Blood homocysteine, blood methionine, urine methylmalonic acid	• Molecules related to cobalamin metabolism	• For diagnosis/exclusion of cobalamin C-related TMA • Blood homocysteine and urine methylmalonic acid are elevated in cobalamin C-related TMA, while blood methionine is reduced
Diagnosis/exclusion of primary noncomplement-mediated TMA		
Genetic tests of DGKE, MMACHC, INF2, PLG, VTN, vWF, F12	• Screening for pathogenic variants in non-complement related genes	• For diagnosis/exclusion of primary, noncomplement-mediated TMA • DGKE gene should be tested in infantile onset TMA • MMACHC gene should be tested to confirm the diagnosis of cobalamin C-related TMA if the screening biochemical tests (blood homocysteine and methionine, urine methylmalonic acid) suggest this disorder
Diagnosis of primary, complement-mediated TMA		
Genetic tests of CFH, MCP/CD46, CFHRs, CFI, C3, CFB, THBD/CD141	• Screening for pathogenic variants in complement-related genes	• For molecular confirmation of the clinical diagnosis of the congenital form of complement-mediated TMA
Anti CFH-autoantibodies	• Screening for anti-CFH autoantibodies	• For diagnosis/exclusion of the acquired form of complement-mediated TMA
Further investigation in primary complement-mediated TMA		
CH50, AP50, CFH activity	• Complement functional assays	• Low CH50 may result from consumption of complement factors in complement-mediated TMA but also from other causes such as hepatic disease. It may also be marker of eculizumab therapy • Low AP50 is common during the active phase of complement-mediated TMA but may be low also in STEC-HUS and other disorders • Decreased CFH activity implies a CFH mutation or anti-CFH autoantibodies

Table 26.1 (Continued)

Test	What does it measure?	Comments
C3, C4, CFH, CFI, CFB, MCP/CD46	• Levels of complement components and inhibitors	• C3 is low in only 30–50% of patients with complement-mediated TMA (nonspecific) • Low C4 is associated with complement classical pathway disorders and not with complement-mediated TMA • Low CFH, CFI, or MCP/CD46 may signify mutations in these genes
C5b-C9, C3d, Bb	• Degree of complement activation	• High C5b-9 levels (membrane attack complex) expected in active complement mediated TMA; may be also seen in STEC-HUS • High C3d in combination with low C3 levels associated with C3 consumption rather than deficiency • High Bb and low CFB level found in both, complement mediated TMA and STEC-HUS

disease. In hereditary TTP, recessive mutations in the gene encoding for ADAMTS13 are responsible for the deficiency, while autoantibodies against ADAMTS13 cause the more common acquired TTP [1–3, 9, 10]. TTP was historically almost universally fatal, but the systematic use of plasma exchange (PE) therapy decreased mortality to <10% [2].

With a frequency of 1–3/100 000, STEC-HUS is the most common type of TMA in children [2, 7, 11]. The term "hemolytic uremic syndrome" was first proposed in 1955 for children with renal failure, anemia, and thrombocytopenia, and subsequently a preceding hemorrhagic colitis was described [12, 13]. In 1982, during an investigation of outbreaks of hemorrhagic colitis, *E. coli* O157:H7 was identified as a pathogen and in the same year the association between HUS and STEC was described [1, 3, 11]. The terms "D+ HUS" (diarrhea positive HUS) for HUS caused by STEC or other rarer enteric bacteria and "D−HUS" (diarrhea negative HUS) for other TMA should be deferred, as some (albeit rare) patients with STEC-HUS do not have diarrhea, while up to 30% of patients with complement-mediated TMA may have diarrhea at presentation [2, 5].

Complement-mediated TMA is primarily caused by mutations in complement factors (regulators and/or activators), leading to uncontrolled activity of the complement alternative pathway (AP), but it can be also caused by acquired abnormalities such as antibodies against complement factor H (CFH) [2, 4, 5, 14].

Primary noncomplement-mediated TMA is caused by mutations in genes that are typically not related to the complement system. The first of these is cobalamin C-related TMA, which is a hereditary metabolic cause of TMA caused by recessive mutations in methylmalonic aciduria and the homocystinuria type C protein (MMACHC) gene. Patients usually present in infancy with diverse developmental abnormalities and primarily neurologic symptoms. However, TMA can also occur in these patients as abnormalities in cobalamin (vitamin B12) metabolism may lead to endothelial dysfunction. This disorder is uncommon but relevant, since both diagnostic tests (serum homocysteine and urine methyl-malonic acid levels) and efficient therapies (with hydroxycobalamin, folinic acid, and betaine) are available, simple, and inexpensive [3, 15, 16] Table 26.1. Another disorder in this group is diacylglycerol kinase ε (DGKE)-related TMA. Homozygous mutations in DGKE result in infantile aHUS, but may also cause membranoproliferative glomerulonephritis (MPGN) or a clinical and pathological overlap between these two disorders. The mechanism is unknown, but may be related to protein kinase C-mediated upregulation of prothrombotic factors. Proteinuria, often nephrotic, is a major component of this disorder and most patients slowly progress to end-stage renal disease (ESRD) [2–4, 6, 17–19]. Recently, patients from two different families were found to have TMA presumably caused by mutations in inverted formin-2 (INF2) gene, which is also known to be involved in focal and segmental glomerulosclerosis (FSGS). Interestingly, two patients from one family were also diagnosed with the hereditary peripheral neuropathy disorder Charcot–Marie–Tooth [20]. It is likely that TMA-causing mutations in novel genes will be added to this group of primary noncomplement TMA in the future.

Many diseases and conditions may lead to secondary TMA. Infectious agents include bacteria other than STEC, which can produce Shiga toxin (such as *Shigella dysenteriae*), *Streptococcus pneumoniae*, and viruses such as HIV and influenza A and B [2, 7, 21–24]. TMA may complicate autoimmune diseases such as systemic lupus erythematosus (SLE), catastrophic antiphospholipid syndrome (CAPLS), and systemic sclerosis [2, 25–28]. It can be seen in association with other glomerular disorders, including immunoglobulin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. A (IgA) nephropathy, anti-neutrophil cytoplasmic antibody (ANCA)-associated vasculitis, and others, although this may be a histopathologic finding only without the typical clinical findings [2, 29, 30]. TMA is a known and multifactorial complication of hematopoietic stem cell transplantation [31–34]. It can also complicate solid organ transplantations, including kidney transplants, either as recurrence of known complement-mediated TMA post-transplant or, more commonly, de novo [7, 35, 36]. Many different drugs have been suspected as a cause of TMA, though a clear evidence for causal association has been shown with relatively few. Quinine is an example of a drug which may cause TMA by immune mechanism, while calcineurin inhibitors (CNI) may represent drugs which cause TMA via direct toxicity [2, 3, 37, 38]. Cancer has long been associated with risk of TMA, either caused by malignancy itself or more often resulting from anticancer therapy [2, 39, 40]. Malignant hypertension with concomitant TMA places a clinical dilemma as any TMA can cause hypertension which may be severe, therefore it may not be clear which entity is the cause and which is the consequence [2, 41–44]. Finally, pregnancy and the postpartum period are associated with various TMA syndromes: complement-mediated TMA, TTP, and the TMA-like syndrome HELLP (hemolysis, elevated liver enzymes, and low platelets), which is related to eclampsia [45–48]. Importantly, in nearly all of these secondary forms of TMA abnormalities in complement-related genes have been described in some patients, many of whom were treated successfully with eculizumab, the complement C5-inhibitor [25, 26, 39, 41, 45, 49, 50]. This implies that a proportion of patients with secondary forms of TMA actually have primary complement-mediated TMA and the secondary condition (i.e. pregnancy, drug, infection, etc.) constitutes a trigger or a "second hit" which is required for developing the full picture of TMA, rather than the primary cause of it [2, 4, 21, 25, 26, 34, 41, 42, 45, 46, 48, 49].

The following will focus on the epidemiology, pathophysiology, clinical manifestations, diagnosis, prognosis, and treatment of two entities of the TMA spectrum: STEC-HUS and complement-mediated TMA.

Epidemiology

In children, 85–90% of TMA cases are caused by infection with STEC. STEC-HUS is more frequent in children than in adults, with median age around 2 years, although adults have more severe disease with higher mortality [3, 4]. The annual incidence in Europe and North America is 1.9–2.9 cases per 100 000 children <3–5 years, and it decreases with age [4]. The predominant cause in most of the world is *E. coli* O157:H7 and most occurrences are sporadic [3, 7, 11]. However, outbreaks of O157:H7 or other serotypes are also common, and the most significant recent outbreaks occurred in Germany in 2011 (*E. coli* O104/H4), in Oklahoma, USA, in 2008 (*E. coli* O111/NM), and in Ontario, Canada, in 2000 (*E. coli* O157:H7) [51–54]. Most *E. coli* O157:H7 infections and HUS occur in summer and autumn [5, 9]. The primary reservoir of *E. coli* O157:H7 is the intestinal tract of cattle, and it is more common in rural areas and in countries with high-density cattle raising, such as Scotland and Argentina. Ground beef, lettuce, sprouts, municipal water, and many other sources have been all recognized as major transmission vehicles of STEC, while airborne and person-to-person transmission have also been described [11, 55, 56]. The risk of developing HUS after STEC-colitis is around 10% in sporadic infections, and up to 20% in epidemic outbreaks [4, 7, 11, 55].

Complement-mediated TMA accounts for 5–10% of all HUS cases, with incidence of 0.5–2 cases per million per year [5, 7, 8, 57]. It can occur in children and adults, and may be sporadic (most often) or familial. Genetic mutations affecting genes related to the complement alternative pathway or autoantibodies against CFH are found in 50–60% of cases of complement-mediated TMA [4–6, 8, 57–59]. In 40–50% of patients clinically diagnosed with complement-mediated TMA, no specific cause, genetic or autoimmune, is identified. CFH mutations were the first to be described and are the most common abnormality responsible for complement-mediated TMA, accounting for 24–27% of cases [6, 58, 60, 61]. The second most common mutations (7–9%) are found in the gene encoding for membrane cofactor protein (MCP or CD46), followed by complement factor I (CFI) and complement component 3 (C3) mutations, each of which accounts for 4–8% of cases [6, 58, 60–63]. Mutations in complement factor B (CFB), thrombomodulin (THBD or CD141), and complement factor H-related proteins (CFHRs) are responsible together for 5–10% of cases [6, 58, 60, 61, 64]. Anti-CFH autoantibodies account for 10–15% of cases and are frequently associated in deletions of CFHR1 and 3 [6, 57, 58, 60, 61]. Five to ten percent of complement-mediated TMA patients carry more than one mutation [57, 58, 65]. The presence of one or more mutation and/or the presence of specific genetic risk variants, as discussed in the next section, may increase the risk of disease manifestation [3, 4, 6, 7, 56–58, 60, 65].

Pathophysiology

The common pathologic basis of all TMA is injury to the vascular endothelium with subsequent microvascular thrombosis, which leads to consumptive thrombocytopenia, MAHA, and kidney and other organs injury [2–4, 56, 66].

STEC-HUS

There has been great advancement in understanding the mechanism of the disease since the first description of STEC-HUS. However, one of the main questions regarding STEC-HUS pathophysiology – why only 10–20% of patients with STEC infection develop HUS –remains unanswered [2–4].

Enteric STEC infections are almost never accompanied by bacteremia. Rather, the systemic complications, such as HUS, and at least partially also the intestinal manifestations, are caused by the (Shiga) toxin, which is the key factor in the pathogenesis of STEC-HUS [7, 11]. There are two kinds of toxin, Shiga toxins 1 and 2 (Stx1 and Stx2), with the latter being more virulent. Both toxins are made of two subunits: subunit A is an N-glycosidase which inhibits protein synthesis and subunit B binds to globotriaosylceramide (Gb3, also known as CD77) on the surface endothelial, mesangial, and epithelial (podocytes and tubular) cells, as well as blood cells including monocytes, polymorphonuclear cells, and platelets [3, 4, 7, 11, 55, 56]. The strong expression of Gb3 on glomerular endothelial cells, as well as the apparent propensity of the glomerular circulation to endothelial damage and occlusion, is thought to be the explanation of why the kidney is the main organ involved in STEC-HUS [2, 7, 11, 56]. After inducing hemorrhagic colitis, Stx binds to these blood cells and circulates in the bloodstream. Stx is released from blood cells within microvesicles, a process which both facilitates its transport to the target cells in the kidney and enables the toxin to evade the host immune system. These microvesicles were also shown to be prothrombotic and thus may contribute to the pathogenesis of HUS in several mechanisms [67, 68]. The toxin is subsequently internalized to endothelial and epithelial kidney cells by endocytosis, splits into its A and B subunits, and then – via its B subunit – inhibits the 28S unit of ribosomal ribonucleic acid (rRNA) and thus protein synthesis. This step induces a stress response that can lead to apoptotic cell death [2, 3, 11, 55, 56]. Another effect of Stx is induction of thrombosis by enhancement of tissue factor expression, increasing thrombin formation and vWF secretion, inhibition of fibrinolysis, and direct platelets activation [3, 55, 56, 66, 69]. In addition to its apoptotic and prothrombotic effects, Stx induces inflammation by upregulation of cytokines, chemokines, and adhesion molecules [2, 3, 7, 70].

Complement activation, which is responsible for complement-mediated TMA, has been noted to be involved in STEC-HUS as well over the last 10 years [71–77]. There is evidence of Stx-induced complement activation via both the mannose-binding lectin (MBL) and the alternative complement pathways [71, 72, 74, 77]. Moreover, Stx can bind CFH and significantly delay its activity as a cofactor for CFI-mediated cleavage of C3b on the surface of the endothelial cell, thereby markedly reducing the regulatory activity of CFH on complement activation [74, 76].

Complement-mediated TMA

Dysregulation of the complement alternative pathway is the cause of complement-mediated TMA [2–4, 6–8, 78]. The complement system is part of the innate immune system, which has an important role in targeting and killing of pathogens, and induction of an inflammatory response. It consists of >30 plasma and membrane-bound proteins and has three activation pathways: classical, MBL, and alternative. Activation of each of these pathways leads to production of protease complexes termed C3 and C5 convertases that cleave C3 and C5, respectively, eventually resulting in the formation of the membrane-attack complex (MAC; C5b-9), which causes cell lysis. In addition, activation of C3 and C5 results in the generation of the highly reactive anaphylatoxins C3a and C5a, respectively [2, 3, 6, 8, 78, 79].

Unlike the other two pathways, the alternative pathway is constitutively active as a result of spontaneous, hydrolysis-mediated generation of C3b on both pathogen and normal host cells, therefore requiring tight regulation to limit activation both spatially and temporally [2, 3, 6, 79, 80]. The plasma regulators are CFH and CFI, while MCP (CD46), decay accelerating factor (DAF/CD55), protectin (CD59), and complement receptor 1 (CR1/CD35) are membrane-bound regulators [4, 7, 78, 79]. Thrombomodulin (CD141), encoded by THBD gene, is another membrane-bound protein which is an antithrombotic factor, but also has complement inhibitory activity [6, 8, 81, 82]. Loss of function mutations in these regulatory genes or gain of function mutations in effector genes such as CFB and C3 leads to complement dysregulation and overactivation, eventually causing injury of the vascular endothelium and TMA [3, 4, 6, 7, 60, 62, 64, 78, 79, 83–88].

Pathogenic mutations identified in patients with complement-mediated TMA include nonsense and missense mutations, deletions, splice site changes, and complex rearrangements. Most of these changes are heterozygous, even though many family members with heterozygous mutations are asymptomatic. Thus, the penetrance of these mutations is incomplete and is known to increase with age and with the presence of additional risk factors [2–4, 6, 7, 57, 61]. Genetic risk factors include a second mutation or genetic variants such as specific single nucleotide polymorphisms in CFH or MCP genes, copy-number variations in CFHR 1 and 3, and fusions genes of the CFHRs region [3, 4, 6, 7, 57, 59, 64, 65, 89]. Additionally, there are known environmental triggers for complement-mediated TMA episodes or relapses, including infections, drugs, and pregnancy [2, 6, 7, 45, 46, 48, 79, 90].

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Acquired complement-mediated TMA occurs in the form of autoantibodies against CFH [2, 6, 8, 91–94]. CFH autoantibodies identified in complement-mediated TMA patients exclusively bind to epitopes located to the C-terminus of CFH, thus preventing binding of CFH to endothelial surfaces and C3 [6, 8, 93, 95]. There is a strong (but so far unexplained) association between the homozygous deletion of complement factor H-related proteins 1 and 3 (CFHR1 and CFHR3) and the presence of anti-CFH autoantibodies [2, 6, 8, 92–94, 96].

Clinical Manifestation

The clinical symptoms of TMA reflect anemia, thrombocytopenia, and renal or other organ involvement, and include pallor, fatigue, shortness of breath, oliguria, and edema [4]. In almost all cases of STEC-HUS, manifestations are preceded by severe abdominal pain and diarrhea, which start 2–12 days (average 3) after ingestion of contaminated vehicle. The diarrhea becomes bloody in up to 90% of patients, and 30–60% of patients have fever and vomiting. TMA manifestations in those patients who develop the syndrome occurs after the colitis improves, approximately a week after the onset of diarrhea [3, 4, 7, 11]. Half of complement-mediated TMA episodes are triggered by intercurrent events, including upper respiratory tract infection, gastroenteritis, vaccination, and childbirth [4, 57, 58]. Renal involvement includes hematuria, proteinuria (commonly nephrotic ranged), oliguria, and hypertension, which may be severe, especially in complement-mediated TMA. The severity of renal involvement is greater in adults, and in general varies between mild nephritis without acute kidney injury (AKI) to severe anuric AKI, and many patients with both STEC-HUS and complement-mediated TMA require acute dialysis [3, 4, 7, 97].

Extrarenal manifestations occur in 19–38% of patients with STEC-HUS and complement-mediated TMA [2, 4–6, 61, 98]. Possible mechanisms include vascular injury caused by Stx in STEC-HUS and by complement activation in complement-mediated TMA, as well as hypertension and uremia caused by renal failure [4, 5, 7, 11, 98, 99]. Neurologic involvement is the most common extrarenal manifestation in both STEC-HUS and complement-mediated TMA and includes seizures, alteration in consciousness, hemiparesis, vision loss, and other rarer symptoms [4, 5, 11, 58, 97–100]. Gastrointestinal involvement is also common and includes diarrhea, vomiting, gastrointestinal bleeding, cholelithiasis, pancreatitis, and hepatitis [2, 4, 61, 98, 99]. Cardiac complications include left ventricular hypertrophy, dilated or hypertrophic cardiomyopathy, valve insufficiency, myocardial infarction, and intracardiac thrombus [4, 7, 11, 57, 98, 99]. Other extrarenal manifestations include pulmonary edema, hemorrhage and embolism, ocular complications, and gangrenous fingertips [4, 11, 92, 97–99]. In complement-mediated TMA extrarenal manifestations are more common during the initial 6 months post presentation, but can also occur during the chronic phase [61].

Diagnosis

Figure 26.1 presents a general approach to diagnosis of TMA. The defining laboratory features in TMA include elevated creatinine and urea, thrombocytopenia, and signs of MAHA. The latter include low hemoglobin, high lactate dehydrogenase (LDH), low haptoglobin, negative direct antiglobulin (coombs) test (except in pneumococcal TMA), and evidence of fragmented red blood cells (schistocytes) on peripheral blood film. Urinalysis usually shows hematuria and proteinuria [2, 4, 5, 101].

The typical findings on kidney biopsy are thickening of arterioles and capillaries, endothelial swelling and detachment, subendothelial accumulation of proteins and cell debris, and fibrin and platelet-rich thrombi obstructing vessel lumina. However, biopsy is not requisite for the diagnosis of TMA, and it cannot distinguish between the different etiologies of TMA [2, 3, 5, 6, 8].

The first step in the diagnostic process of a patient with the triad of AKI, MAHA, and thrombocytopenia, who presumably has TMA, is to exclude the other entity which can present with these manifestations, disseminated intravascular coagulation (DIC). DIC and TMA can be easily distinguished by sending coagulation tests as in the former partial thromboplastin time (PTT) and prothrombin time (PT) or international normalized ratio (INR) are prolonged and fibrinogen level is low, while in the latter these tests should be normal [2, 102, 103].

The next step is investigation for the cause of TMA, which is crucial because different forms of TMA have completely different treatments. Since TTP is a common cause of TMA, especially in adults, and it can efficiently be treated via plasma exchange (PE), one of the first priority tests should be the detection of the activity level of ADAMTS13. Activity level >10% rules out TTP [2, 4, 5, 104]. The other common cause of TMA, especially in children, is STEC-HUS, and therefore one should always exclude this cause before diagnosing rarer types of TMA. In STEC-HUS, stool cultures should be positive for *E. coli* O157:H7 or other less common STEC, and another commonly used diagnostic method is polymerase chain reaction (PCR) assay for the bacteria or Stx [11, 55, 105].

Exclusion of a secondary TMA (related to infection, autoimmunity, glomerular disease, stem cell and solid organ

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

transplantation, drugs, cancer, malignant hypertension, or pregnancy) follows the clinical context, history and physical examination, and additional ancillary tests, depending on the specific clinical presentation. Screening for cobalamin C-related TMA, with serum homocysteine and urine methylmalonic acid levels, which are typically high, is recommended [2, 4, 6].

In only 30–50% of patients with complement-mediated TMA are C3 levels low, and they may also be low in other types of TMA [5, 6, 104]. More specific assays such as CH50 (measuring total complement activity), AP50 (measuring alternative pathway activity), CFH functional assay, and levels of complement activation markers such as C3d and C5b-9 allow for insights into functional aspects of the complement system. Additionally, comprehensive screening of all genes currently known to be involved in complement-mediated TMA is recommended, including CFH, MCP/CD46, CFI, C3, CFB, CFHR 1, and 5, and THBD/CD141 [2–6, 57]. Infants should also be tested for mutations in DGKE, which is responsible for a form of primary noncomplement TMA [2, 4, 17, 18, 57]. Finally, anti-CFH autoantibodies should be tested for to diagnose the known acquired form of complement-mediated TMA [5, 6, 57, 104].

However, complement functional assays are available only in few laboratories and, similarly to genetic testing, require long time to being processed. Moreover, only 50–60% of patients with presumed complement-mediated TMA are eventually found to have a disease causing mutation in one of the above-mentioned genes. Thus, complement functional and genetic tests are important to confirm the diagnosis, inform outcome, and guide treatment, but they do not play a role in the acute diagnosis of complement-mediated TMA, which remains clinical and is established after excluding all other forms of TMA. In the era of an efficacious anticomplement therapy, which may completely change outcome, the diagnosis of complement-mediated TMA should be made in a timely manner. Therefore, every patient with no obvious clinical picture of STEC-HUS, TTP, or a secondary TMA, with ADAMTS13 activity >10% and with STEC negative stool culture or PCR should be diagnosed with complement-mediated TMA, at least until proven otherwise, and treated with anticomplement therapy [2, 4, 6, 101, 103].

Prognosis

STEC-HUS

When first described, the mortality of STEC-HUS was >30% for all cases. In more recent years, with an improved understanding of pathogenesis, recognition, and early dialysis for oligoanuric patients, the acute mortality rate has dropped to 1–4% [106, 107]. CNS involvement is the most common cause of death, occurring in <50% of children with STEC-HUS [108], with cardiac failure, pulmonary hemorrhage, bowel perforation, and electrolyte imbalances following [106].

Early literature identified the following risk factors predicting a more severe course of postdiarrheal HUS: oligoanuria, younger age (<2–3 years), high initial leukocyte count, hypertension, and severe colitis [106, 109–115]. More recent studies have found that CNS involvement, high hemoglobin, and low sodium levels were the best predictors of death in STEC-HUS patients [108].

CNS involvement may include seizures, hemiplegia or hemiparesis, extrapyramidal syndrome, and coma. MRI findings in patients showed that all parts of the CNS were susceptible to injury, and that there was no correlation between localization of injury and final prognosis. The overall prognosis in this patient group was poor with nine patient deaths and 13 with severe sequelae [100]. Of note, the exact mechanism resulting in CNS injury may differ from that of renal involvement and treatment may require a multifaceted approach [116].

As mortality has improved markedly in the past few decades, long-term sequelae may still require management in STEC-HUS patients. Persistent hypertension is seen in 5–15%, progression to CKD in up to 18% of children, and ESRD in approximately 3% of patients. Given the multiorgan involvement, complications of the nervous system, heart, gut, biliary system, and pancreas may need to be followed over time [106].

Complement-mediated TMA

The prognosis of complement-mediated TMA has classically been poor, with most patients developing ESRD within 2 years of presentation [5]. However, in the past decade the management of complement-mediated TMA has undergone a paradigm shift and the associated outcomes have evolved as well.

Complement-mediated TMA carried a mortality rate of up to 70% before the advent of terminal complement blockade [7]. Since the monoclonal C5 antibody eculizumab has widely become available, short-term mortality has fallen and outcomes have improved significantly [117–119]. At this time, many long-term outcomes of eculizumab-treated complement-mediated TMA patients have yet to become available.

As a disorder of complement dysregulation, identifying specific mutations can offer prognostic information in complement-mediated TMA. Mutations in CFH [61], CFI, and C3 have been associated with a worse prognosis, while MCP/CD46 mutation carriers with childhood disease onset have shown improved outcomes. Adult patients with no

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

identifiable mutations in a study of 214 patients with complement-mediated TMA were found to have similarly poor prognoses as the above-mentioned subgroups, where children without identifiable mutations had similar outcomes to the MCP/CD46 mutation group [120].

Interestingly, outcomes from this study show discrepancies based on the age of the patient: children with complement-mediated TMA have a higher mortality compared to adults (6–7% vs. <1% at 1 year), whereas progression to ESRD after the first episode was more frequent in adults (46% vs. 16%). Approximately 56% of adult patients progress to ESRD within the first year of illness [120]. Sex, race, time from initial presentation to diagnosis, and family history of complement-mediated TMA do not appear to be associated with risk of progression to ESRD [61].

A substantial number of patients may also develop extrarenal complications in both the chronic and acute phases. Gastrointestinal, cardiovascular, CNS, and pulmonary manifestations may impact adults and children and may require long-term follow-up [61].

The advent of the terminal complement blockader eculizumab has fundamentally shifted the trajectory of illness in complement-mediated TMA, but the disease process still carries considerable morbidity and mortality risk both in the acute and chronic phases.

Treatment

General Supportive Therapy for all TMA

Acute Kidney Injury

Once established, TMA care requires management of oliguric AKI. Fluid and electrolyte intake and output should be carefully calculated and reassessed as patients may be anuric and require fluid restriction. Dietary and other intake restrictions on electrolytes such as potassium or phosphate may be required as the GFR declines. Patients may also have intolerance to oral food intake and may require assistance with enteral feeds or parenteral nutrition. Hypertension management may also be necessary in these patients [121].

Anemia and Thrombocytopenia

Anemia and thrombocytopenia may be profound, and providers are often faced with a dilemma regarding the need for transfusion of blood products. In addition to the typical risks of blood transfusion (e.g. allergic reaction, infection, electrolyte derangement), one must be cognizant of the exposure of the patient to donor antigens and the subsequent production of donor-specific antibodies. In a patient with a potential risk of developing CKD and who may potentially require kidney transplantation, clinicians must be judicious regarding blood transfusions [121, 122].

A patient whose serum hemoglobin concentration is below the center-specific transfusion threshold, but who is well-perfused, hemodynamically stable, and whose other hemolytic markers (LDH, haptoglobin, reticulocyte count) suggest declining hemolysis may be managed expectantly, whereas a patient with a low hemoglobin, ongoing hemolysis, and any signs of cardiovascular instability would likely necessitate a blood transfusion.

Thrombocytopenia can be significant in all TMAs. However, as previously detailed, platelets may contribute to microthrombi formation and may aggravate the underlying microangiopathic cascade, worsening symptoms [121]. The safety of platelet transfusion in STEC-HUS is still uncertain, with mixed data in the literature, but it may be reasonable in patients with evidence of active bleeding or those who are undergoing a surgical procedure, and risks and benefits must be weighed before any decision to proceed with transfusion.

Intravascular volume must be considered with administration of blood products as well, and patients may benefit from diuretics during or following transfusion, though not all will respond [121].

Disease-specific Therapy

STEC-HUS

Prevention

STEC-HUS, unlike other TMAs, has a characteristic antecedent illness of bloody diarrhea. Recognition of this prodromal phase offers clinicians the opportunity to implement preventative measures to reduce the risk of progression to HUS.

IV Hydration

In patients presenting during the diarrheal phase of enterohemorrhagic *Escherichia coli* (EHEC) illness, provision of IV fluids may reduce the risk of subsequent HUS [123]. A recent meta-analysis established an association between lack of fluid administration and higher hematocrit (>23%) at onset of diarrheal illness with poor outcomes including oligoanuria, need for renal replacement therapy, and death [124].

The role of volume expansion even after onset of HUS has also been explored. In a multicentre surveillance program of children with STEC-HUS, early IV volume expansion was associated with significantly better short-term and long-term outcomes compared to historical controls, including a lower rate of CNS involvement. Restoration of the circulating volume was hypothesized to reduce the formation of thrombi and limit hypoxic ischemic injury [125].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

IV volume expansion should therefore be undertaken for patients presenting with STEC-HUS, and should be considered as well for patients presenting with established HUS early in their illness. However, careful monitoring of urine output and total fluid balance is paramount as fluid therapy will need frequent reassessment, particularly in patients who progress to oligoanuria [126].

Antibiotics

There have been mixed results in the literature as to whether use of antibiotics in STEC illness increases the risk of progression to HUS. The available evidence would suggest that providers should limit the use of antibiotics to patients in whom there is a suspicion of sepsis or severe bacterial illness wherein the risks of potentially increasing likelihood of progression to HUS are outweighed by the benefits of infection control [126, 127].

Management

In addition to the supportive management of AKI detailed previously, other modalities have been investigated for their therapeutic potential in STEC-HUS.

Erythropoietin

Erythropoietin (EPO) has been investigated as a potential option to reduce the need for red blood cell transfusion in patients with HUS in small pediatric studies [128]. At this time there is insufficient evidence to recommend EPO as a standard therapy for patients with HUS.

Plasma Infusion and Plasmapheresis

The American Society for Apheresis (ASFA) lists PE as a recommended therapy for STEC-HUS [129], though this treatment plan may not be any more efficacious than supportive care [130–132].

Dialysis

With progression to anuric renal failure, approximately two-thirds of patients with STEC-HUS ultimately require renal replacement therapy [121]. Both hemodialysis and peritoneal dialysis may be used, and evidence for superior outcomes with one modality versus the other is limited.

Renal transplantation is rarely required in STEC HUS, though when necessary the risk of disease recurrence is minimal [133].

Emerging Therapy and Future Perspectives

Eculizumab

While terminal complement blockade is the mainstay of therapy for complement-mediated TMA (as described below), the use of the monoclonal antibody eculizumab in STEC-HUS is being further elucidated. As detailed previously, greater understanding of the mechanism of STEC-HUS has implicated complement dysregulation in the pathogenesis.

Support for use of eculizumab in STEC-HUS was provided in a case series of three children with severe STEC-HUS with neurologic involvement and dialysis-dependent AKI. Administration of eculizumab was associated with a rapid clinical improvement in all three patients [134]. In 2011, during the *E. coli* O104 outbreak in Germany and France, eculizumab was used in more than 250 patients. The patients treated with the drug had a more severe renal injury and more frequent neurological complications at baseline compared to those who were not treated, and outcomes were similar in both groups. This may suggest a lack of drug effect or may be interpreted as treatment benefit as the group treated with eculizumab may have progressed toward worse outcomes [135]. Since then additional case series reported a significant improvement in neurological function in children with STEC-HUS and neurological impairment treated with eculizumab [136, 137]. Of note, renal impairment persisted in most of these patients [138]. While data for eculizumab in STEC-HUS is limited to observational studies, it may be reasonable to consider this drug for patients with severe disease, particularly with neurologic involvement and when standard therapy has failed.

Shiga Toxin Neutralizing Agents

In an attempt to reduce the pathogenicity of the Stx, oral Stx-binding agents have been developed [139], though to date no such agents (either oral or intravenous) have been proven efficacious in human studies and therefore toxin binding agents are not a standard component of STEC diarrheal illness management [121, 140].

Controversy

While supportive management and AKI therapy are well established in STEC-HUS, the questions surrounding early therapy remain. It appears reasonable to trial volume expansion early in the illness course, with careful monitoring. The role of antibiotics has conflicting evidence, though weighing risks and benefits, avoidance in patients with a low risk of sepsis is favored. Eculizumab as a therapy in STEC-HUS is currently under investigation in larger studies. Until these and future analyses can provide more information, we would consider the use of eculizumab in patients with severe STEC-HUS who are not responding to conventional therapy.

Complement-Mediated TMA (aHUS)

Plasma Therapy

Therapeutic PE has previously been recommended as early therapy for complement-mediated TMA [141]. Further analysis of outcomes has revealed that there is limited efficacy only on renal prognosis in patients treated with plasma therapy compared to those who were not [142]. In the era of complement blockade, the importance of plasma therapy has diminished.

Eculizumab

For patients with complement-mediated TMA, terminal complement blockade is the therapeutic option of choice. Eculizumab is a humanized monoclonal antibody that binds the complement protein C5 and prevents production of the proinflammatory anaphylatoxin C5a and the product of the terminal complement cascade C5b-9 [118].

In two prospective phase two trials, eculizumab inhibited TMA in patients with complement-mediated TMA and resulted in a significant improvement in renal function [118]. A follow-up analysis demonstrated that these benefits were maintained after 2 years, with no new safety concerns surrounding the therapy [117, 143]. The safety of eculizumab has been demonstrated in further analyses, wherein the most common adverse effects attributed to the drug were fever, and mild gastrointestinal and respiratory symptoms. No deaths of meningococcal infections were noted as patients were systematically vaccinated (Neisseria meningitidis strains A, C, W, Y, and B, *S. pneumoniae*, *Haemophilus influenzae*) and subjected to long-term antibiotic prophylaxis [14, 144].

Eculizumab, when available, should be initiated within 24–48 hours of onset of disease or admission. In children who have been initiated on plasma therapy as a first-line treatment, a switch to eculizumab should be done as soon as the diagnosis of complement-mediated TMA is made [14, 114]. In autoimmune complement-mediated TMA (e.g. CFH) eculizumab is successful in stabilizing patients in the acute phase, though chronic management should target suppression of disease-causing antibodies. When successful, eculizumab may be discontinued in these patients, who may require long-term immunosuppression [5, 145, 146].

Monitoring of complement activity or eculizumab drug levels may be helpful between doses of the drug, as dose adjustments may be considered if there are signs of insufficient blockade. In the long-term management of patients on eculizumab, routine complement activity monitoring may be unnecessary unless there are concerns for clinical status changes (such as infection, trauma, or other triggers) or relapse [125]. Total complement activity (CH50) may be followed. Of note, the normal range of CH50 may vary depending on individual laboratory assays [5].

Dialysis

As with STEC-HUS, many patients with complement-mediated TMA may require dialysis [142]. Patients may be treated with either hemodialysis or peritoneal dialysis, and to date there is insufficient evidence to recommend on modality over the others. Prospective studies of treatment with eculizumab suggest that it may decrease dialysis dependence [118].

Kidney Transplantation

Before the availability of C5-blockade, post-transplant recurrence of complement-mediated TMA was 60%, with 5-year graft survival of 30% in those patients [147].

For individuals with complement-mediated TMA secondary to a mutation in the gene for a circulating complement regulators (such as CFH, CFI, CFB, or C3), liver transplantation has been used as a means of providing a new source of circulating factor production. Liver-kidney transplant has been used as a viable option to maintain graft function before the advent of terminal complement blockade therapy [147–151].

In patients with complement-mediated TMA at high risk of disease recurrence post-transplant and for those who experience recurrence, eculizumab has also been shown to induce remission and graft function recovery [147, 152–154].

In an observational study of 13 renal transplant recipients who were given eculizumab for post-transplant recurrence of complement-mediated TMA, complete reversal of the disease was seen in all patients. Of note, a delay in initiation of anti-C5 therapy was associated with a low degree of renal functional improvement [152]. Eculizumab therapy is promising for both prevention and cure of recurrent complement-mediated TMA in renal transplant recipients [155].

Treatment Duration

The optimal length of therapy for complement-mediated TMA has yet to be determined. Published literature suggests that different underlying mutations may warrant individualized regimens, as the recurrence risk of the disease may vary with the genetic defect [120]. Tools for monitoring complement activity to help guide eculizumab dosing frequency have had some success in smaller cohorts [156] though no large-scale validation of such tools has yet been completed. Strategies toward restrictive use of eculizumab continue to be studied. Whereas lifelong therapy had previously been advocated, it does appear that withdrawal of the drug, followed by close monitoring for signs of disease recurrence (e.g. hematuria, proteinuria, and hypertension) may be appropriate [157], and prospective studies are needed to provide more insight in this area.

Controversy

While the management of complement-mediated TMA has been revolutionized with terminal complement blockade, there are many questions that remain. Most notable is the appropriate duration of therapy with eculizumab. At this time more data are needed on individual patient risk profiles, complete with genotype-phenotype correlation. Efforts are ongoing in this field to establish optimal treatment regimens.

Conclusion

TMAs represent a disease spectrum for which our understanding has increased dramatically over the past decade. What was once defined as a TTP/HUS spectrum has now expanded into multiple disease processes with many clinically similarities and distinct features. An increasing body of literature supports the role of complement dysregulation as one of the disease-causing mechanisms in the TMA spectrum. Common to the TMA disease entities are the triad of MAHA, thrombocytopenia, and AKI, and the severity of illness can range from mild disease to severe disease with prolonged sequelae and high mortality.

HUS is an entity under the umbrella of TMA. The most common cause, STEC-HUS, has long been considered as independent of the rest of this spectrum of diseases as it has a defined trigger and known secondary cause of microangiopathy. However, it has more recently been discovered that much like in other TMA, complement dysregulation may play a prominent role in the pathophysiology as well.

In complement-mediated TMA the importance of the complement cascade in disease progression has led to a revolution in therapy with the advent of eculizumab, a form of terminal pathway blockade. Since the introduction of this drug, disease remission has become attainable and mortality has improved considerably. Understanding the role of complement in TMA has led to the use of eculizumab in select cases of STEC-HUS as well, and its role in the management of this entity continues to be elucidated.

While complement pathway blockade has offered the prospect of improved outcomes, questions remain to be answered regarding the optimal dosing or duration of therapy. In STEC HUS, the notion of preventative management or neutralizing toxins has thus far not shown any benefit in clinical studies, though investigations are ongoing. In complement-mediated TMA, although many mutations have been defined, others continue to be discovered. The significance and therapeutic potential of these mutations is still unknown and further study in genetics will hopefully help to inform future clinical trials in this area.

Introduction

Major physiological adaptive changes to renal hemodynamics, and glomerular and tubular function occurs with pregnancy. Normal physiological adaptations leading to hyperfiltration in pregnancy are not pathogenic in women with normal kidneys, but may unmask underlying chronic kidney disease (CKD) for the first time or contribute to worsening of existing CKD. This may manifest as temporary or permanent loss of renal function, and adverse pregnancy outcomes. Therefore pregnancy is an important challenge to the maternal kidney.

This chapter primarily discusses pregnancy in women with CKD at all stages. Clinical decision-making in this high-risk cohort is focused mainly on risk assessment for maternal and fetal outcomes, with very limited evidence regarding interventions. Appraisal of the literature is hampered by the quality of existing data, and there are large knowledge gaps regarding best clinical practice. Observational studies of small, often heterogeneous, and usually retrospectively studied cohorts may not be readily compared. Definitions of CKD differ between studies and over time, with the widespread introduction of CKD staging highlighting the outcomes of pregnancy with less severe CKD. Registry and population cohort studies have illuminated outcomes but often lack detailed clinical data for more complex analysis of risks and outcomes.

Maternal (obstetric and renal) and perinatal outcomes worsen as preconception estimated glomerular filtration rate (eGFR) declines. Hypertensive disorders of pregnancy often drive premature delivery and thereby define fetal outcomes. Management approaches are usually extrapolated from other cohorts at risk of preeclampsia or those with chronic hypertension. Over time, there has been growing confidence in supporting pregnancies in women with kidney disease, even those receiving dialysis, and for women after kidney transplantation. It is no longer routine practice to advise against pregnancy in these women.

Parenthood remains an important goal, but the desire for motherhood is balanced with fears of compromising their own and their child's health. Approaches to care involve understanding the patient's experiences and values whilst acknowledging medical risks. Key management points relate to meticulous preconception planning, informed shared decision-making about the options, and timing and management of pregnancy based on individualized assessment of risks. The involvement of multidisciplinary expert teams, and careful maternal and fetal surveillance throughout pregnancy are essential.

Epidemiology

Chronic Kidney Disease

Defining CKD in pregnant women is challenging, especially where preconception kidney function is unknown – this is common given that assessment of kidney function is not routine in pregnancy. Robust prevalence data is lacking for many populations, with significant heterogeneity between studies that often have small numbers. Definitions vary, data is often historical, and clinical care practices may differ between centers and change over time. In population pregnancy datasets, kidney data is poorly captured, whereas renal registry datasets lack detailed pregnancy data. In all cohorts, early pregnancy loss is difficult to capture and likely underestimated. These factors limit comparison and risk quantification [1], and

should be considered when interpreting studies and when synthesizing data from different studies.

The largest study identifying CKD in pregnancy was a Norwegian population-based data linkage study of 5655 births from 3405 women, assessing eGFR by the Modification of Diet in Renal Disease (MDRD) formula. This study found CKD in 3.3% of pregnancies, with 2.4% with stage 1, 0.8% with stage 2, and 0.1% with stage 3 [2]. This data may be extrapolated to similar countries, but the true prevalence of CKD in most pregnant cohorts remains unknown.

Dialysis

The number of pregnancies in patients receiving dialysis reported in the literature is increasing over time, although they remain rare [3, 4]. Absolute pregnancy rates are difficult to define and compare. The Australian and New Zealand Dialysis and Transplant Registry (ANZDATA) has reported the pregnancy rate in chronic hemodialysis patients was 8.4/1000 patient-years between 2001 and 2011, with a live birth rate of 1.26/1000 patient-years [5]. Comprehensive survey data from Belgium reported a conception rate of 0.3/1000 patient-years, and a study from Japan showed 3.4% of women of childbearing age conceived [6–8]. An Italian study found that a live birth rate was 0.7–1.1 per 1000 women per year compared to the national rate of 72.5 per 1000 women per year [9]. These data suggest that the birth rate in patients on peritoneal dialysis (PD) is lower than that in hemodialysis recipients [3–5]. The reasons for this are uncertain, but may be due to hypertonic fluid disrupting implantation or causing adhesions [10], or change in dialysis modality to prior to conception [5].

