cohort study from the UK Clinical Practice Research Datalink, using the prevalent new metformin user, matched 1 : 1 with patients adding or switching to sulfonylureas. The study looked at 77 138 metformin new users of whom 25 699 added or switched to sulfonylureas between 1998 and 2013. During a mean follow-up of 1.1 years, sulfonylureas were associated with an increased risk of myocardial infarction (HR 1.26, 95% CI 1.01–1.56), all-cause mortality (HR 1.28, 95% CI 1.15–1.44), and severe hypoglycemia (HR 7.60, 95% CI 4.64–12.44) compared with metformin monotherapy [226]. Given the lack of observational data to support a differentially positive effect in patients with DKD it is unlikely that sulfonylureas will be further studied.

Thiazolidinediones

Thiazolidinediones (TZDs) are a class of oral hypoglycemic agents that improve glycemic control primarily by decreasing insulin resistance, thus improving the insulin sensitivity of the liver and peripheral tissues. They have also been implicated in reducing pancreatic beta cell apoptosis, and are predominantly metabolized by the liver. Despite the demonstrated anti-inflammatory and antifibrotic effects in experimental models [227–230] and lack of a need for dosage adjustments in patients with CKD, TZD use is generally avoided in CKD due to side effects such as refractory fluid retention, a reported increase in heart failure, and increased fracture risk.

The PROspective pioglitAzone Clinical Trial (PROactive) study randomized 5238 high-risk subjects with type 2 DM with established macrovascular disease to pioglotazone or matching placebo [231]. In a mean follow-up of 34.5 months, the pioglitazone-treated group had fewer secondary endpoints (composite of all-cause mortality, nonfatal myocardial infarction, and stroke) (301 vs. 358, HR 0.84, 95% CI 0.72–0.98, $P = 0.03$) when compared with the placebo. The incidence of hospitalization with heart failure or mortality rates from heart failure did not differ between groups. In a follow-up analysis of the PROactive study, although pioglitazone (5.7%) was associated with more serious heart failure events during the study than placebo (4.1%) ($P = 0.007$), pioglitazone was associated with lower fatal/nonfatal MI (28% risk reduction [RR], $P = 0.045$) and ACS (37% RR, $P = 0.04$) compared to placebo in the subgroup of participants with significant heart failure [232]. A post hoc analysis investigated the relationship between CKD and incident CVD in this population as well as the effects of pioglitazone treatment on recurrent CVD. CKD, defined as an eGFR <60 ml/min per 1.73 m^2, was present in 597 (11.6%) of 5154 patients. More patients with CKD reached the primary composite endpoint (all-cause mortality, acute myocardial infarction (AMI), stroke, ACS, coronary/carotid arterial intervention, leg revascularization, or amputation above the ankle) than patients without CKD (27.5% vs. 9.6%, $P < 0.0001$) as well as secondary composite endpoint (defined above). A greater decline in eGFR was observed in the pioglitazone-treated group (between-group difference 0.8 ml/min/1.73 m^2/year) than with placebo [233].

The RECORD study randomized 4458 individuals with type 2 DM with inadequate control while on metformin or sulfonylurea in combination with rosiglitazone showed at 18 months that HbA1c reduction is similar between rosiglitazone added to metformin or sulfonylureas [234]. In a further interim analysis (3.75 years follow-up) the same group presented outcomes and deaths from cardiovascular causes in all 4447 subjects. Although there were no statistically significant differences between the rosiglitazone versus control groups regarding myocardial infarction and death from CV causes or all-cause, there were more people with heart failure in the rosiglitazone group than in the control group (HR 2.15, 95% CI 1.30– 3.57) [235]. The final analysis of the RECORD study, with a mean 5.5-year follow-up, showed that addition of rosiglitazone to glucose-lowering therapy in people with type 2 DM increased the risk of heart failure and fractures, especially in women. The addition of rosiglitazone to the therapeutic regimen of people with type 2 DM was not associated with reduced risk of overall cardiovascular morbidity or mortality compared with standard glucose-lowering medications. A meta-analysis that included 20 191 subjects with either prediabetes or type 2 DM who had CHF examined the risk of exacerbation of congestive cardiac failure (CCF) in those taking TZDs compared with control and found the risk of CCF was higher in people given TZDs (RR 1.72, 95% CI 1.21–2.4, $P = 0.002$). There was no heterogeneity of effect across the seven studies, suggesting that it is a class effect of TZDs. However, a higher rate of CV death was not observed [236]. There were no kidney outcomes reported in these studies. A Cochrane systematic review which is undergoing an update [153] reported that thiazolidinediones may make little or no difference on all-cause mortality (2 studies, 147 participants; RR 0.35, 95% CI 0.06 to 2.23; $I^2 = 0\%$, *low certainty evidence*) and heart failure (2 studies, 123 participants; RR 0.34, 95% CI 0.01 to 8.13; *low certainty evidence*), compared to placebo or control (Table 24.7).

Blood Pressure Lowering in DKD

Observational studies show a strong relationship between a higher level of BP and an increased risk of kidney failure and worsening kidney function in DKD. Optimal

Table 24.7 Thiazolidinediones versus placebo/control in people with type 2 diabetes mellitus and chronic kidney disease

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of Participants (No. of studies)	Quality of the evidence(GRADE)	Conclusions
All-cause mortality Mean follow-up: 25 weeks	RR 0.35 (0.06 to 2.23)	36 fewer per 1,000(from 52 fewer to 68 more)	147 (2 studies)	Low	Thiazolidinediones may make little or no difference on all-cause mortality
Heart failure Mean follow-up: 18 months	RR 0.34 (0.01 to 8.13)	11 fewer per 1,000(from 16 fewer to 114 more)	123 (2 studies)	Low	Thiazolidinediones may make little or no difference on heart failure
Kidney failure	-	-	-	-	No studies were found that looked at kidney failure

CI = Confidence interval; RR = Relative risk

BP control is accepted as an important therapy in the prevention and progression of CKD in diabetes, although the optimal targets for BP in patients DKD have not been determined [237–241].

The UKPDS study suggested that a target BP of <150/85 mmHg was associated with a reduction in microvascular events, including kidney outcomes [194]. In the Systolic Hypertension in Europe (Syst-Eur) trial, a target systolic BP of <150 mmHg was associated with a lower incidence of proteinuria among those with diabetes and in the overall study group was associated with fewer people developing a creatinine >177 mmol/l [242]. The Appropriate Blood Pressure Control in Diabetes (ABCD) normotensive study found that achieving a systolic BP of <130 mmHg was associated with fewer people developing moderately increased urine protein and reduced risk of progression from moderately to severely increased urine protein [243]. A study in type 1 DM found that a target mean arterial pressure of 92 mmHg (125/75) was associated with a reduction in proteinuria [244].

Intensive Versus Standard BP Lowering in DKD

The ACCORD BP trial examined whether an spontaneous bacterial peritonitis (SBP) of <120 mmHg in patients with type 2 DM at high CV risk provided greater cardiovascular protection than an SBP of 130–140 mmHg [245]. The study did not find a benefit in the primary endpoint (i.e. nonfatal MI, nonfatal stroke, and cardiovascular death) comparing intensive BP treatment (mean BP achieved 119/64 mmHg on 3.4 medications) with standard treatment (mean BP achieved 143/70 mmHg on 2.1 medications). Stroke was significantly reduced in the intensive BP treatment groups. The ACCORD BP study found less progression of proteinuria in the intensive BP lowering group, but this was associated with increased risk of AKI events [245]. A follow-up analysis found the intensive BP/intensive glycemia, intensive BP/standard glycemia, and standard BP/intensive glycemia groups all showed benefit for reducing the risk of major CVD when compared to the standard glycemia/standard BP control group in the BP trial [246].

In ADVANCE, the intensive BP intervention arm (a single-pill, fixed-dose combination of perindopril and indapamide) showed a significant reduction in the risk of the primary composite endpoint (major macrovascular or microvascular event) and in the risk of death from any cause and of death from cardiovascular causes [247]. Compared with the placebo group, the patients in the intensive BP lowering arm experienced an average reduction of 5.6 mmHg in SBP and 2.2 mmHg in diastolic blood pressure (DBP). The ADVANCE-ON study reported that the reductions in the risk of all-cause mortality in the intensive arm were attenuated but remained significant [130]. The Hypertension Optimal Treatment (HOT) trial included patients with and without diabetes and compared DBP targets of ≤90, ≤85, and ≤80 mmHg. Post hoc analyses found cardiovascular benefit with more intensive targets in the subpopulation with diabetes [248].

A meta-analysis of five RCTs enrolled 7312 adults with type 2 DM comparing intensive BP targets (upper limit of 130 mmHg systolic and 80 mmHg diastolic) with standard targets (upper limit of 140–160 mmHg systolic and 85–100 mmHg diastolic) and found no significant reduction in mortality or nonfatal MI. There was a statistically significant 35% RR reduction in stroke with intensive targets, but the absolute risk reduction was only 1% and intensive targets were associated with an increased risk for adverse events such as hypotension and syncope [249]. The threshold of BP lowering in diabetics with CKD remains controversial [250].

Pharmacotherapy for BP Lowering

RAAS Blockade

RAAS blockade using various drugs, including angiotensin converting enzyme (ACE) inhibitors, angiotensin receptor blockers (ARBs), direct renin inhibitors, and mineralocorticoid receptor antagonists have shown efficacy in animal models of DKD. In humans, RAAS inhibition has proved to be the single most effective therapy for slowing the progression of DKD.

The CAPTOPRIL study was the first large trial to examine the effect of ACE inhibitors on the progression of advanced DKD. The study randomly assigned 409 patients with type 1 DM, overt proteinuria (protein excretion ≥500 mg/day), and reduced kidney function to captopril 25 mg three times a day or matching placebo. There was a 48% reduction in risk for doubling of serum creatinine concentration and a 50% reduction in the composite endpoint of death, dialysis therapy, or transplantation [251]. This trial established the efficacy of ACE inhibitors independent of BP control in slowing the progression of DKD in patients with type 1 DM and overt proteinuria. The other trials using RAAS blockade in patients with type 1 DM including the (Renin-Angiotensin System Study [RASS] [252], Diabetic Retinopathy Candesartan Trial [DIRECT] -Prevent 1, and DIRECT-Protect 1) [253] failed to show that RAAS blockade prevented the development of moderately increased urine protein in those with normoalbuminuria at baseline.

The Effect of Irebesrtan in the Development of Diabetic Nephropathy in Patients With T2DM (IRMA-2) trial randomly assigned 590 patients with type 2 DM and moderately increased urine protein to irbesartan 150 mg daily,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

irbesartan 300 mg daily or matching placebo with follow-up for 2 years to determine the effect of irbesartan in prevention of new onset of overt proteinuria. Irbesartan reduced the risk for the development of overt proteinuria (defined as albumin excretion >200 mg/day) in a dose-dependent benefit [254]. The Irbesartan in Diabetic Nephropathy Trial (IDNT) [144] and the Reduction of Endpoints in Non Insuline Dependent Diabetes Mellitus (NIDDM) with the Angiotensin II Antagonist Losartan (RENAAL) [143] study independently showed irbesartan and losartan, respectively, can delay the progression of DKD in patients with type 2 DM, overt proteinuria, and reduced kidney function. IDNT randomly assigned 1715 participants to irbesartan, amlodipine, or placebo with follow-up for a mean of 2.6 years. BP was targeted at <135/85 mmHg and was achieved with agents in classes other than those under study. Independent of BP control, irbesartan reduced the risk for the composite outcome of doubling of serum creatinine concentration, kidney failure, or death as compared to amlodipine or placebo. The RENAAL trial followed up 1513 patients with type 2 DM and overt proteinuria for a mean of 3.4 years and demonstrated that losartan 100 mg daily was superior to placebo to reduce the risk for the same composite endpoint as in IDNT [143]. Taken together, these studies provide robust evidence supporting the benefit independent of BP lowering of RAS-blocking medication on slowing the progression of DKD. Despite the dramatic benefit with ARB therapy, many participants on ARB therapy still ended up with kidney failure, therefore novel therapy and drug development is required for prevention of progressive DKD.

In patients with type 2 DM with early and incipient nephropathy, mixed results were observed. In the Heart Outcomes Prevention Evaluation (HOPE) trial, the use of ramipril was not effective in preventing new onset microalbuminuria [255]. The Bergamo Nephrologic Diabetes Complications Trial (BENEDICT) study randomly assigned patients to one of four arms (placebo, trandolapril, verapamil, or trandolapril plus verapamil) for at least 3 years with a goal BP <120/80 mmHg. The two arms containing trandolapril showed a benefit in preventing the development of albuminuria, with post hoc analyses suggesting that the effect was independent of BP reduction [256]. The Randomized Olmesartan and Diabetes Microalbuminuria Prevention (ROADMAP) trial followed up 4449 participants for a median of 3.2 years. There was a statistically significant difference in BP between the olmesartan and placebo arms. The primary analysis of the trial showed that olmesartan prevented or delayed the onset of moderately increased urine protein, with moderately increased urine protein developing in 8.2% versus 9.8% of participants (olmesartan vs. placebo). However, the olmesartan group had lower BPs and an increase in CV deaths [257], although the study was not powered to assess this as an endpoint. In recent years, new studies have been conducted in people with DKD, comparing RAAS blockade with placebo or no treatment.A Cochrane systematic review which is undergoing an update [258] reported that ACE inhibitors may make little or no difference on all-cause mortality (24 studies, 7413 participants; RR 0.91, 95% CI 0.73 to 1.15; I^2 = 23%, *low certainty evidence*), fatal or nonfatal stroke (2 studies, 4944 participants; RR 1.02, 95% CI 0.80 to 1.31; I^2 = 0%, *low certainty evidence*) and fatal or nonfatal myocardial infarction (3 studies, 5100 participants; RR 0.79, 95% CI 0.57 to 1.09; I^2 = 0%, *low certainty evidence*) compared to placebo or no treatment. The effects of ACE inhibitor on cardiovascular mortality and doubling of serum creatinine were very uncertain (Table 24.8).