Transplantation

Since the first successful birth post renal transplantation in 1958, the rate of conception and numbers of live births post kidney transplantation have continued to increase [11]. The ANZDATA registry has reported a rate of 20/1000 patient years from 1996 to 2005 with a live birth rate of 16/1000 patient-years [4, 11]. The United States Renal Data System registry reported a pregnancy rate of 33/1000 patient-years [12]. The UK Obstetric Surveillance Study recognized all pregnancies in renal transplant recipients, with a rate of 7.6/1000 patient-years [13]. Italian data revealed a birth rate of 5.5–8.3 per 1000 women [14]. The impact of widespread use of mycophenolate mofetil immunosuppression on pregnancy rates in patients with transplant or glomerulonephritis in the recent era of care is yet to be determined.

Acute Kidney Injury

The epidemiology of acute kidney injury (AKI) in pregnancy depends on the geographical location and definition used, and the literature is highly variable. AKI diagnosis based on rise in serum creatinine (absolute value >90 μmol/l, doubling of serum creatinine) is likely more common but poorly captured in studies. In the developed world, AKI is uncommon and predominantly due to volume loss or hypertensive disorders of pregnancy, and less commonly de novo renal disorders. AKI requiring acute dialysis in pregnancy is rare, occurring in 1 per 10 000 (95% confidence interval [CI] 0.8–1.1) [15]. By contrast, in developing nations AKI is mainly due to sepsis and rates are higher but variable [16].

Pathophysiology

Physiological Changes with Pregnancy

The kidney undergoes marked physiological and structural changes to adapt to the demands of pregnancy, occurring as early as 6 weeks from conception and continuing postpartum (summarized extensively in the paper by Odutayo et al. [17]). These physiological changes are essential adaptions to maintain maternal and fetal health, but previously unidentified kidney disease may be exposed and underlying renal dysfunction may worsen. Systemic hemodynamic changes include vasodilatation mediated by hormones including relaxin and nitric oxide, decreased systemic vascular resistance and increased cardiac output [18]. A nadir in the mean arterial pressure occurs by 18–24 weeks, with subsequent rise in later gestation. Concomitantly, the renin-angiotensin system is activated in pregnancy. Renal tubular changes occur due to complex shifts in hormone responsiveness, with a net increase in total body sodium and potassium, resetting of receptor thresholds for antidiuretic hormone release, and fall in plasma osmolality [17].

All of these factors contribute to expanded plasma volume, increased renal plasma flow (by 50–80%), and increased glomerular hyperfiltration (by 50%) but *without* glomerular hypertension [19]. It is important to note that many physiological studies of pregnancy are historical and lacking contemporaneous data exploring hyperfiltration in mothers who are older or have comorbidities of diabetes and obesity.

Structural changes of the renal tract also occur, with increased kidney size due to expansion of intravascular and interstitial volume. Ureteral and pelvic dilatation is commonly seen, may mimic obstruction, and predisposes to urinary stasis and infection.

Fertility and CKD

Fertility is affected by CKD and declines as renal function worsens. Mechanisms include impaired ovulation due to hormonal dysregulation with hyperprolactinaemia and decrease

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in gonadotropin-releasing and luteinizing hormone pulsatility, decreased ovarian reserve and decrease in libido [20–22]. Women may also be discouraged from conceiving due to concerns for their health [23]. Intensive dialysis may increase the ability for conception [24], but transplantation remains the main mechanism for restoring fertility.

Diagnosis

Markers of Kidney Function in Pregnancy

In normal pregnancy, GFR increment results in greater creatinine clearance and fall in serum creatinine by the second trimester. An accurate estimation of GFR is consequently difficult, with reliance on serum creatinine alone. The gold standard 24 hour urine collection for creatinine or inulin is impractical for clinical use. Commonly used formulae to estimate GFR are not validated in pregnancy. The Cockcroft–Gault formula underestimates GFR compared to inulin clearance and overestimates compared to 24-hour urine creatinine clearance. The MDRD and CKD – EPI formulae underestimate GFR [25–27]. The international classifications of AKI are also not validated in the pregnant population.

Urinary protein excretion increases during pregnancy and can rise until delivery; proteinuria up to 300 mg/24 h may be observed in normal pregnancy [28]. There are multiple contributory mechanisms, including physiological hyperfiltration, reduced tubular protein reabsorption, and increase in glomerular basement membrane pore size. Whilst 24-hour collection is still considered gold standard, the spot protein:creatinine ratio can be used instead for assessing significant proteinuria above 30 mg/mmol and is also validated in hypertensive women [29].

Diagnosing Pregnancy in Patients with CKD

Renal excretion of β-human chorionic gonadotropin (β--HCG) is reduced in renal impairment and thus urine pregnancy tests can be falsely positive [30]. Irregular menstruation is often observed in advanced CKD, and thus serial β-HCG and ultrasound is a better indicator of gestational age than the date of the last menstrual cycle [30]. β-HCG is used in antenatal screening for aneuploidies, which can increase false positives and should be interpreted with caution [31, 32]. Pregnancy-associated plasma protein A (PAPP-A) used in first trimester screening panels is elevated in patients receiving heparin and unpredictable in late-stage CKD [32, 33].

Diagnosing Preeclampsia in Patients with CKD

Differentiating superimposed preeclampsia from worsening CKD due to pregnancy is a diagnostic challenge due to the common features of hypertension, proteinuria, and progressive renal dysfunction [34]. Superimposed preeclampsia with inpatients with underlying CKD contributes to worse outcomes of preterm delivery and small for gestational age. Parameters such as liver function tests and platelet count can assist with differentiation. Systemic lupus erythematosus (SLE) nephritis flares can be difficult to separate from preeclampsia; systemic features of SLE and low complement levels, and elevated double-stranded DNA can aid differentiation [35, 36]. Doppler ultrasound of the umbilical artery to assess changes in waveform and vascular resistance can be useful. Whilst only small studies have been performed, results suggest a high specificity for predicting preeclampsia [34, 37].

Novel biomarkers including soluble fms-like tyrosine kinase (sFlt), placental growth factor (PIGF), and serum placental protein 12 may help in differentiating and predicting preeclampsia in women with CKD [34, 38]. A meta-analysis reviewed use of the sFLT:PIGF ratio as a predictive and diagnostic marker of preeclampsia, and found in both low and high risk patients this could predict development of preeclampsia with a sensitivity of 80%, specificity of 92%, positive likelihood ratio of 10.5, and negative likelihood ratio of 0.22 [39]. Larger cohort studies are needed to clarify the diagnostic benefit of these markers.

Kidney Biopsy

The safety of kidney biopsy in pregnancy is contentious. A systematic review of 197 biopsies showed a complication rate of 7% with the highest risk period being after 25 weeks gestation [40]. It is rarely indicated for differentiation between preeclampsia and primary renal pathology. Biopsy should be undertaken cautiously, preferably in early pregnancy, and only when clinical management is likely to substantially alter based on biopsy results. Otherwise it should be deferred until after delivery. Postpartum kidney biopsy to investigate abnormal renal function or proteinuria commonly identifies pathological glomerular disease [41]. Preconception kidney biopsy may be very informative in assisting with pregnancy planning and risk stratification, especially for transplanted women and those with SLE nephritis.

Prognosis

Impact of Maternal Kidney Disease on Pregnancy Outcomes

There is a substantial body of evidence from cohort and population studies that both maternal and fetal outcomes are worse with any degree of renal dysfunction compared

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to women without CKD, and deteriorate along the continuum of CKD severity [14, 42–46]. The key adverse maternal pregnancy complication is worsening hypertension or preeclampsia, which likely drives preterm delivery and high cesarean section rates. There is increased risk of premature birth, low birth weight, small for gestational age, neonatal intensive care unit admissions, and infant death [3]. Risks are compounded by comorbidities, particularly chronic hypertension and proteinuria (>1 g/day), and some primary diseases [47]. Chronic hypertension is highly prevalent in women with CKD, and alone confers a 7–8-fold relative risk of preeclampsia, which drives other adverse perinatal outcomes [48]. Hypertension is an additive risk for adverse outcome when combined with any stage of CKD [2, 14]. Early-stage CKD may be underrecognized in pregnancy, but also confers an increased risk of pregnancy complications and adverse perinatal outcome compared to women with no CKD, and is not entirely benign [2, 14, 43]. Reassuringly maternal mortality is very rare [3].

Impact of Pregnancy on Kidney Function

The influence of pregnancy on renal outcomes is not always predictable or guaranteed despite best efforts at risk stratification, which makes counseling a challenge. Our understanding of the risk of decline in kidney function with pregnancy in women with CKD has been informed by several cohort studies [14, 46, 49]. A large systematic review showed no difference in renal outcomes between women with or without CKD in pregnancy (Table 27.1). However, this review included few studies in women with advanced CKD who are at greatest risk of declining renal function during and after pregnancy, and evaluated substantial renal decline only [43]. A long-standing cohort study indicated that across all stages of CKD, pregnancy was associated with an increase in hypertension, increase in proteinuria, and worsening of CKD stage postpartum, and the risk increased based on preconception CKD stage [14]. A smaller longitudinal cohort study in later stages of CKD showed proteinuria >1 g/24 h and an eGFR under 40 ml/min/1.73 m^2 predicted decline in eGFR postpartum [46].

Overall, preconception kidney function is an important predictor of risk of decline in kidney function during and after pregnancy, but it must be considered along with other factors such as hypertension, proteinuria as an indicator of chronic damage or primary disease activity and renal biopsy information. In addition, antenatal complications such as infection, preeclampsia and hypovolaemia may cause an AKI, which can also have an impact on longer-term outcomes.

Primary Disease and Pregnancy Outcomes

The impact of primary renal disease varies depending on the specific disease and the severity of kidney dysfunction (which may not always be reported or comparable between studies). The most robust data exists for IgA nephropathy, where the preconception kidney function, proteinuria, and hypertension are the key prognostic factors [53, 57]. There is little data on other glomerular diseases and pregnancy. An exception is SLE nephritis, where clear evidence suggests maternal and fetal outcomes are worse irrespective of renal function, particularly with antiphospholipid syndrome or active renal disease [35, 47]. Active disease pre conception and during pregnancy is associated with increased maternal and fetal morbidity [35, 36, 47, 58]. A meta-analysis of outcomes of pregnancy with SLE nephritis (Table 27.1) found increased risk of SLE flares, hypertension, preeclampsia, premature birth, and low birth weight, particularly in women with active SLE nephritis [47]. Diabetic nephropathy is also an additive risk factor for worse outcomes for both type 1 and type 2 diabetic women who already have higher rates of pregnancy complications [54, 59, 60]. There may be an increased risk of congenital malformations with diabetic nephropathy above that of poorly controlled diabetes alone [61].

Pregnancy and Dialysis

Pregnancies in the hemodialysis population have historically had poor outcomes. Since the 1990s, with better perinatal care and understanding of the importance of intensive dialysis, outcomes have improved, with increased live birth rates of 70–80% [4]. However, pregnancies in chronically dialysed women remain complicated by maternal hypertension (50–70%), preeclampsia (18–67%), polyhydramnios (up to 40%), intrauterine growth restriction (17–77%), and prematurity and low birth weight (50–100%) [3–5, 62]. Compared to transplanted patients, patients receiving hemodialysis have a higher rate of growth restriction, placental abruption, blood transfusion, and intrauterine death [63]. Enhanced clearance of urea and other molecules through intensified dialysis regimens (at minimum >20 hours per week) has beneficial effects on fetal mortality, birth weight, and gestational age, and is especially relevant in women with minimal residual renal function [62]. The presence of residual renal function, particularly being nondialysis dependent at time of conception, leads to higher live birth rates (up to 90% for pregnancies reaching 20 weeks of gestation) compared to those who conceive once established on hemodialysis with less residual function [5, 64]. No studies have assessed the level of renal function at which

Table 27.1 Summary of selected systematic reviews relevant to kidney function assessment, pregnancy in women with kidney disease, and transplants.

Author (year)	Title	Search period	Studies	Patients (pregnancies)	Inclusion criteria	Analysis method	Data quality (as per reviewers)	Key findings
Diagnosis and management								
Cote, et al. (2008) [29]	Diagnostic accuracy of urinary spot protein:creatinine ratio for proteinuria in hypertensive pregnant women: systematic review	1980–2007	13	1241	Studies that compared urinary protein creatinine ratio or albumin creatinine ratio with urine protein excretion over 24 h in pregnant women with hypertension	Quality Assessment of Diagnostic Accuracy Studies tool for assessing validity; diagnostic meta-analysis	Minimal study heterogeneity. Studies inadequately described selection criteria, disease spectrum and test execution.	Spot PCR can exclude proteinuria of >0.3 g/day in hypertensive women. Sensitivity 83.6%; specificity 76.3%; positive likelihood ratio 3.53; negative likelihood ratio 0.21.
Piccoli et al. (2013) [40]	Kidney biopsy in pregnancy: evidence for counseling? A systematic narrative review	1980–2010	39	243 biopsies in pregnancy; 1236 post	Studies on kidney biopsy in pregnancy with >5 patients. Excluded renal transplant	Narrative synthesis	Heterogeneous cohorts; only narrative review possible	Higher complication rate for renal biopsies in pregnancy compared to postpartum (7% vs.1%). Biopsy led to therapeutic changes in 66% of cases.
Tong et al. (2015) [50]	Perspectives on pregnancy in women with chronic kidney disease: systematic review of qualitative studies	To April 2014	15	257	Qualitative studies on experiences of adult women with pregnancy and CKD	The Enhancing transparency in reporting the synthesis of qualitative research framework; thematic synthesis	The review was limited by study cohort heterogeneity. Pregnancy was not always the major focus of the study.	Seven themes identified: pursuing motherhood, failure to fulfill social norms, fear of birth defects, exacerbating disease, decisional insecurity and conflict, control and determination, withholding emotional investment.
Transplantation								
Bar et al. (2001) [51]	Pregnancy outcome after cyclosporine therapy during pregnancy: a meta-analysis	NA	15	410	Studies reporting congenital malformations with babies exposure to cyclosporine, with >10 patients	Meta-analysis	Definition of malformation varied. Studies were at risk of publication and selection bias.	Overall prevalence of malformations with cyclosporine exposure was similar to the background rate in the general population.
Deshpande et al. (2011) [52]	Pregnancy outcomes in kidney transplant recipients: a systematic review and meta-analysis	2000–2010	50	3570 (4706)	Studies on pregnancy, obstetric, delivery complications in kidney transplant recipients Case reports, abstracts and articles not in English were excluded	Meta-analysis	Potential patient overlap between studies (repeated inclusion). Definitions and classification of key outcomes varied between studies. Reporting and selection bias was likely due to voluntary reporting.	Live birth rate was higher and miscarriage rate was lower than the general population (possibly due to bias). Preeclampsia, gestational diabetes, preterm delivery, and cesarean section were higher than the general population. Hypertension, proteinuria and elevated serum creatinine were associated with adverse outcomes.

Dialysis								
Piccoli et al. (2016) [3]	Pregnancy in dialysis patients in the new millennium: a systematic review and meta-regression analysis correlating dialysis schedules and pregnancy outcomes	January 2000–December 2014	126	647 (681)	Studies on pregnancy in chronic dialysis patients who started dialysis in the first 20 weeks of gestation; gestation >24 weeks; with >4 patients	Meta-analysis	Study cohorts were heterogeneous. Historical studies were excluded.	Fewer hours of dialysis per week was associated with preterm deliveries, small for gestational age births. Lower incidence of small for gestational age babies in hemodialysis compared to peritoneal dialysis.
Piccoli et al. (2010) [40]	Pregnancy in dialysis patients: is the evidence strong enough to lead us to change our counseling policy	2000–2008	10	78 (90)	Studies of pregnancy in dialysis with >5 patients	Descriptive narrative review	Studies had varied definition of outcomes and study period with high heterogeneity and low numbers.	Intrauterine death, polyhydramnios, preterm delivery and small for gestational age were prevalent in dialysed women. Possibility of a healthy child was 50–100%.
Chronic kidney disease								
Bramham et al. (2014) [48]	Chronic hypertension and pregnancy outcomes: systematic review and meta-analysis	To June 2013	55	(795 221 pregnancies)	Studies of pregnant women with chronic hypertension excluding women with superimposed preeclampsia with >20 women	Preferred Reporting Items for Systematic Reviews and Meta-Analyses, guidelines; Newcastle-Ottawa scale for grading; meta-analysis	Study cohorts were heterogeneous.	Women with hypertension in pregnancy had a high incidence of preeclampsia, cesarean section, preterm delivery, low birth weight, intensive care unit, admission and perinatal death.
Nevis et al. (2011) [45]	Pregnancy outcomes in women with chronic kidney disease: a systematic review	To June 2010	13	Cases 2682, controls 26 149	Studies that reported fetal or maternal outcomes in women with CKD with small size >5, dialysis and transplant patients were excluded	Descriptive review and meta-analysis	Confounding factors were adjusted in analyses in only six studies. Studies were often small and retrospective, with a risk of selection, ascertainment, surveillance and misclassification bias.	The risk of adverse fetal outcomes of premature birth, small for gestational age, intrauterine growth restriction, low birth weight and stillbirth were two times higher in women with any CKD. Due to study limitations, definitive risks for women with CKD are not able to be quoted on the basis of this literature.
Zhang et al. (2015) [43]	A systematic review and meta-analysis of outcomes of pregnancy in CKD and CKD outcomes in pregnancy	1946–2014	23	(506 340)	Cohort and case control studies of women with CKD and maternal or fetal outcomes, and with a non-CKD control group. Studies of women with a history of autoimmune disease, on maintenance HD, kidney transplant, or acute kidney injury were excluded.	GRADE system for assessing study quality; meta-analysis	The outcomes of preeclampsia and premature delivery had high-grade evidence quality. The other outcomes were very low grade due to heterogeneity. Studies included had few women with renal impairment.	Pregnancy in women with CKD had a greater risk of preeclampsia, premature delivery, small for gestational age and cesarean section. Proteinuria was a risk factor for preeclampsia and preterm delivery. Pregnancy was not a risk factor for progression of kidney disease, but included patients had mainly early-stage CKD.

Table 27.1 (Continued)

Author (year)	Title	Search period	Studies	Patients (pregnancies)	Inclusion criteria	Analysis method	Data quality (as per reviewers)	Key findings
Blom et al. (2017) [53]	Pregnancy and glomerular disease: a systematic review of the literature with management guidelines	1980–February 2016	18	887 (1414)	Studies on frequency of live births of women with biopsy proven glomerulonephritis with >10 cases	Narrative review	Significant study heterogeneity which precluded pooling of data thus review was narrative.	Regardless of etiology of glomerular disease, increased proteinuria, hypertension or renal dysfunction were associated with worse pregnancy outcomes
Piccoli et al. (2013) [54]	Type 1 diabetes, diabetic nephropathy, and pregnancy: a systematic review and meta-study	1980–2012	35	(1 511)	Studies on pregnancy outcomes in women with type 1 diabetes and nephropathy with <5 sample size	Narrative review	Studies were highly heterogeneous and only narrative review was possible.	The evidence on pregnancy outcomes in diabetic nephropathy in scarce. The risks of adverse pregnancy events are high and have not changed over time. Stillbirth and fetal death are in increased in diabetic nephropathy compared to other primary disease.
Piccoli et al. (2018) [12]	A systematic review on the materno-fetal outcomes in pregnant women with IgA nephropathy: A case of "late maternal" preeclampsia	2000–April 2017	27	581 (729) control 562	Case reports or case series that reported on pregnancy outcome or renal function in women with IgA nephropathy	Meta-analysis	There was heterogeneity in terms of definitions, populations, outcomes and follow up duration. Meta-analysis was conducted. Most studies had women with normal kidney function.	No increased risk in progression of kidney disease in women with IgA who had pregnancy vs. no pregnancy. Adverse pregnancy outcomes were increased compared to healthy controls – 10× increased risk of preeclampsia and hypertension. Preterm birth and risk of low birth weight babies was increased to a lesser degree. Authors hypothesized that late preeclampsia may have less impact on fetal outcomes.
Liu et al. (2016) [55]	A systematic review and meta-analysis of kidney and pregnancy outcomes in IgA nephropathy	1966–2015	4	273 (376) vs. 241 IgA without pregnancy	Cohort or case control studies of patients with biopsy proven IgA on pregnancy outcomes	GRADE criteria to assess study quality; meta-analysis	Moderate quality evidence. No evidence of publication bias.	No increase in the risk of adverse renal outcomes compared to IgA nephropathy without pregnancy. There were high rates of preeclampsia, infant loss, preterm delivery and low birth weight.
Smyth et al. (2010) [47]	A systematic review and meta-analysis of pregnancy outcomes in patients with SLE and SLE nephritis	1966–2009	37	1 842 (2 751)	Studies of pregnancy outcomes with at least 1 month of follow-up	Cochrane search strategy; meta-analysis	Studies are mainly observational and subject to reporting and selection bias.	Controlling SLE activity prior to conception is important as active SLE nephritis and antiphospholipid antibodies increase the risk of maternal hypertension and poor fetal outcomes.
Wu et al. (2018) [56]	Management and outcomes of pregnancy with or without lupus nephritis: a systematic review and meta-analysis	2000–June 2017	16	1760	Cohort or cross sectional studies comparing Pregnant women with SLE without nephritis vs. without nephritis	Newcastle–Ottawa Scale and Strengthening the Reporting of Observational Studies in Epidemiology checklist to assess study quality; meta-analysis	Statistical heterogeneity was seen across the studies.	Worse maternal and fetal outcomes were seen with SLE nephritis. Anti- Ro antibodies had worse outcome. More immunosuppression was used in SLE nephritis.

Reviews relating to pregnancy in non-CKD or mixed cohorts are not included due to space constraints. Analysis methodology describes systems used for grading quality of studies (if done), and broad method of data synthesis (narrative, thematic or meta-analysis).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. dialysis should be commenced to optimize pregnancy outcomes or the impact of commencement of dialysis for fetal indications on maternal renal survival.

There is less data on pregnancy in peritoneal dialysis recipients, which remains very rare [3, 5]. Successful pregnancy outcomes have been observed in women receiving PD throughout pregnancy, but peritonitis remains the main concern [65]. Most women are switched to hemodialysis [5], and there is some data suggesting fetal outcomes are better with peritoneal dialysis than haemodialysis [3].

Pregnancy Outcomes after Kidney Transplantation

Transplantation restores fertility and offers an opportunity to achieve parenthood with less risk than in dialysed women. In the recent era, elective termination rates have fallen and transplanted women are very likely to have a live birth (overall live birth rates of 76–98% in pregnancies reaching 20 weeks gestation) [66, 67]. Compared to patients receiving dialysis, the maternal and fetal outcomes post transplant are superior, though the rate of conception remains lower than in the general population [9, 63]. However, obstetric complications remain high, with increased risk of gestational hypertension, preeclampsia (seen in 25–35% of pregnancies), growth restriction, and preterm birth (in 30–50%) [52, 63, 68, 69]. Australian registry analysis demonstrated a mean difference in gestational age of 3.5 weeks, gestational weight of 873 g, and lower perinatal survival for babies born to transplanted mothers compared to the general population [66]. Higher gestational diabetes rates have been reported in some studies [52], but not consistently [66, 68]. A transplantation-to-conception interval of under 2 years has been associated with higher rates of gestation diabetes, preeclampsia, and cesarean section [52]. Similar to the CKD cohort, preconception kidney function and chronic hypertension are predictive of adverse obstetric outcomes, particularly preeclampsia [52, 68–71]. Majak et al. reported the risk of preeclampsia increased in women with chronic hypertension, previous preeclampsia or preconception serum creatinine ≥125 μmol/l. The effect of each risk factor was cumulative, and those with all three factors had a 96% risk of preeclampsia [72]. Immunosuppression exposure, infections, and diabetes may influence outcomes but the data defining this are limited. Despite longer immunosuppression exposure, women who are transplanted in childhood have similar outcomes in pregnancy to those transplanted in adulthood [67].

Impact of Pregnancy on Transplant Outcomes

Several registry and cohort studies have reported that graft and patient failure is not accelerated by pregnancy, although it is worth noting that 30–40% of women will have graft failure by their child's 10th birthday and 10–20% will not live to see their child into adulthood [11, 69, 70, 73]. Pregnancy is less likely to adversely impact graft outcomes in women with normal and stable allograft function. There is growing data demonstrating that preconception graft function predicts long-term graft function after pregnancy [67, 68, 70–72]. In one cohort study where detailed kidney function data was available at multiple time-points, the risk of decline in graft function during pregnancy and at 12 months postpartum was increased as preconception creatinine declined. Women with serum creatinine >140 μmol/l had worse renal trajectory and risk of graft loss [68]. Preeclampsia can increase the risk of temporary decline in kidney function but has not been shown to impact adversely on longer term graft outcome [72]. Time from transplant to pregnancy may also influence outcomes, with one large US study suggesting pregnancies within 3 years post transplantation were associated with poorer survival [74] but this was not consistently demonstrated in other cohorts [11, 66].

The longer-term impact of immunosuppression modification, particularly cessation of mycophenolic acid derivatives, for facilitation of pregnancy remains unknown. Episodes of acute rejection in pregnancy are reassuringly low (2–14.5%) and no higher than in the nonpregnant population [52, 69, 73, 75–77]. This could be under-reported as biopsy may selectively be avoided during pregnancy. De novo allo-sensitization is frequent after nontransplant pregnancy, but only reported in 6% of transplanted women, presumably due to immunosuppression use [78].

Treatment

Prepregnancy Counseling and Planning

Parenthood should be discussed early to determine the optimal "window" for conception based on an individual's life plan and clinical situation. There is increasing support for women with CKD or transplants in pursuing motherhood, and clinical practice guidelines no longer advise against pregnancy but encourage counseling with individual risk stratification based on relevant comorbidities. Given the morbidity associated with pregnancy, careful planning is essential with effective contraception in place. This provides the opportunity to optimize health and risk factors for adverse outcomes and adjust medications. In addition, clinicians can obtain multidisciplinary assessment, engage additional expertise, for example preimplantation genetic testing for inherited diseases, assess fertility and confirm the best timing of pregnancy [79, 80].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Navigating pregnancy can be emotionally daunting for women with CKD or transplants. Counseling should incorporate shared decision-making, which involves understanding patient values and perspectives, balancing the emotional vulnerabilities, while sensitively acknowledging the medical risks [23]. Women with CKD have described the need to balance social expectations and their strong desire for motherhood with fears regarding disease exacerbation, their own survival, and fetal harm. Explanation of medical risk should avoid catastrophizing and be balanced with a women's values of autonomy and family, focusing on shared decision-making and provision of hope [23, 81]. In a retrospective study of women managed in a specialized multidisciplinary preconception counseling clinic for CKD, 92% found expert counseling useful in assisting with decision-making [80]. Risk stratification based on key factors associated with adverse pregnancy outcome can identify areas where maternal health may be optimized (Table 27.2).

Optimize Maternal Health Pre Conception

Women planning pregnancy should cease smoking, commence folic acid and vitamins, exchange teratogenic medications for pregnancy-safe options, and address relevant comorbidities including infection, anemia, and diabetes. Primary renal disease should be controlled or in remission, and transplant function and immunological parameters should be stable. Assessment of renal status should include abiopsy if necessary to clarify diagnosis, disease activity or exclude subclinical rejection. Optimization of glycaemic control in patients with diabetes can reduce maternal and fetal adverse outcomes [59]. Vesicoureteric reflux and polycystic kidney disease confer increased risk of urinary tract infections [90]. Symptomatic urinary tract infections and asymptomatic bacteriuria are associated with maternal sepsis as well as preterm birth and low birth weight and should be treated aggressively [91].

Table 27.2 Recommendations for treatment and management of women with CKD in pregnancy.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Preconception counseling	We recommend expert pre conception counseling be undertaken early to enable shared decision making about parenthood options for women with CKD	Moderate	Strong [23, 50, 80, 81]
Risk assessment	We recommend using pre-conception kidney function as the primary parameter for assessing risk of adverse pregnancy and renal outcomes	Moderate	Strong [43, 45]
Cessation of mycophenolate mofetil and Mycophenolic acid	We suggest MMF or MPA be ceased at least 3 months prior to conception due to embryotoxicity	Moderate	Strong [82, 83]
Cessation of ACEI or ARB	We suggest in continuing ACEI/ARB until conception in selected women, where the benefit of controlling proteinuria may outweigh fetal risks from early first trimester exposure	Very low	Weak [48, 84, 85]
Controlling hypertension	We suggest controlling hypertension prior to conception and during pregnancy Aiming for a target blood pressure of 140/90 may reduce episodes of severe hypertension in pregnancy and does not adversely affect the fetus	Moderate	Strong [2, 46, 86]
Prophylactic aspirin	We suggest women at high risk of preeclampsia with CKD, kidney transplant, hypertension or SLE as their primary disease take prophylactic low-dose aspirin from the first trimester for preeclampsia prevention	Very low (in CKD population); moderate-strong in general pregnancy cohorts	Strong [87, 88]
Intensive dialysis	We suggest that dialysis delivery be intensified in pregnant women receiving renal replacement therapy, tailored to residual renal function More than 20 and up to 36 h per week should be considered in women with no residual function, but must be balanced with what can be tolerated and accommodated	Low–moderate	Strong [40, 46, 89]

SLE nephritis should be quiescent 6 months prior to conception to minimize risk of disease flare and improve odds of pregnancy success [35, 47]. Hydroxychloroquine should be continued during pregnancy as cessation is a risk factor for disease flare and continuation improves fetal outcome [58, 92, 93]. A meta-analysis of hydroxychloroquine use found no increase in rate of congenital malformation but observed more spontaneous abortion, possibly from indication bias related to underlying disease activity [94]. All patients with SLE should be screened for antiphospholipid antibodies as they portend a worse prognosis [35, 36, 47]. Antiphospholipid syndrome with thrombosis should be treated with anticoagulation. Screening for anti-Ro and anti-La antibodies should occur to identify those at risk of neonatal cardiac SLE, particularly given hydroxychloroquine can reduce this risk [35, 95–97].

Hypertension

Controlling hypertension before and during pregnancy is essential. There is insufficient evidence for blood pressure targets in pregnancy with CKD, though consensus guidelines recommend a target of <140/90 [98–100]. The CHIPS trial showed tighter control of blood pressure reduced episodes of maternal hypertension over 160/110 mmHg without adverse fetal outcomes, but this has not been studied in CKD populations [86, 101]. Antihypertensive therapy should be changed to pregnancy-safe drugs such as labetalol, methyldopa, and nifedipine, but there are no data to guide choice of one agent over another [13, 79]. Angiotensin receptor blockers (ARB) and angiotensin converting enzymes inhibitors (ACEI) are contraindicated beyond the first trimester due to risk of renal dysplasia, oligohydramnios, neonatal renal failure, and fetal death [102]. More recent population studies suggest hypertension and underlying comorbidities may be teratogenic rather than ACEI or ARB themselves [48, 84, 85]. Continued stabilization of proteinuria with these drugs, with careful surveillance for pregnancy, may be recommended in selected women where the risk of prolonged cessation of renin-angiotensin blockade outweighs the potential fetal risk from exposure at conception [103].

Pregnancy Management: General Principles

Once pregnant, multidisciplinary antenatal care and a tailored plan for maternal and fetal surveillance should be established based on CKD stage, comorbidity, and transplant status (Figure 27.1) [79]. Careful vigilance should occur for declining maternal renal health, superimposed preeclampsia, fetal growth restriction, polyhydramnios, and infection, as these events will define timing of delivery.

Women should commence low-dose aspirin (75–100 mg daily) before 12 weeks and continue until late in the third trimester. Reduction in preeclampsia risk due to aspirin has been demonstrated in low-risk [101] and high-risk populations [87, 104]. A meta-analysis that included moderate- to high-risk patients, including those with CKD and hypertension, confirmed a risk reduction of 0.47 (95% CI 0.36–0.62) vs. 0.78 (95% CI 0.61–0.99; $P < 0.01$), if commenced prior to 16 weeks gestation [88]. These conclusions have been extrapolated to patients with CKD and incorporated into guidelines [72, 99, 105].

Given pregnancy is a prothrombotic state, women with nephrotic range proteinuria should be considered for prophylactic anticoagulation [79], although there are negligible outcomes data. Nutrition should be evaluated and supplementation provided as required. Gestational diabetes screening should occur earlier than routine screening in women with risk factors for diabetes including prodiabetogenic medications such as glucocorticoids or calcineurin inhibitors. Managing anemia in pregnancy with concurrent CKD can be challenging due to increased iron requirements with dose increases of 30–50% required in pregnancy [106]. Erythropoietin (EPO)-stimulating agent dose may increase due to EPO resistance from increase cytokines production in pregnancy.

There are no data available on optimal timing of delivery in a CKD population and thus decisions should be based on local practice, and maternal and fetal health. Cesarean section is not specifically indicated other than for obstetric reasons, but rates are substantially higher in women with CKD or post transplant, likely due to need for emergency delivery [14, 45]. In patients with renal transplantation, cesarean sections should be performed with input from the transplant surgical team regarding anatomy. Breastfeeding while receiving medications considered safe in pregnancy should not be discouraged, as fetal drug exposure is minimal compared with intrauterine exposure and benefits may outweigh risks [107]. Contraceptive options should be discussed and implemented postpartum, and may require careful consideration based on patient preferences and guidelines for contraception in women with medical comorbidity [13].

Immunosuppression

Immunosuppression may require manipulation prior to conception for both transplanted women and those with glomerulonephritis [13], although the impact this has on renal outcomes is unknown. Observation for 3–6 months to ensure renal condition remains stable is recommended. Calcineurin inhibitors, glucocorticoids, and azathioprine are most commonly used and have no increased risk of

congenital malformation [51, 108–110]. Cyclosporine levels decline in pregnancy and require dose alteration [108]. Similarly, the pharmokinetics of tacrolimus are altered in pregnancy-related shifts in albumin and hematocrit, with a decrease in the inactive, bound fraction that is measured in assays. Tacrolimus trough levels reach a nadir in the second trimester [68, 108]. Subsequent dose alterations by up to 25% can increase the unbound active fraction that is not currently routinely measured, increasing toxicity risk [111, 112]. Mycophenolate mofetil causes birth defects and miscarriage [82, 83] so should be ceased 3 months prior to conception, usually with conversion to azathioprine, which is transferred to the fetus but not activated due to absence of inosinate pyrophosphorylase. Safety data on mammalian target of rapamycin in pregnancy is limited though it may affect fetal growth therefore cessation is advised [113]. Treatment of transplant rejection in pregnancy should be as per local practice. Options for treating acute glomerulonephritis, including SLE nephritis in pregnancy, are also limited, with reports of use of steroids, myophenolate mofetil cyclophosphamide, and rituximab, all of which have adverse safety profiles in pregnancy [13]. Tacrolimus may be a useful therapy for SLE nephritis in pregnancy but further data are required [114]. Women with SLE should receive hydroxychloroquine pre conception and throughout pregnancy due to fetal benefits [47].

Dialysis Management

There is no evidence base regarding when to initiate dialysis in pregnant patients with CKD [67]. Women with advanced CKD may require commencement of dialysis during pregnancy for maternal symptoms, hypertension or fluid management, or reducing urea levels, which improves fetal outcomes [115].

In women who conceive while receiving chronic hemodialysis, intensive dialysis has been demonstrated to improve fetal outcomes [3, 62] due to increased urea clearance causing less fetal solute diuresis and polyhydramnios [14]. Historically a target urea of under 17.9 mmol/l (50 mg/dl) was recommended [46], with further studies confirming better outcomes with low urea targets [3]. A large meta-analysis of 681 pregnancies from 126 studies reviewed dialysis schedule and pregnancy outcomes, demonstrating a relationship between greater number of dialysis hours and reduced risk of small gestational age and preterm delivery [3]. Intensive dialysis (>36 h/week) compared to <20 h/week was associated with higher live birth rates (85% vs. 48%), greater birth weight, and older gestational age [89]. Logistically, this is challenging but can be achieved through daily or nocturnal dialysis. The degree of residual renal function is important to outcomes [5, 64]. Less dialysis may be required if residual renal function is present, substantially reducing the dialysis burden [89].

Intensive dialysis offers better control maternal of hypertension and fluid status, although fetal and placental hypoperfusion from excessive fluid removal should be avoided, with regular clinical assessment as women gain weight [62, 89, 116]. Other sequelae of intense dialysis include electrolyte imbalance with risk of hypokalaemia, hypocalcaemia, and hypophosphatemia requiring dialysate changes [62, 116, 117]. Increased protein loss requires careful dietetic management of dietary protein intake [62, 118]. Increased folate supplementation to 5 mg/day is advised to reduce risk of neural tube defects [116].

There are few data on the use of peritoneal dialysis in pregnancy. Outcomes may be inferior to pregnancies managed with hemodialysis, but direct comparison cannot be made with the existing evidence base [3]. Increasing dialysis delivery through PD can be a successful management strategy, but a growing uterus may limit exchange volumes and clearance, and cause catheter migration [65].

Management of Transplanted Women

The management of women post kidney transplantation should incorporate the general principles as outlined above. Determining the appropriate timing of conception post transplant is a balance between stabilization of graft function and fitting into the window of fertility. Guidelines recommend conception only 1–2 years post transplantation [39, 119], although the optimal time is unknown and early pregnancy post transplant (within 3 years) may impact on graft function [74]. Registry data suggest most women wait 3–5 years before conceiving [66]. Prior to conception, graft function should be stable on pregnancy-safe immunosuppression, with controlled hypertension and low risk of rejection or infection [39, 119]. Other specific management includes adjustment of immunosuppression and other relevant medication such as antivirals and antihypertensives. Surveillance should be undertaken of allograft dysfunction, gestational diabetes, bacterial infection, particularly urinary tract, viral infection, including cytomegalovirus and herpes simplex virus, and vigilant monitoring for preeclampsia and rejection.

Conclusion

Many physiological changes occur during pregnancy affecting the kidney, and management of kidney disease in pregnancy presents a number of challenges to clinicians, particularly as the evidence base that underpins complex

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. clinical decision-making is weak. Risk of adverse outcomes for mother and baby are present in even mild CKD and escalate with disease severity and added comorbidity. Experience in managing these complex pregnancies has increased over recent decades, with a change in approach to cautious optimism. The need to incorporate shared decision-making between patients, families, and a multidisciplinary team, with an understanding of patients' motivations and values, is an essential part of embarking on this journey with this group of high-risk women.

ANCA-associated Vasculitis

Maria Prendecki and Stephen McAdoo

Imperial College London, London, UK

Introduction and Definitions

The antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides (AAVs) are a group of systemic necrotizing vasculitides which affect small to medium-sized blood vessels. There is a spectrum of organ involvement, including the kidney, lungs, nerves, gut, and ear, nose, and throat (ENT). AAVs are classified on the basis of clinical and pathological features into granulomatosis with polyangitis (GPA), microscopic polyangitis (MPA), eosinophilc granulomatosis with polyangitis (EGPA), and renal limited vasculitis (RLV). The 2012 Chapel Hill Consensus Conference (CHCC) nomenclature of vasculitis defines AAVs as necrotising vasculitis which predominately affects small vessels such as capillaries, venules, arterioles, and small arteries. There must be few or no immune deposits present [5]. The CHCC definitions of GPA, MPA, and EGPA are summarized in Table 28.1. The CHCC is a nomenclature system rather than a diagnostic classification. The 1990 American College of Rheumatology (ACR) criteria provides diagnostic criteria for GPA and EGPA but not MPA; but ANCAs were not included as part of the diagnostic criteria. Based on the results of the Diagnostic and Classification Criteria for Vasculitis (DCVAS) study, new criteria for classification of GPA, EGPA, and MPA to standardize the classification of these diseases to support clinical research were co-jointly endorsed by the American College of Rheumatology (ACR)/European Alliance of Associations for Rheumatology (EULAR) have recently been published [6,7,8]. These classification criteria are shown in Table 28.2.

Prior to 1979 it was assumed that all cases of rapidly progressive glomerulonephritis (RPGN) were caused by immune complex deposition or circulating antiglomerular basement membrane (anti-GBM) antibodies. Stilmant et al. recognized that in fact many of these cases were pauci-immune, and in 1982 the first report of circulating ANCA associated with a pauci-immune glomerulonephritis (GN) was published [9, 10]. The two major targets of ANCA have been shown to be myeloperoxidase (MPO) and proteinase 3 (PR3), enzymes expressed in the granules and lysosomes of neutrophils and monocytes [11–13]. GPA is more commonly associated with PR3-ANCA positivity and MPA with MPO-ANCA, although there is considerable overlap and around 10% of patients with MPA or GPA will be ANCA negative. In EGPA around 40% of patients are reported to be ANCA positive, and vasculitic features such as GN are more

Table 28.1 Definitions for AAV.

Microscopic polyangiitis (MPA)	Necrotizing vasculitis, with few or no immune deposits, predominantly affecting small vessels. Necrotizing glomerulonephritis and pulmonary capillaritis are very common. No granulomatous inflammation is seen.
Granulomatosis with polyangiitis (Wegener's) (GPA)	Necrotizing granulomatous inflammation usually involving the upper and lower respiratory tract, and necrotizing vasculitis affecting predominantly small to medium vessels. Glomerulonephritis is common.
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss) (EGPA)	Eosinophillic necrotizing granulomatous inflammation, often involving the respiratory tract, and necrotizing vasculitis predominantly affecting small to medium vessels. Often associated with asthma and eosinophilia.

Table 28.2 ACR/EULAR Classification Criteria for ANCA-Associated Vasculitides (AAVs).