The same Cochrane review reported that ARB may make little or no difference on all-cause mortality (11 studies, 4260 participants; RR 0.99, 95% CI 0.85 to 1.16; I^2 = 0%, *low certainty evidence*), and has uncertain effects on cardiovascular mortality (6 studies, 878 participants; RR 3.36, 95% CI 0.93 to 12.07; *low certainty evidence*), fatal or nonfatal stroke (2 studies, 619 participants; RR 0.76, 95% CI 0.32 to 1.77; I^2 = 0%, *low certainty evidence*) and fatal or nonfatal myocardial infarction (2 studies, 619 participants; RR 0.43, 95% CI 0.11 to 1.65; *low certainty evidence*), and may prevent doubling of serum creatinine (4 studies, 3280 participants; RR 0.84, 95% CI 0.72 to 0.97; I2 = 37%, *low certainty evidence*) compared to placebo or no treatment (Table 24.9).

Combination Therapy

In the Antihypertensive and Lipid Lowering Treatment to Prevent Heart Attack (ALLHAT) trial subgroup, 13 101 participants with type 2 DM were randomly assigned to chlorthalidone, amlodipine (dihydropyridine calcium channel blocker [CCB]) or lisinopril. Despite the chlorthalidone-treated group having a lower systolic BP when compared with lisinopril or amlodipine, no difference in the primary endpoint of combined fatal coronary heart disease or nonfatal or fatal MI (HR 0.97, 95% CI 0.86–1.10) was seen between amlodipine and chlorthalidone. The Avoiding Cardiovascular events through Combination therapy in Patients Living with Systolic Hypertension (ACCOMPLISH) trial compared benazepril/amlodipine combination treatment with benazepril/thiazide therapy [259]. The trial enrolled 6946 high-risk participants with type 2 DM and 2842 participants with high CV and kidney risk. The primary endpoint was a composite of MI, stroke, CV death, hospitalization for angina, resuscitated cardiac arrest, and coronary revascularization. Benazepril/amlodipine reduced occurrence of the primary event compared to benazepril/thiazide in all subjects with diabetes (8.8% vs. 11%; HR 0.79, 95%

Table 24.8 ACEi versus placebo/no treatment in people with diabetic kidney disease.

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of Participants (No. of studies)	Quality of the evidence(GRADE)	Conclusions
All-cause mortality Mean follow-up: 2.9 years	RR 0.91 (0.73 to 1.15)	11 fewer per 1000 (34 fewer to 19 more)	7413 (24 studies)	Low	ACEi may make little or no difference on all-cause mortality compared to placebo/no treatment
Cardiovascular mortality Mean follow-up: 2.3 years	RR 0.67 (0.13 to 3.57)	16 fewer per 1000 (43 fewer to 126 more)	5625 (17 studies)	Very low	It is very uncertain whether ACEi makes any difference on cardiovascular mortality compared to placebo/no treatment
Doubling of serum creatinine Mean follow-up: 4 years	RR 0.69 (0.47 to 1.01)	13 fewer per 1000 (23 fewer to 0)	6702 (8 studies)	Very low	It is very uncertain whether ACEi makes any difference on doubling of serum creatinine compared to placebo/no treatment
Fatal or nonfatal stroke Mean follow-up: 7 years	RR 1.02 (0.80 to 1.31)	1 more per 1000 (9 fewer to 15 more)	4944 (2 studies)	Low	ACEi may make little or no difference on fatal or nonfatal stroke compared to placebo/no treatment
Fatal or nonfatal myocardial infarction Mean follow-up: 3.2 years	RR 0.79 (0.57 to 1.09)	6 fewer per 1000 (13 fewer to 3 more)	5100 (3 studies)	Low	ACEi may make little or no difference on fatal or nonfatal myocardial infarction compared to placebo/no treatment

ACEi = Angiotensin converting enzyme inhibitors; CI = Confidence interval; RR = Relative risk

Table 24.9 ARB versus placebo/no treatment in people with diabetic kidney disease.

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of Participants (No. of studies)	Quality of the evidence(GRADE)	Conclusions
All-cause mortality Mean follow-up: 2.2 years	RR 0.99 (0.85 to 1.16)	1 fewer per 1000 (20 fewer to 22 more)	4260 (11 studies)	Low	ARB may make little or no difference on all-cause mortality compared to placebo/no treatment
Cardiovascular mortality Mean follow-up: 1.6 years	RR 3.36 (0.93 to 12.07)	17 more per 1000 (0 to 78 more)	878 (6 studies)	Low	ARB have uncertain effects on cardiovascular mortality compared to placebo/no treatment
Doubling of serum creatinine Mean follow-up: 2.9 years	RR 0.84 (0.72 to 97)	45 fewer per 1000 (79 fewer to 8 fewer)	3280 (4 studies)	Low	ARB may prevent doubling of serum creatinine compared to placebo/no treatment
Fatal or nonfatal stroke Mean follow-up: 2.8 years	RR 0.76 (0.32 to 1.77)	9 fewer per 1000 (26 fewer to 30 more)	619 (2 studies)	Low	ARB have uncertain effects on fatal or nonfatal stroke compared to placebo/no treatment
Fatal or nonfatal myocardial infarction Mean follow-up: 2.8 years	RR 0.43 (0.11 to 1.65)	13 fewer per 1000 (20 fewer to 15 more)	619 (2 studies)	Low	ARB have uncertain effects on fatal or nonfatal myocardial infarction compared to placebo/no treatment

ARB = Angiotensin receptor blockers; CI = Confidence interval; RR = Relative risk

CI 0.68–0.92). In an intention-to-treat post hoc analysis, lower events of CKD progression in the benazepril plus amlodipine group compared to the benazepril plus hydrochlorothiazide group (HR 0·52, 95% CI 0.41–0.65, $P < 0{\cdot}0001$) [260]. Although the peripheral oedema is common among both groups with CKD, angioedema was more frequent in the benazepril plus amlodipine group than in the benazepril plus hydrochlorothiazide group. Based on this evidence, for persons in whom combination therapy with an ACE inhibitor is being considered, a dihydropyridine CCB is preferable to a thiazide/thiazide-like diuretic.

Combination RAAS blockers or the addition of a renin inhibitor such as alliskerin to an ACE inhibitor or angiotensin 2 receptor blocker has not been a positive strategy to reduce progressive loss of kidney function. On the contrary, three large RCTs (ONTARGET, VA-NEPHROND, and ALTITUDE) have shown such interventions increase risk of AKI and hyperkalemia in individuals with DKD [261–263]. Although the combination of agents that block the RAAS are generally not recommended in the management of DKD, a network meta-analysis has also identified dual RAAS blockade as a promising potential therapy if it can be offered safely [264].

Miniralcorticoid Receptors Inhibitor

Aldosterone blockade reduces CV mortality in patients with heart failure and reduces albuminuria [265–267]. Potential mechanisms of action include promotion of salt and water loss, potentially improving volume and BP management, with antifibrotic and antioxidant effects demonstrated in animal studies. The third-generation mineralocorticoid receptor antagonist finerenone has been shown to reduce albuminuria DKD at 90 days without significant safety concerns. The phase 2 study involved 821 participants with type 2 DM, of whom 36.7% had albuminuria (uACR ≥300 mg/g) and 40.0% had an eGFR of ≤60 ml/min/1.73 m^2. Finerenone demonstrated a dose-dependent reduction in uACR. The prespecified secondary outcome of hyperkalemia leading to discontinuation was not observed in the placebo and low-dose finerenone groups, but showed an increasing incidence with higher doses [267]. The impact of adding a mineralocorticoid receptor antagonist to background standard of care including an ACE inhibitor or ARB is being evaluated in the Efficacy and Safety of Finerenone in Subjects With Type 2 Diabetes Mellitus and Diabetic Kidney Disease (FIDELIO-DKD) [268] and Efficacy and Safety of Finerenone in Subjects With Type 2 Diabetes Mellitus and the Clinical Diagnosis of Diabetic Kidney Disease (FIGARO-DKD) trials [269]. The pre-specified meta-analysis FIDELITY, which included FIDELIO-DKD and FIGARO-DKD trials presented at the European Society of Cardiology 2021 Congress demonstrated that the non-steroidal mineralocorticoid receptor antagonist finerenone in addition to ACE inhibition or ARB in patients with CKD and type 2 DM decreased 4-point MACE (HR 0.86, 95% CI 0.78, 0.95) compared to placebo. Other non-steroidal mineralocorticoid receptor antagonists (apararenone, esaxerenone) have been examined in smaller non kidney and CV outcome based trials. The endpoints of this study consist of a composite of first occurrence of the composite endpoint of onset of kidney failure, a sustained decrease of eGFR ≥40% from baseline over at least 4 weeks, and kidney death (primary endpoint for FIDELIO-DKD and secondary endpoint for FIGARO-DKD study). A Cochrane systematic review which is undergoing an update [270] showed that mineralocorticoid receptor antagonist probably makes little or no effect on all-cause mortality (8 studies, 14293 participants; RR 0.90, 95% CI 0.80 to 1.00; I^2 = 0%, *moderate certainty evidence*), cardiovascular mortality (4 studies, 13366 participants; RR 0.88, 95% CI 0.76 to 1.02; I^2 = 0%, *moderate certainty evidence*), myocardial infarction (3 studies, 13080 participants; RR 0.92, 95% CI 0.75 to 1.13; I^2 = 0%, *moderate certainty evidence*), stroke (5 studies, 14259 participants; RR 0.99, 95% CI 0.82 to 1.2; I^2 = 0%, *moderate certainty evidence*) and kidney failure (3 studies, 13080 participants; RR 0.86, 95% CI 0.73 to 1.01; I^2 = 0%, *moderate certainty evidence*) compared to placebo or no treatment (Table 24.10).

Lipid Lowering

Dyslipidemia is common in people with diabetes and CKD. Individuals with diabetes and CKD typically have lower levels of high-density lipoprotein (HDL) cholesterol, high triglyceride, and low-density lipoprotein cholesterol (LDL-C) levels, hence a more atherogenic profile. The evidence that low LDL-C concentration reduces the risk of CV events in patients with diabetes and early CKD generally reflects the evidence reported in the general population.

The Cholesterol Treatment Trialists' (CTT) Collaboration meta-analysis of >170 000 subjects receiving statin found that for every 1.0 mmol/l reduction in LDL-C: low-density lipoprotein-cholesterol there was an approximately 20% reduction in CVD events, regardless of baseline LDL-C [271]. The effects of statins on all fatal and nonfatal CV outcomes were similar for participants with or without diabetes (14 trials, >18 000 participants with diabetes) [272]. The updated CTT meta-analysis of 170 000 participants showed that additional reductions in LDL-C (down to approximately 1.0–2.0 mmol/l) with more intensive therapy further reduced the incidence of major vascular events and that these reductions could be achieved safely, even in individuals with lower baseline LDL-C levels [273]. The IMproved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) showed that the addition of ezetimibe to simvastatin in participants with recent ACS provided CVD event benefit compared to use of simvastatin alone. The event reductions were particularly evident in people with type 2 DM [274].

The data from more advanced CKD are largely derived from the Study of Heart and Renal Protection (SHARP) trial [271]. SHARP randomized 9438 participants >40 years old with CKD (mean eGFR of 27 ml/min/1.73 m^2) to receive simvastatin 20 mg plus ezetimibe 10 mg daily or placebo and

Table 24.10 Mineralocorticoid versus placebo in people with diabetes mellitus and chronic kidney disease.

Outcomes	Relative effect (95% CI)	Absolute effect| (95% CI)	No. of Participants (No. of studies)	Quality of the evidence(GRADE)	Conclusions
All-cause mortality Mean follow-up: 20 months	RR 0.90 (0.80 to 1.00)	9 fewer per 1,000(from 18 fewer to 0)	14293 (8 studies)	Moderate	Mineralocorticoid receptor antagonist probably makes little or no effect on all-cause mortality
Cardiovascular mortality Mean follow-up: 22 months	RR 0.88 (0.76 to 1.02)	7 fewer per 1,000(from 13 fewer to 1 more)	13366 (4 studies)	Moderate	Mineralocorticoid receptor antagonist probably makes little or no effect on cardiovascular mortality
Myocardial infarction Mean follow-up: 12 months	RR 0.92 (0.75 to 1.13)	2 fewer per 1,000(from 7 fewer to 4 more)	13080 (3 studies)	Moderate	Mineralocorticoid receptor antagonists probably makes little or no difference on myocardial infarction
Stroke Mean follow-up: 16 months	RR 0.99 (0.82 to 1.2)	0 per 1,000 (from 5 fewer to 6 more)	14259 (5 studies)	Moderate	Mineralocorticoid receptor antagonist probably makes little or no effect on stroke
Kidney failure Mean follow-up: 28 months	RR 0.86 (0.73 to 1.01)	6 fewer per 1,000(from 12 fewer to 0)	13080 (3 studies)	Moderate	Mineralocorticoid receptor antagonist probably makes little or no effect on kidney failure

CI = Confidence interval; RR = Relative risk

followed them for 5 years. Thirty-three percent of the patients ($n = 3023$) were receiving maintenance dialysis at randomization and 23% ($n = 2094$) of the participants had diabetes, with equal proportions in the simvastatin plus ezetimibe and placebo groups. The study showed statin plus ezetimibe therapy was associated with a 17% RR in the risk of the major atherosclerotic events (coronary death, myocardial infarction, nonhemorrhagic stroke, or any revascularization) compared with placebo (HR 0.83, 95% CI 0.74–0.94). This finding was attributable in large part to significant reductions in nonhemorrhagic stroke and arterial revascularization procedures. There was no reduction in the risk of all-cause mortality, and among the patients with CKD not treated by dialysis at randomization ($n = 6247$), treatment with simvastatin plus ezetimibe did not reduce the frequency of doubling of the baseline serum creatinine concentration or progression to kidney failure. Although the study was not powered to reliably estimate the effect of treatment on primary outcomes among clinical subgroups, the proportional effect on major atherosclerotic events did not appear to differ between those with or without diabetes.