Granulomatosis with polyangiitis (GPA)		Microscopic polyangiitis (MPA)		Eosinophilic granulomatosis with polyangiitis (EGPA)	
Bloody nasal discharge, nasal crusting, or sino-nasal congestion	+3	Perinuclear ANCA or anti-myeloperoxidase ANCA positivity	+6	Maximum eosinophil Count >1 x 10^9/liter	+5
Cartilaginous involvement (Any of inflamed ear or nose cartilage, hoarse voice/stridor, endobronchial involvement or saddle nose)	+2	Pauci-immune glomerulonephritis	+3	Obstructive airway disease	+3
Conductive or sensorineural hearing loss	+1	Lung fibrosis or interstitial lung disease	+3	Nasal polyps	+3
Cytoplasmic antineutrophilic antibody (ANCA) or anti-proteinase 3 ANCA positivity	+5	Sino-nasal symptoms or signs	+3	Cytoplasmic ANCA or anti-proteinase 3 ANCA positivity	–3
Pulmonary nodules, mass, or cavitation of chest on imaging	+2	Cytoplasmic ANCA or anti-proteinase 3 ANCA positivity	–1	Mononeuritis multiplex/ motor neuropathy due to radiculopathy	+1
Granuloma or giant cells on biopsy	+2	Eosinophil Count >1 x 10^9/ liter	–4	Extravascular eosinophilic predominant inflammation	+2
Inflammation or consolidation of the nasal/ paranasal sinuses on imaging	+1			Hematuria	–1
Pauci-immune glomerulonephritis	+1				
Perinuclear ANCA or antimyeloperoxidase ANCA positivity	–1				
Eosinophil Count >1 x 10^9/liter	–4				
Total score of ≥5 for diagnosis of GPA		Total score of ≥5 for diagnosis of MPA		Total score of ≥6 for diagnosis of EGPA	
Sensitivity 93% (95%-CI 87-96%)		Sensitivity 91% (95%-CI 85-95%)		Sensitivity 85% (95%-CI 77-91%)	
Specificity 94% (95%-CI 89-97%)		Specificity 94% (95%-CI 92-96%)		Specificity 99% (95%-CI 98-100%)	

Adapted from reference 6-8.

common in the patients with ANCA positivity [14]. This chapter will focus on the management of MPA and GPA as there are several differences in the pathogenesis, features, and management of EGPA. A summary of the quality of the evidence and strength of the recommendation for treatment of the AAVs is shown in Table 28.3.

Epidemiology

AAVs are rare conditions with reported annual incidence between 13 and 20 cases per million individuals in Europe [15]. There is a slight male preponderance and peak age of onset of AAV has been reported as age 55–64, 65–74, and more than 75 years in different studies [16–18]. AAV is very rare in childhood. Within Europe there may be a geographical variation in AAV subtype, with reported higher incidence of GPA in Northern Europe and MPA in the south [19]. This trend to geographic variation was also present in studies conducted in the United States, where there is higher prevalence of GPA in northern states and more MPA in southern states. Studies comparing the UK and Japan showed a similar incidence of AAV in the two populations, but the majority of the Japanese population had MPA and GPA was extremely rare [20]. Within France, the prevalence of AAV was twice as high in those with a European background than in those of non-European ethnicity [21]. Studies in Sweden and the UK have both reported increasing incidence of AAV since the early 1980s although it is not clear whether this represents a true increase in disease or reflects greater awareness of the condition and the more widespread availability of ANCA testing [22, 23].

There is a genetic basis for AAV, and this may underlie some of the reported population differences. There are two published genome-wide association studies (GWAS), both carried out in patients of Northern European ancestry, which identified both MHC and non-MHC genetic associations with AAV [24, 25]. There is a stronger genetic association related to the antigenic specificity of ANCA than there is to clinical phenotype, and MPO-ANCA and PR3-ANCA may define differing diseases. In PR3-ANCA related disease there are strong associations with *PRTN3*, the gene which

Table 28.3 Treatment for AAV.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Remission induction			
Cyclophosphamide and corticosteroids	Oral or IV cyclophosphamide should be used for induction therapy in patients with severe or organ-threatening AAV. Pulsed treatment with IV cyclophosphamide is equivalent to oral treatment for remission induction but may result in increased risk of relapse.	High (IV vs. oral-low)	1A [1, 2]
Rituximab and corticosteroids	Rituximab is an alternative to cyclophosphamide, particularly in those who are unable or unwilling to receive cyclophosphamide such as patients wishing to preserve fertility. Some guidelines restrict the use of rituximab to those unable to receive cyclophosphamide. Rituximab may be superior to cyclophosphamide for remission induction in patients presenting with relapsing disease.	High	1B [1, 2]
Adjunctive plasma exchange in renal vasculitis	There is insufficient evidence for routine use of adjunctive plasma exchange but current guidelines recommend it for patients with RPGN, creatinine>500 μmol/l at diagnosis or those with pulmonary hemorrhage.	Low	2D [1, 2]
Remission maintenance			
Azathioprine	Azathioprine is as effective as oral cyclophosphamide for remission maintenance, but is safer with fewer adverse events.	Moderate	1B [1]
Rituximab	Rituximab is as effective as azathioprine in preventing major relapse with similar levels of adverse events. Some guidelines include rituximab as an alternative therapy for remission maintenance.	Moderate	1B [1]
MMF	MMF is less effective than azathioprine in preventing relapse but may be used as an alternative in patients who are intolerant or allergic to azathioprine. Guidelines vary as to whether MMF or methotrexate should be second line.	Moderate	1B [1]
Methotrexate	Methotrexate can be used for remission maintenance in patients unable to tolerate azathioprine. There are similar relapse rates in patients treated with methotrexate and those treated with azathioprine but more severe adverse events with methotrextate. Methotrexate should not be used in those with eGFR<30 ml/min and dose should be adjusted in patients with eGFR<60 ml/min. Guidelines vary as to whether MMF or methotrexate should be second line.	Moderate	1B/1C [1, 2]
Co-trimoxazole	There is no evidence to support the use of co-trimoxazole for remission maintenance.	Low	2B [2]

GRADE assessment of the evidence [3, 4]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different is very high.
AAVs, antineutrophil cytoplasmic antibody-associated vasculitides; eGFR (estimated GFR), ; IV, intravenous; MMF (Mycophenolate mofetil); RPGN, rapidly progressive glomerulonephritis.

encodes PR3, *SERPINA1*, the gene encoding α1-antitrypsin, and HLA-DP. MPO-ANCA-associated disease is linked to HLA-DQ polymorphisms. There are several other HLA and non-HLA genes which have been associated with AAV [26].

There are also several reported environmental associations with AAV such as toxins, drugs, and infections. In patients with ENT disease and anti-PR3 ANCA, infection may precede disease relapse and nasal carriage of *Staphylococci* correlates with relapse [27]. This may be due to molecular mimicry whereby antibodies against microbial antigens cross-react with self antigen [28]. Drugs, including propylthiouracil, hydralazine, and penicillamine, are associated with positive ANCA serology, and less commonly may be associated with clinical vasculitis [29, 30]. An association with levamisole-contaminated cocaine, positive ANCA serology, and clinical disease resembling GPA has also been

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. reported [31]. Environmental triggers such as silica and heavy metal exposure have also been implicated as triggers. After the 1995 Kobe earthquake in Japan there was a regional threefold increase in disease incidence, suggesting that air pollutants can play a role in the etiology of disease [32]. In some studies, but not others, an association with farming has been reported [33, 34].

Pathogenesis

There are several clinical observations which support a role for ANCA being directly pathogenic. Most patients with AAV have circulating ANCA and in some studies ANCA titer has been shown to predict relapse [35]. There is a reported case of neonatal AAV following placental transfer of MPO-ANCA, resulting in renal disease and pulmonary hemorrhage shortly after birth [36]. Another case report describes no clinical disease despite maternal-fetal transfer of MPO-ANCA [37]. Removal of antibodies using plasmapheresis and use of B cell targeted therapies have both been shown to be effective treatments for AAV [38–40]. These findings are supported by experimental work from both in vitro experiments and in vivo models of AAV. Passive transfer models in mice, where anti-MPO antibodies are raised in MPO-deficient mice and then transferred into naïve recipients, results in the recipient mice developing a severe vasculitis with crescentic GN and pulmonary hemorrhage [41]. in vitro, neutrophils which have been primed with TNF(Tumor necrosis factor)α, lipopolysaccharide (LPS), or complement (C5a) can be activated by ANCA, causing degranulation, ROS production, and endothelial cell damage [42–44]. ANCA are also mediators of NETosis, a form of neutrophil cell death which occurs with release of neutrophil extracellular traps (NETs). Patients with AAV have increased levels of NETs in their circulation and NETs have been shown at sites of tissue damage in AAV [45]. Although there is much evidence for the pathogenicity of ANCA and ANCA-induced activation of neutrophils, ANCA are not always pathogenic. Ten percent of patients with AAV are ANCA negative, and ANCA can either persist in clinical remission or recur without evidence of relapse. Natural anti-MPO antibodies have been identified in healthy individuals and these are of lower avidity and titer than antibodies in patients with AAV [46]. One study of MPO-ANCA has shown that anti-MPO antibodies from healthy individuals had different target epitopes to anti-MPO antibodies from patients with AAV [47].

Complement is increasingly recognized to play a role in the pathogenesis of AAV. Mice deficient in C5 or depleted of complement did not develop disease in the passive antibody transfer model of AAV described above. C4-deficient mice were not protected, suggesting a role for the alternative and not the classical pathway [48]. Mice with knock-in of the human C5a receptor (C5aR) and MPO-AAV respond to treatment with an antagonist of human C5aR (CCX168; avacopan) and have decreased disease severity. A phase II trial has shown avacopan was noninferior to high-dose glucocorticoids when used in combination with rituximab or cyclophosphamide for induction of remission [49].

The mechanisms underlying the development of ANCA are less well understood. One suggested mechanism is that of molecular mimicry. An atypical ANCA, antihuman lysosome-associated membrane protein-2 (anti-LAMP-2) antibody, has been identified in patients with pauci-immune GN. It has 100% sequence homology with FimH, a protein present on gram negative bacteria, and when rats are immunized with FimH they develop GN and antibodies which cross-react with human and rat LAMP-2 [28]. Another potential mechanism is of anti-idiotype interactions to peptides complementary to the auto-antigen, such as complementary PR3 peptides which are homologous to some *Staphylococcus aureus* peptides [50]. There is also a role for disordered T cell responses: patients with AAV have defective Treg suppressor function and increased frequency of a T cell subset which is resistant to the suppressive effects of Tregs [51, 52]. Regulatory B cells have also been shown to be decreased in patients with AAV [53, 54].

Clinical Features

AAV is a multisystem disease and clinical presentation varies widely in both severity and organ involvement. Patients often have a nonspecific prodromal illness which may precede diagnosis by several weeks or months, with features such as fever, anorexia lethargy, arthralgia, or weight loss. Patients may have asymptomatic urinary abnormalities early in disease course (or in those with milder disease) but renal involvement typically presents as a RPGN. In MPA 90% of patients will have evidence of renal disease, compared to 80% of those with GPA and around 40% of those with EGPA [55]. In GPA extrarenal features of disease are common, with 90% of patients having lung or ENT involvement. Patients with MPA often have more severe renal involvement. Other organ systems involved include the skin, nervous system, eyes, musculoskeletal system, and gastrointestinal tract [55]. In EGPA patients typically have features of asthma and nasal polyps with peripheral blood eosinophilia. In patients with RPGN, as disease progresses, features of overt renal failure will develop and patients may have symptoms related to salt and water overload such as

Table 28.4 Summary of diagnostic tests in patients with suspected AAV.

Investigation	Results/comments
FBC	Leucocytosis Thrombocytosis Normochromic normocytic anemia
CRP, ESR	Often raised but nonspecific
Renal function	Raised urea and creatinine in patients with RPGN
Complement C3, C4	Normal or elevated in AAV. Low C3/C4 may indicate bacterial infection such as endocarditis or immune complex GN. Isolated low C3 is seen in postinfectious GN or C3 glomerulopathy.
Immunoglobulins	Polyclonal hypergammaglobulinemia may be present. Prior to commencing cytotoxic therapies, hypogammaglobulinemia should be excluded.
Viral serology: HBsAg, HIV, HCV Ab	Prior to initiating immunosuppressive therapies
Blood cultures	To investigate for the presence of bacterial endocarditis in patients with ANCA positivity and systemic symptoms
ANCA	IIF or immunoassay
anti-GBM, ANA, dsDNA	To investigate for other causes of RPGN
Urine dipstick	Hematuria and proteinuria. Leukocyturia often represents the presence of nonspecific inflammatory cells.
Urine microscopy	Needs to be performed by a skilled operator on fresh urine. Red cell casts are seen in glomerulonephritis.
Urine PCR	Low-grade proteinuria is common. In RPGN decreased glomerular blood flow limits protein filtration.
Renal biopsy	Pauci-immune, necrotizing, creacsentic GN
Skin biopsy	Leukocytoclastic vasculitis
ENT or lung biopsy	Granuloma often seen
Nerve biopsy	Necrotizing vasculitis of associated small and medium blood vessels
Pulmonary function testing	Raised KCO in 25% of patients with pulmonary hemorrhage

AAV, ANCA-associated vasculitis; ANA, anti-nuclear antibody; ANCA, Anti-neutrophil cytoplasmic antibody; anti-GBM, anti-glomerular basement antibody; C3, complement component 3; C4, complement component 4; CRP, C-Reactive Protein; dsDNA, double stranded DNA; ENT, Ear-Nose-Throat; ESR, Erythrocyte Sedimentation Ratio; FBC, Full blood count; GN, Glomerulonephritis; HBsAg, Hepatitis B surface antigen ; HCV Ab, Hepatitis C Virus antibody; HIV, Human immunodeficiency virus; IIF, indirect immunofluorescence; RPGN, rapidly progressive glomerulonephritis.

breathlessness, cough, orthopnea, and peripheral oedema or to uremia such as itch, anorexia, and fatigue. Relapse of disease is common and occurs in 30–50% of patients.

Diagnostic Tests

The usual screening test for ANCA is to perform indirect immunofluorescence (IIF) on neutrophils; positive samples are then used in antigen-specific immunoassays to determine ANCA specificity. Due to the increasing availability of high-quality immunoassays for MPO- and PR3-ANCA, the current consensus is that these tests can be used for screening without absolute need for IIF [56]. In patients with renal involvement a renal biopsy is usually performed. The diagnostic tests used to diagnose and evaluate AAV are summarized below and in Table 28.4.

Hematological and Biochemical Tests

Full blood count may show leucocytosis, thrombocytosis, or normochromic normocytic anemia. Raised C reactive protein and erythrocyte sedimentation rate are often present. Raised urea and creatinine will be present in those with RPGN. Urine dipstick may show hematuria, proteinuria or leukocyturia, and urine microscopy should be used to confirm the presence of hematuria and to identify red cell casts. Urinary protein leak should be quantified using a spot urine protein:creatinine ratio (uPCR); proteinuria is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

often low grade (<100 mg/mmol) and usually will be subnephrotic (<300 mg/mmol) [57].

Imaging

Chest imaging (radiograph or computed tomography) should be undertaken in all patients with respiratory symptoms such as cough, dyspnea, or hemoptysis, and may show pulmonary infiltrates suggestive of hemorrhage, nodules or cavitation. There should be a low threshold for chest screening in patients in whom a diagnosis of AAV is suspected.

Renal imaging with ultrasound should be performed to exclude structural kidney diseases prior to renal biopsy, but in patients with AAV will usually be normal or show nonspecific features of acute kidney disease such as changes in echogenicity. Other imaging should be directed toward symptoms such as imaging of the sinuses, gut, retro-orbital space or nervous system.

Physiological Testing

Lung function testing may show an increased diffusing capacity for CO (KCO) in pulmonary hemorrhage, whereas it should be low in other causes of pulmonary infiltrates such as pulmonary oedema. However, raised KCO is only present in 25% of patients with pulmonary hemorrhage and normal or low KCO does not have a good negative predictive value [58]. Patients with pulmonary hemorrhage may also be too unwell to undergo testing. Other physiological tests will be guided by the patient's clinical presentation, such as nerve conduction studies or echocardiography.

ANCA Testing

Indirect Immunofluorescence

IIF is usually performed on ethanol-fixed neutrophils, with two patterns of staining seen in positive samples: cytoplasmic (c-ANCA), which is associated with anti-PR3 antibodies, and perinuclear (p-ANCA), which is typically seen with anti-MPO antibodies. An atypical pattern is seen rarely and comprises cytoplasmic, perinuclear, and nuclear staining; it is associated with several antigen specificities [59]. The perinuclear pattern seen with MPO-ANCA arises due to the process of ethanol fixation, which leads to MPO dissolving from the neutrophil granules and attaching to the nucleus. When formalin-fixed neutrophils are used this does not occur and a cytoplasmic pattern is seen with both MPO and PR3-ANCA. Atypical ANCA IIF can be seen in other diseases such as inflammatory bowel disease, HIV, bacterial endocarditis, or related to drug-induced autoimmunity. A range of atypical target antigens have been described, including lactoferrin or elastase.

Antigen Specific Tests

Several immunoassays are available, including enzyme immune-assays (EIAs), bead-based multiplex assays, fluorescent enzyme immune assays (FEIA), and immunoblot assays. These assays usually detect IgG and provide quantitative results. It was previously recommended that a positive IIF should be followed by an antigen-specific test, however recent studies have shown that immunoassays are more sensitive and specific than IIF [60]. Additionally, IIF can be labor intensive and automated interpretation is not available worldwide. Current guidelines recommend immunoassay testing for PR3 and MPO-ANCA for diagnosis of AAV without need for IIF [56]. In patients with a high index of suspicion for AAV, IIF should be carried out despite negative immunoassay results. Anti-MPO or anti-PR3 antibodies have good positive predictive values for the diagnosis of AAV but have been reported in other inflammatory conditions and are not diagnostic. A histological diagnosis is required for definitive diagnosis where possible [61].

Histological Tests

In patients with clinical evidence of renal disease such as urinary abnormalities or deranged renal function, renal biopsy is the gold standard for diagnosis. The typical pattern of glomerular injury seen on light microscopy is of necrotizing and crescentic GN: immunofluorescence will show minimal or negative staining for immunoglobulin or complement, and electron microscopy may show microthrombi or degranulation of neutrophils but no or minimal immune deposits [62, 63]. A histopathological classification system has been developed for AAV with four categories of disease: focal, where <50% of glomeruli are affected, crescentic, where >50% of glomeruli contain cellular crescents, sclerotic, where >50% of glomeruli are globally sclerosed, and mixed, where normal, crescentic, and sclerotic glomeruli are all present and >50% of glomeruli are affected [63]. The classification system has been shown to predict renal outcomes in AAV with patients with sclerotic lesions least likely to recover renal function. [63] Biopsy of other sites of disease may also be undertaken, such as skin, ENT, lung, or nerve, particularly if there is diagnostic uncertainty.

Treatment

Modern immunosuppression regimes have transformed patient outcomes in patients with AAV. Prior to the 1960s, mortality at 1 year was as high as 80%, whereas current studies show 1 year survival of around 90% [64]. Usually an initial period of intense immunosuppression is used to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. induce remission followed by a period of sustained low-dose treatment to prevent relapse.

Remission Induction

The most widely used first-line treatment regimen for induction of remission in patients with AAV and severe disease is cyclophosphamide Table 28.1 and high-dose glucocorticoids with the addition of plasma exchange for those with severe renal impairment or RPGN. An example induction treatment regimen is shown in Table 28.5.

Cyclophosphamide

Several clinical trials have studied the optimum route, dose, and duration of treatment with cyclophosphamide. There are four published studies of oral versus pulsed intravenous (IV) cyclophosphamide, the largest and most recent of which is the Randomized Trial of Daily Oral vs Pulse Cyclophosphamide as Therapy for ANCA-Associated Systemic Vasculitis (CYCLOPS) trial, which included 149 newly diagnosed patients with either GPA or MPA and renal involvement, but not life-threatening disease Table 28.7 [65]. It showed no difference in time to remission between the two groups, but lower cumulative cyclophosphamide doses in the IV arm with lower rates of leukopenia [65]. Long-term follow-up of this study showed higher relapse rates in the group treated with IV cyclophosphamide but no difference in ESRD, morbidity, or mortality [66]. Of the available published guidelines, European League Against Rheumatism (EULAR)/European Renal Association – European Dialysis and Transplant Association (ERA-EDTA) and British Society of Rheumatology (BSR) guidelines favor IV over oral cyclophosphamide, and Kidney Disease Improving Global Outcomes (KDIGO) recommend either oral or pulsed IV cyclophosphamide at clinician discretion [1, 2, 67] Table 28.6. Only one study has investigated the duration of treatment with IV cyclophosphamide (without subsequent maintenance therapy) and it showed no difference in mortality, duration of remission, or infection rate between six and 12

Table 28.5 Initial treatment of severe AAV [1, 2].

Agent	Route	Initial dose	Comments
Cyclophosphamide	IV, oral	IV: 15 mg/kg every 2 weeks for three pulses then every 3 weeks PO: 1.5–2 mg/kg/day	Reduce dose in severe renal impairment or in older patients (>60 years)
Glucocorticoids	IV, oral	IV methylprednisolone for 3 days PO prednisolone 1 mg/kg/day (max. 60 mg) for 4 weeks then gradual taper 3–4 months	
Rituximab	IV	375 mg/m^2 weekly for 4 weeks or 2 × 1 g infusions 2 weeks apart	Alternative to cyclophosphamide in some guidelines [1]
Plasma exchange		60 ml/kg volume replacement to a maximum of 4 l with human albumin solution or fresh frozen plasma if bleeding risk (pulmonary hemorrhage or recent kidney biopsy)	Monitor platelet count (aim >70 × 10^9/l); fibrinogen (aim >1 g/l and replace with cryoprecipitate if necessary); corrected calcium (aim normal range)

IV, intravenous; PO (Per os)

Table 28.6 Summary of evidence for pulsed vs. oral cyclophosphamide induction therapy for AAV.

Outcome	Number of participants (number of studies)	Comparative risks		Relative effect	Quality of evidence (GRADE)
		Continuous CYC	Pulsed CYC		
Death	278 (4)	206/1000	159/1000 (91–272)	RR 0.77 (0.44–1.32)	Low
RRT	245 (4)	74/1000	141/1000 (68–289)	RR 1.9 (0.92–3.91)	Low
Relapse	235 (4)	181/1000	324/1000 (201–519)	RR 1.79 (1.11–2.87)	Low
Serious infections	278 (4)	348/1000	247/1000 (132–463)	RR 0.71 (0.38–1.33)	Very low

Table 28.7 Summary of clinical trials investigating pulsed vs. oral cyclophosphamide induction therapy for AAV.

Study	Design	Primary end point	Results	Secondary end points	Comments
CYCLOPS [65]	Open label, parallel RCT Daily oral vs. pulsed CYC	Time to remission	No difference: median 3 months in both groups No difference in proportion in remission	Lower cumulative CYC does in pulsed IV group and lower incidence of leukopenia No difference in other adverse events or death	Lower relapse rates in daily oral CYC group on retrospective long-term follow-up (median 4.3 years) Low risk of bias
Adu 1997 [70]	Parallel RCT Daily oral CYC followed by AZA (at median 3 months) vs. pulsed CYC	Drug toxicity	More leukopenia in CCAZP group	No difference in number in complete remission at final follow-up, relapse rates, death or requirement for RRT	Patients in pulsed group had poorer renal function at baseline than oral group
Guillevin 1997 [71]	Parallel RCT Daily oral vs. pulsed CYC	Remission induction and death	No difference in proportion of patients in remission at 6 months No difference in 5-year survival	Greater relapse rates in pulsed CYC group Lower cumulative CYC dose in pulsed group and fewer severe side effects (infection, PCP)	Recruitment terminated early due to significantly differing rates of severe side effects and relapse rates between the groups
Haubitz 1998 [72]	Parallel RCT Daily oral vs. pulsed CYC	Disease progression Nonremission at 12 months Relapse up to 1 year after end of CYC Severe adverse events	Patient survival, remission rate, relapse rate similar between two groups Decreased cumulative CYC dose, and leukopenia and severe infections in IV group		Four patients excluded due to protocol violations Study terminated early when significant differences between the two groups found

AAV(ANCA-associated vasculitis), AZA, azathioprine; CCAZP(oral cyclophosphamide followed by azothioprine); CYC, cyclophosphamide; PCP, *Pneumocystis jirovecci* pneumonia; RCT(Randomized control led trial).

pulses. There were fewer relapses in the group of patients treated with 12 pulses [68]. Published guidelines recommend 3–6 months treatment with oral cyclophosphamide based on time to remission in studies of maintenance therapy [69].

Glucocorticoids

High-dose glucocorticoids should be used as part of initial treatment, but there is limited evidence for the benefit of IV pulsed methylprednisolone other than in the MEPEX trial, where it was shown to be less efficacious than plasma exchange (PEX) when added to cyclophosphamide and oral steroids for severe disease [38]. Dose and duration of oral steroids varies between published guidelines, and duration of therapy is often guided by patient response and relapse. There are no published studies comparing glucocorticoid regimens; one meta-analysis of 13 studies concluded that studies with longer courses of glucocorticoids were associated with fewer relapses although there was considerable heterogeneity between other immunosuppressive agents used between studies [73]. The Plasma Exchange and Glucocorticoids in Severe ANCA- Associated Vasculitis (PEXIVAS) trial is a large multicenter RCT including patients with moderate to severe renal impairment (eGFR(estimated GFR)<50 ml/min) or pulmonary hemorrhage, which was designed to provide definitive answers regarding PEX in AAV but also included a comparison of high- and low-dose glucocorticoid in both arms [74]. It showed that a reduced dose of oral glucocorticoid (following pulsed IV methylprednisolone in both groups) was noninferior on the composite primary end point of ESRD or death and was associated with fewer serious infections [75].

Plasma Exchange

Current guidelines advocate the addition of PEX as adjunctive therapy in patients with severe pulmonary or renal disease, particularly those who are refractory to initial treatment with cyclophosphamide and high-dose glucocorticoids. The largest published study to date, MEPEX, included 137 patients with severe renal disease (creatinine >500 μmol/l or dialysis requiring at presentation) and randomized them to either receive seven plasma exchanges or IV methylprednisolone. There was improved renal survival in the PEX group

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

at 3 months and decreased requirement for dialysis at 12 months [38]. Long-term follow-up of this group (median follow-up of 3.95 years) showed no difference in a primary composite end point of death or ESRD [76]. There are seven other published studies investigating plasma exchange as an adjunctive therapy. A Cochrane review and a meta-analysis have both reviewed the current evidence for PEX in AAV (summarized in Table 28.8) [3, 77]. Both concluded that PEX may be of benefit in preventing ESRD and death at 1 year, however this was not thought to be conclusive as the overall quality of the evidence is low and there is heterogeneity between included studies [77]. The PEXIVAS trial (described above) has been reported in abstract form and has shown no benefit of PEX on the primary composite outcome of death from any cause or ESRD (28% of PEX group vs. 31% in the no-PEX group, HR 0.86, 95% CI 0.65–1.13, $P = 0.27$). Further subgroup analysis and publication of the full trial is awaited [75].

Rituximab

Rituximab is recommended in most guidelines as an alternative induction agent in patients who are unable to receive or who are resistant to cyclophosphamide; the EULAR/ERA-EDTA guidelines recommend treatment with either agent with no requirement for intolerance or resistance to cyclophosphamide [1, 2].

There are two published RCTs comparing rituximab to cyclophosphamide in AAV for first-line induction therapy [39, 78]. Both studies used a dose of rituximab of 375 mg/m^2 body area weekly for 4 weeks, and patients received high-dose glucocorticoids initially. In the rituximab versus cyclophosphamide in ANCA-associated renal vasculitis (RITUXIVAS) trial, patients in the rituximab arm also received two doses of IV cyclophosphamide with the aim of ensuring early control of severe disease [39]. Rituximab was noninferior to cyclophosphamide in both trials, and in the Rituximab for the Treatment of Wegener's Granulomatosis and Microscopic Polyangiitis (RAVE) trial, rituximab seemed to be more effective than cyclophosphamide for those with disease relapse rather than de novo presentation. Subgroup analysis of patient in the RAVE trial who had evidence of renal impairment showed that rituximab was also noninferior to cyclophosphamide in these patients, although the trial did not include a large number of patients with severe renal involvement (median eGFR at trial entry was 41 ml/min in the rituximab group and 50 ml/min in the cyclophosphamide group) [79]. These trials and a summary of the evidence for rituximab induction therapy are shown in Table 28.9 and Table 28.10. Remission induction using a combination of low-dose cyclophosphamide and rituximab in combination with a steroid-sparing approach has been described in an open-label cohort study. Long-term outcomes in this

Table 28.8 Summary of evidence for adjunctive PEX in AAV.

Outcome	Number of participants (number of studies)	Comparative risks		Relative effect	Quality of evidence (GRADE)
		Control	Plasma exchange		
Death at 1 year	267 (5)	189/1000	195/1000 (117–310)	RR 1.03 (0.62–1.64)	Low
Dialysis at 1 year	235 (6)	376/1000	169/1000 (109–271)	RR 0.45 (0.29–0.72)	Low

Table 28.10 Summary of clinical trials investigating rituximab vs. cyclophosphamide as induction therapy for AAV.

Study	Design	Primary end point	Results	Secondary end points	Comments
RITUXIVAS [37]	Parallel RCT Rituximab vs. CYC in a 3 : 1 ratio	Sustained remission at 12 months Severe adverse events	No difference in remission rates at 12 months (76% RTX vs. 82% CYC) No difference in rates of severe adverse events	No difference in mortality	Patients in the RTX arm also received two pulses of IV CYC with doses 1 and 3 of RTX
RAVE [76]	Parallel RCT	Complete remission without prednisolone during the first 6 months	No difference in remission rates (64% in RTX arm, 53% in CYC arm)	No difference in adverse events	Rituximab superior in those with relapsing disease

AAV(ANCA-Associated Vasculitis); CYC, cyclophosphamide; IV, intravenous; RCT(Randomized control led trial); RTX, rituximab.

group were favorable when compared to historical cohorts and a prospective trial of this treatment regimen may be warranted [80].

Other Induction Agents

Several studies have compared other induction agents to cyclophosphamide in AAV and these could be considered for resistant disease but are not currently recommended for severe disease in published guidelines.

There are three trials which have compared MMF(Mycophenolate mofetil) to cyclophosphamide for induction of remission. The Mycophenolate Mofetil versus Cyclophosphamide for Remission Induction of ANCA-Associated Vasculitis (MYCYC) trial was a noninferiority trial comparing 6 months of induction with MMF to 6–10 pulses of IV cyclophosphamide, which to date has only been presented in abstract form, and it failed to demonstrate noninferiority of MMF [81]. Cochrane review of the three trials showed remission at 6 months was better with MMF compared to cyclophosphamide (RR(relative risk ratio) 1.17, CI 1.02–1.35), and there were no difference in adverse event rates between the groups [3, 81–83]. Patients with RPGN or severe renal failure were excluded from these studies.

One trial has compared methotrexate to cyclophosphamide, showing it to be noninferior with no difference in mortality or rates of remission at 6 months. Again, patients with severe renal impairment were not included in this trial and there was longer time to remission and higher relapse rates at 18 months in patients treated with methotrexate. Median time to relapse was 13 months in those treated with methotrexate and 15 months in the cyclophosphamide group [84, 85].

Based on the studies using MMF and methotrexate published guidelines recommend the use of either of these agents in patients with mild and nonorgan-threatening disease, with a preference for MMF in those who have evidence of renal involvement.

Other studies have investigated intravenous immunoglobulin, infliximab, and alemtuzumab and these could be considered for resistant disease [86–89].

Remission Maintenance

Current guidelines recommend that patients with severe AAV who are in remission after induction therapy with high-dose glucocorticoids plus cyclophosphamide/rituximab should be treated with low-dose glucocorticoids plus another immunosuppressive agent. Most commonly, azathioprine is recommended with methotrexate or MMF as an alternative [2, 69]. Introduction of azathioprine at 6 months after induction therapy has been shown to be noninferior to continuing cyclophosphamide to 12 months on rates of relapse at 18 months, and is associated with fewer adverse events [90]. Long-term follow-up of this study suggested there may be greater frequency of relapse in the group treated with azathioprine although this was not statistically significant [91]. Azathioprine has also been shown to be superior to MMF for remission maintenance but with similar rates of adverse events in MMF and azathioprine groups [92]. One trial has shown similar rates of relapse in patients treated with methotrexate or azathioprine for remission maintenance; however, the primary end point of this trial was safety of methotrexate rather than efficacy [93]. There were similar numbers of adverse events between the two groups but severity of adverse events was greater in those treated with methotrexate [93]. These studies are summarized in Table 28.11.

One RCT has investigated the duration of azathioprine maintenance therapy comparing tapering after 1 year or 4 years in patients with anti-PR3 AAV. This showed no significant difference in relapse-free survival at 4 years

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. between the two groups [94]. The prolonged Remission-Maintenance Therapy in Systemic Vasculitis (REMAIN) study also investigated duration of maintenance therapy and included 117 patients with stable remission following induction with cyclophosphamide and prednisolone. It showed that more prolonged maintenance treatment with azathioprine and prednisolone (48 months vs. 24 months) was associated with significantly lower risk of relapse. The prolonged treatment group had better renal outcomes but there was no difference in patient survival [95].

Rituximab is increasingly being used as an agent for remission maintenance in some centers. The Maintenance of Remission using Rituximab in Systemic ANCA-associated Vasculitis (MAINRITSAN) trial included 115 patients who were randomized to either rituximab or azathioprine for remission maintenance after induction therapy with cyclophosphamide and glucocorticoids Table 28.12 [40]. Rituximab was superior to azathioprine in preventing relapses (5% vs. 29% at 28 months) and adverse event rates were similar between the two groups. Long-term follow-up of this study shows that rituximab remains superior at 60 months (relapse free survival 37.2% vs. 57.9%). Again, the adverse event profile was similar between the two groups [96]. The MAINRITSAN 2 trial went on to compare fixed rituximab dosing every 6 months to a patient-tailored approach with rituximab re-dosing when CD19+ B cells or ANCA returned. Relapse rates were similar between the two arms (17.3% relapse rate in the tailored group vs. 9.9% in the scheduled treatment group); the tailored treatment group received fewer rituximab infusions over the study period [97].

Treatment of Relapse

Relapse is usually treated in the same way as patients presenting with de novo disease. Patients with minor relapses may respond to an increase or reintroduction of their oral immunosuppression or steroids. Those with severe relapse should be treated with high-dose glucocorticoids with cyclophosphamide or rituximab. Long-term follow-up of the RAVE study suggested that relapsing patients may respond better to rituximab than cyclophosphamide [79]. Additionally, cumulative cyclophosphamide exposure should be taken into account when planning to re-dose patients.

Co-trimoxazole

Prophylaxis against *pneumocystis jirovecci* is recommended in all patients receiving induction therapy with cyclophosphamide or rituximab. First-line treatment is with co-trimoxazole with pentamidine nebulizers as second line. There are also two studies which have investigated the role of co-trimoxazole in relapse prevention in patients with PR3-ANCA disease [98, 99]. There was a suggestion that the use of co-trimoxazole may reduce the risk of relapse at 1 year, particularly pulmonary relapse, but Cochrane review of the two studies found this result to be nonstatistically significant and so a firm conclusion regarding the use of antibiotics for remission maintenance was not possible (Table 28.13) [3].

Prognosis

Current studies estimate survival in patients with AAV to be around 90% at 1 year and around 70% at 5 years, a significant improvement following the introduction of modern immunosuppression regimens [64, 100]. A substantial cause of mortality within the first year is infection rather than active vasculitis, emphasizing the need for further research into better targeted therapies with better side-effect profiles [101, 102]. One year survival free of ESRD is approximately 75% and is 50% at 5 years [64]. The increased mortality in patients with AAV persists at long-term follow-up with increased rates of thrombosis, cardiovascular disease, malignancy, and infections when compared to the general population [102, 103]. In one study, predictors of mortality included advanced renal failure and older age [101]. Despite this, it is not the case that older patients should not be considered for aggressive treatment. One multicenter retrospective analysis of patients ≥75 years showed that patients who were not treated with cyclophosphamide or rituximab had significantly lower survival at 2 years (72.9% with cyclophosphamide, 81.3% with rituximab, and 45.0% with no/other treatments) [104].

Despite the improvements in mortality, in patients who have renal disease as part of their AAV the risk of relapse has remained relatively constant over recent years. One large

Table 28.13 Summary of evidence for antibiotics as maintenance therapy in AAV.

Outcome	Number of participants (number of studies)	Comparative risks		Relative effect	Quality of evidence (GRADE)
		Placebo	Co-trimoxazole		
Remission at 1 year	111 (2)	796/1000	907/1000 (780–1000)	1.14 (0.98–1.33)	Low

The authors comment that one of the two studies has multiple limitations in the study design.

study has shown a cumulative relapse rate of 11% at 1 year and 35% at 5 years with no change in relapse rates over the 25 year study period [64]. Patients with PR3-ANCA disease are more likely to experience relapse than those who are MPO-ANCA positive or ANCA negative; presence of lung disease and older patient age have also been shown to predict relapse in some studies [105, 106]. The utility of ANCA titer for predicting relapse is debatable although it may correlate better in patients with renal disease where some studies have shown rising ANCA titer may predict relapse [35, 107].

Patients with AAV who require renal transplant have clinical outcomes which are comparable or better to those with other causes of ESRD [108]. Transplant should be deferred until patients are ≥1 year from remission as one study has shown that risk of death post transplant was greatest in those transplanted less than a year after remission [109]. The risk of recurrent disease is low after transplantation and relapse rates seem to be lower in more modern studies, possibly due to the current transplant immunosuppression regimens used [108, 110].

Conclusions

AAV are a group of rare, multisystem, small and medium vessel vasculitides. Modern immunosuppression regimens using more effective and targeted drugs have significantly improved morbidity and mortality, and mortality in the first year is more likely to be due to complications of treatment than active vasculitis. There are several available evidence-based guidelines for treatment which are based on high-quality RCTs. Most authorities recommend induction treatment with high-dose glucocorticoids plus cyclophosphamide or rituximab and maintenance therapy with low-dose glucocorticoids and azathioprine.

Introduction

Monoclonal gammopathies consist of a heterogenous group of disorders defined by the presence in serum and/or urine of a paraprotein produced by an abnormal B-cell clone. The clone usually derives from plasma cells when the paraprotein is IgG, IgA, IgD, or light chain only and $CD20^+$ lymphocytic clones including lymphoplasmacytic clones when it involves an IgM. In its advanced state, monoclonal gammopathy may indicate symptomatic malignant disorder such as multiple myeloma, Waldenström macroglobulinemia, or other non-Hodgkin lymphomas. More frequently, the clone can remain quiescent for a prolonged period of time defining monoclonal gammopathy of undetermined significance (MGUS) [1].

Renal complications associated with monoclonal gammopathy are frequent. They can be separated into two categories according to the characteristics of the underlying B-cell clone. The first group of renal diseases always occurs in the setting of high tumor mass with production of large amounts of monoclonal immunoglobulins. The prime example is light-chain cast nephropathy, which almost invariably complicates high tumor mass B-cell disorder, particularly symptomatic multiple myeloma [2–4]. Although rare, another example is glomerular deposition of monoclonal IgM during high tumor mass lymphoplasmacytic lymphoma (Waldenström macroglobulinemia) [5]. The second group includes all renal disorders caused by a monoclonal immunoglobulin secreted by a nonmalignant B-cell clonal disorder that does not require treatment for the tumor burden. These are currently referred to as monoclonal gammopathy of renal significance (MGRS) [6, 7]. In this setting, structural peculiarities of the paraprotein, particularly the variable domain, and not the rate of production are the main determinants of renal lesions [6, 8]. The spectrum of renal diseases in MGRS is vast and can be classified according to the localization of renal lesions (glomerular, tubular, vascular, etc.), and to the composition and the pattern of ultrastructural organization of deposits. Tubular lesions include light-chain proximal tubulopathy related to endolysosomal engorgement of proximal tubular cells by light chains and crystal-storing histiocytosis defined by crystalline inclusions within interstitial histiocytes. Glomerulopathies are featured either by organized deposits which can be fibrillar (Ig-related amyloidosis), microtubular (type I and type II cryoglobulinemic glomerulonephritis, immunotactoid glomerulopathy), or crystalline deposits (crystalglobulinemic glomerulonephritis), or by nonorganized deposits (monoclonal immunoglobulin deposition disease [MIDD] and proliferative glomerulonephritis with monoclonal immunoglobulin deposits [PGNMID]). The third subgroup includes glomerular lesions not induced by the deposition of the monoclonal immunoglobulin but by its functional activity. The most common is C3 glomerulopathy associated with monoclonal gammopathy where deposits are composed of C3 complement fraction only, consecutive to local or systemic activation of the complement alternative pathway (CAP) by the monoclonal immunoglobulin [9, 10].

Diagnostic Evaluation

The diagnosis of monoclonal immunoglobulin-related kidney diseases almost always requires a kidney biopsy. The only exception is Ig-related amyloidosis, where the diagnosis could be made from other tissue [11]. Renal pathological diagnosis relies on careful examination of kidney biopsy samples by light microscopy, immunofluorescence studies, and electron microscopy [9, 12]. At a minimum, immunofluorescence studies must include antibodies against kappa and lambda light chains to determine monoclonality. Determination of IgG subclasses would help support the monoclonal nature of the immunoglobulin deposits, especially if a monoclonal immunoglobulin could not be identified in the blood or urine. However, IgG subclass restriction without light-chain restriction is not considered to be monoclonal as it can occur in polyclonal immunoglobulin deposition disease [7]. Antibodies against heavy chain constant domains may be needed in cases of heavy chain deposition disease (HCDD) to look for heavy chain truncation [13]. In some cases, additional studies are required to identify the nature of deposits, such as immunoelectron microscopy or laser microdissection followed by mass spectrometry [14–17].

Hematological workup is crucial for clonal identification because the same kidney lesion can occur in different B-cell disorders, and treatment differs according to the plasmacytic or lymphocytic nature of the clone. Bone marrow aspiration and biopsy are required, including the use of sensitive techniques (flow cytometry, molecular analysis) to better identify small clones [7]. Peripheral blood flow cytometry is helpful in identifying clones of chronic lymphocytic leukemia or monoclonal B-cell lymphocytosis [18].

Extrarenal manifestations can occur in some monoclonal immunoglobulin-related kidney diseases and may be clinically significant. It is important to identify the involvement and impairment of the extrarenal organs so these can be managed appropriately. Cardiac evaluation with echocardiogram and cardiac biomarkers such as N-terminal pro-brain natriuretic peptide (NT-proBNP) and troponin T are standard of care in patients with Ig-related amyloidosis [19, 20]. This is also recommended in patients with MIDD that have cardiac-related symptoms [21]. Liver involvement can be detected by liver function test and imaging studies. Nerve involvement is not uncommon in amyloidosis and can involve both peripheral nerves and the autonomic nervous system [20]. Assessment of these impairments is important as it can affect therapeutic strategies by altering drug elimination and tolerability of adverse effects [22].