The 4D study [275] investigated 1255 subjects with type 2 DM receiving maintenance hemodialysis who were randomly assigned to receive 20 mg of atorvastatin or matching placebo daily. During a median follow-up period of 4 years, atorvastatin had no significant effect on the primary endpoint (RR 0.92, 95% CI 0.77–1.10), defined as composite of death from cardiac causes, fatal stroke, nonfatal myocardial infarction, or nonfatal stroke, except that there was an increase in the risk of fatal stroke (RR 2.03, 95% CI 1.05–3.93) among those receiving atorvastatin. Atorvastatin reduced the rate of all cardiac events combined (RR 0.82, 95% CI 0.68–0.99, $P = 0.03$, nominally significant), but not all cerebrovascular events or combined or total mortality. In another study in individuals receiving hemodialysis, the AURORA study [276], 2776 participants (approximately 20% diabetic) were randomized to rosuvastatin 10 mg or matching placebo daily, with a mean follow-up of 3.2 years. A similar effect of rosuvastatin was shown on CV primary outcomes. There was a small but statistically significant increase in the incidence of hemorrhagic stroke in the diabetic patients who received rosuvastatin, an observation also reported in the 4D study. A post hoc analysis of the 731 diabetic patients receiving hemodialysis reported a 32% risk reduction of composite primary endpoints among patient with diabetes on hemodialysis in the treated arm (HR 0.68, 95% CI 0.51–0.90) [277].

There were three randomized trials that examined the effect of fibrates relative to placebo in patients with diabetes and CKD. The Veterans Affairs High-density lipoprotein Intervention Trial (VA-HIT) [278] found evidence that gemfibrozil reduces risk of major cardiovascular events (fatal coronary heart disease, nonfatal MI, and stroke) by 42% compared with placebo (RR 0.58, 95% CI 0.38–0.89) in a post hoc analysis of 297 individuals with low eGFR (GFR <75 ml/min/1.73 m^2) and diabetes. The Diabetes Atherosclerosis

Intervention Study (DAIS) [279] and the Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) study [280, 281] reported that fenofibrate treatment significantly lowered the risk of developing new onset of moderately increased urine protein compared with placebo (RR 0.87 in patients with type 2 DM, 95% CI 0.77–0.97). Fenofibrate also promoted regression from moderately increased urine protein to normoalbuminuria (RR 1.15, 95% CI 1.04–1.28, $n = 2260$, two trials), but did not change the risk of progression from moderately to severely increased urine protein (RR 1.07, 95% CI 0.43–2.63, one trial, $n = 97$).

Placebo-controlled trials evaluating the addition of the PCSK9 inhibitors evolocumab and alirocumab to maximally tolerated doses of statin therapy in participants who were at high risk for atheroscletoric CVD demonstrated an average reduction in LDL cholesterol of 36–59%. These agents can be considered as adjunctive therapy for patients with diabetes at high risk for or who require but are intolerant to high-intensity statin therapy [282, 283]. The effects of this class of agents on CVD outcomes in patients with CKD remain unknown.

Antiplatelet Agents

The use of antiplatelet and antithrombotic agents in patients with DKD or CKD for prevention of CVD has not been robustly studied. The Antithrombotic Trialists' (ATT) collaborators conducted a patient-level meta-analysis of the six large trials of aspirin for primary prevention in the general population. These trials included 95 000 participants, including almost 4000 with diabetes. The study found aspirin reduced the risk of serious vascular events by 12% (RR 0.88, 95% CI 0.82–0.94), and the largest reduction was for nonfatal MI, with little effect on CVD death (RR 0.95, 95% CI 0.78–1.15) or total stroke [284]. A post hoc analysis of the HOT trial indicated net benefit for prevention of CV events for aspirin in patients with CKD and high BP, but predominantly included patients with relatively mild CKD [248]. Evidence supports use of either ticagrelor or clopidogrel in combination with aspirin for at least 1 year in patients following an ACS if no percutaneous coronary intervention was performed, and clopidogrel, ticagrelor, or prasugrel if a percutaneous coronary intervention was performed [285]. In patients with diabetes and prior myocardial infarction, adding ticagrelor to aspirin significantly reduces the risk of recurrent ischemic events, including cardiovascular and coronary heart disease death [286]. Post hoc analyses of trials of other antiplatelet agents have raised questions of whether the balance of benefit and harm is the same in patients with diabetes and/or CKD [287] and whether some agents may be more effective in CKD than others [288]. These results need to be interpreted with caution, as most participants with CKD had mild CKD. There are potential harms associated with antiplatelet/antithrombotic agents. Given the very high rates of thrombotic and embolic events (venous and arterial), particularly in advanced CKD, more studies are needed to investigate the longer-term benefits of these therapies in diabetes with CKD.

Promising Biomarkers in Predicting Risk of DKD

Not all patients with albuminuria progress to kidney failure or CVD, and the same is true of many patients with impaired kidney function (eGFR $<60\,\text{ml/min/1.73\,m}^2$), therefore an intensive search for novel biomarkers in blood or urine that could improve diagnostic and prognostic precision in early or later stages of DKD has been ongoing during the past decades.

In a longitudinal cohort study of 410 patients with type 2 DM with 12 years of follow-up, 59 patients developed kidney failure and 84 patients died without kidney failure. Baseline circulating tumor necrosis factor receptor (TNFR1) and TNFR2 were associated with risk for kidney failure. The cumulative incidence of kidney failure for patients in the highest TNFR1 quartile was 54% after 12 years but only 3% for the other quartiles ($P < 0.001$). In Cox proportional hazard analyses, TNFR1 predicted risk for kidney failure in both proteinuric and nonproteinuric groups [289]. Similar findings were reported in a cohort of American Indians with type 2 DM in which elevated serum concentrations of TNFR1 or TNFR2 were associated with increased risk of kidney failure after accounting for traditional risk factors including uACR and eGFR [290].

Using propensity scoring methodology the ADVANCE cohort was divided into those who developed major kidney endpoints ($n = 102$) compared to the control ($n = 179$). This subsidiary analysis showed the baseline total and active TGF-β1 were substantially increased, and bone morphogenetic protein 7 (bone morphogenetic factor (BMP)-7) levels decreased in people with type 2 DM who subsequently developed kidney endpoints compared to matched controls, despite relatively normal baseline kidney function in both groups. The c-statistic was 0.94 for circulating BMP-7 combined with total and active TGF-β1 compared to that of eGFR and uACR combined (c-statistic of 0.73) [291]. Hara et al. have shown that anti-erythropoietin receptor (EPOR) antibodies were found to be a promising marker in 112 Japanese patients with type 2 DM with CKD with a mean follow-up period of 45 months. The event-free rate of kidney events (defined as kidney failure requiring dialysis) in the patients with antibodies was significantly lower than in those without. The presence of EPOR antibodies confers an HR of 2.78 of kidney failure in individuals with DKD [292]. Promising, large, prospective validation cohort

studies conducted in conjunction with clinical trial to confirm the potential clinical use of these circulating biomarkers is required before routine testing can be recommended in clinical practice.

Novel Interventions Under Current or Recent Investigation in DKD

Given the escalating numbers of patients with DKD, new therapies are constantly in development. A snapshot of treatments in early and late phase trials is shown in Table 24.11; however, results are not yet available.

Conclusion

The growing global burden of DKD needs urgent attention to identify novel treatment strategies to prevent progressive kidney failure and its complications. Several proven treatments supported by evidence are available, but the gap in delaying the progression of DKD warrants discovery of novel therapies. The diagnosis of DKD, which traditionally relies on measuring and monitoring of uACR and kidney function in combination with clinical assessment, may not identify individuals at risk of progressive kidney disease. New markers are constantly being evaluated to improve diagnostic and prognostic precision, but validated evidence for their use is lacking. The discovery, development of an evidence base, and then implementation of new therapeutic agents is necessary for patients with DKD, and will benefit affected individuals, their families, and the community.

Table 24.11 Novel therapeutics being trialed in DKD.

Aldosterone receptor antagonist		Phase 2 study completed
Bardoxolone methyl	TSUBAKI Study	Phase 2 study recruiting
	BEACON	Phase 3 study terminated due to safety concerns
C–C chemokine receptor type 2 (CCR2) antagonism		Phase 2 study completed
Dapagliflozin		Phase 4 study recruiting
Endothelin-A antagonist atrasentan		Phase 3 ceased due to futility
Exenatide		Phase 4 study active but not recruiting
Mineralocorticoid receptor antagonist/finerenone		Phase 2 study completed and Phase 3 underway
		Phase 3 study recruiting
Nox1/4 inhibitor (oral GKT137831)		Phase 2 study completed: negative results in type 2 DM@ with DKD#
		Now being studied in type 1 DM with DKD
Phosphodiesterase 5 inhibitor		Phase 2 study completed
Pirfenidone		Phase 3 study recruiting
Pyridorin		Phase 3 study terminated due to lack of funding

Nox1/4 inhibitor: NADPH oxidase Nox 1 and Nox 4 inhibitor
DM: diabetes mellitus
DKD: diabetic kidney disease

Introduction

Lupus nephritis is an important manifestation of the multisystem autoimmune disease systemic lupus erythematosus (SLE) with clinical features ranging from asymptomatic abnormalities on urine microscopy, to the nephrotic syndrome, to rapid loss of kidney function. It is important to frame the current evidence base for the treatment of lupus nephritis into some historical context (Figure 25.1). It is nearly half a century since the first randomized controlled trial (RCT) in lupus nephritis was published, and this period can be divided into three eras based on the standard of care at the time: steroid alone, steroid plus cytotoxic then steroid plus mycophenolate. The first histological classifications developed because percutaneous kidney biopsy enabled analysis of histology in life rather than at autopsy. Every decade since has seen developments and refinements to the way the disease is classified histologically and thus reported to clinicians by pathologists. Before end-stage kidney disease (ESKD) programs became widely available, many patients with lupus nephritis died from renal failure. With improved immunosuppressive therapies, fewer patients now progress to ESKD and the lower mortality in the modern era may also be attributed to improvements in supportive care with renin-angiotensin system inhibitors to reduce blood pressure and proteinuria, increased use of hydroxychloroquine, better management of complications of treatment such as infection, and better management of cardiovascular risk factors. This chapter presents the current treatment for lupus nephritis and the evidence base behind it (Table 25.1).

Definition

Lupus nephritis is the term for kidney involvement in patients with SLE and is defined by clinical features, laboratory abnormalities, and the histological findings on kidney biopsy. Because SLE involves multiple systems, the disease is best defined by diagnostic criteria such as the American College of Rheumatology (ACR) [1,2] or the Systemic Lupus International Collaborative Clinics (SLICC) [3] criteria (Table 25.2). Lupus nephritis is also heterogeneous and is best defined by a specific histological classification, the International Society of Nephrology (ISN) Renal Pathology Society (RPS) Classification (Table 25.3) [4,5].

Epidemiology

SLE predominantly affects young females from non-Caucasian populations, particularly African Americans. The female: male ratio is 9 : 1 [6]. Three SLE surveillance programs in different United States populations reported almost 4000 prevalent cases of SLE and 752 incident cases between them over a 3-year period [7–9]. The prevalence per 100 000 population using the ACR criteria in African American, Hispanic, Asian, and Caucasian females ranged from 182 to 477, 58 to 179, 50 to 165, and 73 to 122, respectively. The corresponding figures in males were 18–59, 12–22, 5–25, and 5–11, respectively. Prevalence data are lacking in African, subcontinental, and South Asian cohorts [10].

An international inception cohort of 1826 patients with SLE reported that 38.3% of people with SLE have a "renal disorder" [11]. In the United States surveillance studies [7–9], the proportion with "renal disorder," defined as proteinuria or urinary casts in the ACR criteria, ranged from 32 to 45% and, like SLE itself, was consistently highest in African Americans and lowest in Caucasian Americans. Lupus nephritis may also differ by sex. In a meta-analysis of clinical features by sex, males had greater odds of renal involvement (OR 1.51, 95% CI 1.31–1.75), whereas females were more likely to have skin, joint, and serosal involvement [6].

Pathophysiology

In SLE there is disordered immune regulation leading to loss of self-tolerance, production of autoantibodies, and formation of immune complexes. In lupus nephritis, these immune complexes either deposit in, or form within, the kidney. This leads to complement activation, inflammation, and ultimately the various histopathological lesions and clinical manifestations of lupus nephritis.

Preceding these events is genetic susceptibility. Genetic factors play an important role in SLE and lupus nephritis, and the wide variety of gene loci that increase the risk of SLE and lupus nephritis go some way to explaining the clinical heterogeneity of the disease. Concordance of SLE in monozygotic twins is 24% compared to 2% in dizygotic twins and some specific alleles of the major histocompatibility complex on chromosome 6 are strongly associated [10]. For example, having both HLA-DRB1*03 : 01 and DRB1*15 : 01 alleles conferred greater risk for SLE than being homozygous for one allele in a large genotype association study [11]. In this study, the greater the number of risk polymorphisms, the greater the odds of SLE. In African

Table 25.1 Treatment for lupus nephritis.

Treatment	Recommendation	Certainty of evidence (relevant outcome measure)	Strength of recommendation
All patient with lupus nephritis			
	We recommend that all patients with lupus nephritis be treated with hydroxycholoroquine.	*Low*	Strong [13–16]
ISN/RPS Class I disease			
	We suggest treatment only for extrarenal manifestations of SLE.	*Very low*	Weak
ISN/RPS Class II disease			
	We suggest treatment only for extrarenal manifestations of SLE. Consider immunosuppressive treatment if substantial proteinuria or evidence of podocytopathy.	*Very low*	Weak
ISN/RPS Class III or IV disease, with or without Class V			
Induction			
Mycophenolate	We suggest mycophenolate (i.e. 3 g per day of mycophenolate mofetil in divided doses) be used for initial treatment of lupus nephritis Class III or IV because it is equivalent in inducing remission to cyclophosphamide but has an overall more favorable toxicity profile.	*Low* (complete remission, partial remission) *Moderate* (alopecia with cyclophosphamide, diarrhea with mycophenolate)	Weak [17–18]
Cyclophsophamide	We suggest that intravenous cyclophosphamide (either 0.5–1.0 g/m^2 monthly or 0.5 g fortnightly for six doses) be used as an alternative to mycophenolate to induce remission in lupus nephritis because it is equivalent to mycophenolate. This could be for patients who do not tolerate mycophenolate or whose disease is resistant to mycophenolate.	*Low* (complete remission, partial remission)	Weak [17–18]
Mycophenolate plus tacrolimus	We suggest that mycophenolate mofetil plus tacrolimus be considered as a third alternative as although it was better than intravenous cyclophosphamide at inducing complete remission, results are from a single center with participants largely of Asian ethnicity.	*Low* (complete remission, stable kidney function)	Weak [17–18]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Corticosteroid	We recommend that corticosteroids be included with the above regimens as they were a component of these regimens in all RCTs. The dose (prednisolone 0.6–1.0 mg/kg/day) and use of intravenous methyprednisolone should be dictated by severity of renal and extrarenal disease and reduced as quickly as possible. It should be noted that major infections were similar in comparison with prednisolone alone with prednisolone plus cytotoxic.	*Moderate* (major infection)	Strong [17]
Maintenance			
Mycophenolate	We recommend mycophenolate be continued as maintenance therapy because treatment results in less renal relapse and doubling of serum creatinine than azathioprine and with a more favorable toxicity profile than azathioprine. Whether and when to withdraw maintenance therapy is not known.	*Moderate* (renal relapse, doubling of serum creatinine) *Low* (leucopenia)	Strong [17–18]
ISN/RPS Class V disease with no proliferative (Class III or IV) disease			
Nonimmunosuppressive	We suggest that all patients with Class V lupus nephritis receive "anti-proteinuria" therapy with blockade of the renin-angiotensin system.	Low	Strong
Immunosuppressive	We suggest that patients with pure Class V lupus nephritis who have nephrotic syndrome or persistent nephrotic range proteinuria can be treated with similar immunosuppression to Class III or IV disease.	Low	Weak [17]
	We suggest that a calcineurin inhibitor could be considered as it was effective in inducing remission in one RCT.	Low	Weak [19]
	We suggest that for patients with Class V lupus nephritis and proteinuria below 3 g/day, the decision to treat with immunosuppression and the choice of immunosuppression be guided by individual patient risk factors.	Low	Weak
ISN/RPS Class VI disease			
	We recommend immunosuppressive therapy not be given to patients with Class VI disease.	*Very low*	Strong

GRADE assessment of the certainty of the evidence [20]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Table 25.2 Major diagnostic criteria for the diagnosis of SLE.

Organ	ACR criteria [1,2]	SLICC criteria [3]
Skin	Malar rash	Acute cutaneous lupus
	Discoid rash	Chronic cutaneous lupus
	Photosensitivity	
Mucosa	Oral ulcers	Oral ulcers
Hair		Alopecia
Joint	Nonerosive arthritis in ≥2 joints	Synovitis in ≥2 joints
Serosa	Pleuritis or pericarditis	Typical pleurisy or pericardial pain lasting ≥1 day
Kidney	Renal disorder = proteinuria>0.5 g/day or > 3+ on dipstick OR cellular casts of any type	Renal = proteinuria>0.5 g/day or equivalent protein:creatinine ratio OR red blood cell casts
Nervous system	Seizures OR psychosis	Seizures, psychosis, mononeuritis multiplex, myelitis, peripheral or cranial neuropathy, or acute confusion
Hematological	Haemolytic anemia OR leukopenia (<4000/ml twice) OR lympnopenia (<1500/ml twice) OR thrombocytopenia (<100 000/ml)	Haemolytic anemia Leukopenia (<4000/ml once) OR lympnopenia (<1000/ml once) Thrombocytopenia (<100 000/ml)
Immunological	Immunological: positive lupus erythrmatosus cell test OR anti-dsDNA OR anti-Sm antibody OR false-positive syphilis serology	Positive ANA
	Abnormal ANA titer	Elevated anti-dsDNA
		Positive anti-Sm
		Positive anti-phospholipid antibody
		Low complement
		Direct coombs test

ACR, American College of Rheumatology; ANA, antibodies directed against nuclear components; anti-dsDNA, anti-double-stranded DNA; SLE, systemic lupus erythematosus; SLICC Systemic Lupus International Collaborative Clinics.

American patients, the coding alleles G1 and G2 of the APOL1 gene are strongly associated with nondiabetic kidney disease. In lupus nephritis, the presence of two APOL1 gene risk alleles increased the odds of developing ESKD 2- to 3-fold, and development of ESKD occurred 2 years earlier than in people without two risk alleles [21].

After genetic susceptibility, the next event in developing SLE is the loss of immune tolerance to endogenous nuclear material with autovaccination leading to production of antinuclear antibodies [22]. When cells die, the presence of nuclear material in the extracellular space is minimized by apoptotic cell death or phagocytic clearance. If the methylation state of nuclear material is altered, a failure to recognize the nuclear material as "self" and, worse, interpreting the material to be viral nucleic acid by Toll-like receptors on antigen presenting cells, leads to immune activation by various mechanisms and production of autoantibodies such as anti-double-stranded DNA (anti-dsDNA) [23]. Some of these mechanisms, such as B lymphocyte stimulator (Blys or B-cell activating factor "BAFF"), A Proliferating Inducing Ligand (APRIL) and co-stimulatory molecules are targets of novel therapies (Figure 25.2) [22].

This immune activation and proliferation of autoreactive T and B cell populations leads to production of various antibodies directed against nuclear material, including anti-dsDNA. Although clearly important to measure clinically and pathogenic in experimental models, the precise role anti-dsDNA antibodies play in lupus nephritis is still being elucidated. Binding directly to cross-reactive antigens such as annexin II or indirectly to chromatin material that deposits in the kidney leads to effects such as cell proliferation and recruitment of inflammatory cells [24].

The variable pattern of immune complex deposition contributes to the diversity of histological lesions in lupus nephritis. Immune complex deposition or formation restricted to the mesangium generally leads to milder disease (ISPN/RPS Class I and II), immune complexes in the subendothelial space causes the most kidney-threatening forms of lupus nephritis (ISPN/RPS Class III and IV), and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 25.3 The ISN/RPS classification of lupus nephritis with 2018 clarifications.

Class	Description	Detailed description	ISN/RPS 2018 Clarifications
I	Normal	Normal by light microscopy (LM), mesangial immune deposits may be present on immunofluorescence (IF) or electron microscopy (EM)	
II	Mesangial disease	Mesangial hypercellularity; subepithelial or subendothelial immune deposits not visible by LM, but may be evident on IF or EM	Mesangial hypercellularity defined as ≥4 mesangial cell nuclei surrounded by matrix and away from the hilum
III	Focal lupus nephritis	Focal (<50% of glomeruli) segmental or global disease; lesions may include: • endocapillary hypercellularity • subendothelial immune deposits visible on LM as "wire loop" lesions • adhesions • fibrinoid necrosis • crescents	The term "endocapillary hypercellularity" replaces the term "endocapillary proliferation" as cells other than endothelial cells may be present. Adhesions, fibrinoid necrosis specifically defined Definition of crescent changed to extracapillary hypercellularity involving ≥10% (*not 25%*) of the circumference of Bowman's capsule; cellular, fibrocellular and fibrous crescents defined by proportion of fibrous and cellular elements New classification recommends *not* using the categories of global (G) and segmental (S), and not using terms for active (A), chronic (C) and active and chronic (A/C) lesions; rather, a semiquantitative scoring system is suggested
IV	Diffuse lupus nephritis (sometimes referred to as "diffuse proliferative lupus nephritis")	Diffuse (≥50% of glomeruli) segmental or global disease; lesions as per Class III but more widespread; features of membranoproliferative (mesangiocapillary) pattern may be present	Clarifications as per Class III
V	Membranous lupus nephritis	Subepithelial immune deposits in a typical membranous pattern; there may be mesangial deposits and hypercellularity May be present with focal (Class V + III) or diffuse (Class V + IV) disease	
VI	Advanced sclerosing lupus nephritis	Global glomerulosclerosis in ≥90% of glomeruli	Likely to be removed in future classifications as rarely seen

ISN/RPS, International Society of Nephrology/Renal Pathology Society.

subepithelial immune complexes cause membranous disease (ISPN/RPS Class V). This binding to intrarenal autoantigens results in complement activation, activation of Fc receptors, recruitment of inflammatory cells, and tissue inflammation [23]. Untreated, this inflammation leads to tissue damage, fibrosis, and loss of kidney function.

Diagnosis

The diagnosis of lupus nephritis ultimately rests on the kidney biopsy and histological classification of the lesion. Because the histological classification is pertinent to subsequent discussion, this will be described first.

Histological Classification of Lupus Nephritis

The current histological classification of lupus nephritis has been developed over many decades and continues to evolve (Figure 25.1 and Table 25.3) [4,5]. These classifications formed an important component of the inclusion criteria for the RCTs that provide the evidence base for treatment of lupus nephritis and an appreciation of their evolution over time is important. The earliest classification of the glomerular lesions in SLE was published in 1964 by Pollak et al. [25], who analyzed kidney tissue from 176 biopsy and necropsy specimens collected between 1953 and 1962 to study the natural history of the disease. They classified what they saw under the microscope as normal, lupus glomerulits with "mild local and focal changes in the glomerular tuft," active

lupus glomerulonephritis with "a more severe proliferative and membranous process, frequently associated with necrotizing features," or membranous lupus glomerulonephritis with "diffuse thickening of the glomerular basement membrane." Baldwin et al. published a similar study in 1970 and used the terms "focal proliferative lupus nephritis" and "diffuse proliferative lupus nephritis" in place of "lupus glomerulitis" and "active lupus glomerulonephritis," respectively [26]. The first World Health Organization (WHO) classification was formulated at conferences in Buffalo, New York in 1974 and Geneva, Switzerland in 1975 but did not appear in peer-reviewed literature until 1978, when it was used "with minor changes" in a study reporting the clinical course of 56 patients over time [27]. This classification introduced mesangial lesions as a distinct entity. Advanced sclerosing glomerulonephritis was added at the International Study of Kidney Diseases in Children Meeting in Paris in 1980 and this classification was published in Churg's *Renal Disease: Classification and Atlas of Glomerular Diseases* [28]. Further revisions were made in 1995 and published in the second edition of that textbook [29]. Along the way, debate about the distinction between Class III and Class IV disease, and definitions of terms such as "proliferative" has continued. A Consensus Conference at which the ISN and RPS combined to refine this classification took place at Columbia University, New York in 2002 [4] and this ISN/RPS classification, which is now in widespread use (Table 25.3) continues to be refined in order to improve clarity and reproducibility [5].

Patients who have been recruited into RCTs of therapy have generally had a kidney biopsy demonstrating ISN/RPS Class III, IV, and/or V lupus nephritis, or equivalent in older classifications, and had to meet the ACR or SLICC criteria for a diagnosis of SLE. In clinical practice it is possible to have lupus nephritis diagnosed on kidney biopsy without strictly meeting all of the clinical criteria.

Clinical Presentations of Lupus Nephritis

The kidney is but one organ involved in SLE, a chronic condition that relapses and remits over time. Thus, lupus nephritis can be the first presentation of SLE, can occur in someone with a known diagnosis of SLE, or can recur in someone with SLE who has previously had lupus nephritis. Given the epidemiology of lupus nephritis, young non-Caucasian females presenting with features of glomerular disease such as nephrotic syndrome should have lupus nephritis high on the list of differential diagnoses, even in the absence of known SLE. The presence of systemic symptoms such as fever or weight loss, musculoskeletal, serosal or skin features should raise that clinical suspicion even higher. Clinical features of SLE are variable and involve multiple systems. Two diagnostic criteria (Table 25.2) are widely used to help clinicians make a diagnosis of SLE and report sensitivity and specificity for a diagnosis of SLE to be greater than 90% [3].

The "renal disorder" criteria in both classifications are based on urinary findings: a measure of proteinuria and the presence of red blood cells or casts in the urine. In a predominantly Caucasian population of 499 patients with lupus nephritis, 35% presented with urinary abnormalities such as hematuria or proteinuria, 35% presented with nephrotic syndrome, 18% presented with nephritic syndrome, and 6% had rapidly progressive renal failure [30]. Over time, the proportion with nephrotic syndrome has remained stable and the more severe clinical presentations declined (Figure 25.3).

The work-up of a patient with suspected lupus nephritis, whether or not they have known SLE, takes into account clinical symptoms, assessment of glomerular disease activity, and serological abnormalities. Glomerular disease activity is assessed with urine microscopy for evidence of glomerular bleeding such as dysmorphic red blood cells and casts, assessment of urine protein excretion, and measurement of kidney function. Serological testing in lupus includes measurement of complement activity, with C3 and C4 being the most widely available tests, antibodies directed against nuclear components (ANA), which are sensitive but not specific for lupus, and anti-dsDNA antibodies, which are more specific for lupus. Other evaluations might include general measures of inflammation such as erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) and evaluation of extracted nuclear antigens (ENA), which include various antibodies associated with specific SLE manifestations. A person with lupus nephritis will typically have positive ANA, depressed levels of complement components C3 and C4, and raised anti-dsDNA.

Because of the high prevalence of kidney disease in SLE, careful periodic assessment of kidney function and glomerular disease activity as described above is also part of the ongoing management of patients with SLE. Patients who have been diagnosed with or treated for lupus nephritis require close monitoring of these parameters and a fall in C3 and C4 and a rise in anti-dsDNA may precede onset of significant kidney disease.

Importantly, definitions of renal remission and renal relapse in clinical trials are based on the glomerular disease features, particularly proteinuria. Although there is no consensus for the definition of remission in lupus nephritis [14], a common definition of complete remission following induction therapy is the return of serum creatinine to normal, urinary protein excretion to less than 0.5 g/day, and an inactive urinary sediment. This was used

in the 2018 Cochrane review update [17]. A common definition of partial remission is a fall in proteinuria to less than 3.0 g/day if baseline proteinuria was greater than 3.0 g/day, or a greater than 50% reduction if baseline proteinuria was less than 3.0 g/day in addition to stabilization of serum creatinine to within 25% of baseline, as used in the induction phase of the Aspreva Lupus Management Study (ALMS) Group study [31]. Renal relapse, or "flare," in clinical trials is defined variously as an increase in proteinuria and/or creatinine. For example, in the maintenance phase of the ALMS study, this required a doubling of urinary protein:creatinine ratio from the end of induction with proteinuria above either 1 or 2 g/day depending on whether the postinduction value was above or below 0.5 g/day [32].