Because paraprotein-associated renal disorders are heterogeneous, management requires collaborative work between hematologists and nephrologists. Early diagnosis and efficient chemotherapy targeting the causal B-cell clone are mandatory to improve renal prognosis and patient survival [22].

Pathophysiology

The kidney disease may complicate an already diagnosed clonal B-cell disorder or reveal a previously unknown hematological disease. Renal disease in B-cell lymphoproliferative disorders may result from two main pathophysiological mechanisms that can even coexist in the same patient, i.e. the intrinsic nephrotoxicity of the secreted monoclonal immunoglobulin and malignant infiltration of the renal parenchyma by malignant B-cells, which will not be addressed further in this chapter. The physicochemical properties of monoclonal immunoglobulin appear to be the main determinant of their nephrotoxicity as well as influencing the topography and pattern of kidney lesions. Deposition of all or part of the monoclonal immunoglobulin is the most common mechanism and this can occur in various ultrastructural patterns (amorphous, crystalline, fibrillar, or microtubular) of deposits or inclusions. Other mechanisms include complement activation, autoantibody activity or cytokine secretion induced by the monoclonal immunoglobulin (Table 29.1) [10, 39].

Nephrotoxic Monoclonal Free Light Chains

Several mechanisms of nephrotoxicity of free light chains (FLCs) have been described. These include extracellular deposition in AL amyloidosis (organized deposits) and light-chain deposition disease (LCDD) (nonorganized deposits), and precipitation/crystallization in cast nephropathy and light-chain proximal tubulopathy [8, 40]. Under physiological conditions, polyclonal FLCs, as other low molecular weight proteins, are freely filtered by the glomerulus and reabsorbed in proximal tubular cells by the megalin/cubilin multiligand receptor complex [41]. FLCs are then degraded in endolysosomal vesicles and only a minute amount is present in the final urine [42]. During symptomatic multiple myeloma large amounts of monoclonal FLCs are filtered by the glomerulus, overwhelming the reabsorption capacity of the endocytic receptors megalin/cubilin in the proximal tubule. This allows the monoclonal FLCs to flow into the loop of Henle. Cast nephropathy results from the interaction of these FLCs with uromodulin (Tamm–Horsfall protein) in lumen of the thick ascending limp of the loop of Henle, leading to tubular obstruction and acute kidney injury (AKI). Uromodulin is the most abundant protein excreted in the urine under physiological conditions, but its complete

Table 29.1 Summary of the main pathological and hematological findings in paraprotein associated renal disorders.

Localization of renal lesions	Kidney disease	Mechanism of renal toxicity	Ultrastructural appearance	Characteristics of monoclonal gammopathy	Reference
Glomerular	Ig-related amyloidosis	Deposition	Fibrils	λ > κ, IgM<10% in AL amyloidosis Truncated γ in AH amyloidosis LC + truncated HC in AHL amyloidosis	[19, 23]
	MIDD	Deposition	Nonorganized	κ > λ in LCDD (usually Vκ1 or Vκ4) Truncated HC (mostly γ) in HCDD LC + truncated HC in LHCDD	[13, 21, 24]
	PGNMID	Deposition	Nonorganized	Mostly IgG3 (κ > λ)	[25]
	Immunotactoid GN	Deposition	Microtubules	Mostly IgG1 (κ > λ)	[26, 27]
	Type I cryoglobulinemia	Deposition/precipitation	Microtubules/crystals	Mostly IgG or IgM	[28]
	Type II cryoglobulinemia	Deposition	Curved short tubular structures Nonorganized	IgM acting as a rheumatoid factor	[12]
	C3 glomerulopathy	CAP activation		IgG	[29–31]
Tubular	Cast nephropathy	Precipitation	Crystals	κ > λ	[4, 32]
	Proximal tubulopathy	Precipitation	Mostly crystals	κ (>90%, mostly Vκ1)	[33, 34]
	Cristal-storing histiocytosis	Precipitation	Crystals	κ	[35, 36]
Vascular	Thrombotic microangiopathy	CAP activation or cytokine mediated or unknown	Microvascular endothelial cell injury	IgG in atypical hemolytic-uremic syndrome IgA = 50% in POEMS syndrome (λ ~ 100%)	[37, 38]

AL, amyloid light chain; AH, amyloid heavy chain; AHL, amyloid light and heavy chain; CAP, complement alternative pathway; HC, heavy chain; HCDD, heavy chain deposition disease; Ig, immunoglobulin; LC, light chain; LCDD, light chain deposition disease; LHCDD, light and heavy chain deposition disease; MIDD, monoclonal immunoglobulin deposition disease; PGNMID, proliferative glomerulonephritis with monoclonal immunoglobulin deposits; POEMS, polyneuropathy-organomegaly-endocrinopathy-monoclonal protein-skin changes; Vκ, variability subgroup of kappa light chain.

function remains incompletely understood [43]. The binding affinity of FLCs for uromodulin is influenced by the molecular structure of the third complementarity-determining region (CDR3) that specifically recognizes a nine amino-acid domain of uromodulin [44–47]. Facilitating factors that increase light-chain precipitation and/or their interaction with uromodulin have been well described in conditions such as dehydration, hypercalcemia, nonsteroidal drug use, furosemide, and acidic urine [48–50]. Kidney injury in cast nephropathy is also perpetuated by interstitial inflammation and fibrosis induced by the monoclonal FLCs. In vitro studies and animal experiments have shown that excessive endocytosis of myeloma light chains triggers oxidative stress, activation of NF-κB, and release of inflammatory mediators (IL-6, IL-8, MCP-1, and TGF-β) leading to tubulo-interstitial inflammation, fibrosis, and morphologic alteration of the tubular epithelium [48, 51, 52].

Most other types of kidney injury related to pathogenic light chains occur in patients with small B-cell or plasma cell clones with low amounts of monoclonal immunoglobulin [6, 10]. In this context, the kidney toxicity is not driven by the tumor burden but is related to structural peculiarities of the monoclonal FLC [8]. For example, light-chain proximal tubulopathy is mostly related to kappa light chains that are restricted to the Vκ1 subgroup and derive from only two germline genes (Vκ1-33 and Vκ1-39). Some mutations in the variable domain confer a resistance to proteolysis, leading to the formation of crystals within the endolysosomal compartment of proximal tubular cells [53]. Accumulation of these light chains in proximal tubules inhibits receptor-mediated endocytosis and provokes urinary leak of phosphate, uric acid, glucose, amino acids, and low-molecular-weight proteins, with proximal (type 2) renal tubular acidosis [54]. On the other hand, most light chains involved in renal AL-amyloidosis are derived from two germline Vλ genes (Vλ6-57 and Vλ3-1), but no common structural peculiarities have been identified. However, germline gene usage influences the organ tropism with predominant kidney involvement in Vλ6-57 patients and more common cardiac involvement in Vλ1-44 patients [55–57]. Structural peculiarities of light chains have been also reported in LCDD with overrepresentation of the Vκ4 and Vκ1 subgroup of variability, abnormal glycosylation, and high isoelectric point values of variable domain complementarity determining regions, possibly accounting for tissue deposition along the anionic proteoglycans of the basement membranes [21, 58–61].

Nephrotoxic Monoclonal Free Heavy Chains

The deposition of free monoclonal heavy chains is a rare condition seen in AH amyloidosis and HCDD. The most striking feature of deposited heavy chains is the deletion of the first constant (CH1) domain [13, 62, 63]. The nephrotoxic heavy chain is often undetectable by electrophoresis and immunofixation. In this context, immunoblotting is a useful technique to detect small amounts of truncated heavy chains. However, this technique is not widely available. In HCDD, cationic charges of the heavy chain variable domain probably favor the formation of amorphous deposits along renal basement membranes [13].

Nephrotoxic Monoclonal Entire Immunoglobulins

Mechanisms of toxicity of entire immunoglobulins in PGNMID, immunotactoid glomerulonephritis, and cryoglobulinemic glomerulonephritis are poorly understood. These disorders are mostly induced by monoclonal IgG1 or IgG3 known to induce complement activation through the classical pathway [9, 39]. Immunoglobulin deposits usually coexist with C3 and sometimes C1q and C4 deposits [64, 65]. Complement activation through the classical, lectin or alternative pathway is probably a main determinant of glomerular hypercellularity and inflammation in these disorders. Experimental studies in mice have shown that in cryoglobulinemic glomerulonephritis the pattern of kidney lesions depends on peculiarities of the molecular structure of pathogenic IgG [66, 67].

Complement and Cytokine Activation Associated with Monoclonal Gammopathy

Recent studies have shown that the incidence of monoclonal gammopathy in patients >50 years old with C3 glomerulopathy is high [29, 68–70]. This association is not fortuitous as suggested by the presence in some cases of autoantibody activity against CAP regulatory proteins (anti-factor H antibody and C3Nef) and by the beneficial effect of clone-directed therapy [30]. However, the mechanism of complement activation is different in the majority of patients and may involve bystander polyclonal antibodies directed against CAP regulatory proteins or direct activation of the CAP by the monoclonal immunoglobulin [71]. Cytokine activation is probably involved in thrombotic microangiopathy-like lesions in polyneuropathy, endocrinopathy, organomegaly, monoclonal gammopathy, and skin changes (POEMS) syndrome. This disease is characterized by striking elevation of serum vascular endothelial growth factor (VEGF) levels that probably account for glomerular endothelial cell injury [37, 72].

Diagnosis

Tubulointerstitial Lesions

Light-chain Cast Nephropathy

AKI is present at diagnosis in approximately 30% of patients with symptomatic multiple myeloma. AKI is mostly related to light-chain cast nephropathy, a myeloma defining event invariably associated with high tumor mass [73]. Apart from multiple myeloma, light-chain cast nephropathy has been also described in Waldenström macroglobulinemia, chronic lymphocytic leukemia, and other lymphomas [64, 74–77]. Patients with cast nephropathy typically present with severe AKI, sometimes requiring dialysis. AKI is isolated or associated with general symptoms related to high tumor mass such as skeletal pains related to lytic bone lesions. Urine protein electrophoresis typically shows prominent light-chain proteinuria with albuminuria <10% [78, 79]. In around 50% of patients, cast nephropathy is triggered by facilitating factors, namely dehydration, hypercalcemia, infection, or nephrotoxic drugs (nonsteroidal anti-inflammatory agents, diuretics, angiotensin-converting enzyme inhibitors or angiotensin receptor blockers) [32, 78, 80]. The use of modern contrast media has not been associated with cast nephropathy in recent large series [78]. The risk of cast nephropathy is influenced by the amount of monoclonal light chains excreted in the urine and is particularly high when light-chain proteinuria exceeds 2 g/day [81].

Histologically, the cast nephropathy is defined by the presence of periodic acid Schiff (PAS) stain negative and fractured casts in distal tubule lumina, often with crystalline appearance and usually accompanied by giant cell reaction and tubulorrhexis (Figure 29.1). Severe interstitial inflammation is often present and plays a role in the development of irreversible fibrosis and chronic kidney injury. The presence of numerous casts has been found to be predictive of a poor renal prognosis [32]. On immunofluorescence, the casts stain brightly with anti-kappa or anti-lambda antibody. Ultrastructural examination reveals the crystalline organization of the casts [12].

Light-chain Proximal Tubulopathy

Light-chain proximal tubulopathy rarely occurs in the context of symptomatic multiple myeloma or overt lymphoid malignancy, and most cases fall into the spectrum of MGRS [33, 82]. The frequency is low and light-chain proximal tubulopathy represents 5% of Ig-related renal diseases. The median age at diagnosis is around 60 years, with a slight male predominance [33, 34]. Patients typically present with slowly progressive chronic kidney failure with tubular proteinuria and Bence Jones proteinuria usually of kappa isotype. The presence of hypouricemia and hypophosphatemia must encourage further explorations to detect proximal tubule dysfunction. However, signs of tubular dysfunction may be absent in patients with more advanced kidney impairment. The complete form of proximal tubulopathy, referred to as light-chain associated Fanconi syndrome, is defined by the urinary leak of low molecular weight proteins, phosphate, uric acid, glucose, and amino acids. Patients who exhibit only some of these features are considered to have a partial Fanconi syndrome. Patients may also present with prominent bone symptoms, including stress fractures, secondary to hypophosphatemic osteomalacia [33, 83]. Thus, searching for monoclonal gammopathy is mandatory in adults with symptoms of proximal tubule dysfunction.

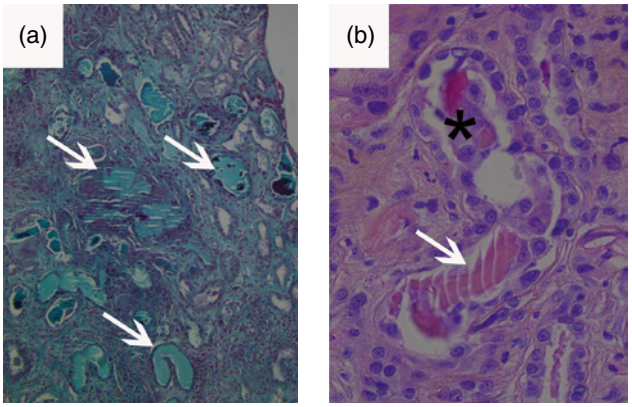

Figure 29.1 Myeloma cast nephropathy by light microscopy. (a) Masson's trichrome staining (×200). Representative example of cast nephropathy with numerous typical polychromatophilic and fractured casts (arrows) associated with interstitial fibrosis and inflammation. (b) Hematoxylin and eosin staining (×400). Typical cast (arrow) with giant cell (asterisk) and tubulorrhexis.

The kidney biopsy shows typically rhomboid-shaped hypereosinophilic and PAS-negative crystals within proximal tubular cells. Their detection by light microscopy is sometimes difficult, highlighting the diagnostic value of immunofluorescence and ultrastructural examination, which should be systematically considered in the presence of suggestive lesions such as focal proximal tubule dedifferentiation and atrophy (Figure 29.2) [33, 84, 85]. In some cases, antigenic epitopes normally recognized by antibodies routinely used may be sequestered by the crystalline lattice, resulting in false negative results. Ancillary techniques are then needed, including immunofluorescence on paraffin-embedded tissue after protease digestion or immunoelectron microscopy [85, 86]. Light-chain proximal tubulopathy may also manifest with accumulation of light chains within proximal tubular cells without crystal formation. These patients often present with evidence of tubular injury, but Fanconi syndrome is rare [34, 87, 88].

(b) Electron microscopy (×50 000). Abundant rhomboid crystals (arrows) surrounded by a single membrane within the cytoplasm of proximal tubular cells.

Crystal-storing Histiocytosis

Crystal-storing histiocytosis is a rare complication of symptomatic myeloma or MGRS, defined by the accumulation of light-chain crystals in histiocytes. These histiocytes are commonly seen in the bone marrow but can be found in other sites such as kidney, perirenal fat, lungs, cornea, and joints. Crystal-storing histiocytosis may coexist with light-chain proximal tubulopathy and/or cast nephropathy [35, 36].

Glomerular Lesions

Glomerular Disorders with Organized Immunoglobulin Deposits

Immunoglobulin-related Amyloidosis

Immunoglobulin-related amyloidosis is the most common glomerular lesion associated with monoclonal gammopathy [23]. The average age at diagnosis is 65 years, with a slight male predominance (approximatively 60% of cases). Among this group, AL-amyloidosis is the most frequent subtype where amyloid is composed of monoclonal light chains (usually lambda). In rare cases, immunoglobulin-related amyloidosis is derived from fragments of heavy chains and light chains (AHL) or heavy chains only (AH). AL-amyloidosis is the prototype of MGRS, since most patients present at diagnosis with an isolated monoclonal gammopathy or indolent B-cell clone [9]. Progression to symptomatic myeloma is unusual [89, 90]. AL-amyloidosis complicates lymphoplasmacytic proliferation with secretion of monoclonal IgM in less than 10% of patients [91, 92]. The diagnosis of amyloidosis is based on the demonstration of Congo-red deposits with dichroism and birefringence under polarized light [93]. Since more than 35 proteins have been described as amyloidogenic precursors, characterization of the native protein is the cornerstone of management. Immunofluorescence analysis of frozen tissues, using anti-light and anti-heavy chain antibodies should be preferred to immunohistochemistry, which has lower diagnosis sensibility and specificity [94]. Minimally invasive biopsies (salivary glands, abdominal fat) should be performed as first-line. When tissue biopsies fail to demonstrate amyloid deposition or are insufficient for amyloid typing, biopsy of a clinically affected organ (kidney, liver, gastrointestinal tract, or endomyocardial tissue) should be considered. When a kidney biopsy is performed in patients with renal involvement, it allows characterization of amyloid deposits in most cases (Figure 29.3). The incidence of bleeding complications in systemic AL-amyloidosis after kidney biopsy appears acceptable when performed by experience physicians [95]. Deposits that stain positive for lambda light chain in most cases, predominately in the mesangium and along the glomerular basement membranes, are often associated with interstitial and vascular deposits. Electron microscopy may be useful to confirm the presence of amyloid deposits, particularly in earlier disease stages, and typically shows randomly arranged fibrils of 7–10 nm in external diameter that initially predominate in the external aspect of the glomerular basement membrane. When the nature of the deposits remains indeterminate with routine technics, additional explorations must be carried out, such as immunoelectron microscopy or mass spectrometry after laser microdissection. [9]

All organs can be affected in immunoglobulin-related amyloidosis. Kidney involvement is the most frequent, found in two-thirds of patients at diagnosis. The heart is the most common extrarenal organ involved followed by peripheral nerves and liver. Macroglossia, periorbital purpura or skeletal muscle pseudohypertrophy are particularly suggestive symptoms but are rarely present [19]. Renal manifestations include glomerular symptoms in most cases with abundant proteinuria predominantly composed of albumin, usually without hematuria or hypertension. Nephrotic syndrome and chronic kidney disease (CKD) are observed in approximately 50% of cases at diagnosis. When the deposits are predominantly tubulointerstitial and vascular, chronic interstitial nephritis with polyuria due to defective urine concentration ability and slowly progressive CKD with little proteinuria is possible [96]. Organ involvement in systemic AL amyloidosis is now defined by consensus criteria, updated at the 2010 meeting of the International Society of Amyloidosis in Rome [20].

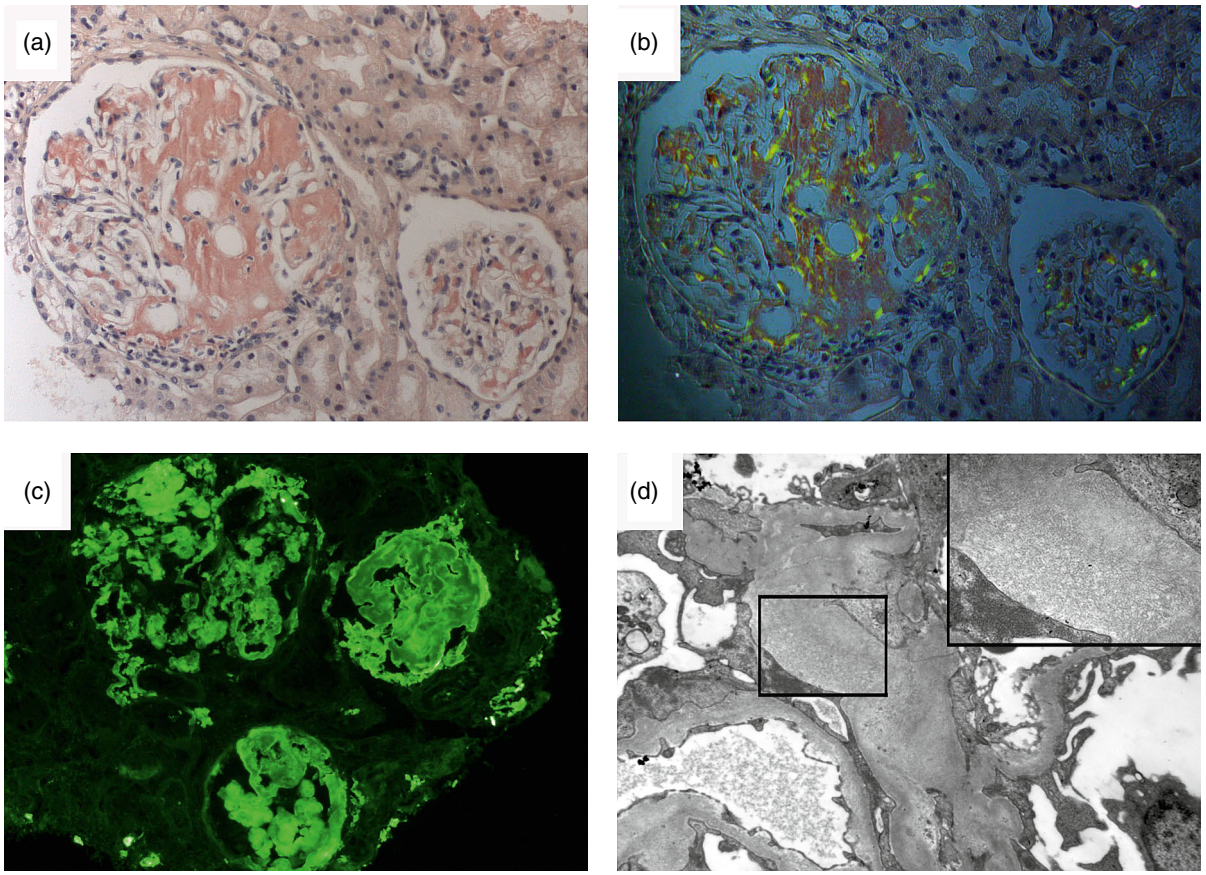

Figure 29.3 AL-amyloidosis. (a and b) Light microscopy (Congo red staining, ×200). Glomerular mesangial and capillary wall Congo red positive deposits (a) with characteristic dichroism and apple green birefringence under polarized light (b). On immunofluorescence (×200) glomerular amyloid deposits stain brightly for lambda light chain (c) with negative staining for kappa light chain (not shown). (d) By electron microscopy (×12 000, insert ×50 000), amyloid deposits are composed of haphazardly oriented fibrils ranging from 7 to 14 nm in diameter.

Immunotactoid Glomerulonephritis

Immunotactoid glomerulonephritis, also referred to as glomerulonephritis with organized microtubular monoclonal immunoglobulin deposits (GOMMID), is a very rare entity (fewer than 100 cases in the literature) characterized by Congo red negative deposits that show typical ultrastructural organization into microtubules of 10–60 nm in external diameter, with a distinct hollow core at magnification of less than 30 000. By definition, cryoglobulin testing should be negative. Deposits are monotypic by immunofluorescence, mostly composed of IgG1κ, usually associated with C3. Light microscopic appearance is not specific, but membranous nephropathy or membranoproliferative glomerulonephritis patterns are commonly observed (Figure 29.4). Most patients present with nephrotic range proteinuria, hematuria, kidney insufficiency, and hypertension. Immunotactoid glomerulonephritis has been mostly reported in patients with MGRS or chronic lymphocytic leukemia with an average age of 60 years [26, 27, 97].

Cryoglobulinemic Glomerulonephritis

Cryoglobulins are immunoglobulins that precipitate under cold exposure. Three types exist but only two contain monoclonal immunoglobulin. Type 1 is composed of a single type of monoclonal immunoglobulin (usually IgG or IgM) and type 2 (mixed) contains classically a monoclonal IgM acting as a rheumatoid factor against polyclonal IgG [98]. The underlying condition is plasma cell dyscrasia or lymphoproliferative disorder, particularly lymphoplasmacytic lymphoma. Type II mixed cryoglobulinemia is observed in around 10% of patients with chronic virus C infection. Glomerulonephritis is more common with type II cryoglobulinemia. Median age is 62 years old and it is more common in women. [28] Renal presentation includes classically proteinuria and microscopic hematuria, sometimes with moderate chronic kidney insufficiency. Severe hypertension is commonly observed. Some patients may present an acute nephritic syndrome characterized by hematuria,

Membranous pattern of injury associated with focal duplication of glomerular basement membranes (arrow). (b) By electron microscopy (×50 000), the deposits are composed of microtubules with hollow centers and organized in parallel arrays (arrows).

usually macroscopic, severe proteinuria and hypertension, and acute kidney failure. Extrarenal manifestations are common and often present as purpura, ulcers, peripheral neuropathy, and arthralgia [28]. On light microscopy (Figure 29.5a,b), cryoglobulinemic glomerulonephritis shows membranoproliferative or endocapillary proliferative glomerulonephritis with intracapillary infiltrating monocytes and large PAS-positive intraluminal immune deposits (thrombi). Careful immunofluorescence analysis is crucial to determine the type of cryoglobulinemia, as both IgM and IgG are present in type 2 cryoglobulinemia without clear light-chain restriction due to the presence of polyclonal IgG. By electron microscopy (Figure 29.5c), deposits predominate in the subendothelial space and intracapillary lumen, and appear focally organized (microtubular or "fingerprint" substructure) [9].

Glomerular Disorders with Nonorganized Immunoglobulin Deposits

Monoclonal Immunoglobulin Deposition Disease

Randall-type MIDD is the most common glomerulopathy with nonorganized deposits. MIDD commonly occurs in the context of a plasma cell disorder with criteria for symptomatic multiple myeloma in nearly 25% of cases and for MGRS (including smoldering myeloma in around 25% of patients) in the remaining patients [21, 24, 99]. The diagnosis is made on approximately 0.5% of kidney biopsies on native kidneys. It is usually discovered around the age of 60 years, with a slight male predominance [21, 24, 100]. According to the composition of deposits, three categories are distinguished: LCDD, HCDD, and light- and heavy-chain deposition disease (LHCDD). MIDD is characterized by linear nonorganized Congo red-negative monoclonal immunoglobulin deposits along basement membranes [9]. As immunoglobulin-related amyloidosis, MIDD is a systemic disease with prominent kidney manifestations, but heart, liver, or peripheral nerve involvement may be encountered [21]. In the kidney, deposits are invariably observed along tubular basement membranes, and in most cases in the mesangium, glomerular basement membranes, and around arteriolar myocytes. The most common histologic feature is glomerulosclerosis mimicking diabetic nephropathy (Figure 29.6). The usual presentation is progressive kidney failure and glomerular symptoms, including nephrotic

syndrome in half of patients. Uncommonly, MIDD may manifest with slowly progressive kidney disease without significant proteinuria. In this context, glomerulosclerosis is uncommon and deposits predominate in the renal vascular and tubular compartments [101, 102]. LCDD occurring in the context of symptomatic multiple myeloma usually coexists with cast nephropathy and has similar presentation and outcome as pure cast nephropathy [21].

Proliferative Glomerulonephritis with Monoclonal Immunoglobulin Deposits

PGNMID is a rare glomerular disorder defined by nonorganized immunoglobulin (most commonly IgG3) and complement component deposits in the glomerular capillary walls and mesangium, mimicking an immune complex-mediated glomerulonephritis (Figure 29.7). Around 100 cases are reported in the literature. The average age at diagnosis is 55 years old. Multiple myeloma is rare and around two-thirds of patients have no detectable monoclonal component by standard techniques [25, 103]. PGNMID appears as a renal limited disorder with prominent glomerular symptoms and frequent CKD. The risk of recurrence after kidney transplantation has been reported to be as high as 90% [104].

Glomerular Disorders without Immunoglobulin Deposits

C3 Glomerulopathy Associated with Monoclonal Gammopathy

C3 glomerulopathy regroups two entities characterized by glomerular C3 deposition without immunoglobulin: C3 glomerulonephritis and dense deposit disease. Both entities are associated with dysregulation of the CAP. By electron microscopy, dense deposit disease is distinguished from C3 glomerulonephritis by the presence of characteristic "sausage-shaped" intramembranous electron dense deposits [105]. Patients typically present with glomerular

Granular nonorganized electron-dense deposits (arrows) predominant in the subendothelial space of glomerular basement membrane.

symptoms (proteinuria and hematuria) and progressive CKD. In patients over 50 years of age, most cases of C3 glomerulopathy are associated with a circulating paraprotein [29, 31, 68, 70]. Although direct evidence of a link between monoclonal gammopathy and C3 glomerulopathy is lacking in most patients, the implication is suggested by the presence in some cases of autoantibody activity of the monoclonal immunoglobulin against CAP regulatory proteins and by the beneficial effect on renal outcome of a clone-directed therapy [30, 70].

Thrombotic Microangiopathy Associated with Monoclonal Gammopathy

The term "thrombotic microangiopathy" refers to a diverse group of disorders linked by a common histologic finding of endothelial cell injury. Two categories associated with monoclonal gammopathy have to be distinguish: (i) microangiopathy with hemolytic anemia (MAHA) which can occur in patients with MGRS, symptomatic multiple myeloma, and Waldenström macroglobulinemia, and (ii) glomerular microangiopathy associated with POEMS syndrome where hemolysis and thrombocytopenia are absent [7].

Treatment

Indication of Therapy

Indication of therapy in MGRS is driven by renal damage due to the nephrotoxic immunoglobulin produced by the clone. Therapy in MGRS aims to improve renal survival and in selected patients to reduce the risk of recurrence after renal transplantation. Treatment decisions should also take into account the presence of extrarenal manifestations and the patient's status [22]. Light-chain cast nephropathy seen only in malignant disease is not MGRS and treatment is a medical emergency [106, 107].

Clone-directed Therapy

The current therapeutic approach in MGRS is to eradicate the underlying B-cell clone with chemotherapy. If the clone is plasmacytic, usually secreting a monoclonal IgG, IgA, or light chain, treatment should be based on antimyeloma agents. The strategy mainly relies on bortezomib, usually combined with an alkylating agent and dexamethasone (CyBorD regimen) that produces rapid and deep hematological response. Bortezomib is easy to use in patients with impaired renal function since it does not require dose adaptation. High-dose melphalan followed by autologous stem cell transplantation (ASCT) may be a therapeutic option in some patients with plasma cell clone. However, mortality and morbidity related to ASCT increase in patients with renal impairment, and some patients may worse their renal function during the procedure. Since melphalan is eliminated by renal excretion, dose adaptation is needed in patients with CKD stage 3 or above. In case of relapsing or refractory disease, immunomodulatory drugs should be considered. Lenalidomide must be used with caution in patients with renal dysfunction since this drug is predominantly eliminated through renal excretion and may sometimes worsen renal function with unclear mechanism, particularly in patients with AL amyloidosis [108]. Thalidomide and pomalidomide are probably more appropriate since they do not require dose adaptation. Anti-CD38 monoclonal antibodies, which are highly effective in symptomatic multiple myeloma and are currently being evaluated in AL amyloidosis, are likely to be increasingly used in the treatment of various MGRS [10, 22]. If the clone is lymphoplasmacytic (usually producing a monoclonal IgM) or lymphocytic, the treatment should be based on rituximab-containing regimens [22]. The choice and modality of chemotherapy in light-chain cast nephropathy remains to be defined. The goal of therapy is to rapidly reduce the rate of production of FLCs, a key factor to induce renal response [106, 107]. The use of high-dose steroids seems mandatory because of their anti-inflammatory properties. Bortezomib-based therapy is associated with high rate of renal response in light-chain cast nephropathy[109].

Symptomatic Measures

Cast Nephropathy

Symptomatic treatment is a key step in the management of cast nephropathy. It is based on the rapid correction of precipitating factors such as treatment of infection with non-nephrotoxic antibiotics and correction of hypercalcemia using bisphosphonates despite their potential nephrotoxicity. Hydration is essential with administration of hypotonic (half normal) saline to reduce aggregation of Tamm–Horsfall protein and its interaction with urine FLC [106, 107]. The use of adjuvant supportive measures to rapidly reduce the level of FLCs is still debated. Two randomized trials using high cutoff (HCO) dialyzer for the removal of serum FLC produced different results in terms of renal recovery. The European trial (EuLITE) had randomized patients to a standard dialysis with a high-flux dialyzer versus extended dialysis using a HCO dialyzer in addition to bortezomib-based triplet chemotherapy. In this study a similar hemodialysis independence rate (60%) was observed in both groups [110]. The French randomized clinical trial with biopsy-proven cast nephropathy reported that intensive HCO hemodialysis does not significantly increase early hemodialysis-independence rate but results in significantly higher 6 and 12 month-renal recovery rates compared to intensive hemodialysis with conventional high-flux dialyzers [78]. Further larger studies are needed to confirm the benefice of extracorporeal removal of FLCs in light-chain cast nephropathy.

Ig-related Amyloidosis

Symptomatic measures, adapted to organ failures, are essential in the management of Ig-related amyloidosis. In patients with nephrotic syndrome, fluid retention and edema require treatment with loop diuretics often given at a high dose or combined with other diuretics. Caution is required in the use of standard treatment of cardiac failure in patients with amyloidosis. Calcium inhibitors, β-blockers, and digitalis are to be avoided due to excess toxicity. Amiodarone should be considered as first-line therapy for arrhythmia. Angiotensin converting enzyme inhibitors can promote hypotension and are often poorly tolerated. In patients with severe, life-threatening cardiac involvement, pacemaker or defibrillator implantation may be required [19, 90].

Other Glomerular Disorders

As in other glomerulonephritis, the use of angiotensin converting enzyme inhibitors and/or angiotensin receptor blockers is essential to control blood pressure and to reduce proteinuria.

Proximal Tubulopathy

Symptomatic measures to prevent osteomalacia are mandatory, including phosphate, calcium, and vitamin D supplementation. Prophylaxis against hypokalemia is often necessary [33].

Kidney Transplantation

Recent advances in chemotherapy result in improved patient survival. Selected patients with CKD stage V are now eligible for renal transplantation. Due to the risk of recurrence, hematological remission seems mandatory before considering a renal transplant [104, 111–113]. The long-term results of renal transplantation in MGRS, particularly the risk of infection and neoplasia, remain to be evaluated.

Conclusion

The spectrum of renal complications associated with paraproteins is heterogeneous and the diagnosis relies on careful examination of biopsy samples by light microscopy, immunofluorescence studies, and in most cases electron microscopy. Identification of the underlying B-cell clone is crucial for treatment strategy.

Primary Immune Complex-mediated Membranoproliferative Glomerulonephritis and C3 Glomerulopathies: A Clinical Approach

Fadi Fakhouri

Department of Nephrology and Immunology, Centre Hospitalier Universitaire de Nantes, Nantes, France

Introduction

Primary immune complex-mediated membranoproliferative glomerulonephritis (IC-MPGN) and C3 glomerulopathies (C3G) have attracted a substantial body of basic and clinical research in the last decade. This has been mainly due to the recent dynamics in the field of complement study and the development of an increasing number of complement modulators. These nephropathies have been recently reclassified with the individualization of a new subtype, C3 glomerulonephritis (C3GN), and experimental and clinical studies have dissected complement pathway involvement in their pathogenesis. Nevertheless, the rarity of theses renal diseases and the absence to date of prospective controlled trials are clear limitations to an "evidence-based" approach to these glomerulopathies.

Definitions

Primary IC-MPGN is classically defined by peculiar pathology findings in kidney biopsy [1]: (i) on light microscopy study, a mesangial matrix expansion and "double contour" aspects due to a duplication of the glomerular basement membrane, and (ii) on immunofluorescence study, a coexistence, in equal intensity, of immunoglobulins (mainly IgG), and complement components (mainly C3) deposits. IC-MPGN are subdivided in two types: MPGN type I with mesangial and endomembranous immune deposits and MPGN type III with endo and extramembranous immune deposits.

C3G are characterized by exclusive or predominant (≥ 2+ intensity than any other type of deposit) glomerular C3 deposits [2, 3]. C3G are divided into two subtypes based on electron microscopy study findings: C3G with electron-dense deposits in the glomerular (and tubular) basement membrane, called "dense deposits disease" (DDD) [4], and C3G without such deposits, called C3 glomerulonephritis (C3GN) [5]. The precise composition of dense deposits remains elusive. They probably contain complement activation products (C9) but not predominantly C3 [2].

On light microscopy study, C3G display variable patterns of renal pathological findings: a typical aspect of MPGN in half of the cases [6], a "mesangial" pattern (mild expansion of the mesangial matrix, no "double contour") [5], a crescentic pattern [7, 8], and in some instances a pathological presentation very similar to the one noted in acute post-infectious glomerulonephritis (exsudative endocapillary proliferation) [6].

These definitions have several limitations. First, the pathological MPGN pattern is not specific of primary MPGN. It is also encountered in a wide variety of secondary MPGN [9], ranging from systemic disease-associated MPGN (lupus and cryoglobulinemic nephritis, Sjögren's disease nephropathy) to infection-related glomerulopathy (hepatitis C), but also chronic thrombotic microangiopathy or DGK (Diacylglycerol kinase) epsilon-associated nephropathy [10]. Second, the pathological patterns of IC-MPGN and C3G vary from one patient to another but also over time in a given patient in terms of the relative abundance of C3 and Ig deposits [11], but also and more importantly in terms of mesangial, endocapillary, and/or extracapillary proliferation.

Epidemiology

Primary IC-MPGN and C3G are rare types of nephropathy. In a recent series from the United States [12], MPGN types I and III represented between 2.5% and 4.5% of all glomerular

diseases diagnosed in kidney biopsies. DDD accounted for less than 0.5% of all glomerulopathies. The incidence of these diseases was stable between 1986 and 2015. In another study from the United States [12], less than 0.3% of all patients reaching end-stage renal disease (ESRD) between 1996 and 2013 had MPGN (probably combining IC-MPGN and C3G) as a primary renal diagnosis. C3GN is a more recently (2010) [2, 5] individualized entity and no specific incidence is available.

Pathophysiology

IC-MPGN and C3G are prototypic complement-mediated diseases, with an activation of the complement cascade initiated by distinct mechanisms. On one hand, it is assumed that IC-MPGN results from the deposition in the glomerulus of immune complexes [9] that triggers the activation of the classical complement pathway, starting with activation of C1, C4, and C2 leading to the formation of the classical pathway C3 convertase (C4b2a) which cleaves C3, generates a classical C5 convertase (C4b2a3b), and ultimately leads to the activation of C5 and of the complement terminal pathway. C5b generation leads to the assembly of the membrane attack complex (C5b, 6, 7, 8, 9), which induces cellular injury. IC deposition triggers mesangial cells proliferation, and in some cases tissular injury leads to inflammatory cells influx, release of proteases and reactive oxygen species, capillary wall necrosis, and extracapillary proliferation. "Double contour" aspects have been long been attributed to an expansion of the mesangial matrix that dissociates the two leaflets of the glomerular basement membrane. The pathogenesis of "double contour" may, however, be more complex and is not fully understood.

The assumption that IC deposition is the primary trigger of IC-MPGN is challenged by pathological findings in repeat biopsies in patients with this type of nephropathy. Ig deposits vary widely from one biopsy to another in a given patient and may even disappear following treatment, whereas C3 deposits usually persist [11, 13]. Besides, complement classical pathway activation, exemplified by C4d deposition, has been documented in only few cases of primary IC-MPGN [14]. Finally, patients with IC-MPGN frequently display features of alternative pathway activation (see infra).

On the other hand, C3G is believed to derive from a dysregulation of the alternative C3 convertase in the circulation. C3 convertase (C3bBb) is a key enzyme of the complement alternative pathway (CAP) that cleaves C3, leading to the formation of the C5 convertase and ultimately to the activation of the complement terminal pathway and the generation of the membrane attack complex. The alternative complement pathway is in a state of low-grade continuous activation (rapidly amplified upon infections) and thus requires tight control. This control targets predominantly the C3 convertase with three main inhibitors that prevents the formation of the C3 convertase through the binding and inactivation of the C3b. These inhibitors include complement factor H (CFH), factor I (FI), and membrane-cofactor protein (MCP). The loss of the regulation of this C3 convertase in the circulation leads to an increased release of the C3 degradation products (C3c, Cb, C3d) and their deposition in the kidney. This pathophysiological hypothesis is supported by animal models. Piglets of the Norwegian Yorkshire breed as well as mice deficient in CFH, develop a C3GN reminiscent of the human disease [15, 16]. The CFH−/− mice model has provided valuable insight into the pathogenesis of C3G and its dynamics, particularly regarding the potential clearance of renal complement deposits following the restoration of tight control of the C3 alternative convertase [17].

In patients with C3G dysregulation of the alternative C3 convertase arises rarely (<10% [18]) from inactivating mutations in the genes coding for CFH, FI, or MCP or activating mutations in the genes coding for the two main components of the C3 convertase, C3 and factor B. Nevertheless, C3G and to a lesser extent MPGN patients have a range of autoantibodies that target the alternative complement pathway, particularly the C3 convertase. The most frequent and extensively documented type of autoantibody is the C3 nephritic factor (C3Nef), an IgG that stabilizes and prolongs the half-life of the C3 convertase. More recently, a C5nephrtic factor has been identified that stabilizes the C5 convertase leading to an excessive activation of the C5 and of the complement terminal pathway [19]. Anti-CFH, anti-C3, and anti-factor B antibodies have also been reported in patients with C3G and more rarely IC-MPGN [18, 20, 21].

Clinical Presentation and Outcome

The available data regarding the clinical presentation and outcome of C3G and IC-MPGN derive from retrospective series which included a substantial number of patients in regard of the rarity of the disease. The four largest recent series from France [5], the United States [22], the United Kingdom [23], and Italy [24] included between 80 and 173 patients. Two series included only C3G patients [22, 23] and the remaining two C3G and IC-MPGN cases [5, 24]. What conclusions can be drawn from the published studies?

First, C3G is a severe renal disease. The median age of affected patients ranges from 12–15 (DDD) to 28 years [5, 22, 24] and 38–40% of affected patients have a disease onset in childhood [18, 23]. It is associated with a nephrotic syndrome in 16–41% of cases and progresses to ESRD in 20–41% of cases after a median follow-up of 28 months to 11 years [18, 20, 22, 24]. In addition, the disease recurs in up to 40–60% of the kidney grafts [18], but some recurrences are subclinical and do not affect the survival of the renal graft. The same severity of disease has been reported in patients with IC-MPGN [24]: 43–65% present with a nephrotic syndrome, 44% progress to chronic kidney disease and up to 40% reach ESRD. Forty-two percent of patients have a recurrence of the nephropathy in the renal graft [18].