Role and Interpretation of the Kidney Biopsy in Lupus Nephritis

A kidney biopsy is critical to making a diagnosis of lupus nephritis and determining treatment. The indications for performing a kidney biopsy in SLE are not dissimilar to non-SLE presentations. Presentations with the nephrotic syndrome, nephritic syndrome, and/or rapidly progressive kidney failure warrant a kidney biopsy. Hematuria and/or non-nephrotic proteinuria in patients with SLE are also strong reasons to consider a kidney biopsy, particularly proteinuria of 0.5 g/day or greater. Because clinical features don't always match histological features, a lower threshold should be applied to the decision to perform a kidney biopsy in patients with SLE. The potential risks of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the procedure should be weighed against the potential benefits of a kidney biopsy in each clinical situation. The benefits of a kidney biopsy in patients with suspected lupus nephritis include (i) the appropriate classification of the renal lesion to enable an appropriate level of immunosuppressive therapy (i.e. pure membranous versus membranous with proliferative lesions), (ii) identification of alternative diagnoses or other renal pathology, including thrombotic microangiopathy in antiphospholipid syndrome, and (iii) assessment of tubule-interstitial damage that is important for prognosis [33]. On occasions, one might consider treating a patient with a severe clinical presentation (i.e. overt nephrotic syndrome) and clinical and laboratory features of SLE without a kidney biopsy. However, the arguments in favor of kidney biopsy are sufficiently strong in most cases. Furthermore, because lupus nephritis is a disease that remits with treatment but can relapse over time, many patients with lupus nephritis have multiple kidney biopsies over the course of their disease.

After the biopsy is performed, the clinician should review the histology face to face with the renal pathologist to marry the clinical, laboratory, and histological features of each patient. It is insufficient to just determine which "Class" of lupus nephritis one is dealing with. Face-to-face review enables discussion of the adequacy of the biopsy upon which therapeutic decisions with important consequences are being made. Given the classification relies on the proportions of glomeruli involved, at least 10 glomeruli should be available for light microscopic examination [4], but preferably more. Immunofluorescence for immunoglobulin and complement components is also essential as lupus nephritis usually has extensive immune deposition, particularly of IgG, C3, and C1q, and lack of immune deposition should prompt consideration of other diagnoses. Activity and chronicity have been designated "A," "C" or "A/C" in older histological classifications of lupus nephritis but the most recent report recommends an activity and chronicity scoring system rather than these designations [5]. Such a scoring system is based on that derived by National Institutes of Health (NIH) investigators where a score of 0, 1, 2, or 3 was applied to histological features of activity such as glomerular cell proliferation, leukocyte exudation, karryorrhexis, fibrinoid necrosis, cellular crescents, hyaline deposits, and interstitial inflammation [34]. A similar score was applied to features of chronicity: glomerular sclerosis, fibrous crescents, tubular atrophy, and interstitial fibrosis. This report assessed this semiquantitative scoring against outcome and reported that the combination of tubular atrophy, glomerular sclerosis, and cellular crescents portended the poorest renal outcomes. A modified version of this scoring system has been proposed for further assessment in the latest ISN/RPS report [5]. This report also recommended against the terms "global" and "segmental" that were introduced with the 2002 Classification as their clinical significance was uncertain.

Prognosis

The natural history of lupus nephritis was described in the first description of the different histological appearances by Pollak [25]. After up to 8 years of follow-up, eight of 10 patients with normal kidney biopsy survived, 17 of 23 with lupus glomerulitis survived, 15 of 47 with active lupus glomerulonephritis survived, and all seven patients with membranous glomerulonephritis survived. Twenty-six of the deaths in the active lupus glomerulonephritis group were attributed to renal failure. Similarly, in one of the earlier RCTs for lupus nephritis [35], 50 patients were enrolled, 23 died, and 15 deaths were attributed as "renal death." Only one of the 15 "renal deaths" received renal replacement therapy, the rest dying of renal failure at an average age of just over 20 years.

The efficacy of modern therapy, including modern supportive care, is demonstrated by the improvements in 5-year survival of Class IV lupus nephritis over the decades from 17% in the 1950s and 1960s to 55%, 80%, and 82% in the decades that followed [36]. In 499 patients with lupus nephritis referred to Italian referral centers from 1970 to 2016, 19.8%, 5.9%, and 3.6% died in the periods 1970–1985, 1986–2001, and 2002–2016, respectively. Corresponding figures for ESKD were 24.8%, 9.1%, and 1.3% [30]. In the international inception cohort of the SLICC investigators recruited between 1999 and 2012, 700 of 1827 were considered to have lupus nephritis though only 395 had a kidney biopsy [11]. This showed predominantly Class III (26.8%), Class IV (43.2%), and Class V (31.8%) disease. In patients with lupus nephritis, the 10 year cumulative incidence of ESKD was 10.1% (95% CI 6.6–13.6%) compared to 0.5% in those without lupus nephritis. The 10-year cumulative incidence of death was 5.0% (95% CI 2.3–7.6%) with lupus nephritis and 3.6% (95% CI 0.9–6.2%) without.

Treatment

Lupus nephritis is a classic autoimmune condition that requires giving enough immunosuppression to treat the disease adequately, but not enough to cause harm. The goals of treatment are (i) to induce remission and relieve symptoms of nephrotic syndrome and (ii) to preserve kidney function in the long term. The first goal is relatively straightforward to assess in RCTs (although definitions of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

remission may vary) but the second goal requires very long-term follow-up of relatively infrequent outcomes. The challenge is to simultaneously achieve both of these goals and minimize toxicity of therapy.

Who to Treat

As stated, treatment decisions should be made after careful review of the clinical data and kidney biopsy. In general, ISN/RPS Class I lesions have a good prognosis and do not require specific therapy apart from what is required to treat extrarenal manifestations of SLE. For Class II disease, the minority in biopsy studies, the risk of progressing to more kidney-threatening lesions is difficult to determine. Published reports have few patients, and those that are biopsied again are biopsied for a worsening clinical presentation. Of 19 patients from Hong Kong whose initial biopsy demonstrated Class II lupus nephritis (5% of lupus nephritis biopsies at that institution), 10 required a second biopsy a median of 33 months (range 7–109) after the first [37]. Of these, nine demonstrated more severe disease on the second biopsy (Class III 2, Class IV 5, Class V 2). Similarly, of 41 Argentinian patients who had an initial biopsy with Class II lupus nephritis, 18 had a second biopsy a median of 40 months (range 11–120) later for clinical flares and 17 demonstrated more severe disease (Class III 4, Class IV 10, Class V 3) [38]. The Kidney Disease Improving Global Outcomes (KDIGO) Guidelines [39] suggest treatment directed only at extrarenal manifestations of SLE if proteinuria is less than 1 g/day and immunosuppressive therapy as for minimal change disease if proteinuria is more than 3 g/day (graded 2D in the GRADE system, the lowest level of evidence). The Joint European League Against Rheumatism and European Renal Association–European Dialysis and Transplant Association (EULAR/ERA-EDTA) Guidelines also suggest no treatment in Class II disease if proteinuria is less than 1 g/day; however, this guideline suggests 0.25–0.5 mg/kg/day of prednisolone if proteinuria is above 1 g/day (with other immunosuppressive therapy if required to taper steroid) [40]. Thus, immunosuppressive therapy in Class II disease may be used where a podocytopathy is considered possible, which emphasizes the importance of a thorough and thoughtful review of the kidney biopsy with the renal pathologist. However, there is no RCT evidence that treating Class II lupus with immunosuppression prevents progression to more severe lupus nephritis (Classes III–V).

The majority of RCTs in lupus nephritis have enrolled patients with Class III, IV, and/or V disease, or equivalent in older classifications [25]. Thus, there is a good evidence base for treating these lesions, which are known to have a much worse prognosis than other lesions. This will be discussed in the following sections with treatment of pure membranous Class V disease considered separately.

Class VI disease is essentially near-ESKD and so immunosuppression is not recommended unless it is required for extrarenal disease. These patients generally require preparation for renal replacement therapy.

Therapies Recommended for all Patients

Nonimmunosuppressive Therapy

As in other forms of glomerulonephritis, non-immunosuppressive therapy for lupus nephritis is intended to reduce proteinuria and control hypertension. Although RCTs assessing the kidney protective effects of renin angiotensin system inhibitors have not been performed specifically in lupus nephritis, these agents delay progression in non-diabetic proteinuric nephropathies [41]. Given that hypertension often requires treatment in lupus nephritis, it is reasonable to extrapolate such data to lupus nephritis and recommend the use of renin-angiotensin system inhibitors.

In addition to hypertension, other cardiovascular risk factors warrant attention as people with SLE are at 2–3-fold greater risk of cardiovascular disease [42] and this risk is greater again in patients with lupus nephritis [43]. Traditional cardiovascular risk factors likely combine with inflammation (particularly interferon pathways) and therapies such as corticosteroids to augment this risk [44, 45]. Again, in the absence of RCTs specifically in people with lupus nephritis, one is left to extrapolate the benefits of lipid-lowering therapy in non-lupus studies. It is noteworthy that systematic reviews have demonstrated the benefit of lipid lowering in women, who make up the majority of SLE patients, as well as men [46], and in people with chronic kidney disease (CKD) [47]. Thus, controlling blood pressure, smoking cessation, and lipid-lowering therapy are important considerations for prevention of cardiovascular disease in the long term.

Supportive therapy also includes prevention of venous thromboembolism in patients who are nephrotic, prophylaxis for opportunistic infections such as *Pneumocystis jirovecii*, prevention and management of corticosteroid-induced osteoporosis, and active management of fertility issues in females and males who may be exposed to large cumulative doses of cyclophosphamide.

Antimalarial Therapy

Antimalarial therapy with hydroxychloroquine is recommended for all patients with lupus nephritis. Although this is not based on high-quality RCTs and systematic reviews, analysis of a mixture of randomized and non-randomized studies suggests that antimalarials are effective at preventing lupus flares and prolonging survival [13,15].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Antimalarial therapy is widely recommended for the treatment of constitutional symptoms in SLE guidelines [14] and may delay progression to an estimated glomerular filtration rate (eGFR) <60 ml/min [16]. The most concerning adverse effect is retinal toxicity, which is greater with chloroquine than hydroxychloroquine, and the Royal College of Ophthalmologists recommends annual screening for retinopathy after taking hydroxychloroquine for more than 5 years, or earlier if receiving a dose of more than 5 mg/kg/day, renal impairment, or concurrent tamoxifen use [48]. The risk of retinal toxicity is considered low on a dose of 200 mg daily, which is sufficient for most people.

Immunosuppressive Therapy for Class III and IV Disease, Alone or Combined with Class V

Induction Versus Maintenance Therapy

Immunosuppressive therapy aims to induce and maintain disease remission to maximize patient and renal survival. Induction therapy may last for 6 months or more. Important clinical outcomes such as death and ESKD are more difficult to study in RCTs because they require either a very large sample size or very long follow-up. RCTs of induction therapy have been of insufficient follow-up (median 12 months, range 2.5–48 months) and sample size (only three trials have recruited more than 350 participants) to assess these outcomes [17]. Complete remission at 24 weeks is commonly reported and generally defined as proteinuria less than 0.5 g/day with normal (or near normal) serum creatinine and normal urinalysis. Maintenance therapy follows induction therapy and cannot be considered as entirely separate. Studies of maintenance therapy require much longer follow-up and outcomes include doubling of serum creatinine, ESKD, death, and renal flare. The definition of renal flare is dependent on how complete a remission was achieved after induction. Measures comprising the definition of renal flare in one RCT [32] included a doubling of a measure of proteinuria with proteinuria above 1 g/day (or 2 g/day depending on earlier response), a 25% increase in creatinine, and new or increased red blood cells or casts on urine microscopy. Regimens for induction and maintenance therapy are described according to the three major eras of treatment for lupus nephritis (Figure 25.1).

Corticosteroids Alone

The earliest reports of lupus nephritis demonstrated benefit in treating patients with high doses of corticosteroids. For example, the report by Pollack with the first histological classification reported better renal outcomes in active lupus glomerulonephritis with high-dose versus low-dose corticosteroid [25]. Fourteen of 31 patients receiving high-dose corticosteroids survived compared to one of 16 patients receiving low-dose corticosteroids. Although corticosteroids have not been compared to placebo in an RCT, they have remained an integral component of treatment regimens. A common starting dose is 1 mg/kg daily (up to 60 mg/day) with varying rates of tapering. Intravenous methylprednisolone is included in some regimens and may be considered for more severe clinical presentations, such as with crescents on biopsy. Although effective in gaining control of active disease, corticosteroids have substantial metabolic, cosmetic, and other toxicities that influence tolerability and adherence. There is therefore much merit in finding treatment regimens that use minimal corticosteroid doses [49].

Cyclophosphamide or Azathioprine plus Corticosteroids

The benefit of adding cytotoxic therapy to corticosteroids was demonstrated in a pooled analysis of eight trials that included between 13 and 50 participants each [50]. Patients receiving steroid combined with cytotoxic therapy (either cyclophosphamide or azathioprine) were less likely to experience renal deterioration, ESKD or die as a result of their nephritis compared to patients receiving steroids alone. All-cause mortality did not differ. The first large RCT randomized 107 patients between 1969 and 1981 to prednisolone either alone, with azathioprine, with oral cyclophosphamide, with azathioprine plus oral cyclophosphamide, or with intravenous cyclophosphamide [51]. The last two groups were introduced part-way through the trial in 1973. Oral and intravenous cyclophosphamide in combination with corticosteroids was superior to corticosteroids alone in preventing doubling of serum creatinine and ESKD, and oral and intravenous cyclophosphamide exhibited similar efficacy and safety. This was the first of a series of trials performed through the National Institutes of Health in the United States, the so-called "NIH" studies.

The NIH regimen consisted of six 0.5–1.0 g/m^2 doses of intravenous cyclophosphamide every month adjusted according to the white cell count, along with prednisolone 0.5 mg/kg/day. This regimen was then compared to a similar dose of prednisolone plus six infusions of methylprednisolone 1.0 g/m^2 every month (steroid alone), and a third arm in which patients continued to have intravenous cyclophosphamide every 3 months for 2 years after the initial six doses of cyclophosphamide (cyclophosphamide "maintenance") [52]. This RCT recruited 65 patients between 1981 and 1991. Continuing cyclophosphamide as maintenance resulted in fewer exacerbations after the first 6 months, and fewer patients experienced a sustained doubling of serum creatinine in this group than the short course (6 months) of cyclophosphamide group and the steroid alone group (15%

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

vs. 35% vs. 48%, respectively). A subsequent study recruited 82 patients between 1986 and 1990 and modified the steroid-alone regimen, continuing monthly doses of methylprednisolone for at least 12 months (maximum 36 doses) [53]. Two intravenous cyclophosphamide arms were similar to the previous study except that one was combined with monthly methylprednisolone. This latter combination therapy group had more renal remission (proteinuria <1 g/day) than the cyclophosphamide alone and methylprednisolone alone groups: 17 of 28 vs. 13 of 27 vs. 7 of 27, respectively. After a median of 11 years of follow-up, the probability of no treatment failure (first occurrence of death, doubling of serum creatinine, or need for off-protocol immunosuppression) was ~70% in the combination group, ~55% in the cyclophosphamide alone group, and ~40% in the methylprednisolone alone group [54]. During follow-up, 17 of 27 patients randomized to methylprednisolone alone received cyclophosphamide and the benefits of these regimens came at a cost: 36% of the combination therapy patients had avascular necrosis, 60% developed amenorrhoea at a median age of 33 years, and 26% experienced herpes zoster infection.