The available data indicate that DDD, C3GN as well as IC-MPGN share the same severe renal presentation and outcome. DDD pattern was associated with an increased risk of ESRD in two studies [18, 23] but not in the three remaining ones [22, 24]. Thus, the clinical relevance of the current classification of C3G and IC-MPGN remains debated. This is in keeping with the results of a retrospective study performed by Little and colleagues [25]. The authors retrospectively analyzed 70 cases of DDD and IC-MPGN diagnosed between 1972 and 1995, and thus before the individualization of C3GN. After a mean follow-up of 13 years, 59% of patients progressed to ESRD. The median time to ESRF was 8.3 years. In multivariate analysis, the severity of interstitial fibrosis, crescent formation, and mesangial proliferation was independently associated with ESRD. Age and MPGN type did not predict renal survival. Regarding renal transplantation, younger age at initial diagnosis and the presence of crescents on the biopsy of native kidneys were independently associated with recurrence of the disease in the renal graft in multivariate analysis. MPGN type was not associated with recurrence. Thus, intensity of inflammatory (crescents) and fibrotic changes in the kidney biopsy predict better the renal outcome of MPGN and C3G than the usual pathological classification of C3G and IC-MPGN [11].

Second, the clinical course of the disease is variable from one patient to another and most strikingly in a given patient over time. Most C3G patients present with chronic subacute forms of the disease characterized mainly by persistent nephrotic syndrome and mildly altered renal function, with 40–50% of patients progressing gradually toward ERSD. Some patients experience acute deterioration of their nephropathy (worsening proteinuria and/or renal function) that may be triggered by infections [24, 26] and a minority (8% of C3G cases in one series [22]) present with a rapidly progressing form of the disease [27–30].

Renal Pathological Findings

Renal pathological features are obviously different in each subtype of MPGN. They are also variable from one patient to another within the same subgroup of MPGNs and in a given patient from one kidney biopsy to another [11]. The paradox of these nephropathies is that a renal disease classified as MPGN may not disclose on light microscopy study typical features of MPGN. This is particularly true for C3G. In a recent series from the United States [22], 61% of C3GN and only 35% of DDD cases had an MPGN pattern. Seventeen percent of C3GN and 35% of DDD cases had a mesangial proliferative pattern, and 13% and 15% had a diffuse endocapillary proliferative pattern reminiscent of the one found in acute post-infectious glomerulonephritis. Besides, cellular or fibro-cellular crescents were found in 17% of C3GN cases and 10% of DDD cases. This wide spectrum of pathological findings in C3G has also been outlined by previous studies [23].

IC-MPGN cases also disclose variable patterns of pathological findings. One of the most striking findings is the variability of the relative abundance of C3, C1q, and immunoglobulin (IgM, IgG, and IgA) deposits in repeat biopsies in patients with IC-MPGN [11]. In some instances, IgG deposits may even disappear while C3 deposits persist [31], a finding that may question the pathogenic relevance of immunoglobulin deposits in IC-MPGN. In addition, data documenting an activation of the classical complement pathway by IC within the kidney in patients with IC-MPGN remain scarce. In a study [14], C4d (a marker of alternative pathway activation) staining was assessed in 18 biopsy specimens of immune-complex GN (including three primary IC-MPGN), 30 biopsy specimens of C3GN, and 13 biopsy specimens of post-infectious GN. In 15 out of 18 biopsies of IC-MPGN, bright (2–3+) C4d staining was detected, whereas only six (20%) cases of C3GN had only trace/1+ C4d staining. C4d staining was negative in six (46%) of 13 biopsies of acute postinfectious glomerulonephritis.

Laboratory Work-up

Complement Assays

C3G is a prototypic complement-mediated disease. Similarly, it is assumed that renal injury in IC-MPGN is mediated by complement activation triggered by immune complex deposition [9]. However, features of systemic activation of complement cascade are invariably found in patients with MPGN. For instance, a low C3 plasma level

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

is noted in only 36–74% of patients with C3GN [18, 22–24] and in 15–84% of DDD patients [18, 22–24]. In IC-MPGN patients, C3 levels are low in 46–76% of cases [18, 24]. This is probably related to the fact that assays of circulating components of CAP do not necessarily reflect activation of complement within the renal tissue. Thus, normal complement component levels do not exclude the diagnosis of C3G and IC-MPGN. Interestingly, a low C4 plasm level (a marker of classical pathway activation) is present in a minority of patients with IC-MPGN (2% [18]) and the majority (70% [24]) of these patients have normal C4 and low C3, and thus features of alternative pathway activation rather than classical pathway activation. This is in sharp contrast to secondary forms of IC-MPGN (lupus and cryoglobulinemia-associated nephritis) that are characterized by decreased C4 serum levels.

Another activation product of the complement pathway, soluble C5b-9 (a marker of the terminal complement pathway), has been assessed in patients with MPGN, especially since the availability of the C5 blocker, eculizumab. In a large series of 127 cases of C3G [19], soluble C5b-9 levels were elevated in 60% of patients. However, the clinical relevance of this marker, particularly in the prediction of a clinical response to C5 blockade, remains uncertain (see infra).

The incidence of complement gene novel or rare variants is relatively low in patients with MPGN [18, 20, 22, 24], 16% in IC-MPGN, 16–33% in DDD, and 12–25% in C3GN, especially if compared to the incidence of such variants in another complement-mediated renal disease, hemolytic uremic syndrome (40–70%) [32]. The most frequently reported variants in MPGN patients are in the CFH gene (19–17%). Some of these variants lead to a total absence or a decrease in CFH plasma level while others are believed to affect the regulatory function of the protein (cluster of variants in the SCR1-3 mediating the interaction of CFH with C3b) [18, 20, 24]. Variants in the FI (0–6%), C3 (0–8%), factor B (0–2%), and MCP (0–2%) and thrombomodulin (0–1%) coding gens have been more rarely reported in IC-MPGN and C3G patients [18, 20, 22, 24]. The pathogenicity and thus clinical relevance have not been documented for the majority of these detected variants A peculiar type of C3G, highly prevalent in the Chypriote population, has been linked to internal duplication of the gene coding for complement factor H-related protein 5 (CFHR-5) leading to a decreased binding of the mutant protein to C3b [33].

In contrast, autoantibodies that interfere with the regulation of the CAP are frequently detected in C3G and IC-MPGN patients. The most documented type of autoantibodies is the C3Nef, which stabilizes the alternative C3 convertase and thus amplifies the activation of the CAP. It is present in 78–86% of DDD patients, 38–45% C3GN, and 40–53% of IC-MPGN [18, 24]. The more recently characterized C5 nephritic factor (C5Nef) [19], an autoantibody that stabilizes the C5 convertase, is present in 49% of C3G patients. C5Nef is more frequently associated with C3GN than DDD (88% vs. 33% [19]) and its presence correlates with the level of soluble C5b-9. Other types of autoantibodies have been reported in MPGN (mostly C3G) patients: anti-CFH antibodies (7–12% of patients [19, 20]), anti-C3 antibodies (2–3% [19, 34]), and anti-Factor B antibodies (2–3% [19, 34]).

Thus, MPGN appears to be related to an acquired rather than constitutional dysregulation of the complement system (mostly the CAP). However, autoantibodies detected in these patients interfere with the CAP regulation *in vitro* but their clinical relevance is still debated. In addition, the presence of autoantibodies that target the CAP in patients with IC-MPGN suggests that these nephropathies are driven not only by an activation of the classical complement pathway (triggered by immune complexes) but also by a dysregulation of the CAP.

Monoclonal Gammopathy

Several studies have outlined an association between monoclonal gammopathy and C3GN [35–37]. In the largest series of 201 patients with C3G, 29% had monoclonal gammopathy (excluding cryoglobulinemia). As expected, the prevalence of monoclonal gammopathy in patients with C3G increases with age: 36%, 59%, and 94% for the age ranges of 50–59, 60–69, and 70–79 years, respectively [37]. Even though this study may carry a recruitment bias, the association between C3GN and monoclonal gammopathy is increasingly recognized. However, there is to date no definite proof that monoclonal gammopathy per se interferes with complement dysregulation and hence is involved in the pathogenesis of the disease. Patients with monoclonal-associated C3GN have features of CAP activation (low C3 plasma level in 44% of patients) but also carry polyclonal autoantibodies interfering with the CAP regulation: C3Nef in 7% of cases (vs. 45% in all C3GN), anti-FH antibodies in 17% of cases (vs. 11%), and even anticomplement factor I and anticomplement receptor 1 antibodies [38]. In the majority of tested cases (77%) [38], these autoantibodies do not share heavy and light chain characteristics with the monoclonal gammopathy. Thus direct proof of a link between monoclonal gammopathy and C3GN is still lacking. The induction of the remission of C3GN with chemotherapy is only indirect evidence with potential bias [37].

Toward a Global Approach for C3G and IC-MPGN

A global approach that takes into account several clinical and biological parameters is probably the most appropriate for C3G and IC-MPGN. Such approach has been recently developed by Iatropoulos and colleagues [24] using the Italian registry of C3G and IC-MPGN. Their study aimed to classify patients based on 24 variables: clinical (gender, age, triggering event at onset, familiarity for nephropathy), biological (hematuria, proteinuria, renal impairment), pathological (degree of renal inflammation and fibrosis, type and intensity of immune deposits), and those related to complement work-up (markers of complement activation, presence of complement gene variants). They identified four clusters of patients each including patients with similar presentation and renal outcome. Patients with C3G and IC-MPGN were distributed across the four subtypes. One cluster had a worse renal outcome as compared to the other clusters (renal survival at 10-year follow-up of 55% versus 85–90%). This cluster was characterized by (i) a low frequency of decreased C3 level, increased C5b-9 levels, complement genes variants, and inflammatory changes in the kidney and (ii) marked renal fibrotic changes. However, this difference in terms of renal survival may be related mainly to the intensity of fibrosis in the kidney and the absence of renal inflammatory changes that could be amended by treatment with steroids and immunosuppressors. Nevertheless, such an elegant global approach may be the key for the design of targeted individualized treatment of C3G and IC-MPGN.

Treatment of C3G and IC-MPGN

There is to date no specific treatment for C3G and IC-MPGN as no available commercialized drug targets the initial and main driver of the disease, C3 and IC deposits. The currently used drugs aim mostly to control the renal inflammation (crescents, mesangial/endocapillary proliferation) that may arise in some patients. In addition, the clinical boundaries between C3G and IC-MPGN are unclear and thus it is unclear whether treatments of these two types of MPGN should differ. Finally, there is to date no large prospective controlled trials assessing treatments options in C3G and IC-MPGN. One can only rely on open-label small prospective studies or retrospective series (Table 30.1).

The most assessed treatment in MPGN patients (mostly C3G) is mycophenolate mofetil (MMF) [39, 40], with two published series. The first, from Spain, was retrospective and multicentric. It included 60 patients with C3G with a median age of 27 years. Median serum creatinine (SCr) was 1.4 mg/dl, median estimated glomerular filtration rate (eGFR) was 66 ml/min/1.73 m^2, median proteinuria was 3.8 g/24 h, and 52% of patients had a nephrotic syndrome at baseline. The patients were divided into three groups:

a) 22 patients received MMF and steroids. The median initial dose of MMF was 1 g/day and the median treatment duration was 18 months.
b) 18 patients received immunosuppressors other than MMF: steroids alone ($n = 11$), steroids, and cyclophosphamide ($n = 7$).
c) 20 patients received no immunosuppressors.

All patients were treated with conventional antihypertensive and antiproteinuric drugs. The median follow-up was 47 months. Partial or complete clinical remission was achieved in 86% of patients treated with MMF and steroids, 50% of patients were treated with the other immunosuppressors and 25% of patients with no specific treatment ($P = 0.018$). A doubling of SCr occurred in 0%, 39%, and 35% of patients in the three groups, respectively ($P = 0.002$). The percentages of patients reaching ESRD (16-month follow-up) were 0%, 16%, and 35% in the three groups respectively ($P = 0.08$). Finally, six (27%) patients treated with MMF + Cs showed a proteinuria relapse after MMF dose tapering. This study, the first to suggest the efficacy of MMF and steroids in the treatment of C3G, carries several limitations. It was retrospective and included a limited number of patients. Pathological assessment of the kidney biopsies performed in included patients took into account the extent of fibrotic changes but not the inflammatory changes that are a major predictor of response to treatment and outcome. Furthermore, patients with significant renal fibrosis and limited inflammatory changes and thus a less active disease were probably more likely to not receive immunosuppressors. For instance only 20% of patients who received no immunosuppressor had a nephrotic syndrome at baseline as compared to 77% and 55% of patients treated with MMF or another immunosuppressor. Finally, the analysis of the individual cases of the 22 C3G patients treated with mycophenolate and steroids suggests that some of these patients had rapidly progressing glomerulonephritis, a subtype of MPGN highly likely to respond to an anti-inflammatory treatment.

The second study from the United States [40] was also retrospective but was based on a single registry. It included 30 patients with C3G and treated with MMF among 120 C3G patients diagnosed between 1997 and 2015. The median age of MMF-treated patients was 25 years, median SCr was 1 mg/dl, and median proteinuria/creatininuria ratio was 3.2 g/g. The median dose of mycophenolate was 2 g/day and the median time on therapy was 24 months.

Table 30.1 Main series and prospective trials that assessed treatment options in patients with C3G and IC-MPGN.

References	Type of study	Drug assessed	Number of patients	Main results	Limitations	Level of evidence
MMF in C3G						
Rabasco et al [39]	Retrospective, national, multicentric.	Cs + MMF Other IS (Cs ± CYP)	Total: $n = 60$ Cs + MMM ($n = 22$) Other IS ($n = 18$) No IS ($n = 20$)	Partial or complete clinical remission[a] achieved in 86% of MMF + Cs patients, 50% of patients with other IS, and 25% of patients with no IS ($P = 0.018$). A doubling of SCr occurred in 0%, 39%, and 35% of patients in the three groups, respectively (0.002). The percentages of patients reaching ESRD (16 months follow-up) were 0%, 16%, and 35% in the three groups, respectively ($P = 0.08$). Six (27%) patients treated with MMF + Cs showed a proteinuria relapse after MMF dose tapering.	Retrospective and multicentric. Limited number of included patients. Patients with significant renal fibrosis and limited inflammatory changes were probably more likely to not receive IS. Some patients treated with Cs + MMF had RPGN, a subtype of MPGN highly likely to respond to an anti-inflammatory treatment.	Low
Avarese et al [40]	Retrospective, single register.	Cs + MMF Cs + various IS	Total: $n = 73$ Cs + MMF ($n = 30$) Cs alone ($n = 23$) Cs + CNI ($n = 7$) Cs + RTX ($n = 7$) Cs + CYP ($n = 6$)	67% of patients treated with MMF + Cs were classified as responders[b] to treatment as compared to 39%, 33%, 29%, and 29% of those treated with Cs alone, Cs + CYP, CNI, and RTX. Patients who responded to MMF + Cs tended to have lower initial proteinuria and higher soluble membrane attack complex levels as compared to nonresponders (not statistically significant). Fifty percent of patients who responded to eculizumab had a proteinuria relapse after treatment tapering/discontinuation.	Retrospective study. Limited number of patients in each treatment group. Patients with significant renal fibrosis and limited inflammatory changes were probably more likely to not receive IS. Comparison between responders and nonresponders to MMF (and between MMF and other IS) did not take into account the presence or absence of inflammatory changes in the kidney.	Low
MMF in IC-MPGN						
Jones et al [41]	Retrospective	Cs + MMF	Cs + MMF ($n = 5$) Compared to seven untreated patients (six with IC-MPGN and one with DDD)	In the MMF + Cs group, proteinuria decreased from 5 g/day at baseline to 1.9 g/24 h ($P = 0.003$) at 6 months, 1.96 g/24 h ($P = 0.003$) at 12 months, and 2.59 g/24 h ($P = 0.015$) at 18 months. No change in proteinuria over 18 months in occurred in the control group (MMF + Cs vs. controls, $P = 0.03$). In the MMF + Cs group, serum albumin concentration increased from 29 g/l at baseline to 36.6 g/l at 6 months, 38.2g/l at 12 months, and 37 g/l after 18 months.	Retrospective with very limited number of patients. Relatively low dose of MMF (mean dose of 1 g/day) and high dose of Cs (60 mg/day initially).	Absent

Table 30.1 (Continued)

References	Type of study	Drug assessed	Number of patients	Main results	Limitations	Level of evidence
Eculizumab in C3G						
Le Quintrec et al [27]	Retrospective, multicentric	Eculizumab	26 patients (13 children/ adolescents) with C3G	23% of patients had a global clinical response, 23% a partial clinical response, and 54% no response[c]. Compared with those who had a partial clinical or no response, patients who had a global clinical response had lower estimated glomerular filtration rates, a more rapidly progressive course, and more extracapillary proliferation in kidney biopsy.	Retrospective design without a control group, relatively small number of cases. Inclusion of pediatric and adult cases.	Low
Bomback et al [42]	Prospective, open-label, noncontrolled, and monocentric	Eculizumab.	Six patients: three with DDD (one with a recurrence in the renal graft), three with C3GN (including two with a recurrence in the renal allograft).	After 12 months of treatment, two patients had a decrease in serum creatinine, one patient had a significant reduction in proteinuria. Three patients had no clinical response, including one with an improvement in inflammatory changes in the kidney. Changes in soluble C5b–9 serum levels paralleled the improvement in serum creatinine and proteinuria.	Noncontrolled. Very limited number of patients.	Low

C3GN, C3 glomerulonephritis; CNI, calcineurin inhibitor; Cs, corticosteroids; CYP, cyclophosphamide; DDD, dense deposits disease; IS, immunosuppressors; MMF, mycophenolate mofetil; RPGN, rapidly progressing glomerulonephritis; RTX, rituximab; SCr, serum creatinine.

[a] Complete remission was defined by eGFR of 460 ml/min/1.73 m^2 (or a return to ±15% of baseline values in those with eGFR < 60 ml/min/1.73 m^2) and proteinuria <0.5 g/24 h. Partial remission was defined by a proteinuria reduction of >50% (and a proteinuria value of o3.5 g/day in patients with nephrotic range proteinuria at baseline), plus stabilization (±25%) or improvement in renal function.

[b] Complete remission of the disease was defined by a stable or improved eGFR with decline in proteinuria/creatininuria ratio to <0.5 g/g creatinine. Partial remission was defined by stable or improved eGFR with >50% decline in proteinuria/creatinuria ratio to between 0.5 and 3.5 g/g Cr by urine protein-to-Cr ratio at last follow-up. Stable eGFR was defined as within 15% of baseline. Patients were categorized as "responders" if they had either complete or partial remission concordant with MMF treatment.

[c] Response to eculizumab was characterized as: (1) global clinical response, defined as (a) >50% decrease in serum creatinine concentration and urinary protein-creatinine ratio (UPCR) and serum albumin concentration >3 g/dl or (b) the persistence of normal serum creatinine concentration (±10%) and albumin concentration >3 g/dl and normalization of UPCR (<150 mg/g), or (2) partial clinical response, defined as (a) <50% decrease in serum creatinine concentration, albumin concentration > 3 g/dl, and >50% decrease in UPCR or (b) the persistence of normal serum creatinine concentration (±10%), albumin concentration >3 g/dl, and >50% decrease in UPCR.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Mycophenolate mofetil was associated with steroids in 93% of cases. Twenty patients (67%) had a response to MMF and achieved partial or complete response to treatment. The median time to response was 10 months. Four out of eight patients who discontinued MMF had a proteinuria relapse. The remission rate with MMF in combination with steroids (67%) was higher than the one achieved with steroids alone (39%), steroids in combination with cyclophosphamide (33%), calcineurin inhibitor (29%), and rituximab (29%).

Mycophenolate mofetil has been assessed in a single small retrospective series of IC-MPGN patients [41]. Five patients with IC-MPGN were treated with MMF (mean dose 1.1 g/day) and high-dose steroids. At baseline, their median SCr was 1.1 mg/dl (mean creatinine clearance of 108 ml/min) and their mean proteinuria was 6 g/day. Their evolution was compared to that of seven untreated patients, six with IC-MPGN and one with DDD. In the mycophenolate and steroids group, proteinuria decreased from 5 g/day at baseline to 1.9 g/24 h ($P = 0.003$) at 6 months, 1.96 g/24 h ($P = 0.003$) at 12 months, and 2.59 g/24 h ($P = 0.015$) at 18 months. No change in proteinuria over 18 months in occurred in the control group (MMF + steroids vs. controls, $P = 0.03$). In the MMF + steroids group, serum albumin concentration increased from 29 g/l at baseline to 36.6 g/l at 6 months, 38.2 g/l at 12 months, and 37 g/l after 18 months.

In all, the level of evidence of the usefulness of mycophenate mofetil in C3G is low and absent in IC-MPGN. Nevertheless, mycophenolate associated to a variable dose of steroids is increasingly used in patients with chronic/subacute nephrotic patients with C3G and by analogy in patients with IC-MPGN.

The availability of the first complement inhibitor, the C5 blocker, eculizumab, has initially raised a lot of interest in this drug as a potential treatment for MPGN. Eculizumab has been assessed in two series of C3G patients, with very discrepant results. The largest one from France was retrospective [27], noncontrolled, and included 26 patients, of whom 13 were children or adolescents. At the initiation of eculizumab therapy, 42% patients had chronic kidney disease, 73% had nephrotic syndrome, 27% had rapidly progressive disease, and 12% required dialysis. Median time from diagnosis to eculizumab treatment initiation was 16 months. The eculizumab regimen was similar to the one used in atypical hemolytic uremic syndrome (HUS) [32]: 900 mg intravenously per week for 4 weeks and then 1200 mg intravenously on week 5 and every other week afterward. At eculizumab treatment initiation, median SCr concentration was 0.6 mg/dl in children/adolescents and 2.3 mg/dl in adults, corresponding to a median eGFRs of 110 and 28 ml/min/1.73 m^2, respectively. Twenty-three percent of patients had a global clinical response, 23% had a partial clinical response; and 54% had no response. Compared with those who had a partial clinical or no response, patients who had a global clinical response had lower eGFRs, a more rapidly progressive course, and more extracapillary proliferation on kidney biopsy. Age, extent of renal fibrosis, frequency of nephrotic syndrome, low serum C3 and C3Nef, and elevated soluble C5b-9 concentrations or complement gene variants did not differ between responders and nonresponders.

The second smaller series from the United States [42] included six patients: three patients with DDD (one patient had a recurrence of the disease in the renal allograft) and three patients with C3GN (two patients had a recurrence of the disease in the renal allograft). The eculizumab regimen was similar to the one used in atypical HUS. After 12 months of treatment, two patients had a decrease in SCr and one patient had a significant reduction in proteinuria. Three patients had no clinical response, including one with an improvement in inflammatory changes in the kidney. Changes in soluble C5b-9 serum levels paralleled the improvement in SCr and proteinuria. No series or trials have to date assessed the use of eculizumab in IC-MPGN but one case report has suggested some efficacy of the drug [43].

No definitive conclusions can be drawn from this series regarding the use of eculizumab in C3G and IC-MPGN. Nevertheless, eculizumab does not appear to be the specific long-awaited treatment for MPGN. The lack of a significant impact of eculiuzmab on the course of MPGN may be due at least in part to the fact that these nephropathies have two aspects. All patients with MPGN display immune deposits (C3 with or without immunoglobulins) and a variable minority of patients have additional features of glomerular inflammation (mesangial and endocapillary proliferation, crescents) that probably depend on the release of C5a and/or C5b. Eculizumab most probably treats only one aspect of the disease (inflammatory changes) with no or very limited impact on C3 and immunoglobulins deposits. Eculizumab may be a potent inflammatory drug in patients with inflammatory forms of C3G, as suggested by the retrospective French series [27] where only patients with crescentic and rapidly progressing forms of C3G had a significant and cost-effective response to eculizumab.

Conclusion

Experimental and clinical studies have transformed the perspective in the management of C3G and IC-MPGN. It remains unknown, however, whether the distinction between these two types of nephropathies within the group of MPGN is clinically relevant. There is to date no specific

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. treatment of C3G and IC-MPGN, which directly targets the initial driver of the disease, C3, and possibly immunoglobulins deposition. Nevertheless, several complement modulators that inhibit the activation of the alternative C3 convertase are currently being developed [44] and specific treatment for C3G and IC-MPGN may be within our reach.

Cardiovascular Disease and CKD

Tomoko Usui, Masaomi Nangaku, and Tetsuhiro Tanaka

Division of Nephrology and Endocrinology, The University of Tokyo Hospital, Bunkyo-ku, Tokyo, Japan

Introduction

Chronic kidney disease (CKD) is an important risk factor for cardiovascular morbidity and mortality. Cardiovascular disease (CVD) is the name for a group of disorders of the heart and blood vessels, including hypertension, coronary heart disease, cerebrovascular disease, peripheral vascular disease, and heart failure. Reduced kidney function and raised albuminuria are both independent risk factors for CVD [1, 2]. By 2013, cardiovascular death attributable to reduced glomerular filtration rate (GFR) outnumbered end-stage renal disease (ESRD) death in both developed and developing countries [3].

The increased risk of CVD in CKD patients is partly attributed to high prevalence of comorbidities, such as hypertension, diabetes mellitus, dyslipidemia, and obesity. There is not high-quality evidence for the selection of treatment of CKD patients to prevent CVD. Many randomized controlled trials (RCTs) have investigated treatment of disease associated with CVD, but CKD patients are often excluded from these RCTs. It is not clear whether the results of clinical studies in patients with non-CKD may be extrapolated to CKD patients. The increased risk of CVD in CKD patients is not fully explained by the traditional risk factors. The nontraditional risk factors derived from CKD itself may also be important. Systematic reviews and meta-analysis of post hoc analysis of the CKD subgroup and observational studies are performed to produce evidence for CKD patients.

This chapter examines the evidence for the epidemiology, pathophysiology, diagnosis, prognosis, and management of CVD in people with CKD (Table 31.1). We excluded kidney transplant or dialysis patients that will be covered in other places (Parts 6, 7, and 9).

Definition

CVD is a name for the group of disorders of the heart and blood vessels. This includes hypertension, coronary heart disease, cerebrovascular disease, peripheral vascular disease, and heart failure. CVD may progress over years and CKD patients may develop cardiomyopathy, valve dysfunction, and arrhythmia (e.g. atrial fibrillation) or sudden cardiac death.

Epidemiology

In a cohort of 3033 patients with CKD stages 3–4 (mean age 66.8 years, 65% men), the prevalence of CVD was examined [19]. CVD was divided into atherosclerotic (coronary artery disease [CAD], peripheral artery disease, and stroke) and nonatherosclerotic (heart failure, arrhythmia, and valvular heart disease). In age groups <65, 65–74, 75–84, and ≥85 years the prevalence of atherosclerotic CVD was 18.7%, 35.5%, 42.9%, and 37.8%, respectively, and that of nonatherosclerotic CVD, 14.9%, 28.4%, 38.1%, and 56.4%, respectively. The prevalence of both atherosclerotic and nonatherosclerotic CVD increased with older age.

The prevalence of heart failure in CKD patients is high and it was similar among studies. In the European Heart Failure Pilot Survey, comorbidities of a total of 3226 outpatients with chronic heart failure were examined; the highest comorbidity was CKD (41%) [20]. In the Swedish Heart Failure Registry and the Asian Sudden Cardiac Death in Heart Failure registry, prevalence of CKD in patients with heart failure was 43.9% and 45.4%, respectively [21, 22].

In the Atherosclerosis Risk in Communities (ARIC) study, 10 328 subjects were followed for median of 10.1 years

Table 31.1 Treatment for cardiovascular disease (CVD) with chronic kidney disease (CKD).

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Blood pressure lowering	We suggest blood pressure lowering to prevent cardiovascular events for patients with CKD. There was little evidence to support the preferential choice of particular drug classes for the prevention of cardiovascular events in CKD. The specific target blood pressure is not confirmed for patients with CKD.	High (cardiovascular events)	Moderate [4–6]
Statin therapy	We suggest statins to decrease cardiovascular mortality and events in early stages of CKD.	High (cardiovascular mortality in CKD stages 3–5) Moderate (major cardiovascular events in CKD stages 3–5)	Weak [7–9]
Antiplatelet agents	We suggest antiplatelet agents can be used to lower risk of myocardial infarction. Patients with CKD (any stage) may reasonably choose not to receive antiplatelet agents based on the very low certainty that treatment makes any difference to mortality and stroke, and there is increased risk of major or minor bleeding.	Low	Weak [10]
Glycemic control	We suggest sodium glucose co-transporter-2 (SGLT2) inhibitors may be used in patients with diabetes and CKD to lower kidney failure and cardiovascular events risk. Patients with diabetes and CKD may reasonably choose not to receive SGLT2 inhibitors based on the very low certainty that the treatment makes any difference on mortality and may increase genital infections and creatinine.	Moderate (kidney failure and cardiovascular events)	Moderate [11, 12]
Anticoagulants	We suggest warfarin to prevent mortality, ischemic stroke, or thromboembolism in patients with atrial fibrillation and CKD. We suggest direct oral anticoagulants to prevent stroke and systemic embolic events without increasing risk of major bleeding events among atrial fibrillation patients with CKD compared to warfarin.	Low (warfarin) Moderate (direct oral anticoagulants, stroke, and systemic embolic events) Low (direct oral anticoagulants, major bleeding events)	Moderate [13, 14]
Coronary revascularization	We suggest percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG) for coronary artery disease with CKD. We suggest drug-eluting stents compared to bare-metal stents for PCI. PCI is associated with lower early (30 days) mortality, but the need for repeat revascularization was significantly higher compared to CABG.	Low	Moderate [15, 16]
Dietary restrictions	We suggest that reduced dietary salt may be used to reduce blood pressure. Long-term effect of reduced dietary salt on cardiovascular events is not confirmed.	Very low	Weak [17, 18]

and incident atrial fibrillation cases was identified [23]. Incidence of atrial fibrillation by estimated glomerular filtration rate (eGFR) ≥90, 60–89, 30–59, and 15–29 ml/min/1.73 m^2 was 6.4, 5.6, 9.5, and 36.2 per 1000 person-years, respectively, and by urinary albumin to creatinine ratio <30, 30–299, and ≥300 mg/g was 5.8, 14.6, and 26.3 per 1000 person-years, respectively. The reduced kidney function and higher albuminuria were associated with higher incident atrial fibrillation.

Pathophysiology

CVD is the primary cause of morbidity and premature mortality in CKD. There may be several reasons for the increased risk of CVD in CKD patients [24]. CKD patients have increased prevalence of traditional and nontraditional risk factors for CVD. CKD itself is an independent risk factor for CVD. CVD and many risk factors for CVD are also risk factors for CKD. CKD and CVD interact to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

contribute to the progression of both diseases, resulting in the cardiovascular and kidney disease progression cycle.

Systemic vascular remodeling may cause CVD. The risk of stroke and myocardial infarction increased with elevating blood pressure in a large cohort with or without CKD [25]. The subjects with CKD had increased risk of CVD with higher blood pressure compared to subjects without CKD. The association of blood pressure and CVD may be increased in CKD patients.

The long-term pressure and volume overload in CKD causes concentric left ventricular hypertrophy and left ventricular dilation [26]. Cardiomyopathy progression will cause diastolic and systolic dysfunction. In a cohort of patients with CKD stages 3–4, 30% had left ventricular hypertrophy [27]. The left ventricular mass increase was confirmed in 36% of a CKD cohort with creatinine clearance between 25 and 75 ml/min/1.73 m^2 [28]. After 1 year, left ventricular mass increased in 25% of the subjects. The independent risk factors for left ventricular growth were decrease in hemoglobin level and increase in systolic blood pressure. Anemia may also cause left ventricular hypertrophy.

In a cross-sectional study of 118 hemodialysis patients, systolic blood pressure, pulse pressure, extra-coronary atherosclerosis, and vascular calcification correlated with left ventricular mass [29]. In a cohort of patients with CKD stage 5D, the prevalence of left ventricular hypertrophy was 16.4% [30]. The left ventricular hypertrophy was associated with higher mortality during the follow-up period of 2 years. During the 10-year follow-up of 123 patients undergoing hemodialysis, 16 died of sudden cardiac death [31]. The worsening of left ventricular mass index (LVMI) was highly associated with the sudden cardiac death.

Dyslipidemia of CKD patients is characterized by dysregulated high-density lipoprotein cholesterol (HDL-C) and triglyceride-rich lipoprotein metabolism [32]. Plasma triglyceride concentration is frequently elevated in patients with CKD. These abnormalities in CKD patients may cause dysregulation of lipid metabolism, which contributes to atherogenic change and increases the risk of CVD.

Abdominal obesity is known to be associated with increased risk of CVD. In a prospective cohort of 537 subjects with ESRD, waist circumference was associated with all-cause and cardiovascular mortality [33]. Adipose tissue secretes a number of adipokines and cytokines and works as an important organ [34]. The complex role of adipose tissue as not only an energy storage organ but its interaction with the systemic vascular system is not fully known.

Atherosclerotic and arteriosclerosis change may be the cause of CVD in CKD patients. Many studies report the existence of subclinical atherosclerosis in CKD patients. Even among asymptomatic subjects aged 23–43 years, subjects with albuminuria had significantly higher intima-media thickness than those without albuminuria [35]. Aortic stiffness measured by aortic, brachial artery, and femoral pulse wave velocity was independently associated with cardiovascular mortality in ESRD patients [36].

In 117 autopsy subjects with CAD, the association between coronary artery calcification (CAC) and CKD was evaluated [37]. CAC was present in the intimal plaque of both nonkidney and kidney patients. Age, smoking, diabetes, calcium phosphorus product, inflammation, and kidney function were associated with intimal calcification. In a study of 1541 CKD patients, the association between CAC and cardiovascular events during an average follow-up of 5.9 years was examined [38]. CAC was independently and significantly related to risk of CVD, myocardial infarction, and heart failure in CKD patients.

Endothelial dysfunction has been proposed to be an early phase of the atherosclerotic process [39]. It is characterized by a shift in the actions of the endothelium toward reduced vasodilation, a proinflammatory state, and prothrombotic properties. Reduced nitric oxide generation, oxidative excess, and reduced production of hyperpolarizing factor are the mechanisms in endothelial dysfunction. Upregulated adhesion molecules, generation of chemokines, and production of plasminogen activator inhibitor-1 participate in the inflammatory response. Vasoactive peptides, an endogenous nitric oxide inhibitor, and dyslipidemia may also interact to contribute to these mechanisms.

In addition to traditional risk factors, many nontraditional risk factors that are directly and indirectly associated with CKD contribute to CVD pathophysiology. In a meta-analysis of 21 cohort studies, the association between routinely collected risk factors and CVD was examined [40]. Left ventricular hypertrophy, serum albumin, phosphate, urate, and hemoglobin were associated with the increased risk of CVD.

Low-grade inflammation is recognized as a common pathway of CKD and CVD [41]. Increased inflammation markers, such as high-sensitivity C-reactive protein (hs-CRP), white blood cell count, and fibrinogen, were associated with peripheral artery disease in CKD patients [42]. After a median follow-up of 6.3 years, the same inflammation markers were associated with increased risk of incident peripheral artery disease [43]. Higher levels of hs-CRP and interleukin-6 (IL6) were also associated with higher risk of sudden cardiac death in a cohort undergoing hemodialysis or peritoneal dialysis [44].

Cardiac and kidney diseases interact in both acute and chronic settings [45]. The bi-directional links between cardiac and kidney function are perceived as cardio-renal syndrome. The interaction includes activation of the renin-angiotensin aldosterone system (RAAS), activation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of the sympathetic nervous system, uremic toxins, malnutrition, bone and mineral disorder, and oxidative stress [46–52]. Acute kidney injury (AKI) was associated with increased risk of heart failure, acute myocardial infarction, and stroke [53]. Anemia was associated with increased risk of stroke and coronary heart disease [54, 55]. The mechanism by which cardio-renal syndrome advances CVD has not been fully elucidated.

Serum potassium level may also be an important risk factor for CVD in CKD patients. A cohort of nondialysis CKD patients was followed for a median of 2.8 years [56]. Mortality, major adverse cardiovascular events, and hospitalization were significantly higher among those with both low and high serum potassium levels. A predialysis serum potassium of 4.6–5.3 mEq/l was associated with the greatest survival in a cohort of 81 013 maintenance hemodialysis patients followed for 3 years [57]. In a retrospective study of 228 hemodialysis patient deaths, 80 patients met the criteria of sudden death [58]. Patients with sudden death had high prevalence of congestive heart failure (CHF) and CAD (CHF or CAD were present in 71%), and 25% had a serum potassium level less than 4.0 mEq/l. In CKD patients with CAD, hyperkalemia (serum $K > 5.0$ mEq/l) occurred more frequently than hypokalemia (serum $K < 3.5$ mEq/l) (16.7% vs. 3%), and hyperkalemia was associated with risk of sudden cardiac death [59]. Potassium works as a critical factor to maintain cardiovascular health [60]. CKD patients may have serum potassium abnormalities, which includes both hypokalemia and hyperkalemia. The factors associated with abnormal potassium levels are declined kidney function, endogenous, and exogenous catecholamine activity, activation of RAAS and anti-RAAS inhibitor agent and RAAS blocker agents, and potassium wasting diuretics.

Diagnostic Tests

CVD is highly prevalent in CKD patients. Early detection of CVD in CKD patients may lead to modification of risk factors and pharmacological intervention. However, diagnosis of CVD in CKD patients may be difficult. The accuracy of diagnostic tests is often reduced. The symptoms of CVD may be difficult to distinguish from volume overload or uremia in CKD patients. There are several systematic reviews for the diagnosis of CVD in CKD patients [61–65]. The diagnostic tests to evaluate CVD in CKD patients are outlined in Table 31.2.

Biochemical Abnormalities

Clinical practice guidelines and review of diagnosis of CVD in CKD recommend biomarkers including lipid profile, hs-CRP, B-type natriuretic peptides (BNP), and troponins.

Lipid Profile

It is recommended that CKD patients be evaluated with a lipid profile (total cholesterol, low-density lipoprotein cholesterol [LDL-C], high-density lipoprotein cholesterol [HDL-C], triglycerides, nonhigh-density lipoprotein cholesterol [non-HDL-C]) [66, 67]. The lipid profile should be measured in the fasting state. Fasting mainly affects triglycerides level and does not affect HDL-C level. The appropriate frequency of the measurement of lipid profile is not known. Some guidelines recommend lipid-lowering therapy with treatment target of LDL-C < 70 mg/dl or non-HDL-C < 100 mg/dl. However, the Kidney Disease: Improving Global Outcomes (KDIGO) Guideline for Lipid Management does not recommend the treat-to-target strategy due to the lack of its benefit in any clinical trial [66].

Inflammation

Inflammation markers such as hs-CRP, IL-6, tumor necrosis factor (TNF), and white blood cell counts are found to be associated with increased risk of CVD events and mortality. However, there are no thresholds or criteria to diagnose the increased risk of CVD for those markers.

The frequency of sudden cardiac death and its association with inflammation and other risk factors were examined among 1041 incident dialysis patients from the CHOICE (Choices for Healthy Outcomes In Caring for ESRD) cohort over a median 2.5 years of follow-up [68]. Of all subjects, 22% of all mortality in this cohort was due to sudden cardiac death. The highest tertiles of hs-CRP and of IL-6 were each associated with twice the risk of sudden cardiac death compared to their lowest tertiles when adjusted for demographics, comorbidities, and laboratory factors. Among 543 patients with stage 5 CKD, IL-6, white blood cell counts, and TNF independently predicted all-cause mortality during the follow-up of 28 months [69].

B-Type Natriuretic Peptides

Brain natriuretic peptide (BNP) and N-terminal pro-B-type natriuretic peptide (NT-proBNP) are used for diagnosis and prognosis of heart failure. NT-proBNP has a longer half-life than BNP and it may be less sensitive to acute change. The plasma BNP and NT-proBNP levels are higher in CKD patients [70–72]. The BNP level is influenced by kidney function, anemia, obesity, and heart failure.

Table 31.2 Summary of diagnostic tests in cardiovascular disease (CVD) with chronic kidney disease (CKD).

Test	What does it measure?	Comments
Biochemical		
Lipid profile	• Includes total cholesterol, low-density lipoprotein (LDL) cholesterol, high-density lipoprotein (HDL) cholesterol, non-HDL-cholesterol, triglycerides	• The current guideline recommend to measure lipid profile at first presentation with CKD • No further measurement is required unless the results would change management
High-sensitivity C-reactive protein	• Measures circulating high-sensitivity C-reactive protein (hs-CRP) • Reflects increased inflammation status, which is associated with increased risk of CVD events and mortality	• No thresholds of change is specified in CKD patients
B-type natriuretic peptides	• Measures circulating B-type natriuretic peptides (BNP) or N-terminal-pro-BNP (NT-pro-BNP) concentration • Commonly used with patients with symptoms of heart failure • Association with abnormal echocardiographic findings	• CKD patients have elevated BNP and NT-pro-BNP levels • No thresholds of change is specified in CKD patients
Troponins	• Measures circulating cardiac troponin T (cTnT) or cardiac troponin I (cTnI) • Association with cardiac injury such as myocardial infarction	• Patients with kidney dysfunction have elevated troponins levels • No thresholds of change is specified in CKD patients
Electrocardiogram		
12-lead electrocardiogram	• Measures baseline rhythm, presence of Q waves, chamber enlargement, left ventricular hypertrophy	• Exercise stress electrocardiogram may be performed
24 h Holter monitor	• Records all beats over 24-h period • Identifies ST segment shifts or asymptomatic arrhythmias	
Imaging		
Resting echocardiography	• Evaluates diastolic and systolic function and valve disease	• Noninvasive
Exercise stress echocardiography	• Evaluates exercise-related functional status • Identifies fixed and reversible ischemia	• No radiation • Appropriate for low risk CVD and severe CKD stages
Exercise stress nuclear scintigraphy or Pharmacologic stress imaging	• Evaluates exercise-related functional status • Identifies fixed and reversible ischemia	• Radiation or drug usage • Requires specific scanner, not available in many clinical settings
Left ventricular hypertrophy or left ventricular dysfunction	• Measures left ventricular mass index (LVMI) or left ventricular function by echocardiography • Association with CVD mortality	• Noninvasive • Patients with advanced CKD stages have increased LVMI • Uncertain diagnostic utility in CKD
Carotid intima-media thickness	• Measures the thickness of the intima-media of the artery on an ultrasound image • Association with cardiovascular events	• Noninvasive • Uncertain diagnostic utility in CKD

Table 31.2 (Continued)

Test	What does it measure?	Comments
Cardiac computed tomographic angiography	• Generates calcium score, which can evaluate degree of lumen stenosis if calcification is not severe	• Appropriate for the evaluation of chest pain with uninterpretable stress test • Not appropriate for established coronary artery disease or ESRD
Coronary artery calcification	• Measures coronary artery calcification (CAC) by computed tomography • Association with the risk of CVD	• Radiation • CKD patients have higher CAC scores • Uncertain diagnostic utility in CKD • Not recommended in routine clinical care
Coronary angiography	• Detects blockages in the coronary arteries	• Uses contrast dye containing iodinine, which may cause contrast-associated AKI • Radiation
Single-photon emission computed tomography (SPECT) or positron emission tomography (PET)	• Measures myocardial function, left ventricular volume, and ejection fraction	• Noninvasive • Requires specific scanner, not available in many clinical settings
Cardiac magnetic resonance or cardiac MRI	• Measures left ventricular mass, volume, and ejection fraction	• Noninvasive

Troponin

Troponins (troponin I and troponin T) are used as a marker of myocardium damage [73]. Myocardial infarction is diagnosed a rise and/or fall from the norm of cardiac biomarkers, preferably cardiac troponin (cTn). The diagnosis of myocardial infarction in CKD patients may be difficult because patients with kidney dysfunction can have an increased troponin level, so the diagnosis of myocardial infarction may be difficult [74]. The cTn cutoff levels in patients with kidney dysfunction were significantly higher compared to those in patients with normal kidney function. The optimal cutoff levels to separate AMI from other conditions underlying acute chest pain in the emergency department in patients with kidney dysfunction were close to the elevated baseline levels above the 99th percentile for the 3 s-cTn assays (1.0 times the 99th percentile for Abbott–Architect s-cTnI, 1.2 times the 99th percentile for Siemens Ultra s-cTnI, and 0.9 times the 99th percentile for Beckman–Coulter Accu s-cTnI) and substantially higher for most hs-cTn assays (2.1 times the 99th percentile for Roche hs-cTnT, 1.1 times the 99th percentile for Abbott–Architect hs-cTnI, 3.6 times the 99th percentile for Siemens hs-cTnI, and 2.8 times the 99th percentile for Beckman–Coulter hs-cTnI) [75]. The higher cTnT and cTnI levels in patients with CKD stage 5D show a two to fivefold increase in mortality [76].