Given the concerns of cumulative cyclophosphamide toxicity, the use of lower dose cyclophosphamide (six fortnightly intravenous cyclophosphamide pulses at a fixed dose of 500 mg, followed by azathioprine as maintenance therapy) was compared to the NIH cyclophosphamide regimen described above in the Euro-Lupus Nephritis Trial (ELNT) [55]. This trial showed low-dose cyclophosphamide was comparable to high-dose cyclophosphamide in inducing disease remission but no statistically different reduction in adverse effects of therapy could be demonstrated.

Azathioprine as induction therapy was tested in the very early trials and although it was compared directly to intravenous cyclophosphamide in Austin's study [51], there was insufficient power because this trial included five treatment groups. A study addressing this issue was performed in The Netherlands and randomized 87 people with lupus nephritis to either intravenous cyclophosphamide as per the NIH regimen for 2 years (but at a fixed dose of 750 mg/m^2) or azathioprine 2 mg/kg/day plus three daily pulses of methylprednisolone 1 g at baseline then 2 and 6 weeks later [56]. Patients randomized to cyclophosphamide received oral prednisolone 1 mg/kg/day initially and patients randomized to azathioprine received oral prednisolone 20 mg/day initially. After a median follow-up of 5.7 years, relapses were significantly more frequent in the azathioprine group, and doubling of serum creatinine was also more frequent but did not reach statistical significance. There was more herpes zoster infection with azathioprine, but other parameters such as kidney function and proteinuria were similar. Azathioprine was used for induction of remission in lupus nephritis less frequently than cyclophosphamide. However, azathioprine was commonly used to maintain remission after induction.

The Cochrane Kidney and Transplant group's first systematic review of lupus nephritis included most of the above studies and demonstrated that cyclophosphamide-based regimens reduced the risk of doubling of serum creatinine (relative risk [RR] 0.59, 95% confidence interval [CI] 0.40–0.88) compared to steroid alone, but did not reduce mortality or ESKD [57]. However, the risk of ovarian toxicity was increased with cyclophosphamide, an important toxicity in a patient group that consists predominantly of women of childbearing age. Major infections and herpes zoster infections did not occur more frequently with cytotoxic therapy than with steroids alone.

Mycophenolate Mofetil plus Corticosteroids

In 2000, Chan et al. published a RCT of 42 patients from Hong Kong with WHO Class IV lupus nephritis [58]. They compared mycophenolate mofetil 1 g twice daily and prednisolone 0.8 mg/kg/day for 12 months to oral cyclophosphamide 2.5 mg/kg/day and prednisolone 0.8 mg/kg/day for 6 months then azathioprine 1.5 mg/kg/day and prednisolone for 6 months. Complete remission by 12 months was seen in 17 out of 21 and 16 of 21 patients, respectively. Mycophenolate mofetil thus had similar efficacy, as well as similar infectious complications but no alopecia or amenorrhoea. Given that nephrologists had developed significant experience with mycophenolate in kidney transplant by this stage, it became a viable alternative to cyclophosphamide in lupus nephritis.

Chan's findings were confirmed in a 24-week non-inferiority RCT comparing mycophenolate mofetil to the NIH cyclophosphamide regimen in 140 patients from centers in the United States [59]. Just over half of these participants were African American. Complete and partial remissions occurred in 16 and 21 of 71 patients randomized to mycophenolate mofetil, respectively, and 4 and 17 of 69 randomized to cyclophosphamide, respectively. The difference in complete remissions was significant for "superiority," even though the trial was designed as a noninferiority trial. There were fewer severe infections with mycophenolate mofetil but more patients experienced diarrhea, a known side effect. Subsequently, an international collaboration called the ALMS Study Group (including many United States authors from the aforementioned study) demonstrated in the largest RCT to that time ($n = 370$) that mycophenolate mofetil exhibited similar efficacy in inducing disease remission to intravenous cyclophosphamide (56.2% vs. 53.0%, respectively) [31]. Overall rates of adverse events were similar, although alopecia, nausea, and vomiting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

occurred more often with cyclophosphamide and diarrhea with mycophenolate mofetil. Because it was an international study, there were fewer African American patients but subgroup and post hoc analyses demonstrated that both African American (plus "other") and Hispanic patients had better response rates with mycophenolate mofetil than cyclophosphamide (~60% vs. ~40%). The prespecified interaction between treatment and race was significant ($P = 0.047$).

Importantly, the ALMS Group then randomized the 227 patients who met response criteria at 24 weeks to mycophenolate mofetil 2 g/day or azathioprine 2 mg/kg/day for 36 months [32]. Treatment failure was defined as death, ESKD, doubling of serum creatinine, renal flare or rescue therapy, and occurred in 16.4% of patients receiving mycophenolate mofetil and 32.4% receiving azathioprine. Overall adverse events were common and similar between groups. Prior to this, a RCT comparing quarterly intravenous cyclophosphamide, oral azathioprine, and oral mycohenolate mofetil as maintenance therapy after induction with up to seven monthly doses of intravenous cyclophosphamide demonstrated that the oral azathioprine and mycophenolate mofetil groups had superior event-free survival (events being death or doubling of serum creatinine) to the quarterly intravenous cyclophosphamide [60]. A European study, the MAINTAIN Nephritis Trial, randomized 105 patients to either mycophenolate mofetil or azathioprine at week 12 after all patients received induction with six 500 mg doses of intravenous cyclophosphamide each a fortnight apart [61]. Renal flares occurred in 13 (25%) patients receiving azathioprine and 10 (19%) patients receiving mycophenolate mofetil but there were no significant differences between the groups in any major parameters measured.

The Cochrane Kidney and Transplant Group updated their systematic review in 2012 and this update included the RCTs examining the role of mycophenolate discussed in this section [62]. Mycophenolate mofetil was as effective as intravenous cyclophosphamide for complete remission, stable kidney function, major infection, and mortality, with less ovarian failure (RR 0.15, 0.03–0.80). Used as maintenance therapy, the risk of renal relapse was increased 2-fold with azathioprine compared to mycophenolate mofetil (RR 1.83, 95% CI 1.24–2.71). This systematic review was updated again in 2018 with a total of nine studies (868 participants) comparing mycophenolate mofetil to intravenous cyclophosphamide for induction [17]. The two treatments were equivalent for most outcomes, and findings from this review are used for the Summary of Findings table (Table 25.4). Interestingly, the expected association of more ovarian failure with cyclophosphamide was weakened in this most recent systematic review.

The updated Cochrane review did identify a pilot study ($n = 40$) [63] and larger RCT ($n = 362$) [64] from the same group in China that compared a regimen combining the calcineurin inhibitor tacrolimus 2 mg twice daily with mycophenolate mofetil 500 mg twice daily to intravenous cyclophosphamide 0.75 g/m^2 every month for six doses. Both groups initially received methylprednisolone 500 mg daily for 3 days then prednisolone 0.6 mg/kg. This large RCT demonstrated more complete remission at 24 weeks in the mycophenolate mofetil plus tacrolimus group (45.9%) than the intravenous cyclophosphamide group (25.6%). This promising result has not been replicated and must be interpreted in light of the limited generalizability, being from a homogenous Chinese population, and the influence of the non-immune proteinuria-lowering effect of tacrolimus where a proteinuria-based definition of complete remission was used.

The Current Era: Biologic Therapies

Conventional immunosuppressive therapy with corticosteroids plus either mycophenolate or intravenous cyclophosphamide has considerably improved the outlook for patients with Classes III, IV, or V lupus nephritis, with responses at 24 weeks in one large study of more than 50% with either therapy [31]. However, there remains considerable treatment-related toxicity and room to improve efficacy. As our understanding of the pathophysiology of lupus nephritis evolves, so-called biologic therapies targeted at specific immunological processes (Figure 25.2) have been developed [65]. Results with these agents to date have been suggestive but inconclusive.

Rituximab is a monoclonal antibody that binds specifically to CD20 and depletes autoreactive B cells (but not plasma cells) and reduces autoantibody production [65]. The Lupus Nephritis Assessment with Rituximab (LUNAR) study recruited 144 participants and compared rituximab to placebo when added to standard therapy of mycophenolate mofetil and corticosteroids and demonstrated no difference in clinical outcomes between groups after 12 months [66]. In a post hoc analysis of patients who received rituximab, achieving complete B cell depletion (zero B cells per μl), shorter time to complete B cell depletion, and longer duration of complete B cell depletion were all associated with increased odds of complete response [67]. A rituximab-based regimen has been used at Imperial College London and non-randomized results reported [68]. The purpose of this regimen is to reduce oral corticosteroid use and it consists of rituximab 1 g plus methylprednisolone 500 mg given at days 1 and 15, with mycophenolate mofetil commencing at 500 mg twice daily and titrated up to 1500 mg twice daily (or the maximum tolerated dose). In this series of 50 consecutive

Table 25.4 Summary of findings: treatment of lupus nephritis.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Intravenous cyclophosphamide versus corticosteroids alone					
All-cause mortality	226 (5)	3 fewer (80 fewer to 139 more)	0.98 (0.53–1.82)	Low ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone may make little or no difference to mortality
End-stage kidney disease	452 (4)	90 fewer (148 fewer–7 more)	0.63 (0.39, 1.03)	Moderate ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone probably decreases end-stage kidney disease
Complete remission in proteinuria	13 (1)	0 (no events in control group)	2.63 (0.13–54.64)	Very low ●○○○	It is uncertain whether mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide makes any difference to complete remission in proteinuria
Doubling of serum creatinine	228 (4)	162 fewer (237–47 fewer)	0.59 (0.40–0.88)	Moderate ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone probably decreases doubling serum creatinine
Renal relapse	84 (2)	337 fewer (403–166 fewer)	0.23 (0.08–0.62)	Moderate ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone probably decreases renal relapse
Stable kidney function	278 (5)	118 more (0–265 fewer)	1.20 (1.00–1.45)	Moderate ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone probably increases stable kidney function
Ovarian failure	147 (3)	222 more (19 fewer–628 more)	2.18 (1.10–4.34)	Low ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone may increase ovarian failure
Major infection	291 (6)	19 fewer (75 fewer–76 more)	0.87 (0.50–1.51)	Moderate ●●○○	Intravenous cyclophosphamide compared to corticosteroids alone probably decreases major infection
Mycophenolate mofetil versus intravenous cyclophosphamide for initial treatment					
All-cause mortality	826 (8)	6 more (19 fewer–51 more)	1.12 (0.61–2.06)	Very low ●○○○	It is uncertain whether mycophenolate mofetil compared to intravenous cyclophosphamide makes any difference to all-cause mortality
End-stage kidney disease	231 (3)	25 fewer (62 fewer–71 more)	0.71 (0.27–1.84)	Very low ●○○○	It is uncertain whether mycophenolate mofetil compared to intravenous cyclophosphamide makes any difference to end-stage kidney disease
Complete remission	868 (8)	38 more (7 fewer–93 more)	1.17 (0.97–1.42)	Low ●●○○	Mycophenolate mofetil compared to intravenous cyclophosphamide may have little or no difference on complete remission
Partial remission	868 (8)	9 more (47 fewer–77 more)	1.02 (0.89–1.18)	Low ●●○○	Mycophenolate mofetil compared to intravenous cyclophosphamide may have little or no difference on partial remission
Ovarian failure	539 (3)	26 more (39 fewer–48 more)	0.36 (0.02–2.18)	Very low ●○○○	It is uncertain whether mycophenolate mofetil compared to intravenous cyclophosphamide makes any difference on ovarian failure
Major infection	699 (5)	2 more (38 fewer–62 more)	1.02 (0.67–1.54)	Low ●●○○	Mycophenolate mofetil compared to intravenous cyclophosphamide may have little or no difference on major infection

Table 25.4 (Continued)

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Leucopenia	753 (6)	81 fewer (133 fewer–16 more)	0.59 (0.33–1.08)	Moderate ●●○○	Mycophenolate mofetil compared to intravenous cyclophosphamide probably decreases leucopenia
Alopecia	622 (3)	170 fewer (194–129 fewer)	0.29 (0.19–0.46)	Moderate ●●○○	Mycophenolate mofetil compared to intravenous cyclophosphamide probably decreases alopecia
Diarrhea	609 (4)	142 more (64–258 more)	2.42 (1.64–3.58)	Moderate ●●○○	Mycophenolate mofetil compared to intravenous cyclophosphamide probably increases diarrhea
Mycophenolate mofetil plus tacrolimus versus intravenous cyclophosphamide for initial treatment					
All-cause mortality	402 (2)	Not estimable	No events	Absent	No events of all-cause mortality occurred in the studies that evaluated mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide
End-stage kidney disease		Not estimable		Absent	No studies comparing low-dose mycophenolate mofetile plus tacrolimus compared to intravenous cyclophosphamide examined end-stage kidney disease
Complete remission	402 (2)	337 more (17–1049 more)	2.38 (1.07–5.3)	Low ●●○○	Mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide may increase complete remission
Partial remission	402 (2)	0 (83 fewer–106 more)	1.00 (0.78–1.28)	Low ●●○○	Mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide may make little to no difference to partial remission
Stable kidney function	402 (2)	222 more (114–358 more)	1.78 (1.40–2.26)	Low ●●○○	Mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide may increase achievement of stable kidney function
Ovarian failure	34 (1)	Not estimable	No events-	Absent	No events of ovarian failure occurred in the studies that evaluated mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide
Major infection	402 (2)	23 more (31 fewer–820 more)	1.65 (0.11–24.44)	Very low ●○○○	It is uncertain whether mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide makes any difference to major infection
Leucopenia	402 (2)	62 fewer (77 fewer–35 more)	0.23 (0.04–1.44)	Very low ●○○○	It is uncertain whether mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide makes any difference to leucopenia
Alopecia	402 (2)	14 fewer (42 fewer–37 more)	0.78 (0.36–1.72)	Very low ●○○○	It is uncertain whether mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide makes any difference to alopecia
Diarrhea	362 (1)	44 more (3 fewer–163 more)	2.33 (0.92–5.94)	Very low ●○○○	It is uncertain whether mycophenolate mofetil plus tacrolimus compared to intravenous cyclophosphamide makes any difference to diarrhea