Electrocardiogram

The electrocardiogram (ECG) evaluates baseline rhythm, presence of Q-waves, chamber enlargements, and left ventricular hypertrophy. The findings of ECG in CKD patients in acute myocardial infarction may be different from those without CKD [77]. In a study of 1876 elderly myocardial infarction patients, the patients with CKD had lower peak creatinine kinase-MB fraction (CK-MB) level and ST-elevated myocardial infarction was less common compared to those without CKD [78].

Imaging

Echocardiography

Echocardiography is useful for the diagnosis of clinical and subclinical cardiac dysfunction, for the prediction of cardiovascular risk, and in the orientation and follow-up of treatment strategies in CKD patients [79, 80]. Echocardiogram may be repeated for a patient periodically and with changes in symptoms, new clinical event, or a treatment likely to affect cardiac function. Among 567 subjects with CKD and without history of CVD, LVMI evaluated by echocardiogram was an independent risk factor for incident heart failure during median follow-up period of 6.6 years [81]. The delay in or absence of renal replacement therapy results in dyspnea due to fluid overload even if the patient's heart is structurally normal. The new functional classification system of heart failure in patients with CKD stage 5 are proposed to exclude patients with volume overload and a normal heart [82]. The classification is based on patient-reported symptoms and standardized echocardiographic evidence of structural and functional heart abnormalities. When this system was applied to 654 patients who

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. began chronic hemodialysis, 87% of patients had one or more of echocardiographic criteria of heart failure [83]. During a median of 2.4 years, both left and right ventricular systolic dysfunction were independent risk factors for mortality.

Coronary Angiography

Coronary angiography uses contrast dye and X-ray to diagnose CAD. CKD patients need special consideration due to potential contrast-associated AKI [84]. The efficacy of prophylactic intravenous hydration for prevention of contrast-associated AKI differs among studies [85, 86]. The type of contrast media may have different effect on kidney function. The use of iso-molar and low-osmolar contrast media in patients with CKD stage 3–5 showed nonsignificant difference in incidence of contrast-associated AKI in a meta-analysis of randomized trials [87].

Computed Tomography

CAC can be measured by computed tomography. CAC was independently associated with the risk of CVD and mortality in CKD patients [40]. However, the clinical utility of CAC is unknown due to lack of enough data in CKD patients. In a cohort study of 3218 CKD subjects followed for 12.5 years, elevated BNP, NT-proBNP, and cTnT and left ventricular hypertrophy were associated with cardiovascular events or death [88]. CAC did not improve risk prediction when added to traditional risk factors in this study.

Myocardial Perfusion Imaging

Myocardial perfusion imaging is nuclear imaging of the function of myocardium. Single-photon emission computed tomography (SPECT) or positron emission tomography (PET) can be performed [80]. In a prospective cohort study with 299 CKD patients who underwent SPECT, the scores calculated as the difference between stress and rest images were associated with high major cardiovascular or kidney events [89].

Cardiac Magnetic Resonance

Cardiac magnetic resonance or cardiac magnetic resonance imaging (MRI) is noninvasive imaging that does not use contrast administration or radiation. In 72 patients with CKD stage 5D, ECG and SPECT had low sensitivity in detecting myocardial infarction [90]. Cardiac MRI with myocardial delayed enhancement identified unrecognized myocardial infarction.

Prognosis

CKD patients are known to have high risk of cardiovascular morbidity and mortality. Several studies examined the activities of daily living, kidney disease progression, or mortality after cardiovascular events in CKD patients.

A total 3352 CKD patients with CAD diagnosed with angiography were followed for 2 years [91]. At baseline, 31.3% of patients with eGFR ≥90 ml/min/1.73 m^2 had one-vessel, 34.3% had two-vessel, and 33.9% had three-vessel CAD. In patients with eGFR <30 ml/min/1.73 m^2 or on dialysis, the proportion of patients with one-vessel CAD was 16.8% and 54.5% had three-vessel CAD. The significant risk factors for 2-year all-cause mortality were lower eGFR, current smoking, left ventricular ejection fraction, diabetes mellitus, age, and peripheral artery disease. Peripheral artery disease diagnosed with ankle-brachial index <0.9 was also an independent predictor of major adverse cardiovascular events in 3131 CKD patients hospitalized for CVD [92].

Management

As CKD patients are at high risk of cardiovascular morbidity and mortality, the management of both traditional and nontraditional risk factors is of importance [93, 94]. In randomized trials of treatment of traditional risk factors, CKD patients are often excluded. The robust evidence for the management of CKD patients is limited (Tables 31.3–31.8). The control of blood pressure may have some benefits in CKD patients, but the target blood pressure for the prevention of CVD is not confirmed. Lipid-lowering therapy reduced cardiovascular mortality in CKD patients without dialysis or kidney transplant. The risk reduction of CVD by antiplatelet therapy was not confirmed. Some classes of blood glucose agents may reduce cardiovascular events, but there is a lack adequate high-quality studies. Lifestyle modification may be recommended based on observational studies, but few studies have confirmed the effect on CVD in CKD patients. Anticoagulants therapy for patients with atrial fibrillation reduced the risk of thromboembolism and stroke. Coronary revascularization for patients with CAD was evaluated and the short-term and long-term outcome may differ according to the treatment.

Patients with CKD and acute CAD or stroke are less likely to receive evidence-based medicine [95–98]. The reason for this attitude toward CKD patients may be due to atypical symptoms and difficulty in the diagnosis of CVD in CKD patients, or concerns of AKI after diagnostic method or treatment. Meta-analysis of 10 observational and randomized clinical studies examined the association between early invasive approach and all-cause mortality in CKD patients [99]. Early invasive approach was associated with lower risk of mortality.

Table 31.3 Summary of findings: blood pressure control.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1 000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Angiotensin converting enzyme inhibitors versus placebo					
Major cardiovascular events	10 044 (13)	–	HR 0.81 (0.73–0.89)	High	Angiotensin converting enzyme inhibitors may reduce major cardiovascular events
Calcium channel blockers versus placebo					
Major cardiovascular events	1 855 (6)	–	HR 0.74 (0.53–1.03)	Moderate	Calcium antagonists therapy may reduce major cardiovascular events
More intensive blood pressure lowering versus less intensive blood pressure lowering					
Mortality	15 924 (3)	–	OR 0.86 (0.75–0.97)	High	Intensive blood pressure lowering may reduce mortality
Cardiovascular mortality	2 646 (4)	–	HR 0.57 (0.31–1.02)	Moderate	It is uncertain whether intensive blood pressure lowering may reduce cardiovascular death
Composite cardiovascular outcome	2 646 (4)	–	HR 0.81 (0.63–1.05)	Moderate	It is uncertain whether intensive blood pressure lowering may reduce cardiovascular events
Acute kidney failure	2 646 (4)	–	HR 1.46 (1.10–1.95)	Moderate	Intensive blood pressure lowering may increase acute kidney failure
Hyperkalemia	2 646 (4)	–	HR 1.36 (1.01–1.82)	Moderate	Intensive blood pressure lowering may increase hyperkalemia

CI, confidence interval; HR, hazard ratio; OR, odds ratio.
More intensive blood pressure lowering: active blood pressure treatment or intensive blood pressure control.
Less intensive blood pressure lowering: placebo or no treatment or less intensive blood pressure control.

Table 31.4 Summary of findings: statin therapy.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1 000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Chronic kidney disease stages 3–5					
All-cause mortality	28 276 (13)	5 fewer (2–8 fewer)	0.79 (0.69–0.91)	High	Statin therapy leads to slightly lower mortality
Cardiovascular mortality	19 059 (10)	3 fewer (2–5 fewer)	0.77 (0.69–0.87)	Moderate	Statin therapy leads to slightly lower cardiovascular mortality
Major cardiovascular events	36 033 (16)	6 fewer (4–7 fewer)	0.72 (0.66–0.79)	High	Statin therapy probably leads to slightly lower major cardiovascular events
Myocardial infarction	9 018 (11)	–	0.55 (0.42–0.72)	Moderate	Statin therapy may slightly reduce myocardial infarction
Stroke	8 658 (8)	–	0.62 (0.35–1.12)	Low	It is uncertain whether statin therapy prevents stroke
Elevated creatinine kinase	4 514 (10)	–	0.84 (0.20–3.48)	Low	It is uncertain whether statin therapy leads to elevated creatinine kinase
Liver function abnormalities	7 991 (10)	–	0.76 (0.39–1.50)	Low	It is uncertain whether statin therapy leads to liver function abnormalities

Table 31.5 Summary of findings: antiplatelet therapy.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1 000 patients treated for one year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Antiplatelet agents versus placebo or no treatment					
All-cause mortality	16 152 (30)	–	0.95 (0.83–1.07)	Low	It is uncertain whether antiplatelet agents decrease mortality
Cardiovascular mortality	9 337 (19)	–	0.87 (0.65–1.15)	Low	It is uncertain whether antiplatelet agents make any difference to cardiovascular mortality
Myocardial infarction	14 451 (2)	–	0.87 (0.76–0.99)	Low	Antiplatelet agents may prevent myocardial infarction
Stroke	9 544 (14)	–	1.00 (0.58–1.72)	Low	It is uncertain whether antiplatelet agents decrease stroke
Major bleeding	1 592 (27)	–	1.35 (1.10–1.65)	Low	Antiplatelet agents may lead to major bleeding
Minor bleeding	13 106 (3)	–	1.54 (1.26–1.90)	Low	Antiplatelet agents may lead to minor bleeding

Table 31.6 Summary of findings: glucose-lowering therapy.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1 000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Sodium glucose co-transporter-2 inhibitors versus placebo					
Cardiovascular mortality	4 401 (4)	–	HR 0.70 (0.59–0.82)	Moderate	Sodium glucose co-transporter-2 inhibitors may prevent death
Heart failure	2 519 (6)	–	0.59 (0.41–0.87)	Moderate	Sodium glucose co-transporter-2 inhibitors may reduce heart failure
Hospitalization for heart failure	4 401 (4)		HR 0.61 (0.47–0.80)	Moderate	
Hyperkalemia	2 788 (7)	–	0.58 (0.42–0.81)	Moderate	Sodium glucose co-transporter-2 inhibitors may reduce hyperkalemia
	4397 (4)	–	0.80 (0.65–1.00)	Moderate	
Genital infections	3 086 (10)	–	2.50 (1.52–4.11)	Moderate	Sodium glucose co-transporter-2 inhibitors may increase genital infections
Elevated serum creatinine	848 (7)	–	MD 3.82 μmo/l (1.45–6.19)	Moderate	Sodium glucose co-transporter-2 inhibitors may increase serum creatinine
Acute kidney injury	4 397 (4)		HR 0.85 (0.64 to 1.13)	Moderate	It is uncertain whether sodium glucose co-transporter-2 may increase acute kidney injury
Diabetic ketoacidosis	4 397 (4)		HR 10.80 (1.39–83.65)	Low	It is uncertain whether sodium glucose co-transporter-2 may increase acute kidney injury since the number of diabetic ketoacidosis were low (11 versus 1)
Dipeptidyl peptidase-4 inhibitors versus placebo					
Cardiovascular mortality	5 897 (5)		0.93 (0.77–1.11)	Moderate	Dipeptidyl peptidase-4 inhibitors may have little or no effect on cardiovascular death
Heart failure	–	–	–	Low	It is uncertain whether dipeptidyl peptidase-4 inhibitors prevent heart failure
Metformin verses treatment without metformin					
Chronic kidney disease stages 1–3					
All-cause mortality	33 442 (8)	48 fewer (81–6 fewer)	HR 0.77 (0.61–0.97)	Low	Metformin may prevent death

CI, confidence interval; HR, hazard ratio; MD, mean difference.

Table 31.7 Summary of findings: anticoagulant therapy.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1 000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Warfarin versus no warfarin					
Chronic kidney disease stages 1–4					
Mortality	34 852 (7)	–	HR 0.65 (0.59–0.72)	Low	Warfarin may reduce risk of mortality
Ischemic stroke or thromboembolism	34 226 (8)	–	HR 0.70 (0.54–0.89)	Low	Warfarin may reduce ischemic stroke or thromboembolism
Major bleeding	33 920 (7)	–	HR 1.15 (0.88–1.49)	Low	It is uncertain whether warfarin increases risk of major bleeding
Direct oral anticoagulant versus warfarin					
Stroke and systemic embolism events	12 545 (8)	–	0.81 (0.65–1.00)	Moderate	Direct oral anticoagulant probably reduces the incidence of stroke and systemic embolism events compared to warfarin
Major bleeding events	12 521 (8)	–	0.79 (0.59–1.04)	Moderate	Direct oral anticoagulant slightly reduces the incidence of major bleeding compared to warfarin

CI, confidence interval; HR, hazard ratio.

Table 31.8 Summary of findings: coronary revascularization.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1 000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Drug-eluting stents versus bare-metal stents					
All-cause mortality	91 046 (30)	–	0.77 (1.71–1.84)	Low	Drug-eluting stents probably lead to lower mortality than bare-metal stents
Cardiovascular mortality	5 045 (17)	–	0.51 (0.38 to 0.70)	Low	Drug-eluting stents may prevent cardiovascular mortality more than bare-metal stents
Myocardial infarction	64 389 (24)	–	0.90 (0.86–0.95)	Low	Drug-eluting stents may prevent myocardial infarction more than bare-metal stents
Target-vessel revascularization	10 029 (19)	–	0.61 (0.47–0.80)	Low	Drug-eluting stents may prevent target-vessel revascularization more than bare-metal stents
Stent thrombosis	6 714 (2)	–	0.75 (0.55–1.01)	Low	Drug-eluting stents probably lead to lower stent thrombosis than bare-metal stents
Percutaneous coronary intervention with drug-eluting stents versus coronary artery bypass grafting					
Short-term all-cause mortality	25 444 (9)	–	OR 0.33 (0.29–0.38)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to lower short-term mortality than coronary artery bypass grafting
Long-term all-cause mortality	28 521 (14)	–	OR 1.22 (1.15–1.29)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to higher long-term mortality than coronary artery bypass grafting
Heart-related mortality	19 104 (9)	–	OR 1.29 (1.20–1.38)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to higher heart-related mortality than coronary artery bypass grafting
Myocardial infarction	10 579 (12)	–	OR 1.89 (1.11–3.21)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to higher myocardial infarction than coronary artery bypass grafting
Repeat revascularization	28 530 (14)	–	OR 3.47 (2.57–4.69)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to higher repeat revascularization than coronary artery bypass grafting
Cerebrovascular accident	9 319 (9)	–	OR 0.64 (0.51–0.80)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to lower cerebrovascular accident than coronary artery bypass grafting.
Major adverse heart-related and cerebrovascular events	3 420 (8)	–	OR 2.00 (1.39–2.89)	Low	Percutaneous coronary intervention with drug-eluting stents may lead to higher major adverse heart-related and cerebrovascular events than coronary artery bypass grafting

CI, confidence interval; OR, odds ratio.

Blood Pressure Control

CKD patients have high prevalence of hypertension. Blood pressure lowering may be an important strategy to prevent CVD in CKD patients. Blood pressure lowering reduced the risk of major cardiovascular events in a meta-analysis of 26 randomized trials, which included 30 295 CKD subjects [4]. The effect in reducing CVD was similar among subjects with or without CKD. There was no significant difference in the effect on cardiovascular events between angiotensin converting enzyme inhibitors, calcium channel blockers, or diuretics or β blocker based treatment. Compared to less intensive blood pressure lowering, intensive blood pressure lowering was associated with lower mortality in patients with CKD stages 3–5 in the meta-analysis of 18 randomized clinical trials [5]. However, there was not enough data to define the target blood pressure for the prevention of CVD in CKD patients. In the subgroup analysis of 2646 CKD patients in the Systolic Blood Pressure Intervention Trial (SPRINT), the target blood pressure <120 mmHg (intensive group) was compared to <140 mmHg (standard group) for the median follow-up of 3.3 years [6]. The intensive group had a lower rate of all-cause mortality and higher AKI as an adverse clinical event. In the analysis of 9361 patients in SPRINT, the risk factors for AKI were older age, non-Caucasian, lower baseline eGFR, and presence of CVD at baseline [100]. Intensive blood pressure lowering may be suggested to prevent mortality, but careful monitoring of kidney function is necessary in CKD patients, especially among patients with older age or previous CVD.

Statins

Meta-analysis of 50 studies, which includes 45 285 nondialysis CKD patients, comparing the effects of statins on mortality, cardiovascular events, and adverse events, was performed [7]. Compared to placebo, statin therapy reduced all-cause mortality, cardiovascular mortality, major cardiovascular events, and myocardial infarction, but the effect on stroke or risk of related adverse events was uncertain in nondialysis CKD. The statin therapy had little or no effect on mortality or cardiovascular events in CKD patients on dialysis [8]. The effect of statin therapy on mortality or CVD was uncertain in kidney transplant recipients [9].

Antiplatelet Therapy

The effect of antiplatelet therapy in risk reduction of CVD in CKD patients is not confirmed. In the meta-analysis of 30 trials, antiplatelet therapy reduced myocardial infarction but the effect on mortality and increased bleeding was uncertain compared to placebo or no treatment [10]. The platelet dysfunction in CKD patients may be responsible for reduced effect of antiplatelet therapy [101].

Glucose Control

It is not clear whether intensive glucose control is effective in reducing CVD in CKD patients with diabetes [102]. In a meta-analysis of 44 studies, which included 13 036 patients, the effect of glucose lowering therapy in CKD patients with diabetes mellitus was examined [11]. Sodium-glucose co-transporter-2 (SGLT2) inhibitors reduced heart failure but increased genital infection and serum creatinine. SGLT2 probably had little or no effect on cardiovascular mortality. Dipeptidyl peptidase-4 (DPP4) inhibitors had little or no effect on cardiovascular mortality. There was not enough data to examine the effect for other classes of glucose lowering therapy. In the double-blind, randomized Canagliflozin and Renal Events in Diabetes and Established Nephropathy Clinical Evaluation (CREDENCE) trial, oral SGLT2 inhibitor canagliflozin or placebo were assigned to 4401 patients with type 2 diabetes and albuminuric kidney disease [12]. After a median follow-up of 2.6 years, the relative risk of composite kidney outcome was lower by 34%. The risk of cardiovascular death, myocardial infarction, or stroke and hospitalization for heart failure was also lower. Trials of these newer glucose lowering medications (SGLT2, DPP4, and glucagon-like peptide-1 receptor agonist) on cardiovascular outcomes in patients with diabetes and CKD are underway [102].

Metformin reduced all-cause mortality in CKD patients with diabetes in the meta-analysis of 33 442 patients in seven studies [103]. Metformin is not recommended in patients with low kidney function (eGFR <30 ml/min/1.73 m^2) because of the risk of metformin-associated lactic acidosis. A systematic review was performed to examine the risk of metformin-associated lactic acidosis, which suggested that an increased risk of lactic acidosis in metformin-treated patients with CKD may be limited [104]. Metformin may be used in patients with mild to moderate CKD (eGFR 30–60 ml/min/1.73 m^2), but dose adjustment and careful follow-up of kidney function are recommended (when the kidney function declined to eGFR <45 ml/min/1.73 m^2).

Anticoagulant

In patients with CKD and atrial fibrillation, anticoagulant therapy may be suggested to prevent thromboembolism and stroke. The risk of major and minor bleeding must be considered. In a meta-analysis of 11 cohort studies, warfarin therapy reduced the risk of ischemic or thromboembolism and mortality [13]. There was no significant effect on

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk of major bleeding in CKD without ESRD, but there was increased risk of major bleeding in CKD with ESRD.

Direct oral anticoagulants (DOAC) have been developed and are used as an alternative therapy to warfarin. In a meta-analysis of five studies which included 12 545 CKD patients with atrial fibrillation, the effect of DOAC was examined [14]. DOAC therapy reduced incident stroke and systemic embolism and may slightly reduce major bleeding events compared to warfarin therapy. The use of DOAC in CKD stage 5D with atrial fibrillation was not determined due to the lack of high-quality data [105].

Coronary Revascularization

CKD patients with CAD may need myocardial revascularization. In percutaneous coronary intervention (PCI), a bare metal stent (BMS) or drug-eluting stent (DES) is used. Most clinical trials of PCI exclude CKD patients. Using 31 observational or randomized clinical studies with 91 817 patients, the outcome with BMS or DES was evaluated in CKD patients [15]. DES implantation was associated with lower all-cause mortality, cardiovascular mortality, myocardial infarction, and target-vessel revascularization.

Coronary artery bypass grafting (CABG) is another strategy for coronary revascularization. The benefits of PCI or CABG treatment differs, and the outcome may differ in CKD patients compared to non-CKD patients with CAD. In a meta-analysis of 11 studies with 29 246 patients with CKD and multivessel disease, the outcome of PCI with DES and CABG was examined [16]. Compared to CABG, PCI with DES had higher long-term all-cause mortality, cardiac mortality, myocardial infarction, repeat revascularization, and major adverse cardiovascular events, but PCI with DES had lower short-term all-cause mortality and cerebrovascular events.

Lifestyle Modification

Lifestyle modifications are suggested in CKD patients to prevent CVD, but the evidence is mostly from derived observational study or small clinical trials [94]. The recommendations include smoking cessation, exercise, and weight loss, but the effect on CVD prevention in CKD patients is not confirmed.

Physical exercise in CKD patients was associated with improved physical fitness, walking capacity, and cardiovascular dimensions, which include resting systolic and diastolic blood pressures and heart rates [106]. The effect of weight loss intervention was examined in a small number of CKD patients in short duration studies [107]. In a meta-analysis of 13 studies, nonsurgical weight loss reduced proteinuria and blood pressure. The long-term effect on CVD in CKD patients is unknown.

Reduced dietary salt was associated with small reduction in systolic and diastolic blood pressure in normotensive subjects, and greater reduction of systolic blood pressure and no change in diastolic blood pressure in hypertensive subjects [108]. In CKD patients, salt restriction reduced systolic and diastolic blood pressure [17]. The long-term effect of salt restriction on CVD in CKD patients is unknown. The effect of low protein diet in CKD patients without diabetes was examined in the meta-analysis of 10 studies [18]. Low protein diet probably has little or no effect on mortality compared to normal protein diet.

Conclusion

CVD is the major cause of morbidity and mortality in CKD patients. Increased risk of CVD in CKD patients is due to traditional and nontraditional risk factors, some of which are specific to CKD.

Many RCTs excluded CKD patients and therefore the evidence to support the clinical practice of CKD is based on insufficient and low-quality evidence. Due to the difficulty in diagnosis of CVD in CKD patients, CKD patients are less likely to receive evidence-based medicine, and the prognosis tends to be poor compared to non-CKD patients. The adjusted criteria for the diagnosis and treatment of CVD in CKD patients based on the best available recommendations may improve outcomes.

Introduction

Nephrologists are familiar with treating dialysis patients with access infections or peritonitis. Nephrologists are also familiar with the multitude of infectious complications seen in immunosuppressed patients, such as those with vasculitis and those who have received a kidney transplant. However, the vast majority of people with chronic kidney disease (CKD) are seen by general physicians and other specialist doctors, and nephrologists will often be asked on ways to prevent infections and address complications in this broader group of patients, many of whom do not have a specified diagnosis as an underlying cause of CKD.

In this chapter, we discussed the relevant evidence to support management of infectious complications associated with CKD. The focus is on patients with CKD (not on kidney replacement therapy), but frequently evidence to support treatment decisions has been extrapolated from those on dialysis therapy to those on CKD.

This chapter covers what is known about the risk of infection, reasons for the higher infection risk, the risk of infection-associated complications, and how to prevent and treat infections among patients with CKD (Table 32.1). Much of the data on infections as a complication of CKD derives from high-income countries. Due to limited information on whether CKD predisposes to infections that are predominant in low-income settings such as malaria or human immunodeficiency virus (HIV), these conditions are not discussed. Additional infection-related topics are covered in other chapters: infections as a complication of hemodialysis (Chapter 43), peritoneal dialysis (Chapter 48), and transplantation (Chapter 59), and infections which may cause CKD (Chapter 20 and 26).

CKD and Risk of Developing Infections

A 2014 systematic review of CKD and infection risk found 14 studies comparing incidence of infection among people with CKD to the incidence among people without known history of CKD [2]. Figure 32.1 displays the associations of CKD with infection risk. Studies that systematically excluded patients receiving dialysis are grouped separately from studies in which patients receiving dialysis were, or may have been, included together with patients with CKD. Seven studies were set among the general population, and the remainder in higher risk populations (e.g. patients seen in kidney clinics, with diabetes, or of older age). Although a range of infections were investigated, most required hospital admission or blood culture. Unsurprisingly in view of the range of infection outcomes investigated and the diversity of how kidney disease was defined, there was great heterogeneity ($I^2 = 96.5\%$) and no meta-analysis was performed. Nevertheless, all point estimates and most confidence intervals (CIs) suggest a strong and graded association of infection risk with CKD and its severity.

Table 32.1 Chronic kidney disease and infection risk: KDIGO recommendations [1].

Intervention	Recommendation	Certainty of evidence	Strength of recommendation[a]
Antibiotic prescribing	Dosing must take the patient's impaired kidney function into consideration by adjusting the dosing interval (if the drug effect depends on concentration, e.g. aminoglycosides) or dose level (for drugs which require constant levels such as beta-lactams) or considering a nonrenally cleared alternative Consider drug interactions and follow local guidelines to minimize antimicrobial resistance	*Moderate to high* Evidence of drug levels mainly from pharmacokinetic and pharmacodynamics studies with strong observational post-marketing evidence of drug side effects for older drugs Literature on preventing antimicrobial resistance is focused on overall prescribing irrespective of CKD status (unless there is a concern about toxicity or efficacy)	Strong (1A)
Annual vaccination against influenza	KDIGO recommend that all adults with CKD are offered annual vaccination with inactivated influenza vaccine, unless contraindicated [1]	*Low* Extrapolation from observational data analysis. To date there is no/limited evidence of vaccine efficacy for CKD stages specifically. However, given that the vaccine is known to be efficacious in older population overall, amongst whom a sizable proportion have some degree of CKD, there appears overall benefit, especially considering the high rate of infection-related hospitalization for those with CKD. Live-attenuated influenza vaccination has not been tested in patients with CKD.	Strong (1B)
Vaccination with polyvalent pneumococcal vaccine	KDIGO recommend that all adults with eGFR < 30 ml/min/1.73 m^2(GFR categories G4–G5) and those at high risk of pneumococcal infection (e.g. nephrotic syndrome, diabetes, or those receiving immunosuppression) receive vaccination with polyvalent pneumococcal vaccine unless contraindicated [1]	*Low* There are limited observational data on vaccination efficacy by CKD stages. However, given that the vaccine is known to be efficacious in older population overall, amongst whom a sizable proportion have some degree of CKD, there appears overall benefit, especially considering the high rate of infection-related hospitalization for those with CKD.	Strong (1B)
Repeat vaccination with polyvalent pneumococcal vaccine within 5 years	KDIGO recommend that all adults with CKD who have received pneumococcal vaccination are offered revaccination within 5 years [1]	*Low* There are limited data to support a particular revaccination scheme, but in advanced CKD antibody response is less marked and titres decline faster than for people with normal kidney function	Strong (1B)
Immunization against hepatitis B	KDIGO recommend that all adults who are at high risk of progression of CKD and have GFR > 30 ml/min/1.73 m^2 (GFR categories G4–G5) be immunized against hepatitis B and the response confirmed by appropriate serological testing [1]	*Moderate* Those with higher eGFR have shown better seroconversion in response to hepatitis B vaccine	Strong (1B)
Use of live vaccines	Consideration of live vaccine should include an appreciation of the patient's immune status and should be in line with recommendations from official or governmental bodies [1]	*Very low* Due to the fact that people with CKD are often immunocompromised to some degree, as evidenced from observational data analysis, there may be a risk of vaccine-related disease	Not graded
Vaccination in children	Pediatric immunization schedules should be followed according to official international and regional recommendations for children with CKD [1]	*Very low* As pediatric kidney disease is rare, there are no or very limited data on this topic	Not graded

[a] Level of strength of recommendation as per the KDIGO recommendations: Level 1, We recommend; Level 2, We suggest. Letter grading refers to quality of evidence: A, High; B, Moderate.

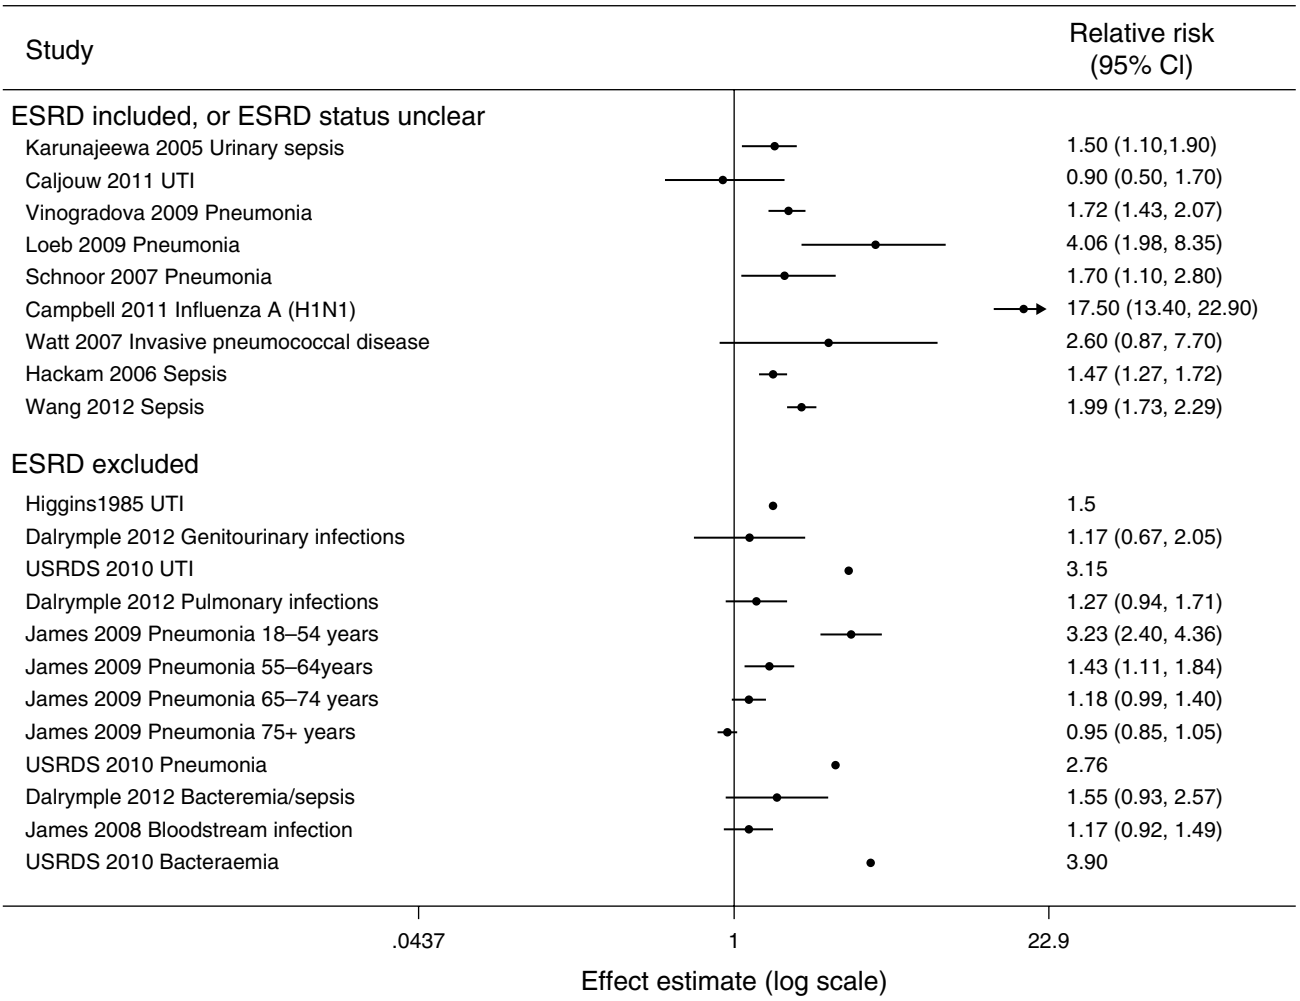

Figure 32.1 Forest plot of all estimates of the association of chronic kidney disease with infection risk (n = 17) from all 14 studies identified. The estimates from Higgins 1985 and USRDS 2010 did not include SEs. Dalrymple 2012: presented estimates compare eGFR 45–59 with eGFR ≥90 ml/min/1.73m^2; James 2009: presented estimates compare eGFR 45–59 with eGFR 60–104 ml/min/1.73m^2; James 2008: presented estimates compare eGFR 45–59 with eGFR≥60 ml/min/1.73m^2. eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; USRDS, US Renal Data System; UTI, urinary tract infection. *Source:* From McDonald et al. [2].

Since this systematic review, there have been a further five studies investigating the association of CKD (defined using estimated glomerular filtration rate [eGFR]) with a range of infections, from the United States [3], Sweden [4], and the UK [5–7]. The results were all consistent with the previous evidence of a graded association between CKD and increased risk of infection.

Most of the available studies of infection in people with CKD have looked at severe infection or hospitalization with infection, such as those of James and colleagues from 2008 to 2009 [8, 9]. These studies used laboratory-confirmed CKD and investigated severe community-acquired infection (sepsis and hospitalization with pneumonia), taking into account underlying comorbidities. Notably, while underlying comorbidity did explain some of the underlying risk, adjustment for the comorbidity did not explain this association fully.

As people with CKD are often multimorbid and frail, it is perhaps unsurprising that people with CKD are more likely to experience severe infections such as sepsis or pneumonia requiring hospitalization. These associations could be due to increased severity of infection rather than increased risk. However, some studies have investigated the association of CKD with community-acquired infection, including infection diagnosed and treated in the community. This approach more fully quantifies the burden of community-acquired infection, an important and common problem, but also isolates the impact of CKD on increased infection risk, distinct from the impact on infection severity.

Studies of infections in primary care have identified associations between lower eGFR and increased risk of a range of infections, including pneumonia, urinary tract infections (UTI), sepsis, skin/soft tissue infections, and gastrointestinal tract infections [4, 5, 10, 11]. Table 32.2 summarizes two studies of community-acquired infection. The Swedish study [4] was set among a cohort of all patients from Stockholm Region with a creatinine laboratory result available. It studied a range of community-acquired infections and showed that there was a graded increase in the risk of community-acquired infections as eGFR declined. Lower respiratory tract infections, UTIs, and sepsis became more common as a percentage of total recorded infections as eGFR declined. An association with skin/soft tissue infections and gastrointestinal tract infections was also observed. No association was found with nervous system and upper respiratory tract infections. The UK study [5] used a similar design among older people with diabetes, who have complete kidney function data due to incentivized testing for kidney function among these patients in the UK. Both the Swedish and the UK study adjusted for underlying comorbidities, which again did not fully explain the associations noted.

In addition to a graded association between eGFR and risk of community-acquired lower respiratory tract infections (LRTI) and sepsis, proteinuria was also independently associated with increased risk of both these community-acquired infections – this is in line with what was seen for severe infections requiring hospitalizations in the atherosclerosis risk in communities (ARIC) study [3].

The observed association between CKD and UTI may need to be interpreted with caution. Recurrent UTIs are very common and frequently require hospitalization among people with CKD. There is a risk that those who have had previous infections may have more frequent assessment for kidney function and repeat UTI. There may also be a particular group of patients in whom the recurrent UTIs have caused CKD, which in turn predisposes them to more infections. Both these issues introduce a problem of reverse causality into the data. While it is evident that UTIs are common among people with CKD, it is not clear whether or to what extent CKD causes UTIs.

In summary, infections are common among people with CKD and the risk of infection increases as kidney function declines. Infections pose a substantive burden to secondary care as people with CKD are likely to require hospitalization owing to the severity of infection, especially with sepsis and severe LRTI. Neither the associations with hospitalization and severe infections, nor those with infections diagnosed and treated in the community, were fully explained by adjustment for comorbidities. Hence, there seems to be a biological association by which the presence of CKD increases the susceptibility to infection risk as well as severity. How this arises will be discussed in the next section.

CKD and Susceptibility to Infection

As discussed above, patients with CKD are at greater risk of infection, even well before any exposure to kidney replacement therapy and its attendant complications [12–16]. This may be due to multiple underlying risk factors, or due to treatment for the kidney disease, or a phenomenon related to reduced immunity as kidney function declines irrespective of the cause of kidney disease. We discuss each of these in turn.

One risk factor that may be underlying the risk of observed infection is having had a previous infection. For

Table 32.2 Studies investigating the associations between CKD and risk of community-acquired infections using electronic health records (since 2014).

Studies of community-acquired infections					Crude IR	RR for eGFR categories in ml/min/1.73m^2 (95% CI)				
Author	Year	Country	Population studied	Outcome	Per 1000 person-years	eGFR 60+	eGFR 45–59	eGFR 30–44	eGFR 15–30	eGFR <15
Xu [4]	2017	Sweden	General population	all infections	95	1	1.08 (1.01–1.14)		1.53 (1.39–1.69)	
McDonald [5]	2015	UK	Diabetes	LRTI	155.8	1	1.03 (1.01–1.04)	1.08 (1.05–1.10)	1.17 (1.13–1.22)	1.47 (1.34–1.62)
				Pneumonia	10.3	1	0.95 (0.89–1.01)	1.19 (1.11–1.28)	1.73 (1.57–1.92)	3.04 (2.42–3.83)
				Sepsis	2.5	1	1.11 (0.99–1.25)	1.51 (1.32–1.73)	2.50 (2.08–3.00)	5.56 (3.90–7.94)

some patients, CKD is a direct result of infection, from recurrent UTIs, to HIV and tuberculosis (TB). However, for the majority of patients with CKD, old age, underlying, or comorbid disease and lifestyle factors, such as diabetes and smoking, are independent risk factors for infection. With regards to old age, the term immunosenescence has been used to describe the changes in immune function that make older people more susceptible to infection [17], mainly via reduced response to vaccination via impaired T-cell function and the interplay of T cells with other parts of the immune system. Diabetes itself is a known risk factor for serious bacterial infections [18], and glycemic control a main risk factor for developing infections and requiring hospitalization with infections [19]. Smoking is a risk factor common to CKD and bacterial and viral infection. Nevertheless, as discussed above, even taking these factors into account, an increased risk of community-acquired infections is consistently observed as eGFR declines.

Treatment for CKD and underlying diseases with steroids and immunosuppressants can further predispose to infection. However, the vast majority of people with CKD in the general population do not have treatment with immunosuppressants or severely immunocompromising disease. Instead, the most common underlying conditions are old age, diabetes, a history of smoking, and exposure to infectious agents from frequent healthcare attendance [12].

CKD itself may have a causal role in increased infection risk through additional disturbance of both innate and adaptive immunity. Chronic inflammation, proteinuria, and uremia may each play separate roles. There are multiple potential mechanisms for CKD to alter cell-mediated and humoral immune system function. A number of observational studies have considered factors such as malnutrition, hypoalbuminemia, anemia, complement loss, disrupted calcium regulation and vitamin D insufficiency, and chronic kidney inflammation [12, 20]. Some of these factors, such as anemia, malnutrition, and low vitamin D, may be modifiable with good clinical care. However, before advocating replacement of vitamin D or treatment of anemia to prevent infections, clinicians should remember that lack of vitamin D and anemia may simply be markers of severity of overall illness and that treating these may fail to change, or possibly even increase, infection risk. For example, vitamin D is a marker of sun exposure, and bed-bound patients may be less likely to be out in the sun, so any observational study is likely confounded by disease severity. A review of existing trials of vitamin D supplementation to prevent acute respiratory infections suggests a potential role for patients with very low vitamin D levels [21]. At present, there are ongoing trials to test whether vitamin D supplementation improves outcomes, including infections in the CKD and dialysis population. In considering anemia as a potential mediator of infection risk, those patients with severe anemia tend to be most multimorbid, and anemia may be a marker of underlying chronic infection. Moreover, anemia of chronic illness may be a result of a physiologic process by which the body tries to sequester iron (with resulting anemia) to prevent increased infection risk [22]. Again, we have to wait for the results from randomized trials to determine whether treating anemia indeed reduces infection risk – it may well be the opposite as intravenous iron can cause an increased risk of infection [23].

As CKD worsens, a reduced response of the adaptive immune system has been observed in the context of a reduced response to vaccinations [24, 25]. This impairment may be in part driven by uremic toxins [26], which impair the T-lymphocyte dependent response (required to respond to vaccinations) [27] and also the phagocytosis response of polymorphonuclear lymphocytes [28, 29]. This reduced response to vaccination itself further increases the risk of vaccine-preventable infections.