Table 25.4 (Continued)

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Mycophenolate versus azathioprine to maintain remission after initial treatment					
All-cause mortality	451 (4)	3 fewer (17 fewer–44 more)	0.87 (0.26–2.92)	Very low ●○○○	It is uncertain whether mycophenolate mofetil compared to azathioprine makes any difference to all-cause mortality
End-stage kidney disease	452 (4)	15 fewer (30 fewer–33 more)	0.59 (0.18, 1.92)	Very low ●○○○	It is uncertain if mycophenolate mofetil compared to azathioprine makes any difference to end-stage kidney disease
Renal relapse	452 (4)	114 fewer (162–45 fewer)	0.57 (0.39–0.83)	Moderate ●●●○	Mycophenolate mofetil compared to azathioprine probably decreases renal relapse
Doubling of serum creatinine	452 (4)	46 fewer (68–3 fewer)	0.46 (0.21–0.97)	Moderate ●●●○	Mycophenolate mofetil compared to azathioprine compared to mycophenolate mofetil probably decreases doubling of serum creatinine
Ovarian failure	177 (2)	10 more (24 fewer–161 more)	1.30 (0.29–5.73)	Very low ●○○○	It is uncertain if mycophenolate mofetil compared to azathioprine makes any difference to ovarian failure
Major infection	412 (3)	8 fewer (49 fewer–66 more)	0.92 (0.51–1.67)	Low ●●○○	Mycophenolate mofetil compared to azathioprine may make little or no difference to major infection
Leucopenia	412 (3)	65 fewer (75–32 fewer)	0.18 (0.05–0.6)	Low ●●○○	Mycophenolate mofetil compared to azathioprine may decrease leucopenia
Alopecia	412 (3)	3 more (31 fewer–74 more)	1.05 (0.51–2.15)	Low ●●○○	Mycophenolate mofetil compared to azathioprine may make little to no difference to alopecia
Diarrhea	307 (2)	53 more (61 fewer–318 more)	1.36 (0.58–3.18)	Low ●●○○	Mycophenolate mofetil compared to azathioprine may make little or no difference to diarrhea

CI, confidence interval. Treatment estimates are drawn from a systematic review with network meta-analysis of randomized controlled trials [17, 18]. GRADE assessment of the certainty of the evidence [20]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

patients, 72% achieved a complete remission at a median of 36 weeks and 90% achieved either complete or partial remission at a median of 37 weeks. Eleven patients relapsed after achieving remission. Oral corticosteroids for more than 2 weeks were only required in two patients who responded and two who did not. Interestingly, 22 of the 50 patients in this report had Class V lupus nephritis. This is relevant because rituximab is increasingly being used for primary membranous glomerulonephritis [69]. This RITUXILUP regimen is the subject of a current RCT (NCT01773616).

Ocrelizumab also selectively depletes CD20+ B cells. In the largest RCT studying lupus nephritis to date, 378 participants were recruited from multiple countries and randomized to placebo, ocrelizumab 400 mg, or ocrelizumab 1000 mg on top of standard care for induction or remission [70]. Standard care, at the discretion of the treating physician, was either mycophenolate mofetil or the ELNT regimen of six fortnightly doses of intravenous cyclophosphamide 500 mg followed by azathioprine 2 mg/kg/day. The primary outcome was response at 48 weeks assessed as either complete, partial, or no response. The trial was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. terminated early because of concerns about an increased frequency of serious opportunistic infections, coupled with the lack of benefit demonstrated in the LUNAR study reported at that time. Opportunistic infections occurred in 0.8% receiving placebo, 3.2% receiving ocrelizumab 400 mg, and 0.8% receiving ocrelizumab 1000 mg. Serious infections were also more frequent in the ocrelizumab 400 mg group and, when stratified by background therapy, more frequent in the patients treated with mycophenolate. This latter subgroup also received more corticosteroid. Because of the early termination, the study outcomes are reported for a modified intention-to-treat group of 223 patients and thus had reduced power. The overall (complete plus partial) renal response rate at 48 weeks was above 50% in all three groups, and the difference in response rate between placebo and the two ocrelizumab groups combined almost reached statistical significance (12.7%, 95% CI −0.8–26.1). The effect appeared greater in the subgroup with ocrelizumab added to the ELNT regimen than when added to mycophenolate mofetil.

Abatacept modulates the CD28-CD80/86 signaling pathway that leads to co-stimulation and T cell activation, and has also been the subject of a large RCT in lupus nephritis [71]. This study compared placebo to two different dosing regimens of abatacept with all patients receiving mycophenolate mofetil and corticosteroids. This trial demonstrated no safety concerns but did not demonstrate a difference in the primary outcome of time to complete response, defined as stable eGFR compared to baseline (within 10%), urine protein:creatinine ratio <30 mg/mmol, and normal urine microscopy on two successive visits (the most stringent definition use in RCTs to date). Using the dataset from this trial, different definitions of complete response from a number of trials as well as that recommended by the ACR [72] were applied [73]. With alternative complete response definitions, the abatacept groups had an estimated difference in complete response of about 15% that was statistically significant. For example, using the ALMS criteria the complete response rates in the placebo, abatacept 10/10 regimen, and abatacept 30/10 regimen were 14, 25, and 30%, respectively, compared to 3, 3, and 5% using the original trial criteria.

Another biologic agent with appealing but not conclusive evidence for benefit in lupus nephritis is belimumab, a monoclonal antibody that inhibits soluble B-lymphocyte stimulator. This agent demonstrated a good response in patients with SLE and thus a post hoc pooled analysis of two trials was performed to assess the renal outcomes [74]. Participants were randomized to two doses of belimumab or placebo on top of standard therapy for active SLE (corticosteroids, hydroxychloroquine). Mycophenolate was used in 10% of the whole cohort ($n = 1684$) and 20% of the 227 patients with renal involvement assessed by the Safety of Estrogens in Lupus Erythematosus National Assessment–SLE Disease Activity Index (SELENA-SLEDAI). Improvement in the renal domain of the SELENA-SLEDAI occurred in 44.6%, 51.1%, and 54.1% of patients receiving placebo, belimumab 1 mg/kg, and belimumab 10 mg/kg, respectively. In the whole cohort, renal flares occurred in 3.0%, 2.5%, and 1.4%, respectively, and the median percentage reduction in proteinuria over 52 weeks was greater in the belimumab groups. However, this agent was not used to treat patients presenting with lupus nephritis and thus should not be extrapolated as a treatment option for such.

Pure Membranous (Class V) Lupus Nephritis

Pure membranous (Class V) lupus nephritis differs from primary membranous glomerulonephritis in that it is associated with an inflammatory disease that relapses and remits, and is less likely than primary membranous glomerulonephritis to remit spontaneously [39]. On the other hand, guidelines suggest similar strategies for treatment [40] such as controlling proteinuria with renin-angiotensin system inhibition if non-nephrotic and reserving immune suppression for more severe (nephrotic) disease. Most of the trials of therapies in lupus nephritis enrolled some patients with Class III, IV, and V disease. In Austin's early trial of 107 patients [51], 16 had pure membranous lupus nephritis and in the more recent ALMS Maintenance Study [32], 35 out of 227 had pure membranous lupus nephritis (more had Class V combined with either Class III or IV). To some degree, it is reasonable to apply the results of these trials to Class V lupus nephritis. There has been little evidence exclusively examining the treatment of class V lupus nephritis. Twenty-three years after his first lupus nephritis RCT, Austin et al. compared the addition of the NIH cyclophosphamide regimen or cyclosporine to prednisone alone in 42 patients with Class V lupus nephritis and nephrotic range proteinuria [19]. Complete remission of proteinuria (to <0.3 g/day) at 1 year occurred in 27% of patients receiving prednisone alone, 60% receiving prednisone plus the NIH cyclophosphamide regimen, and 83% receiving prednisone plus cyclosporine. This supports the use of immunosuppressive agents in patients with nephrotic proteinuria. Treatment for Class V (membranous) lupus nephritis therefore depends on the degree of proteinuria. Patients with proteinuria less than 3.0–3.5 g/day can be treated with renin-angiotensin system blockade to try to reduce proteinuria, just as in primary membranous glomerulonephritis. Other supportive care such as anticoagulation for patients considered at high risk of venous thromboembolism is also important. For patients with "nephrotic" proteinuria above this level, immunosuppression is recommended [39] and this could be any of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. regimens used for Class III and IV lupus nephritis. B-cell targeted therapies such as rituximab are gaining favor in idiopathic membranous glomerulonephritis [69] but what this means for pure membranous (Class V) lupus nephritis remains to be seen.

Summary of Therapies for Class III, IV, and V Disease

The Summary of Findings table (Table 25.4) presents various comparisons of treatment and the treatment effects from the most recent Cochrane Kidney and Transplant meta-analysis [17]. A problem with the lupus nephritis RCT literature is that a wide range of treatments has been studied in RCTs that have mostly been too small to assess important clinical outcomes. Most of the trials cited in this chapter are the largest and least susceptible to bias. To explore comparisons and rank therapies that have not been made directly in RCTs, a network meta-analysis was performed [18]. This allowed both direct and indirect comparisons of treatments. Using intravenous cyclophosphamide as the reference treatment, the odds ratio for complete remission was 1.44 (95% CI 1.00–2.06) with mycophenolate mofetil, and 2.69 (95% CI 1.74–4.16) for mycophenolate mofetil combined with tacrolimus. The limitations of this finding have been discussed previously. These treatments were no different with respect to all-cause mortality or ESKD. Overall, this network meta-analysis confirmed that mycophenolate mofetil is similar to intravenous cyclophosphamide, with a better adverse effect profile for both induction and maintenance therapy.

Special Situations

Very Severe or Nonresponsive Lupus Nephritis

Patients with very severe lupus nephritis are often excluded from RCTs or are a subset of participants. There is no universally accepted definition of "severe" and many people would consider any Class III or IV lupus nephritis to be a "severe" kidney-threatening manifestation of SLE. One arbitrary classification of severe that has been advanced defines "severe" as (i) Class IV lupus nephritis with more than 15% crescents and/or glomerular capillary necrosis, (ii) persistence or relapse despite cyclophosphamide, or (iii) Class III or IV lupus nephritis with elevated serum creatinine [75]. This definition has not been used in RCTs but the common theme is that patients with these features usually have elevated serum creatinine.

Patients with very severe lupus nephritis can be treated with the same regimens described above for Class III or IV disease. There is again no accepted definition of "refractory" or "resistant" disease or what constitutes a failure to respond and over what time frame. Both the KDIGO [39] and EULAR/ERA-EDTA [40] Guidelines recommend switching from one regimen to the other (i.e. to mycophenolate if cyclophosphamide used first or to cyclophosphamide if mycophenolate used first). One must also be confident that the optimal dose has been given. These guidelines don't prefer one regimen over the other. A systematic review specifically addressing severe lupus nephritis reported that mycophenolate and cyclophosphamide were equivalent for short-term outcomes but that there was a suggestion from the data that cyclophosphamide had better long-term outcomes such as preservation of kidney function [75]. However, this was not a pooled analysis of individual patient-level data to enable stratification based on kidney function. The ALMS trial reported outcomes in 32 (out of 370) participants who had an eGFR less than 30 ml/min/1.73 m^2 at baseline [76]. Four of 20 patients randomized to mycophenolate mofetil responded, compared to two of 12 patients randomized to cyclophosphamide ($P = 0.9$) but ultimately this study was underpowered to reach any conclusion regarding patients with eGFR less than 30 ml/min/1.73 m^2.

Other therapies with lower levels of evidence that might be "added on" in very unwell patients not responding to mycophenolate or cyclophosphamide include rituximab (discussed above), intravenous immunoglobulin, or a calcineurin inhibitor. Intravenous immunoglobulin has been reported to be beneficial in case reports [77] but the only RCT in lupus nephritis was small ($n = 14$) and compared intravenous immunoglobulin (IVIg) to cyclophosphamide after 6 months of the NIH regimen of intravenous cyclophosphamide [78]. This was really a trial of maintenance therapy and so is difficult to extrapolate as "add-on" therapy in patients with severe disease. Addition of a calcineurin inhibitor such as tacrolimus as in the RCT of "multitarget" therapy with prednisolone, tacrolimus, and mycophenolate mofetil [64] might be considered. However, in addition to the limitations of this trial that have been discussed, kidney function at baseline was relatively well preserved in this trial (80% had eGFR >60 ml/min). Plasma exchange is also suggested as an option in the EULAR ERA-EDTA guideline [40], although an RCT carried out between 1981 and 1986 was stopped early because there was no benefit of plasma exchange added to prednisolone and oral cyclophosphamide [79]. Patients had quite "severe" disease with segmental and proliferative lesions being required for inclusion and a mean serum creatinine at baseline of ~180 umol/l. It remains to be seen whether rituximab or other biologicals will find their place in very severe lupus nephritis.

Pregnancy and Lupus Nephritis

Most patients with lupus nephritis are women of childbearing age and pregnancy should therefore be discussed early in their course to determine the management to be implemented before conception. Management of pregnancies in women with lupus nephritis requires a multidisciplinary approach and has been recently reviewed [80, 81]. Most women with a history of lupus nephritis have good pregnancy outcomes provided the disease is in remission, and they are lupus anticoagulant negative, not hypertensive, and not non-Caucasian or Hispanic.

Before pregnancy, women with lupus nephritis should be in remission for at least 6 months. Ideally, women will have ceased potentially teratogenic medications such as renin angiotensin system inhibitors, cyclophosphamide, and mycophenolate, and switched to appropriate alternatives. Discontinuation or switching of immunosuppressive medications runs the risk of a flare so should be done before conception and with close monitoring. Hydroxychloroquine is safe in pregnancy and should be continued before, during, and after pregnancy.

Once pregnant, aspirin should be started before 12 weeks gestation and consideration given to anticoagulation in women at risk, such as those with positive lupus anticoagulant or a history of venous thromboembolism.

Close monitoring during pregnancy to detect flares of lupus nephritis or later in pregnancy to detect preeclampsia (and indeed to differentiate one from the other) is essential on top of monitoring for obstetric complications. Management of flares is complicated and depends upon the severity and gestation. Corticosteroids, azathioprine, and calcineurin inhibitors can be used safely at any gestation. Severe or resistant flares bring about very difficult decisions: one must weigh up the risks to the mother and fetus of continuing the pregnancy and using therapies that are more efficacious for the lupus nephritis but less safe for the fetus, against the risks to mother and fetus of delivery of the immediate delivery of the fetus to enable effective therapies.

Withdrawal of Maintenance Therapy

Maintenance therapy can be challenging in lupus nephritis. Once patients are feeling better following induction of remission, it can be hard to convince them that they need ongoing therapy to prevent relapse, particularly when they are experiencing cosmetic and other side effects of corticosteroids. Duration of and withdrawal of maintenance therapy are the subject of debate [82], with the arguments based on whether it is better to minimize treatment toxicity by giving patients time off immunosuppressive therapy or to prevent flares of lupus nephritis, which add to kidney function loss.

The ALMS maintenance trial lasted for 36 months and over this time there were fewer treatment failures or flares with mycophenolate mofetil [32]. Thus, there is evidence to continue mycophenolate as maintenance therapy for 3 years. Beyond this time, evidence for what to do is lacking. In an Italian cohort ($n = 161$) in whom patients in complete remission (proteinuria <0.5 g/day) for 12 months underwent withdrawal of immunosuppression ($n = 73$), 21 (29%) patients had flares during reduction in therapy and 20 of the remaining 52 patients (38%) experienced a flare after withdrawal of maintenance therapy [83]. Overall, these patients received no therapy for 41% of their total follow-up time. These authors recommended that withdrawal of therapy was possible but only after 5 years of maintenance therapy with 3 years in complete remission, and only if done very slowly.

In a group of Argentinian lupus nephritis patients who received maintenance mycophenolate mofetil for 3 years after induction with an NIH cyclophosphamide regimen for 6 months, and who were in complete remission for 12 months (proteinuria<0.5 g/day), a kidney biopsy was performed before mycophenolate mofetil was weaned and ceased over a 6-month period regardless of the kidney biopsy findings [84]. Of the 36 patients who completed the study, 20 were in histological remission at the time of this biopsy (NIH activity index = 0), nine had an activity index 1–2, and seven had an activity index of 3–5. Over the next 24 months 11 patients had a flare of lupus nephritis after ceasing maintenance mycophenolate and 10 of these had an activity index above zero (mainly due to finding endocapillary proliferation and subendothelial deposits). Six of 25 patients who did not flare over 24 months had an activity index of 1 or 2. Although kidney biopsy appears helpful, it must be noted that this study did not demonstrate whether continuation of maintenance immunosuppression if the kidney biopsy was unfavorable would prevent renal flares.

Thus, maintenance therapy should be prolonged and withdrawal of immunosuppression is possible but the benefits (less immunosuppression) and risks (30–40% risk of renal flare) must be carefully weighed up. A kidney biopsy may help to guide the decision.

Renal Replacement Therapy

A major goal of therapy in lupus nephritis is avoidance of ESKD. In the earliest days this meant death for most patients, but now renal replacement therapy is widely available in most, but not all, countries [85]. Although ESKD is an important outcome in the management of lupus nephritis, lupus nephritis is the cause of ESKD in less than 2% of prevalent patients with ESKD [86, 87]. The incidence rate of ESKD is three to four times higher in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

African American patients, who also have a higher mortality [88]. Compared to other patients with ESKD, the patients with lupus nephritis are much younger, more likely to be female, and have less comorbidity from diabetes and cardiovascular disease [87]. Although in the United States mortality rates of patients with ESKD with SLE were similar to people with ESKD who did not have SLE [88], in Australia and New Zealand this was not the case [87]. The adjusted hazard ratio for patient death was 1.33 (1.12–1.58) for patients on dialysis due to lupus nephritis, and 1.87 (1.18–2.98) for kidney transplant recipients, compared to ESKD controls who did not have lupus nephritis.

Despite the possibility of higher mortality, kidney transplant outcomes are still favorable in patients who develop ESKD from lupus nephritis. Five-year renal allograft and death-censored renal allograft survival were 88 and 93%, respectively [87]. Lupus nephritis recurred in 2.3% of kidney transplant in patients in Australia and New Zealand [87], and in 2.44% of kidney transplant recipients in the United States [89]. In the US patients, African American, female and younger patients were more likely to experience recurrence of lupus nephritis, and allograft median survival after recurrence was between 4 and 5 years [89]. The survival of kidneys with recurrent lupus nephritis was similar to those that had rejection and the latter was a far more important cause of graft loss in this study (156 patients lost their graft from recurrent lupus nephritis compared to 1517 from rejection).

Another issue in patients with SLE who develop ESKD from lupus nephritis is whether the SLE becomes "quiescent" or not. Early studies indicate that this is true. In a Dutch population, the mean non-renal SLEDAI was 8.22 ± 6.3 before starting dialysis and 4.41 ± 5.94 when receiving dialysis ($P < 0.01$) and the distribution of the 55 patients with no (SLEDAI = 0), low (SLEDAI = 1–10), or high (SLEDAI > 10) non-renal disease activity was 2, 36, and 17 before dialysis and 19, 28, and 8, respectively, after dialysis [90]. The same authors reported that in 28 patients who received a kidney transplant for lupus nephritis, the number with a non-renal SLEDAI > 10 was 17 before dialysis, three during dialysis and none after transplant [91]. In contrast, a Brazilian study compared 57 patients on dialysis with SLE to 57 controls and defined lupus activity by the SLEDAI score or if patients required prednisolone 20 mg daily or greater [92]. The proportion with SLEDAI scores of 0, 1–3, 4–7, and ≥8 were 19%, 44%, 19%, and 18% for the SLE patients and 63%, 33%, 4%, and 0% for the non-SLE patients, respectively. Thus, SLE disease activity should be actively considered even after renal replacement therapy becomes the primary focus of management.

Conclusion

Lupus nephritis is a kidney-threatening manifestation of SLE for which a number of treatments have been studied in RCTs over many years. However, there is still a long way to go to increase the complete remission rates with these regimens or newer therapies while at the same time reducing the toxicity of treatment. Acquiring good evidence remains a challenge due to the heterogeneity of the disease itself and difficulties with recruiting large numbers of patients into treatment trials, the need to consider both induction and maintenance therapy, and the long follow-up required to measure outcomes such as renal relapse after remission, loss of kidney function, and ESKD.

Introduction

The Nomenclature of TMA

Thrombotic microangiopathy (TMA) describes a group of highly diverse disorders in children and adults that is defined by microvascular thrombosis with characteristic abnormalities of the vascular endothelial lining. Clinically, TMA is characterized by a triad including microangiopathic hemolytic anemia (MAHA), thrombocytopenia, and organ dysfunction, primarily of the kidneys [1–3].

TMA can be hereditary (either familial or sporadic) or acquired, and it can also be primary or secondary to numerous different conditions including infections, immunological diseases, glomerular diseases, stem cell and solid organ transplantation, drugs, cancer, malignant hypertension, and pregnancy [2–4]. Thus, the classification of TMA is challenging and debatable, and today there is no uniform accepted nomenclature in the literature or in clinical practice. Historical classifications were based on clinical features, mainly distinguishing between thrombotic thrombocytopenic purpura (TTP), which is clinically characterized by predominant neurologic involvement and is more common in adults, and hemolytic uremic syndrome (HUS), which involves primarily the kidneys and is more common in children. HUS has been further divided into two diseases, Shiga toxin-producing *Escherichia coli* (*E. coli*)-related HUS (STEC-HUS, *typical* HUS) and *atypical* hemolytic uremic syndrome (aHUS), which has been used for any TMA type that is not related to STEC-HUS or TTP [2–6]. More recent classifications which are based on pathophysiology have evolved due to greater understating of the underlying mechanism of the different types of TMA [2, 3, 5]. We, among other authors, opt to further classify the highly heterogeneous group aHUS according to the different etiologies which cause this syndrome, as shown in Figure 26.1. As aHUS is known to be caused by complement dysregulation the term complement-mediated TMA is preferred. Rare primary TMA are not related to complement may be termed primary noncomplement TMA. All other forms of TMA that are have been included in the aHUS group are classified as secondary TMA, which should be termed based on the underlying disorder, i.e. infection-related TMA, autoimmune disorder-related TMA, drug-related TMA, etc.

The pathophysiology-based classification used in this chapter provides a practical guide for clinicians facing a patient with an undiagnosed TMA. However, the classification of TMA is still evolving, and it is likely that with time new classifications will be suggested as despite great advancement in the revelation of molecular basis of TMA over the last 20 years, a considerable number of cases (up to 30%) are still classified as "unknown" or "idiopathic" TMA, and further pathophysiological insights can be expected [2–4, 7, 8] Table 26.1.

The TMA Spectrum

The first report of TMA, presumably TTP, dates from 1924, when Moschcowitz described a 16-year-old girl with pallor, purpura, and hemiparesis who died with cardiac failure. On autopsy, thrombi were seen in terminal arterioles and capillaries in many organs [1, 3]. It was not until 1982, however, that unusually large multimers of von Willebrand factor (vWF) were found to accumulate in the plasma of patients with chronic TTP, leading to occlusive microvascular platelet thrombi. Subsequently, a deficiency (enzyme activity <10%) of a disintegrin and metalloproteinase with a thrombospondin type 1 motif member 13 (ADAMTS13), a vWF cleaving-protease, was found to be the cause of the

Table 26.1 Summary of diagnostic tests in TMA.

Test	What does it measure?	Comments
TMA diagnosis		
Creatinine, urea	• Kidney function tests	• Both are elevated in TMA and signify AKI
Hemoglobin, haptoglobin, LDH, direct antiglobulin (coombs) test, blood film	• MAHA markers	• Low hemoglobin and haptoglobin • High LDH • Negative coombs test (except in pneumococcal TMA) • Fragmented red blood cells (schistocytes) on blood film
Platelets	• Platelet count	• Thrombocytopenia is usually the first sign to appear and increase in platelets count is usually the first sign of recovery
Further assessment of kidney involvement		
Urine analysis, urine protein, or albumin to creatinine ratio	• Degree of hematuria and proteinuria	• Proteinuria is often nephrotic-ranged • Hematuria is often the first sign of relapse of complement-mediated TMA
Kidney US + Doppler	• Structure of the kidneys, patency of kidney vessels	• Findings in TMA are not specific, however kidney US + Doppler may aid in excluding other clinically relevant kidney diseases such as renal vein thrombosis
Assessment of extra-renal involvement		
Brain MRI	• Structure of the brain	• For assessment of neurologic complications; findings include posterior reversible encephalopathy syndrome (PRES), hemorrhage, infarcts, edema, and others
Chest x-ray	• Structure of the lungs and heart	• For assessment of pulmonary complications; findings include pulmonary edema, pulmonary hemorrhage, and others
ECG, echocardiography	• Heart structure and function, arrhythmias	• For assessment of cardiac complications; findings include left ventricular hypertrophy, cardiomyopathy, valvular disease, myocardial infarction, and others
Abdominal US/CT	• Structure of abdominal viscera	• For assessment of gastrointestinal complications; findings include cholelithiasis, pancreatitis, hepatitis, and others
AST, ALT, GGT	• Liver enzymes tests	• For assessment of hepatitis as a complication of TMA or as a cause of TMA (i.e. in HAV or HCV)
Amylase, lipase	• Pancreatic enzymes tests	• For assessment pancreatitis as a complication of TMA
Exclusion of DIC		
PTT, INR, fibrinogen	• Basic coagulation tests	PTT and INR are prolonged and fibrinogen is low in DIC, while in TMA these tests are usually normal
Diagnosis/exclusion of TTP		
ADAMTS13 activity	• Activity of the vWF cleaving-protease	• Activity level >10% rules out TTP
Diagnosis/exclusion of STEC-HUS		
Stool culture and/or PCR	• Microbiologic tests for STEC identification	• In STEC-HUS these tests are positive for *E. coli* O157:H7 or other less common STEC
Diagnosis/exclusion of secondary TMA		
Blood/stool cultures, viral serology/PCR	• Microbiologic tests for non-STEC pathogens which may cause TMA (i.e. blood culture for pneumococcus, stool culture for *Shigella dysenteriae*, serology for HIV, PCR for influenza)	• For diagnosis/exclusion of infection-related TMA in the relevant clinical context

Table 26.1 (Continued)

Test	What does it measure?	Comments
ANA, anti dsDNA (SLE) Lupus anticoagulant, anticardiolipin antibodies (APLA) Antitopoisomerase I, anti-RNA polymerase III, anticentromere antibody (systemic sclerosis)	• Autoimmune antibodies in SLE • Autoimmune antibodies in APLA • Autoimmune antibodies in systemic sclerosis	• For diagnosis/exclusion of autoimmune disease-related TMA in the relevant clinical context
ANCA, C3, IgA	• Markers of different types of GN	• For diagnosis/exclusion of GN-related TMA in the relevant clinical context • Positive ANCA may signify ANCA-associated glomerulonephritis (GN) • Low C3 is not specific and can be seen in many GN as well as in complement-mediated TMA • Elevated IgA in the right clinical context may suggest IgA nephropathy, but normal IgA is common in this entity
Kidney biopsy	• Histopathology of the kidney	• For diagnosis/exclusion of GN-related TMA and of solid organ transplantation-related TMA in the relevant clinical context • Kidney biopsy is often needed for the diagnosis of the specific type of GN, and of TMA associated with solid organ transplantation, but it is not required for the diagnosis of TMA
Urine/serum β-HCG	• Pregnancy test	• For diagnosis/exclusion of pregnancy-related TMA • Should be part of the diagnostic work-up of any case of TMA in a woman of childbearing age