Figure 32.2 illustrates that the association between CKD and susceptibility to infection is likely driven by a combination of the patient population's age and comorbidities, together with a likely impairment of the adaptive immune system caused by CKD.

Complications of Infections among People with CKD

We review below a number of key complications of infection that are relevant to people with CKD, including mortality, acute kidney injury (AKI), progression to dialysis, and cardiovascular disease. These associations highlight that infections should not be taken lightly, as they may have serious consequences.

Mortality

There is a graded association of CKD with mortality risk from infection. The rate of infection-related mortality and the proportion of deaths due to infection increase as eGFR declines among the general population [3, 30–32]. During 13 years of follow-up in the National Health and Nutrition Examination Survey study (NHANES) study, death from infection occurred in 1.2% of the population with normal eGFR, increasing to 4.6% in those with eGFR 45–59 ml/min/1.73m^2 and 10.3% in those with eGFR < 45 ml/min/1.73m^2. Compared to people with eGFR ≥60 ml/min/1.73m^2, the corresponding hazards of infection-related mortality were 1.36 (95% CI 0.81–2.30) and 2.36-fold (1.04–5.38) higher for eGFR of 45–59 and <45 ml/min/1.73m^2,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Figure 32.2 Risk factors and outcomes of infection in chronic kidney disease.

respectively [32]. Influenza/pneumonia and sepsis are the infections that most commonly cause death in patients with CKD [31]. The graded association of lower kidney function with higher infection-related mortality is repeated in the older population [8, 9, 33, 34], those with diabetes [35], and among older adults resident in nursing homes [34].

The increased risk of death is not simply due to increased risk of acquiring infection. If a patient gets admitted with infection, the presence of CKD worsens their outlook considerably. Several studies show that among those hospitalized with any infection, lower kidney function is associated with higher in-hospital mortality [36] and subsequent long-term all-cause mortality [37] (Table 32.3). The crude mortality rates are significant. In those hospitalized with sepsis/bloodstream infection, 20–22% of patients with eGFR < 60 ml/min/1.73m^2 died in hospital [36, 43], 49–70% died within 28 days [39, 41, 42], 62% died within 90 days [42], and 82% died within a year [39]. In those hospitalized with pneumonia, 9–19% of patients with eGFR < 60 ml/min/1.73m^2 died in hospital [36, 38], 29–47% died within 28 days [42], and 36–53% died within 90 days [42]. In a study enrolling patients hospitalized with infection at four hospitals in China, heightened risks of mortality were greatest in the first 7 days following admission and progressively declined thereafter, but remained significantly elevated at a year following admission [37]. This increased mortality risk can be seen also for infections other than sepsis and pneumonia. In a retrospective Japanese cohort study enrolling patients with smear-positive pulmonary tuberculosis, eGFR of <30 ml/min/1.73m^2 was a risk factor for death with adjusted odds ratio 2.99 (95% CI 1.20–7.51) [40]. In a systematic review of 19 studies of *Clostridium difficile* infection, a pooled analysis of 116 875 patients found the mortality risk associated with CKD was 1.76 (95% CI 1.26–2.47) [44].

For patients with CKD, the implication of an infection for longer term prognosis is also considerable. In a Canadian prospective cohort (CanPREDDICT) of patients with advanced CKD (eGFR 15–45 ml/min/1.73m^2) followed for up to 5 years, those who experienced an infection had over three times increased risk of mortality than those without infection (hazard ratio 3.39, 95% CI 2.65–4.33) [45].

AKI and Increased Risk of Progression to ESKD

It is well established that infection, especially severe infection such as sepsis, increases the risks of AKI and of requiring kidney replacement therapy [46]. Among those with AKI, 86.9% cases were attributed to sepsis or hypovolemia [47]. When an infection occurs, underlying kidney function impairment increases the risk of AKI. In septic shock, patients with CKD (59.5%) had a higher risk of AKI than those without CKD (40.8%) [48]. Among patients infected with influenza A, 67–69% of patients with CKD had AKI [49, 50]. However, there are other studies that have not found associations between CKD and AKI risk in infection [51, 52].

An infection in the context of advanced CKD can propel patients onto dialysis. In the CanPREDDICT study of patients with advanced CKD (eGFR 15–45 ml/min/1.73m^2), those with infection had a 58% increased risk of end-stage kidney disease (ESKD) (hazard ratio 1.58, 95%

CI 1.22–2.05) [45]. In a population-based retrospective cohort study from Taiwan's National Health Insurance Research Database, the overall incidence rate ratio of ESKD adjusted for competing mortality was 23% higher in those with pneumococcal pneumonia than in those without pneumococcal pneumonia ((crude ESKD rates 5.26 vs. 3.10 per 1000 person-years), with an adjusted sub-hazard ratio of 1.14 (95% CI 1.01–1.29) [53].

Cardiovascular Events

It is well known that for the general population acute infections can lead to an acute but temporary increase in the risk of arterial and venous thrombotic events [54, 55]. Downstream effects of acute infections include dysfunction of endothelial, redox, and coagulation systems, all of which occurs in the face of diminished cellular oxygen availability, cytokine storm, sympathetic overload, complement activation, and vasoconstriction of some vascular beds (including that of the kidney) [14, 56, 57]. The CanPREDDICT study of patients with advanced CKD (eGFR 15–45 ml/min/1.73m^2) found that those with an episode of infection had an increased risk of cardiovascular ischemia (hazard ratio 1.80, 95% CI 1.24–2.60) and congestive heart failure (HR 3.22, 95% CI 2.25–4.61) [45].

In summary, kidney dysfunction worsens prognosis in those who present with infection, while infection worsens kidney function acutely and may propel people with advanced CKD onto dialysis. Most important though is the considerable risk of mortality if a person with reduced kidney function is hospitalized with infection. In the case of sepsis, which is known to be more common among people with CKD, there is clear evidence that early recognition and treatment can improve outcomes. Patients with CKD should be advised to seek help early when they have symptoms of infections.

Preventing and Treating Infections among People with CKD

Preventing Infections in CKD

Vaccination is the best strategy for preventing morbidity and mortality from infection, and is vital among this high-risk population. Vaccines particularly relevant for patients with CKD are considered below: pneumococcal and inactivated influenza vaccinations are recommended for patients with CKD, and patients awaiting dialysis or kidney transplant are recommended to be vaccinated against hepatitis B and may benefit from varicella or herpes zoster vaccination [1, 58].

Most research into vaccination in kidney disease has focused on patients with ESKD [59]. Since immune responsiveness declines progressively with worsening kidney function, evidence of vaccine effectiveness and safety among patients with ESKD is included where necessary to indicate likely effectiveness or safety for patients with CKD. Vaccination guidance for kidney transplant recipients and patients with end-stage renal disease (ESRD) is covered in other chapters and should be consulted separately, in particular noting advice on live and live-attenuated vaccines.

Pneumococcal Vaccine

Streptococcus pneumonia is the most common cause of community-acquired pneumonia, which causes a high burden of mortality and morbidity among patients with CKD [5, 42, 60]. Systematic reviews of the effectiveness of pneumococcal vaccine in the general population have been hampered by heterogeneity [61], which may be attributable to varying lengths of follow-up as immunity wanes over time [62]. An observational study that explored how predialysis CKD related to vaccine effectiveness among people aged ≥65 years with diabetes found some evidence that vaccine effectiveness was lower among patients with a history of proteinuria ($P = 0.04$), but no evidence of variation according to eGFR. Vaccine effectiveness was 22% (95% CI 11–31%) in the first year after vaccination, but was negligible after 5 years [63].

Kidney Disease: Improving Global Outcomes (KDIGO) guidelines recommend that all adults with eGFR < 30 ml/min/1.73 m^2 (glomerular filtration rate (GFR) categories G4-G5) and those at high risk of pneumococcal infection (e.g. nephrotic syndrome, diabetes, or those receiving immunosuppression) receive vaccination with polyvalent pneumococcal vaccine unless contraindicated, and that all adults with CKD who have received pneumococcal vaccination are offered revaccination within 5 years [1]. UK guidelines recommend vaccination every 5 years with 23-valent pneumococcal polysaccharide vaccine for children and adults with nephrotic syndrome, CKD stages 4 and 5, and those on kidney dialysis or with kidney transplantation [58].

Influenza

Influenza vaccination has the potential to reduce morbidity and mortality from both influenza and pneumonia. Up to one-third of community-acquired pneumonia may be influenza-related, due to bacterial co-infection or secondary bacterial pneumonia [64]. A 2014 systematic review of influenza vaccination among patients with ESKD found five observational studies, none of which included safety

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

data, and concluded that the evidence on effectiveness was limited and of low quality [65]. One of the included studies is often cited as evidence that influenza vaccination is effective in ESKD; in this observational study of US Medicare patients receiving dialysis, influenza vaccination was associated with lower risk of hospitalization and death [66]. However, McGrath et al. found that US Medicare patients receiving hemodialysis were less likely to be vaccinated if they had frequent or longer hospitalizations or required skilled nursing, suggesting an overestimation of the effectiveness of influenza vaccination in this dataset due to a "healthy vaccinee" effect [67]. When McGrath et al. adjusted the vaccine effectiveness in well-matched seasons for that observed in mismatched seasons (in which little or no vaccine effect should be seen due to mismatch of the influenza type with vaccine), they found little evidence of increased vaccine effectiveness in well-matched years among US Medicare patients receiving hemodialysis [68].

One study explored whether CKD affects vaccine effectiveness among older people with diabetes [63]. The "healthy vaccinee" effect was adjusted for by dividing vaccine effectiveness in winter by that observed in summer. It found a modestly protective effect of influenza vaccination against LRTI (7%, 95% CI 3–12) with no evidence of variation in vaccine effectiveness according to CKD stage. This may be an underestimate for patients with CKD, as vaccine effectiveness diminishes with age and the outcome was not specific to influenza. Given the high morbidity and mortality associated with influenza and secondary pneumonia among patients with CKD, even a low vaccine effectiveness would support vaccination.

KDIGO guidelines recommend that all adults with CKD are offered annual vaccination with influenza vaccine unless contraindicated due to allergy to seasonal influenza vaccine [1]. Live-attenuated influenza vaccination has not been tested in patients with CKD [69]. UK guidelines recommend offering inactivated influenza vaccination to adults with CKD stages 3–5, chronic kidney failure, or nephrotic syndrome, with recommendations for children varying according to age [58].

Hepatitis B

Guidelines for hepatitis B vaccination among patients with CKD have aimed to anticipate the risk of infection from dialysis [70]. Hepatitis B prevalence among patients receiving hemodialysis ranges from 1.1% to 6.1%, and patients who develop hepatitis B while receiving dialysis are more likely to become chronic carriers [70]. Vaccinating patients with CKD stages 3–4 achieves better seroconversion than vaccinating at initiation of hemodialysis [71–73]. Early vaccination may be of additional benefit to patients with diabetic nephropathy who may be at risk through blood glucose monitoring [74]. Most research into hepatitis B vaccination describes effectiveness at seroconversion as a surrogate for protection against hepatitis B infection [70].

A 2004 Cochrane review identified seven randomized clinical trials of hepatitis B vaccine effectiveness among patients with kidney failure [70]. The review found that plasma hepatitis B vaccines are safe and effective at generating protective antibody levels among patients receiving dialysis. The two trials among patients with predialysis CKD found no evidence of a difference in seroconversion following recombinant or plasma vaccine (risk ratio [RR] 0.65, 95% CI 0.28–1.53) [75, 76].

Seroconversion is lower among patients with CKD than the general population [25, 59]. Systematic reviews have found a short-term improvement in seroconversion with intradermal (rather than intramuscular) delivery and no evidence of additional benefit from "double dose" hepatitis B vaccination compared to standard doses [77, 78]. A randomized trial of 165 patients with CKD or receiving hemodialysis compared 20 μg Fendrix to double doses (2 × 20 μg HBsAg) of Engerix vaccine [79]. Fendrix is adjuvanted by monophosophoryl lipid A and adsorbed onto aluminum phosphate. Patients who received Fendrix had higher levels of seroconversion, with faster onset and longer duration of protective antibody levels. There was a higher incidence of pain at the injection site with Fendrix, but no evidence of any difference in serious adverse events. Other adjuvants that have shown promise among patients with kidney disease are levamisole [80], granulocyte macrophage colony-stimulating factor (GM-CSF) [25], and a toll-like receptor 9 agonist [81]. There may be scope to improve hepatitis B immunity for patients with CKD through further research into the optimal vaccine dose, type, route, and schedule.

KDIGO guidelines recommend vaccination for adults with eGFR < 30 ml/min/1.73m^2 and at high risk of progression of CKD, with serological testing to confirm response [1]. UK guidelines recommend vaccinating patients with CKD as soon as it is anticipated they may require dialysis or kidney transplantation, using Fendrix if they are ≥15 years old, testing antibody levels annually, and providing a booster dose for patients with antibodies below 10 mIU/ml [58].

Zoster

CKD increases the risk of herpes zoster, and the CKD patient population also has a high prevalence of diabetes and older age, both of which are risk factors for herpes zoster [82–84]. Herpes zoster may worsen kidney outcomes for patients with CKD [83]. However, older people in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Medicare are less likely to receive herpes zoster vaccination if they have CKD than if they do not [85].

A large observational study of herpes zoster vaccination among Medicare recipients aged ≥65 years found an adjusted vaccine effectiveness of 49% (95% CI 36–56) among people with CKD and 46% (95% CI 9–68) among people with both CKD and diabetes, both similar to that among the general population of older people (vaccine effectiveness 48%, 95% CI 39–56) [82]. Small studies of varicella zoster vaccination among children with kidney disease observed high seroconversion following a second dose (>98%) and antibodies persisting over 3 years [86–88].

Varicella zoster vaccination is part of the routine childhood vaccination schedule in the United States, while the UK vaccinates older people against herpes zoster [58]. Among patients with CKD, who are at greater risk of severe disease than the general population, vaccination may have greater benefits [82]. As both varicella and herpes zoster vaccination use live attenuated virus vaccines, care must be taken to note contraindicating immunosuppression, and susceptibility and eligibility for varicella or herpes zoster vaccination should be considered in advance of immunosuppression for potential kidney transplant candidates [58].

Routine Childhood Vaccinations

In general, children with CKD are at increased risk for vaccine-preventable diseases and should receive all the routinely recommended childhood immunizations as far as possible; however, vaccination is too often delayed or overlooked [89]. Immunosuppression should be considered before delivering live or live-attenuated vaccines (including rotavirus vaccine, varicella zoster vaccine, measles, mumps, and rubella vaccine, and the live-attenuated influenza vaccine). For children with CKD, KDIGO guidelines recommend pediatric immunization schedules should be followed according to official international and regional recommendations [1]. Routine childhood vaccination schedules vary by country and are frequently updated, and so up-to-date guidance should be consulted.

Live Vaccines

Live or live-attenuated vaccines include rotavirus vaccine, varicella, and herpes zoster vaccines, measles, mumps, and rubella vaccine, yellow fever, and the live-attenuated influenza vaccine. Patients with CKD may be receiving immunosuppressive medication or have underlying or comorbid conditions that result in immunosuppression. KDIGO guidelines recommend consideration of live vaccine should include an appreciation of the patient's immune status and follow recommendations from official or governmental bodies [1]. In the United States, the Centers for Disease Control and Prevention advises that the majority of people with CKD, of any stage, have sufficient immune function to receive all live vaccines for which an inactivated vaccine is not an alternative [69].

Vaccination: Summary

In general, patients with CKD are at greater risk of infection and complications from infection. In addition to routine vaccinations, influenza, pneumococcal, hepatitis B, and zoster vaccinations should be considered. Immunosuppression must be considered before delivering live or live-attenuated vaccines, but most patients with CKD may safely receive all live vaccines for which an inactivated vaccine is not available [69].

Vaccination is a vital but under-used tool among patients with CKD [85, 89]. Although it is true that vaccine response can be diminished in CKD compared to the general population, vaccines prevent infections and improve outcomes. Indeed, given the higher risk of vaccine-preventable infection and poorer outcomes of infection associated with CKD, vaccinations are particularly important among this high-risk population.

Treating Infections in CKD

Considering the poor outcomes of infections in those with CKD, it is imperative that infections are treated promptly but appropriately to achieve maximum effect. Patients with CKD are not only subject to infection, but, if inappropriately managed, may plausibly become hosts of antibiotic-resistant pathogens, increasing the treatment difficulty. Higher rates of infection in patients with CKD result in more frequent use of antibiotics [90] and more frequent hospitalization [2, 5, 9], which increases their exposure to microbes including multidrug resistant organisms (MDROs) [91]. A recent study from China indicated the odds of infections by MDROs was 19% and 41% higher in those with eGFR between 30 and 60 ml/min/1.73m^2 and eGFR < 30 ml/min/1.73 m^2, respectively, compared to those with eGFR 60–104 ml/min/1.73m^2 [92].

It is important that treatment does not cause pathogen drug resistance and therefore treatment should be rationalized whenever possible; this means, for example, that self-limiting infections should not be treated with antibiotics. For patients with CKD, vigilance is required and they need to be told at which point they should come back to seek further help and care should their condition worsen, so there is no delay with treatment should it become necessary. The way that patients initially presented and what they were told should be diligently documented so any other healthcare provider will be able to assess whether patients have improved or worsened.

When it comes to actual prescribing of antimicrobial drugs when the infection is deemed to require treatment, it will depend on the health system and the local circumstances as to which drug is chosen. For example, many health systems have ongoing monitoring systems of local antibiotic resistance of key pathogens, with resulting antibiotic treatment handbooks that recommend a particular first-line treatment when a person presents with a particular infection. Antimicrobial stewardship means that whenever possible there should be cultures taken so that treatment can be narrowed down once the pathogen has been identified, to enhance treatment success while minimizing further development of antibiotic resistance. Depending on the health system, some pathogens may need to be notified to central authorities, and infections and treatments given will be monitored. For example, in many hospitals in the UK methicillin-resistant staphylococcal infections are part of quality monitoring, with internal targets. If targets are not met, the hospital's infection control staff will retrain the unit and review infection control policies (e.g. decolonization regimes, swabbing/culturing every patient, etc.) to prevent such infections occurring. Monitoring of infections, treatments given, and outcomes are simpler if electronic health records are used, as this allows standardized centralized analysis. These are all general points of infection control policies that have general value irrespective of CKD status, but the stakes of patient management and antimicrobial stewardship are raised by the higher rate of infection with MDROs among patients with CKD.

Prescribing Antibiotics in CKD

If a patient with CKD requires antibiotics with a drug that is partially or fully renally cleared, dosing must take the patient's impaired kidney function into consideration. How this is approached depends on how the drug acts on the infection (i.e. pharmacodynamics). For drugs that act immediately on the pathogen with an effect dependent on concentration (e.g. aminoglycosides), the dosing interval should be increased. For drugs that require a constant level to be maintained over a prolonged time to eliminate the pathogen (e.g. beta-lactams), patients should be given smaller doses in the normally recommended dosing interval. For some infections, an antimicrobial which is not renally cleared may be an alternative.

In practice, it can be challenging to adjust interval or dose correctly, as this requires an estimate of the underlying kidney function. Especially in the context of AKI, it is very difficult to know what the true kidney function is. Estimating kidney function using the most recent test results before onset of infection will tend to overestimate kidney function during the infection. This is not ideal, but will ensure that a sufficient dose of antibiotic is given to treat the infection effectively, without delay. The dose and interval should then be reviewed once more current test results are available. Estimation should be using the best validated eGFR formula for a given patient, taking into account their body surface area (BSA). The standard eGFR is for a BSA of $1.73m^2$, hence, for the individual the GFR is:

$$GFR = eGFR * BSA / 1.73m^2$$

There are further formulas that can be used to adapt the drug dose as AKI improves or worsens [93]. Ideally, doses should be adapted following measurement of drug levels of nephrotoxic drugs to minimize toxicity and to maximize therapeutic effects, especially if there is prolonged treatment, as, for example, for tuberculosis [94]. At the time of writing, several recent reviews have discussed these issues in more detail and provide dose adjustment tables for a range of antimicrobials [95–97], but this is an area of ongoing research and guidance is evolving rapidly.

Many patients with CKD or AKI will not be managed by nephrologists, and therefore it is important to consider the surrounding health system to understand how treatment and infection outcomes in CKD can be improved. Unsurprisingly, dosing errors and inappropriate prescribing for CKD stage are common in routine practice. Electronic prescribing software has the potential to reduce such errors by identifying CKD through diagnosis or laboratory results, suggesting point of care testing, recommending preferred antimicrobials and dose, and alerting prescribers to drug interactions or kidney dysfunction in the presence of a renally cleared drug. This has been rolled out in settings from hospitals to community pharmacies with varying success [98, 99]. Safely implementing computer-decision support for medication is not straightforward, and outcomes should be monitored. Suboptimal design, alert fatigue, workarounds, and lack of training can result in unintended consequences, while success depends on prescribers finding the alerts valuable and acting on the information received [100].

Other Considerations

Aside from immediately treating the infection, there also should be consideration given to other medications that a patient with CKD is prescribed. This may include checking for drug interactions (taking into account the kidney function of the patient). For patients receiving long-term immunosuppressant medications, more serious or atypical infections may need to be considered as part of a differential diagnosis, and clinicians may need to consider whether there is a need for preventative antibiotics or antiviral medications (discussed in other chapters, e.g. for transplantation).

Conclusions

CKD is a clear risk factor for developing infections, often requiring hospitalization. Hospitalization with an infection may worsen kidney function, and there is a graded increased risk of adverse outcomes including mortality. To prevent poor outcomes, patients need to be aware of these risks, to know when to seek help when they are unwell, and to receive timely and appropriate treatment of their infections. Whenever possible, patients with CKD should be vaccinated against infections to reduce future risks. Future trials of vaccination for infection should consider tailored vaccination programs that take into account the observed reduced immune response in patients with CKD.

Treatment of Anemia in Chronic Kidney Disease

Patrick S. Parfrey

Faculty of Medicine, Memorial University, St. John's, NL, Canada

Introduction

The prevalence of anemia increases as chronic kidney disease (CKD) progresses by stage. Anemia is caused by erythyropoietin deficiency, disordered iron metabolism, blood loss, infection, inflammation, and other less frequent causes.

Patients with CKD and moderate anemia maintain this Hb range for years: most patients with moderate anemia (hemoglobin [Hb] level < 11 g/dl and > = 9g/dl), nondialysis-dependent CKD, and type 2 diabetes are able to maintain a Hb level >9 g/dl (i.e. avoid severe anemia) when followed for an average of 2.3 years [1].

In the Trial to Reduce cardiovascular Events with Aranesp Therapy (TREAT), Hb declined precipitously in the year prior to the development of end-stage renal disease (ESRD) (irrespective of whether assigned to Aranesp or placebo) without biochemical evidence of iron deficiency [2]. Once ESRD occurs, severe anemia is more common and the need for blood transfusions far higher than in nondialysis CKD [3].

Nondialysis CKD and dialysis-dependent ESRD should probably be studied as two separate phases of kidney disease because of the following: (i) different trajectories for Hb levels, (ii) different hemodynamic and metabolic milieus, and (iii) changing pathogenesis of cardiac disease from predominantly atherosclerotic events to an equal prominence of cardiac failure events linked to nonatherosclerotic processes [4].

In cohort studies, anemia has been associated with the development of left ventricular hypertrophy (LVH), heart failure, cardiovascular (CV) hospitalizations, mortality, and diminished quality of life [5–7].

In the early decades of dialysis therapy blood transfusions were the mainstay of anemia therapy, but in the last three decades large clinical trials have been undertaken to determine the efficacy of erythropoiesis-stimulating agents (ESAs) [8–12], and more recently peginesatide [13–14] and intravenous iron [15]. Currently trials of novel prolyl hydroxylase inhibitors (PHI) that stabilize hypoxia inducible factor (HIF) are ongoing. Table 33.1 provides recommendations on the treatment of anemia in chronic kidney disease based on the certainly and strength of the evidence.

Clinical Outcomes in Randomized Controlled Trials

The choice of interventions to treat or prevent anemia in CKD should be influenced by the results of randomized controlled trials (RCTs). The clinical outcomes studied in RCTs include change in Hb levels, blood transfusion rates, CV events, and quality of life. In addition, adverse events need to be considered.

Change in Hb Levels

This is easy to assess, but creates problems because nephrologists tend to focus on the levels at which therapy should begin and target levels for therapy. It would be preferable to individualize therapy by determining whether patients have symptoms attributable to anemia and provide therapy to treat symptoms, rather than treat everybody based on test values.

Table 33.1 Treatment of anemia in chronic kidney disease.

Treatment	Recommendation	Certainty of evidence: *high, weak, low, very low*	Strength of recommendation: *strong or weak*
Blood transfusions	Avoid red cell transfusions to minimize the general risks related to their use (1B)	Weak	Strong
	In patients eligible for organ transplantation avoid when possible red cell transfusions to minimize the risk of allosensitization (1C)	Low	Strong
	The benefits of red cell transfusions may outweigh the risk in patients in whom ESAs are ineffective and in patients at risk from ESA therapy (previous or current malignancy or previous stroke) (2C)	Low	Weak
	The decision to transfuse a CKD patient with nonacute anemia should not be based on any arbitrary Hb threshold, but should be determined by the occurrence of symptoms caused by anemia (2C)	Low	Weak
ESAs	(A) In initiating and maintaining ESA therapy balance the potential benefits of reducing blood transfusions and anemia-related symptoms against the harm in individual patients (e.g. stroke, vascular access loss, hypertension) (1B).	Weak	Strong
	(B) In CKD ND start ESA therapy when Hb falls below 9 g/l. BUT individualize the decision to start ESA therapy based on the rate of decrease of Hb, prior response to iron therapy, the risk of needing a blood transfusion, the risks of ESA therapy, and the presence of symptoms attributable to anemia (2C).	Low	Weak
	(C) In dialysis patients start ESA before Hb falls below 9 g/l by starting ESA therapy when the Hb is between 9 and 10 g/l (2B).	Low	Weak
	(D) In CKD ND and D target Hb should be 10–11.5 g/l (2C).	Low	Weak
	(E) ESAs should not be used to intentionally raise Hb above 13 g/l (1A).	High	Strong
	(F) Avoid ESAs in patients with active malignancy, history of solid organ malignancy, or history of stroke (2C).	Low	Weak
	(G) In patients with ESA hypo-responsiveness avoid repeated escalations in ESA dose beyond double the weight-based dose (2D).	Low	Weak
Intravenous iron	(A) For anemic adult CKD patients not on iron or ESA therapy, in whom a raise in Hb is desired, and whose TSAT is <30% and ferritin is <500 ng/ml, give a trial of IV iron (2C).	Low	Weak
	(B) For adult dialysis patients on ESA therapy, in whom a raise in Hb or reduction dose of ESA is desired, and whose TSAT is <30% and ferritin is <500 ng/ml, give a trial of IV iron (2C).	Low	Weak
	(C) In adult dialysis patients maintain TSAT between 20% and 40% and ferritin between 200 and 700 ng/ml in a proactive fashion (1B).	Weak	Strong

ESA: Erythropoiesis–stimulating agents; CKD: Chronic Kidney Disease; Hb: Hemoglobin; ND: Non Dialysis; D: Dialysis; TSAT: Transferrin saturation; IV: Intravenous.

Blood Transfusions

Avoidance of blood transfusions is sufficiently desirable that it is currently the major reason for treatment of severe anemia (Hb < 9 g/dl).

Cardiovascular Events

Events arising from atherosclerosis of coronary, cerebral, and peripheral arteries occur frequently in CKD. As CKD progresses, LVH and cardiac failure events arising from cardiomyopathy occur more frequently [4]. The temptation is to combine both of these types of CV events, but this should be resisted because they have different pathogeneses. Assessment of CV events requires thousands of patients in RCTs. In addition, surrogate markers for CV events, such as echocardiographic measurement of LVH and left ventricular (LV) diameter and function, are often undertaken, but they do not substitute for clinical outcomes when applying the results of RCTs to clinical decision making.

Quality of Life

Quality of life has multiple domains and questionnaires exist to measure these domains, such as the SF 36 or Kidney Disease Quality of Life (KDQoL). However, anemia treatment is unlikely to influence several of the domains. Consequently, it is advisable to identify a priori prespecified outcomes potentially susceptible to anemia treatment, such as tiredness, vitality, and fatigue. A major problem concerns interpretation of results, especially as the definition of clinically significant changes in symptom scores is not based on strong clinical epidemiology science.

Harms vs. Benefits

Large trials are necessary to provide evidence on the harms:benefits ratio. For example, TREAT was undertaken nearly 20 years after the introduction of ESAs and was big enough to identify the increased risk of stroke in anemic diabetic CKD patients treated to normalize Hb levels with Aranesp [12]. Although some recommend conclusions derived from meta-analysis of all types of trials of a particular agent, sometimes more utility is derived from large RCTs designed to answer a clinical management question.

Erythropoiesis-stimulating Agents

Recombinant human erythropoietins have been used to treat anemia for up to three decades. During the past decade, ESA doses have declined following publication of RCTs demonstrating harm when the target Hb for ESA treatment was normalization of Hb [16]. As a result of these trials, the target Hb is between 10 and 12 g/l. A critical appraisal of these RCTs follows [17].

Treatment of Severe Anemia

There are no large RCTs of ESA therapy in patients with severe anemia (baseline Hb <9 g/dl) in which clinical endpoints and safety were assessed. In 1990, the Canadian Erythropoietin Study Group reported an RCT in which ESA was utilized in 110 hemodialysis patients with Hb levels below 9 g/dl, and three randomly allocated groups were followed (placebo, low target Hb 9.5–11 g/dl, high target Hb >11 g/dl). Baseline Hb was 7.0 g/dl and transfusion requirement was seven transfusions per year. After 8 weeks, 58% ($n = 23/40$) in the placebo group were transfused and only 3% ($n = 1/40$) in the low Hb group. After 6 months, clinically important improvements in fatigue, physical function, and 6-minute walking tests were reported for the low Hb group compared with the placebo group, but no improvement was observed when comparing the low and high Hb groups. A strategy to treat CKD patients with ESAs when Hb falls below 9 g/dl seems justified on the grounds of reduction in transfusions and improvement in quality of life, despite the lack of data on safety.

Treatment of Moderate Anemia

There are several large RCTs of ESA therapy in which baseline Hb was higher than 10 g/dl [8–12]. The intervention being tested in these trials was correction of anemia with ESAs, compared with partial correction of anemia with ESAs in four RCTs [8–11] and with placebo in one [12].

Normal Hematocrit Study

Prevalent hemodialysis patients with symptomatic cardiac disease (congestive heart failure or ischemic heart disease) ($n = 1233$) were enrolled in this RCT [8]. In the normal hematocrit group treated with epoetin, there were 183 deaths and 19 myocardial infarcts, producing 202 primary events, compared with 164 events (150 deaths and 14 myocardial infarcts) in the group in which anemia was partially corrected with epoetin. Although the primary event rate was significantly different ($P = 0.03$), the hazard ratio (HR) was 1.3, with 95% confidence intervals (CIs) being 0.9–1.9, following correction for previous interim analyses. The trial was stopped early, not because of these somewhat equivocal results, but because the intervention being tested was certainly causing harm in a situation wherein the primary hypothesis was unlikely to be proven: 39% had vascular access clotting in the intervention arm and 29% in the control arm ($P = 0.001$).

Canada–Europe Study

Incident hemodialysis patients without symptomatic cardiac disease (congestive heart failure or ischemic heart disease) were enrolled in this RCT [9]. A similar number of patients (n = 596) were enrolled in this study as in the Cardiovascular Risk reduction in Early Anemia Treatment with Epoetin (CREATE) study (see next section) (n = 603), but the primary outcome was not clinical events, but rather change in LV volume index and LV mass index. The change in both indices was similar in the correction of anemia group and in the partial correction group. Nonetheless, important clinical observations were made. A safety signal was observed as 12 neurological events occurred in the high Hb group (13.5–14.5 g/dl target) and four in the low Hb group (9.5–11.5 g/dl target) ($P < 0.05$), a signal confirmed by TREAT (see below) [8]. As one might expect, the high Hb group received significantly fewer transfusions than the low Hb group, but the extent of the benefit was modest: although 9% in the high Hb arm received a transfusion compared with 19% in the low Hb arm (P = 0.004) during the 2-year study, the number of transfusions per patient per year was 0.3 in the high Hb arm and 0.7 in the low Hb arm ($P < 0.0001$) [18].

Cardiovascular Risk Reduction in Early Anemia Treatment with Epoetin study

Predialysis CKD patients (n = 603) with mean estimated glomerular filtration rate (eGFR) equal to 24 ml/min were enrolled in this RCT [10]. Baseline Hb was 11.0–12.5 g/dl. Normalization of Hb with epoetin was compared with late partial treatment of Hb (i.e. when Hb fell below 10.5 g/dl, to a target of 10.5–11.5 g/dl). The trial was underpowered for the primary outcome, a composite of eight CV events. Dialysis was required in significantly more patients in the high Hb group than in the low Hb group, but this may have resulted from the open-label design of the study in which symptoms might have been attributed to uremia with the knowledge that they were not attributable to anemia. This interpretation is supported by the fact that the rate of fall of eGFR in the two groups during the 3-year study was similar and by the results of TREAT, in which renal outcomes were the same in the placebo and high Hb groups [12].

Correction of Hemoglobin and Outcomes in Renal Insufficiency

This RCT was undertaken in 1432 predialysis CKD patients, half of whom had diabetic renal disease; baseline creatinine clearance was 37 ml/min [11]. Withdrawal rate was high: 17% due to renal transplantation and 21% for other reasons. The trial was stopped prematurely at a time when the primary endpoint (death or composite CV event) occurred significantly more often in the high Hb group compared with the low Hb group (P = 0.03). However, there were differences in baseline CV comorbidity such that, when taken into account in multivariate models, the hazard associated with high Hb was no longer statistically significant (P = 0.11) [14]. The conclusion that correction of anemia with erythropoietin is not associated with increased CV events is supported by the results of TREAT [12] in which CV outcomes were the same in the placebo and high Hb groups.

Trial to Reduce Cardiovascular Events with Aransep Therapy

This trial in diabetic patients with moderate anemia is by far the biggest RCT of ESA therapy performed (n = 4038) and had the best research design, as it was placebo-controlled and double-blind [12]. In the intervention arm darbepoetin (Aranesp) was used to achieve Hb higher than 13 g/dl, and in the placebo arm rescue therapy with darbepoetin was undertaken when Hb fell below 9 g/dl and placebo was restarted when Hb was higher than 9 g/dl. Baseline eGFR was 34 ml/min and baseline Hb was 10.4 g/dl. Median follow-up was 29 months, equivalent to 9941 patient-years. Median Hb in the high Hb arm was 12.6 g/dl and in the low Hb arm it was 10.6 g/dl. There were no differences in CV or renal outcomes comparing the two groups. The HR for death/composite CV events was 1.05 (95% CI 0.94–1.17) and for death or ESRD it was 1.06 (95% CI 0.95–1.19). However, there was a substantial increased risk of stroke (HR 1.92, 95% CI 1.38–2.68), although the risk of stroke attributable to the high Hb intervention was relatively small: 5.0% of the high Hb group had a stroke compared with 2.6% in the placebo group. The attributable risk of stroke in those with a prior history of stroke was substantially higher. Venous thromboembolic events occurred significantly more frequently in the high Hb arm (2%) compared with 1.1% in the placebo arm (P = 0.02). A signal that normalization of Hb with darbepoetin may be harmful in patients with a history of malignancy was reported following a post hoc analysis: 14 of 188 (7.4%) patients with a baseline history of malignancy died from cancer in the darbepoetin arm compared with 1 of 160 (0.6%) in the placebo arm (P = 0.002). Red blood cell transfusions were prescribed surprisingly frequently, and more often in the placebo arm (25%) compared with the high Hb arm (15%).

Hyporesponsiveness

A report from TREAT assessed the initial Hb response to darbepoetin (Aranesp) after two weight-based doses at 2-weekly intervals in 1842 diabetic patients with CKD [19]. Patients with a poor response, the lowest quartile who had

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

less than 2% change in Hb level after 1 month, had higher rates of the composite CV events (adjusted HR 1.31, 95% CI 1.09–1.59) or death (adjusted HR 1.41, 95% CI 1.12–1.78) compared with those with a better response. Although this differential effect may be related to comorbidity in hyporesponsive patients, nonetheless it is possible that high ESA doses in hyporesponsive patients may be toxic.

Meta-analyses

Palmer et al. [20] concluded that higher Hb levels in CKD increase risk for stroke (relative risk [RR] 1.51, 95% CI 1.03–2.21), hypertension, and vascular access thrombosis (RR 1.33, 95% CI 1.16–1.53), and probably increase risk for death (RR 1.09, 95% CI 0.99–1.2), serious CV events (RR 1.15, 95% CI 0.98–1.33), or ESRD (RR 1.08, 95% CI 0.97–1.20).

In 2014, a Cochrane review concluded that darbepoetin alfa effectively reduced blood transfusions in adults with CKD stages 3–5, but had little or no effect on mortality [21]. Its effects in adults with CKD stage 5D, kidney transplant recipients, and children with CKD remain uncertain. Another Cochrane review concluded there is currently insufficient evidence to suggest the superiority of any ESA formulation based on available safety and efficacy data [22]. A third Cochrane review concluded that continuous erythropoiesis receptor activator (a new class of third generation ESAs) had little or no effect on patient-centered outcomes compared with placebo, epoetin alfa or beta, or darbepoetin alfa for adults with CKD [23].

A meta-analysis of the effect of ESAs on health-related quality of life (HRQOL) concluded that ESA treatment of anemia to obtain higher Hb targets does not result in important differences (24), despite significant benefits being reported from the Canadian-Europe study [25], CREATE [10], and TREAT [12]. However, there may be a misinterpretation of the importance of the results, particularly if viewed through the lens of requiring a large improvement in symptom scores to be "clinically significant." In TREAT, linear repeated measure models of fatigue incorporated all symptom scores through 97 weeks, together with several baseline and interim predictors of long-term changes in HRQOL. Allocation to the placebo group was similar in magnitude to the effects of having pulmonary disease or CV disease, suggesting that these "modest" changes and fatigue scores were actually clinically important [26].

Peginesatide

Peginesatide is a dimeric pegylated peptide erythropoietic agent which was evaluated in two RCTs published in 2013 [13, 14]. The number of patients allocated to peginesatide in nondialysis CKD was 328 and in dialysis patients it was 1066. As a result of these RCTs, the FDA approved peginesatide for use in dialysis patients, but given the increased risk of CV events in nondialysis CKD patient trials, the FDA did not approve the agent for use in that group of patients.

On 23 February 2013, shortly after publication of the two trials, Affymax and Takeda, the producers of peginesatide, announced a nationwide voluntary recall of all lots of peginesatide injection as a result of new post-marketing reports of serious hypersensitivity reactions, including life-threatening or fatal anaphylaxis [27]. The rate of hypersensitivity reactions reported was 0.2%, of which approximately one-third were serious in nature. A safety signal for hypersensitivity reactions was not reported in the two *NEJM* articles, which supports the belief that these noninferiority studies were too small to provide adequate data for safety.

Intravenous Iron

During the past 6 years, use of intravenous iron has increased following the recommendation by Kidney Disease Improving Global Outcomes (KDIGO) guidelines that iron repletion should be a component of anemia management in CKD [28].

Meta-analysis comparing intravenous versus oral iron supplementation revealed that patients with CKD stages 3–5 were more likely to reach an Hb response >1 g/dl with intravenous iron (risk ratio 1.61, 95% CI 1.39–1.87) and that dialysis patients were even more likely to achieve this response (risk ratio 7.71, 95% CI 1.74–7.94) [29]. Another meta-analysis concluded that significant reductions in ESA dosing may be achieved by iron repletion in the hemodialysis population, and suboptimal iron use may require higher ESA dosing to manage anemia [30]. Nonetheless there were concerns about the safety of increased use of intravenous iron.

Recently, in a multicenter, open-label trial with blinded end-point evaluation, adults undergoing maintenance hemodialysis were randomly assigned to receive either high-dose iron sucrose administered intravenously in a proactive fashion (400 mg monthly, unless the ferritin concentration was >700 μg/l or the transferrin saturation was ≥40%) or low-dose iron sucrose administered intravenously in a reactive fashion (0–400 mg monthly, with a ferritin concentration of <200 μg/l or a transferrin saturation of <20% being a trigger for iron administration) [15]. The primary end point was the composite of nonfatal myocardial infarction, nonfatal stroke, hospitalization for heart failure, or death, assessed in a time-to-first-event analysis.

A total of 2141 patients underwent randomization. The median follow-up was 2.1 years. Patients in the high-dose group received a median monthly iron dose of 264 mg (interquartile range [25th to 75th percentile] 200–336), as compared with 145 mg (interquartile range 100–190) in the low-dose group. The median monthly dose of an ESA was 29 757 IU in the high-dose group and 38 805 IU in the low-dose group (median difference −7539 IU, 95% CI −9485 to −5582). A total of 333 patients (30.5%) in the high-dose group had a primary end-point event, as compared with 343 (32.7%) in the low-dose group (HR 0.88, 95% CI 0.76–1.03, $P<0.001$ for noninferiority). In an analysis that used recurrent-events approach, there were 456 events in the high-dose group and 538 in the low-dose group (rate ratio 0.78, 95% CI 0.66–0.92). The infection rate was the same in the two groups.

These data support an iron repletion high-dose regimen administered proactively rather than a lower-dose reactive regimen.

Prolyl Hydroxylase Inhibitors

HIF is the major transcription factor for the erythropoietin gene. Molecules were created that inhibit the HIF prolyl hydroxylase enzyme, preventing degradation of HIF and thus upregulating the erythropoietin gene. In adults, about 90% of erythropoietin is produced by the kidneys but 10% is produced by the liver. Liver production can respond to prolyl hydroxylase inhibition by producing more endogenous erythropoietin. However, there are many other hypoxia-sensitive genes for which HIF is a key regulatory protein, including angiogenic factors. Consequently, long-term safety is a concern.

Prolyl hydroxylase inhibition (PHI) agents are oral drugs, four of which are already in stage 3 RCTs. They have demonstrated that they can raise and maintain Hb levels in a predictable and controlled manner, while enhancing iron mobilization in patients with nondialysis CKD [31–33].

Roxadustat is being studied in four RCTs in nondialysis CKD comprising 4750 patients, with one RCT comprising 2700 patients and having a primary outcome for major CV events. The same drug is under investigation in 4508 dialysis patients, with one RCT comprising 2100 patients and having a primary outcome for major CV events. Vadadustat is under investigation in 3100 nondialysis CKD patients in two RCTs and in 2600 dialysis patients in two RCTs. Daprodustat is being studied in an RCT of 4500 nondialysis patients, in another of 3000 dialysis patients, and in a third of 300 incident dialysis patients. The fourth drug is Molidustat. The results from these trials will be published during the next 3 years.

Conclusion

Current management of anemia in CKD usually combines use of ESAs and iron repletion, and is driven by the need to avoid both [1] severe anemia and the higher risk of blood transfusions, and [2] normal hemoglobin levels, which were associated with increased CV risk in ESA trials.

Introduction

Cardiovascular (CV)-related mortality is the leading cause of death in patients with chronic kidney disease (CKD) [1]. However, dyslipidemia and treatment of lipids in CKD are distinct from that of the general population. A deeper understanding of how lipids behave in CKD and the results of trial data regarding CKD outcomes or lipid-lowering therapy in CKD patients are needed in order to understand how to properly treat patients with CKD. In this chapter, we will review lipid metabolism, describe changes in lipid particles and metabolism as CKD progresses, the role of these markers in CKD, and the impact of dyslipidemia and treatment with lipid-altering therapies across different stages of CKD.

Dyslipidemia Diagnosis

The Executive Summary of the Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III) [2] provides a description of dyslipidemia in patients. Dyslipidemia may be defined by a total cholesterol (TC) ≥200 mg/dl, low-density lipoprotein cholesterol (LDLc) ≥100 mg/dl, high-density lipoprotein cholesterol (HDLc) <40 mg/dl, and triglycerides (TG) ≥150 mg/dl. These lipid measurements are typically used in conjunction with other comorbid measures to ascertain the 10-year risk of a CV event to evaluate indication of treatment for dyslipidemia. As will be discussed below, alterations in lipid levels across progressing CKD may alter these threshold definitions of dyslipidemia in CKD patients, and the prognosis of dyslipidemia for CV and mortality outcomes may shift as CKD progresses. However, according to the most recent American College of Cardiology and American Heart Association (ACC/AHA) guidelines [3], presence of CKD is considered a coronary risk equivalent and is itself an indication for treatment. Therefore, in patients with CKD, measuring lipid levels may be more useful to determine adherence and response to therapy, rather than as a measure to ascertain disease risk and indicate treatment.

Epidemiology

In the general population, TC, LDLc, and TG are strongly and positively associated with incident CV events [4–6], while HDLc has been associated with a lower risk of CV events. However, reverse associations between these lipid markers and CV events have been described in segments of CKD patients, a so-called "reverse epidemiology."

In nondialysis dependent chronic kidney disease (NDD-CKD), the value of lipid levels in predicting cardiovascular disease (CVD) appeared to attenuate across worsening stages of CKD, although some studies showed conflicting results. Tonelli et al. studied 836 060 adults, including 47 092 NDD-CKD patients (estimated glomerular filtration rate [eGFR] 15–59 ml/min/1.73m^2) from the Alberta Kidney Disease Network and found that the association between higher LDLc and risk of myocardial infarction (MI) was weaker for people with lower baseline eGFR despite that group having a higher absolute risk of MI [7]. Bowe et al.

similarly found an interaction between eGFR category and HDLc for mortality risk where lower eGFR attenuated the lower risk conferred by intermediate HDLc for risk of death in a very large male cohort of US veterans [8]. The study also found a u-shaped association between HDLc and mortality risk across all eGFR groups, where higher mortality risk was observed for patients with HDLc >50 mg/dl. Moreover, Navaneethan et al. further examined HDLc mortality associations in NDD-CKD US veteran patients and reported that HDLc >60 mg/dl was associated with lower all-cause, CV, malignancy-related, and non-CV/nonmalignancy-related deaths among women but not in men [9]. Navaneethan et al. also found a shallower u-shaped relationship between TG and mortality for NDD-CKD patients age 65 years and older, but a direct linear relationship in younger patients [10]. The Atherosclerosis Risk In the Communities (ARIC) study also reported an association of lipids with coronary heart disease similar to that of the general population across eGFR groups in 807 NDD-CKD patients [11]; however, the study was only powered to adjust for four demographic covariates and may have residual confounding. Conversely, another small study of 840 stage 3 and 4 NDD-CKD patients in the Modification of Diet in Renal Disease (MDRD) cohort showed that the significant association of continuous TC with all-cause mortality was attenuated with covariate adjustment, and there was no association of TG, HDLc, and non-HDLc with all-cause or CV mortality [12]. Kovesdy et al. also studied the association between all four lipids and mortality in 1012 NDD-CKD patients in a single-center veteran study and found that compared to the highest quartile of lipid levels, lower lipid levels (TC, LDLc, TG, and HDLc) were associated with higher all-cause mortality [13]. However, these associations were attenuated after adjustment for demographics and abolished after additional adjustment for markers of malnutrition and inflammation complex (or cachexia) syndrome (MICS). Furthermore, in the African American Study of Kidney Disease and Hypertension (AASK) study, higher TC was associated with the CV endpoint in non-MICS NDD-CKD patients, but not in MICS NDD-CKD patients [14].

The concept of this reverse epidemiology relationship between lipids and outcomes in CKD has been attributed to MICS. The MICS concept was introduced by Kalantar-Zadeh et al. for dialysis patients [15] and subsequently defined by a specific diagnosis description [16]. The description of the syndrome includes medical history of weight loss, anorexia, gastrointestinal symptoms, reduced activity, comorbidity, and long dialysis vintage as well as objective examination findings (decreased subcutaneous fat, muscle wasting, low body mass index [BMI], low albumin, and low total iron binding capacity). In a subsequent publication from the same group, the malnutrition-inflammation score (MIS) correlated significantly with inflammatory markers serum interleukin (IL)-6 level and C-reactive protein (CRP) level as well as with several measures of nutritional status and risk of death [17]. In patients with more severe MICS as indicated by a high CRP and low albumin, the levels of TG and other lipid markers were also significantly decreased [18].

Studies have demonstrated the impact of MICS on the relationship between lipids and mortality in dialysis patients. In a cohort of 823 incident dialysis patients, Liu et al. showed that a 40 mg/dl increment in baseline TC was associated with a lower risk of all-cause mortality overall and in the presence of inflammation/malnutrition, but a higher mortality risk in the absence of inflammation/malnutrition in models adjusted for age, race, and sex [19]. Further adjustment for traditional CV risk factors, dialysis modality, comorbidity, and inflammatory markers attenuated the inverse association but strengthened the positive association. In keeping with these findings, another study showed that in dialysis patients, lower serum TC was a significant predictor of death, but higher TC was associated with higher death risk in a subgroup of patients with serum albumin ≥4.5 g/dl [20]. In the Taiwan Renal Registry Data System, in nonatherosclerotic cardiovascular disease (non-ASCVD), both TC >250 mg/dl and <150 mg/dl were associated with a higher risk of mortality compared to the reference (TC 150–200 mg/dl); however, in the ASCVD patients, only TC <150 mg/dl had a higher risk [21]. In a cohort of hemodialysis patients, each 50 mg/dl excess in TG was associated with a progressively lower risk of all-cause and CV mortality in patients with a waist circumference <95 cm but with a progressively higher risk in patients with a waist circumference above this threshold [22].

Kilpatrick et al. also examined the association of lipid markers with mortality in consideration of MICS in a large dialysis cohort [23]. Both higher TC and LDLc showed a paradoxical association with better survival. Hyper-triglyceridemia (>200 mg/dl) also showed a similar trend. The association between a low serum LDLc (<70 mg/dl), which was prevalent among almost 50% of hemodialysis patients in the cohort, and higher all-cause death risk was robust to multivariate adjustment, including MICS markers. In subgroup analyses, these paradoxical associations persisted among most subgroups, although they tended to be stronger among hypoalbuminemic (<3.8 mg/dl) patients and those with a lower dietary protein intake (<1 g/kg/day). Conversely, in African American patients, a high serum LDLc (>100 mg/ml) was associated with a higher adjusted CV death hazard ratio. The authors of the study cautioned that the so-called reverse epidemiology observations of lipids with mortality in dialysis patients should not be considered causal or lead to the nihilistic conclusion of no clinical benefit from cholesterol lowering therapy. Another small study similarly showed lower TC

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. predicted all-cause and CV mortality in hemodialysis patients [24]. Other studies in hemodialysis patients have also shown that higher TG, TG/HDLc ratio, non-HDLc, and non-HDLc/HDLc ratio were inversely associated with mortality risk in hemodialysis patients in models adjusted for markers of malnutrition and inflammation [25, 26]. In the same cohort, higher levels of HDLc [27] and increases in HDLc [28] were associated with higher mortality risk in hemodialysis patients in analysis with MICS adjustment. A further study comparing HDLc-mortality associations in East Coast versus West Coast Hispanic dialysis patients showed the relationship of higher HDLc with mortality differed according to coast and may be explained by geographical variances in racial-ethnic and genetic distinctions [29].

Associations of lipid markers with outcomes in peritoneal dialysis patients have conflicting results. In 1053 continuous ambulatory peritoneal dialysis (CAPD) patients, lower TC levels were associated with a higher risk of all-cause mortality, including in those taking or not taking lipid-modifying medications [30]. Additionally, in a cohort of 749 Korean incident peritoneal dialysis patients, lower TC, LDLc, TG, and HDLc were associated with a higher all-cause mortality risk, and lower TC and LDLc were associated with higher CV mortality risk. However, these associations may be impacted by MICS as well. In a study of nondiabetic CAPD patients, metabolic syndrome (MetS), characterized by elevated TG and lower HDLc, was a predictor of mortality in patients with serum albumin >3.0 g/dl, but not in those with albumin <3.0 g/dl [31]. Another study similarly showed that the association between MetS and mortality in peritoneal dialysis was attenuated after adjustment for CRP. One small study has shown that higher very-low-density lipoprotein cholesterol (VLDLc) was associated with higher mortality risk in peritoneal dialysis patients even after adjustment for MICS covariates [32]; however, additional studies are needed to support this different finding.

In transplanted patients, elevated levels of TC or its subfractions and elevated TG levels have not been shown to be associated with increased risk for patient mortality or allograft loss [33], possibly due to the variability of lipoprotein concentrations and of the factors affecting graft survival. Across CKD stages, the relationship of lipids with mortality and CV outcomes is paradoxical to that observed in the general population.

Dyslipidemia as a Precursor of CKD

CKD is a frequent complication of type 2 diabetes, and type 2 diabetes is the leading cause of CKD [1]. The majority of patients with type 2 diabetes also have features of MetS, including obesity, hypertension, elevated TGs, and low HDLc [2, 34]. In patients with MetS, dyslipidemia occurs due to an increased production and decreased catabolism of VLDLc, thereby resulting in an increase in the fraction of small dense low-density lipoprotein (sd-LDL) and catabolism of HDL attributable to insulin resistance (see Figure 34.1 for a basic comparison of density and lipid

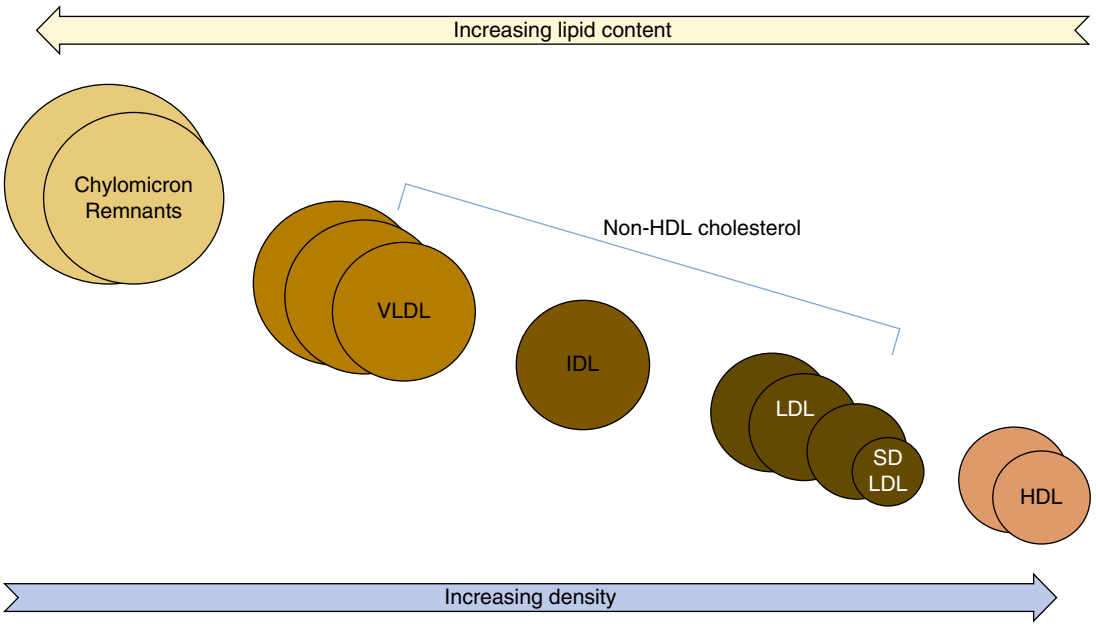

Figure 34.1 Serum lipoproteins: relative density and lipid content. HDL, high-density lipoprotein; IDL, intermediate density lipoproteins; LDL, low-density lipoprotein; SD LDL, small dense low-density lipoprotein; VLDL, very low-density lipoprotein.

content across serum lipoproteins, and Figure 34.2 for a summary of MetS impact on VLDL).

Patients with MetS also have an increased likelihood of developing CKD [35, 36] and the strength of this association seems to increase with the number of MetS components present [37]. Both high TG and low HDLc have been independently associated with the risk of incident CKD [38]. The higher quartile of TG/HDLc ratio at baseline was significantly associated with greater decline in eGFR and increase in urinary protein excretion after adjustment for confounding factors [39, 40]. We conclude that changes in the concentration and composition of lipoproteins characteristic of MetS and type 2 diabetes predict incident CKD and consequently may be transferred to the CKD population and become a feature of CKD.

Dyslipidemia in Nonproteinuric NDD-CKD and Hemodialysis

Dyslipidemia in nonproteinuric NDD-CKD patients is characterized by the same features as dyslipidemia in MetS:

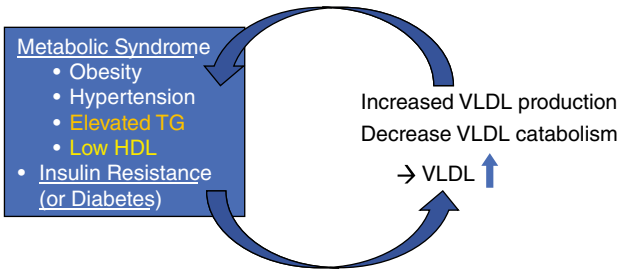

Figure 34.2 Metabolic syndrome impact on lipid metabolism. HDL, high-density lipoprotein; TG, triglycerides; VLDL, very low-density lipoprotein.

increases in TG concentration, changes in LDL subfraction distribution, and decreases in HDLc concentration.

Changes in Triglyceride-carrying Lipoprotein Particles in NDD-CKD

Similar to MetS, dyslipidemia of CKD patients without significant proteinuria is characterized by hypertriglyceridemia, elevated plasma levels of VLDLc, intermediate density lipoprotein (IDL), and chylomicron remnants (Figure 34.1), and additionally low plasma HDLc and its main apolipoprotein (Apo), ApoA-I [41]. While in MetS the primary cause of hypertriglyceridemia is an increased production of VLDL TGs attributable to the increased flow of free fatty acids [42, 43], in NDD-CKD without proteinuria a decreased VLDL metabolism appears to be the main cause [44, 45].

The average TG concentration increases with CKD stage and an inverse association between eGFR and TGs was described [10, 46–48]. The pathophysiology of the defect in TG metabolism in CKD is attributable primarily to an increase in ApoC-III resulting in a decreased catabolic rate of VLDL and IDL [49], with ApoC-III concentration as the only independent predictor of clearance defects (Figure 34.3). On VLDL particles, ApoC-III is an inhibitor of lipoprotein lipase (LPL) activity responsible for VLDL catabolism. In CKD, the ApoC-III fractional catabolic rate is also decreased [50], leading to the increase in its concentration.

The decreased TG removal in CKD is also in part attributable to a decrease in LPL function, although the contribution is not as high as that of ApoC-III [51]. In addition, hypertriglyceridemia of nonproteinuric NDD-CKD is mainly attributable to a lipolytic defect due to a progressive increase in ApoC-III as CKD progresses.

Changes in Triglyceride-carrying Lipoprotein Particles Common to NDD-CKD and Hemodialysis

Additional pathophysiological mechanisms leading to dyslipidemia have been described in hemodialysis patients, although it is not clear to what extent these mechanisms also operate in earlier stages of CKD. In hemodialysis patients, concentrations of VLDLc ApoC-II/C-III ratio were lower (attributed to higher ApoC-III concentrations) even in the presence of normal TG [52]. In addition, studies described the presence of an inhibitor of LPL in the plasma of hemodialysis patients [53, 54]. Another contributor to hemodialysis-related changes in LPL is the progressive decrease in the presence of an activating factor for LPL in the HDL fraction of the serum [55]. Hemodialysis patients also have a defect in the removal of chylomicron remnants [56, 57], resulting in a prolonged circulation time. These studies could be interpreted as a severe defect in postprandial lipoprotein metabolism, specifically a decrease in remnant uptake by the liver, in hemodialysis patients. Other studies have shown that the function of lipases is reduced by increased levels of the angiopoietin-like protein 3 (ANGPTL3) and 4 which is markedly increased in hemodialysis [58, 59]. LPL level seems to decrease with dialysis duration [60], indicating a time effect on the lipolytic deficiency. The use of heparin (which detaches LPL from the endothelium and releases it into the circulation) in hemodialysis has an additional impact on atherogenicity [61]. After a hemodialytic procedure with heparin, readily available LPL in circulation readily metabolizes VLDL, resulting in a significant reduction of TG concentration and an increase in VLDL atherogenic remnants. The authors interpreted their data as showing that heparin administration during hemodialysis leads to a massive production in atherogenic particles because of the acute stimulation of LPL activity not followed by an efficient removal of lipoprotein remnants.

Changes in LDL Common to Nonproteinuric NDD-CKD and Hemodialysis

Although LDLc concentrations in nonproteinuric CKD patients are similar to those of normal controls, there are important differences in LDL kinetics in nonproteinuric CKD and hemodialysis patients as compared to control patients. The fractional clearance rate of LDL is markedly diminished and possibly decreases with the decrease in eGFR [62]. However, since LDL and IDL levels are regulated by both clearance as well as production, there is no clear relationship between clearance and concentration [63].

Since the majority of patients with nonproteinuric CKD and hemodialysis have hypertriglyceridemia, the spectrum of LDL particles is shifted toward smaller and denser particles [64, 65]. As with TG concentrations, sd-LDL is significantly associated with CKD stage and BMI [66]. In hemodialysis patients, even in normotriglyceridemic patients, there are changes in the composition of lipoproteins indicating a shift toward denser subfractions in the absence of hypertriglyceridemia [67], while in hypertriglyceridemia there is an increase in particle number indicating increased atherogenicity for the same amount of LDL cholesterol [68].

Increased oxidative stress is a major contributor to the increased atherosclerosis and CV morbidity and mortality found in uremia [69]. In different stages of CKD there is a marked increase in oxidized LDL [70] or of antibodies against oxidized LDL [71].

Another characteristic of LDL spectrum lipoproteins in CKD is an increased concentration of lipoprotein (a) (Lp(a)), a lipoprotein subclass associated with atherogenic risk. Lp(a) levels have been found to be elevated across the entire spectrum of eGFR in CKD patients [72]; kidney function was inversely correlated with Lp(a) levels, but this relationship is present only in nonproteinuric CKD and for subjects with large Apo(a) isomorphs [73]. The increase in Lp(a) concentration in CKD is attributable to a decreased removal rate [74]. Elevated Lp(a) is associated with a more rapid eGFR decline [75].

Dyslipidemia in Nephrotic Syndrome and Peritoneal Dialysis

In nephrotic syndrome and peritoneal dialysis, additional pathophysiological mechanisms are added to those described for nonproteinuric CKD and hemodialysis.

Nephrotic Syndrome

Early studies described an increase in the production of lipoproteins in nephrotic syndrome in proportion with albuminuria [76–78]. However, this conclusion was questioned when an improved technology was used [79] and showed that VLDL Apo B100 levels were primarily increased as a consequence of a decrease in fractional catabolic rate. However, LDL Apo B100 synthesis rate was significantly increased in nephrotic patients compared to controls and was greater than that of VLDL Apo B100 in some patients, suggesting that LDL may be, in part, derived from a direct secretory pathway. These data indicate that increased VLDL in nephrotic patients results from a decreased catabolism, while increased LDL results from increased synthesis. However, patients with nephrotic syndrome with no

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

hypertriglyceridemia have low fractional catabolic rates of LDL Apo B and no overproduction of LDL Apo B [80]. A receptor mediated uptake of LDL defect plays an important role in regulating LDL Apo B concentration [81].

Patients with nephrotic syndrome were shown to display VLDL enriched with cholesteryl esters (CE), with a CE/TG ratio approximately twice that of controls and plasma cholesteryl ester transport protein (CETP) concentration significantly increased compared to controls. CETP is involved in HDL/VLDL metabolism and mediates the transfer of CE in HDL to VLDL in exchange for TGs. Treatment with corticosteroids or angiotensin receptor blockers reduced proteinuria and LDLc and normalized plasma CETP [82–84]. The drop in CETP correlated with the decrease in LDLc

Other authors identified a role for elevated proprotein convertase subtilisin/kexin type 9 (PCSK9) in the hyperlipidemia of nephrotic syndrome [85, 86] and PCSK9 is corrected by dialysis and normalized after renal transplant [87]. PCSK9 is an enzyme that mediates the catabolism of the LDL receptor, and thereby its inhibition results in an increased LDL receptor number. Plasma PCSK9 level is directly and strongly correlated to total and LDL cholesterol concentrations.

Peritoneal Dialysis

In 1987, Sniderman et al. showed that compared to hemodialysis patients, CAPD patients have higher TC, LDLc, TG, Apo B, LDL-ApoB, and VLDL-ApoB [88, 89]. In addition, the clearance of LDL in CAPD patients has been shown to be markedly decreased in comparison to that of control subjects [90]. Elevated levels of plasma VLDL and reduced levels of plasma HDL were maintained in these patients throughout 5 years of CAPD, whereas the initially increased LDL levels showed a tendency toward normalization [91]. All plasma lipoproteins (VLDL, IDL, LDL, and HDL) are present in the peritoneal effluent. The peritoneal protein clearance correlates positively with plasma levels of TG and LDL, and negatively with plasma HDL. In addition, an inverse correlation was observed between plasma levels of HDL and its peritoneal clearance. The continuous peritoneal loss of HDL and the hypertriglyceridemia contribute most to the persistent low plasma levels of HDL in CAPD patients.

HDL Changes in CKD

In CKD, HDL undergoes a number of structural and functional changes. Researchers have explained that these changes may explain why the relationship of HDL with outcomes in kidney disease patients changes across progressing disease [27, 28].

HDL Structural Changes

In 1966, Lewis et al. described that in anephric patients, HDL is very low, and it increases after transplantation [92]. In uremic patients, hypertriglyceridemia and low LPL (signifying a reduced lipid metabolism) are associated with higher HDLc [93]. Inflammation contributes to the reduction in HDL concentration in end-stage renal disease (ESRD) [94]. ApoA-I, the main HDL lipoprotein, changes inversely with serum concentrations of CRP and the inflammatory marker α 1 acid glycoprotein (α 1AG). Apo A-I fractional catabolic rate was 50% increased in hemodialysis patients, whereas the production rate remained unchanged [95]. Oxidized HDL is also increased in dialysis patients [96].

The protein composition of HDL is also changed, with a higher retinol-binding protein 4, serum amyloid A1, and lipoprotein-associated phospholipase A2, and lower vitronectin [97–99]. The composition changes also correlate with the observed impaired ability of uremic HDL to promote cholesterol efflux from macrophages.

Another characteristic change in HDL composition in CKD, but not in nephrotic syndrome, is lecithin cholesterol acyltransferase (LCAT) deficiency [100, 101]. Paroxonase 1 (PON1), a strong anti-atherogenic enzyme of HDL, activity has also been shown to be diminished in CKD [102]. PON1 concentration is significantly and positively associated with HDLc and Apo A1 [103]. PON1 activity was also shown to be lower in CAPD compared with hemodialysis [104]. PON1 activity in CKD subjects predicted a higher risk of incident long-term adverse CV events [105].

HDL Functional Changes

To demonstrate the functional changes of HDL in CKD, the biological activity of high-density lipoprotein particles in patients with chronic kidney disease (HDL-CKD) is compared with the same activity in healthy controls (HDL-H). HDL-CKD, but not HDL-H, promoted endothelial superoxide production, substantially reduced nitric oxide bioavailability in endothelial cells in vitro, and increased arterial blood pressure in mice [106]. HDL-H, but not HDL-CKD, inhibits the production of inflammatory cytokines by stimulated peripheral monocytes [107]. Compared with HDL-H, HDL-CKD increased the cytokine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

response and disrupted macrophage chemotaxis in human umbilical vein endothelial cells [108]. When the efflux capacity of HDL was tested directly, HDL-CKD from dialysis patients was dramatically less effective than normal HDL-H in accepting cholesterol from macrophages [109]. Statins had no effect on the impairment of HDL-mediated efflux. Cholesterol acceptor capacity of HDL-CKD from dialysis patients was confirmed to be markedly reduced compared with that of HDL-H [110].

Dyslipidemia in Patients with Renal Transplant

There is also a marked variability of lipoprotein concentrations in renal transplant patients [111]. This lipoprotein variability is at least in part attributable to medications used for graft survival, and also to the intensity of statin therapy.

Prednisone

Prednisone in transplanted patients treated with cyclosporin (CsA) resulted in increases in HDL cholesterol [112, 113]. High-dose prednisone resulted in decreased Lp(a) levels 1 week after transplantation [114]. As steroid doses were gradually tapered, Lp(a) concentrations subsequently increased. Transplanted patients treated with alternate day steroids had a significant decrease in both serum TG and TC [115].

Calcineurins

The drugs from this class are CsA and tacrolimus (TAC), and each have a very different metabolic profile. When transplanted patients are treated with prednisone, with or without CsA, the patients receiving CsA demonstrated increased plasma concentrations of LDLc [116]. CsA blood levels are inversely associated with serum Lp(a) levels in renal transplant recipients; this association is independent of prednisone therapy [117]. CsA therapy has opposing effects on plasma Lp(a) and LDLc accumulations. Replacing CsA with TAC, in one study of transplanted patients, resulted in significant decreases in TC, LDLc, and ApoB levels [118]. In other studies, a switch from CsA to TAC significantly decreased TG, ApoB, LDLc, and TC levels [119, 120]. Changes in HDLc in these studies were variable. In a small randomized trial of CsA versus TAC in renal transplantation, the CsA treatment group had significant increases in TC, TG, LDLc, and HDLc [121]. However, the advantages of TAC over CsA in terms of hyperlipidemia should be balanced against the risk of new onset diabetes [122, 123].

Mammalian Target of Rapamycin Inhibitors

The drugs from this class are sirolimus and everolimus, and they have a similar metabolic profile [124]. They are almost invariably used together with calcineurin inhibitors. Conversion of transplanted patients from TAC to sirolimus resulted in a significant increase in TC, LDLc, and TG [125, 126]. This effect is the result of reduced catabolism of Apo B100-containing lipoproteins [127]. During sirolimus uptitration, TG, Apo B100, and ApoC-III levels increased in a dose-dependent manner [128]. Sirolimus expands the free fatty acid pool, and therefore the incorporation of a labeled fatty acid, [13 C4]-palmitate, into TG of VLDL, IDL, and LDL was decreased. The authors suggested that sirolimus-related increased free fatty acid flow is due to an altered insulin signaling pathway resulting in an increased hypertriglyceridemia. Hyperlipidemia induced by sirolimus will also vary with the genetic polymorphism of adenosine triphosphate (ATP)-Binding Cassette (ABC)B1-3435, ABCB1-1236, and IL-10-1082 genes [129].

Lipid-altering Trials in CKD Patients

In 2011, the highly anticipated results of the largest study to date examining the effectiveness of statin therapy in patients with CKD were published. The Study of Heart and Renal Protection (SHARP) included 9270 CKD patients (4650 assigned to combined statin plus ezetimibe therapy and 4620 patients on placebo) [130] aged 40 years or older with no known history of MI or revascularization; 3056 of the patients were on dialysis at the time of study entry. Unlike other prior statin trials that only included NDD-CKD stage 3 patients or dialysis patients, SHARP notably expanded the criteria to include not only those two groups but additionally patients with NDD-CKD stage 4 (41% eGFR 15–29 ml/min/1.73m^2) and stage 5 (20% eGFR < 15 ml/min/1.73m^2). The study had enrollment sites worldwide and included 72% White, 3% Black, 23% Asian, and 3% other or unspecified patients. The mean ± SD age of enrolled patients was 62 ± 12 years, and 31% of patients were age 70 or older. The study's primary outcome of interest was first major atherosclerotic event (nonfatal MI or coronary death, non-hemorrhagic stroke, or any arterial revascularization procedure). Compared to patients on placebo, patients in the simvastatin plus ezetimibe treated arm had a 17% reduction in major atherosclerotic events,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

25% reduction in nonhemorrhagic stroke, and 21% reduction in arterial revascularization procedures. However, there was no difference in the number of coronary deaths, and differences in the number of nonfatal MIs did not reach statistical significance. Subgroup analysis revealed the outcome risk reductions were larger in patients with higher baseline BMI, TC, and LDLc. Strikingly, there was an incrementally lower benefit as CKD progressed with lower eGFR levels or higher excreted microalbumin; however, subgroup analysis did not show significant heterogeneity across these groups. In the SHARP study, there was no excess risk of adverse events for patients on statin therapy.

Soon after the results of the SHARP trial were published, meta-analysis studies pooled the results of statin trials in CKD patients (including SHARP) to determine statin efficacy. Palmer et al., as part of the Cochrane collaboration, reviewed over 50 studies with over 45 000 CKD patients and found that statin therapy in NDD-CKD reduced the risk of major CV events by 18%, risk of all-cause mortality by 21%, risk of CV mortality by 23%, and risk of MI by 45% [131]. The study was not able to find an association between statin therapy and stroke prevention. Although the meta-analysis was not able to thoroughly evaluate potential harms from statin therapy due to lack of systematic reporting of adverse events across studies, no significant association between statin therapy and adverse events, including elevated creatinine kinase, liver function abnormalities, and cancer, was found in the limited data that was available. Similarly, Hou et al. also conducted a meta-analysis that included 31 trials and nearly 50 000 patients with CKD and found that statin therapy reduced CV events by 23%, coronary events by 18%, and all-cause and CV deaths by 9%, but no significant associations were found for stroke or adverse events, including liver function or muscular disorders [132]. Moreover, Hou et al. corroborated the findings of the SHARP trial in demonstrating a decreasing benefit of statin therapy across worsening CKD stage. The meta-analysis found that for CKD stage 3 (which also included two small studies of CKD stage 2 patients), stage 4 (which included one other study aside from SHARP), and stage 5 NDD-CKD (SHARP only) CV outcomes were reduced by 31%, 22%, and 18%, respectively, for statin-treated patients compared to placebo patients.

Statins in Hemodialysis

The SHARP trial also included 3023 patients on dialysis, of which 84% were hemodialysis patients. The study showed there was no heterogeneity of effect for the efficacy of the treatment between dialysis and NDD-CKD patients. However, because the risk ratio for the dialysis subgroup did not reach statistical significance (RR 0.90, 95% CI 0.75, 1.08), many clinicians have interpreted this finding to show that the combined simvastatin plus ezetimibe therapy compared to placebo failed to reduce major outcomes in dialysis patients. Two other larger trials previously evaluated the benefit of initiating statin therapy in dialysis patients. The Deutsche Diabetes Dialyse Studie (4D) [133] enrolled 1255 type 2 diabetic patients on maintenance hemodialysis (median dialysis vintage 8 months) and randomized them to receive either 20 mg of atorvastatin daily or placebo. Lipid-lowering benefit was observed in the statin-treated group after only 4 weeks of the trial, where LDL was reduced by 42% in statin-treated patients. However, after a median follow-up of 4 years there was no difference in primary endpoints (composite of death from cardiac causes, nonfatal MI, and stroke). When outcomes were evaluated separately, statin patients had a reduced risk of all cardiac events, no difference in all-cause mortality risk, but a higher risk of fatal stroke. The Study to Evaluate the Use of Rosuvastatin in Subjects on Regular Hemodialysis: An Assessment of Survival and Cardiovascular Events (AURORA) [134] also investigated the effects of statin (rosuvastatin 10 mg/day) versus placebo therapy; this study included 2776 hemodialysis patients (median dialysis vintage 3.5 years) aged 50–80 years. Similar to 4D, after 3 months the LDL in the statin-treated group had reduced by 43% compared to 2% in the placebo group. However, also similar to 4D, after a follow-up of 3.8 years there was no benefit of statin in reducing the primary endpoint (death from CV causes, nonfatal MI, or nonfatal stroke). Statins also had no effect on the individual components of the primary endpoint and no significant effect on all-cause mortality.

The Hou et al. meta-analysis also examined associations of statin therapy with outcomes in dialysis patients (including the above three trials) and determined that although there was a lack of a significant association for mortality outcomes in the dialysis patients, there was no heterogeneity of effect for all-cause mortality or CV death between dialysis and NDD-CKD patients. However, associations did differ for coronary event and stroke outcomes, which found no benefit of statin therapy for dialysis patients. There was also no heterogeneity of effect between dialysis and NDD-CKD for adverse event outcomes, including liver disorders, creatinine kinase elevation, new cancer onset, muscle pain, and serious adverse events [132].

Statins in Peritoneal Dialysis

Clinical trials examining statin initiation in peritoneal dialysis are limited. SHARP included only 496 peritoneal dialysis patients and failed to find a significant benefit of statin therapy

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in reducing the primary endpoint, although estimates trended toward statin benefit (RR 0.70, 95% CI 0.46, 1.08). However, a propensity score matched retrospective United States Renal Data System (USRDS) cohort study of 1053 peritoneal dialysis patients found that use of lipid-modifying medication (mostly statins) was associated with 26% and 33% lower risk of all-cause and CV mortality, respectively; this was particularly the case in patients with elevated cholesterol levels [135]. Additionally, a propensity score matched cohort analysis of 1024 Korean peritoneal dialysis patients found statin use was associated with 45% lower mortality risk [136]. As discussed above, peritoneal dialysis patients have higher levels of ApoB containing lipoproteins [137], and thereby statin benefit may be different in peritoneal patients compared to hemodialysis patients. Additional trials examining statin initiation in peritoneal dialysis patients and reduction of CV events should be undertaken.

The conclusion drawn from the dialysis trials as summarized by meta-analysis was that statin therapy appears to be ineffective in reducing CV events when initiated in patients already on dialysis. As will be discussed below, these trials provided the evidence to determine guidelines suggesting not to initiate statin therapy in dialysis patients, but to continue therapy after transition to dialysis when statins were already started in late-stage CKD. Although continuation of statin therapy has not been examined in a clinical trial, a recent cohort study [138] of US veteran patients transitioning to dialysis found that continuation of statin therapy after dialysis transition was associated with a 28% lower risk of all-cause mortality and an 18% lower risk of CV mortality in adjusted analysis compared to patients that discontinued statin use. As noted in the invited commentary for this study, this analysis is supportive of statin continuation, but not sufficient "until high-quality randomized clinical trials evaluating this question are conducted" [139].

Statins in Renal Transplant

The use of statins for prevention of CV events in renal transplant patients has to date only been tested in one clinical trial. The Assessment of LEscol in Renal Transplantation (ALERT) trial randomized 2102 renal transplant recipients to fluvastatin 80 mg/day versus placebo and compared the risk of the primary endpoint (cardiac death, nonfatal MI, or coronary revascularization) [140]. After a mean of 5.1 years, LDLc was lowered by 32% in statin-treated patients; however, risk reduction for the primary endpoint was not significant. There were, however, fewer cardiac deaths or nonfatal MI events in the fluvastatin group than in the placebo group. Coronary intervention procedures and other secondary endpoints did not differ significantly between groups. A post hoc analysis of ALERT found benefit of fluvastatin in reducing an alternative primary endpoint of cardiac death or definite nonfatal MI. In subgroup analysis for this endpoint, they also found significant benefit of fluvastatin in patients who were younger, nondiabetic, nonsmokers, and without pre-existing CVD. However, the authors caution that this subgroup analysis is exploratory and overlapping confidence intervals demonstrated no heterogeneity of effect across comparison strata [141]. Another post hoc analysis determined that 32% of patients enrolled in ALERT had MetS and risk of major adverse CV events were reduced by 53% in this group, thereby potentially identifying a group of renal transplant recipients who may benefit from statin therapy. When the study investigators conducted an additional post hoc analysis on patients who were less than 4.5 years after renal transplant at study baseline, they found risk of cardiac death and nonfatal MI was reduced by 56% and concluded the analysis supported introduction of statin therapy early in the post-transplant period [142]. Lastly, an extension study offered open label fluvastatin for two additional years to patients who completed the ALERT trial and included 1652 (92%) of ALERT trial participants. Patients randomized to fluvastatin had a 29% reduction in cardiac death or definite nonfatal MI [143]. A meta-analysis by Palmer et al. summarized statin trials in renal transplant recipients, including the ALERT study, and suggested that statin therapy may reduce CV endpoints, however the current data lacks precision to confirm any benefit and further trials are needed [144].

Statins and Progression of CKD

The benefit of statin therapy in reducing progression of CKD has been examined in most clinical trials; however, the results have been conflicting. In the meta-analysis by Palmer et al. no conclusions could be made about whether statin therapy slowed CKD progression. Although the analysis found a significant benefit of statin therapy on decreasing proteinuria, there was no benefit found for reducing the number of patients transitioning to ESRD. This latter analysis was based solely on the results of the SHARP trial. Another meta-analysis similarly found a benefit of statins in reducing proteinuria outcomes in patients with urinary protein excretion of 30 mg/day or more [145]. They also found that CKD patients receiving statin therapy compared to placebo had less of an eGFR reduction by study end; however, these results seem largely influenced by one study as no benefit was observed in the other nine studies included in the analysis. A more recent meta-analysis by Sanguankeo et al. supported these latter results, finding that statin therapy was associated with a modestly slower

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. eGFR change per year as compared to placebo. They further found that these results were driven by significant findings for high-intensity statins as no significant difference in change in eGFR was found for low or moderate intensity statins. However, in this meta-analysis they found the data were insufficient to study impacts on proteinuria. Other studies have claimed differences in preserving renal function according to statin type or brand [146–148]. To date, the data on the effects of statin on progression of CKD and protein excretion are variable and modest. Additional data are needed to conclude whether statins provide renal protection in patients with CKD.

Statins and Adverse Outcome/ Safety in CKD

Statin safety may be of particular concern in CKD patients who typically also have higher comorbidity and polypharmacy, and may have a higher rate of metabolite accumulation due to decreased renal function and uremia-related muscle injury that could increase risk of myopathy [149]. As mentioned above, results of the meta-analyses evaluating the safety of statin therapy in CKD patients (both non-dialysis and dialysis) demonstrated no excess risk of adverse events such as elevated creatinine kinase, liver function problems, muscle disorders, or cancer onset with statin treatment. Palmer et al., however, noted lack of systematic reporting may contribute to the inability to thoroughly evaluate adverse events. A recent statement from the ACC further supported findings of no excess risks and summarized concerns of statin safety [150]. The report found risk of events including hepatotoxicity, rhabdomyolysis, and new onset of diabetes to be very low at 0.2% or less per year and found no convincing evidence of risk of cancer, cataracts, cognitive dysfunction, peripheral neuropathy, erectile dysfunction, or tendonitis with statin use. In CKD and in particular in both hemodialysis and peritoneal dialysis patients, statins appeared to be safe even in consideration of the polypharmacy in these patients. Although there was no excess risk reported for myopathy, one randomized clinical trial found CKD was a risk factor for myopathy in patients treated with simvastatin 80 mg. The statin safety report therefore provides a table summarizing how to modulate statin therapy with CKD progression and maximum dose per statin type in patients with mild to moderate CKD and ESRD to avoid myopathy risks. The report additionally addresses drug–drug interaction of cyclosporine and statin in renal transplant patients. Cyclosporine has been shown to increase blood levels of statins, which may increase risk of myopathy [151]. According to statin safety guidelines, cyclosporine should be avoided in patients treated with atorvastatin, simvastatin, lovastatin, and pitavastatin, and statin doses should be lowered in patients treated with cyclosporine and fluvastatin, pravastatin, and rosuvastatin.

Statin Dose

Caution for adverse events in CKD patients such as muscle disorders may lead clinicians to prescribe lower dose therapy. One post hoc analysis [152] in 2978 Japanese NDD-CKD patients without history of ischemic heart disease or stroke and moderate hypercholesterolemia evaluated the benefit of low-dose statin therapy (pravastatin 10–20 mg daily) versus placebo and found reduction in coronary heart disease events, all-cause mortality, and stroke. However, results of meta-analyses in CKD patients showed that benefit of statin is related to the strength of LDL lowering and therefore stronger therapy may still be indicated. Most clinical trial data included in the above-mentioned meta-analyses [132] of CKD patients included trials where patients received moderate dose statin therapy versus placebo. The SHARP trial used a combination of moderate dose statin plus ezetimibe, leading to more intense lipid-lowering therapy. To date, two post hoc analyses of randomized control trials have examined the benefit of more aggressive lipid lowering with high-dose statin in CKD patients. The Treating to New Targets (TNT) study [153] randomized patients to atorvastatin 80 mg/day (high dose statin) or 10 mg/day (moderate dose statin) and found the major CV endpoint was reduced by 32% for 3107 CKD (mostly stage 3) patients and reduced by 15% in patients with normal eGFR (median follow-up of 5 years). Moreover, the study reported no difference in safety concerns between the CKD and normal eGFR groups. In the Justification for the Use of statins in Prevention; an Intervention Trial Evaluating Rosuvastatin (JUPITER) primary prevention trial [154], high-dose statin (rosuvastatin 20 mg) was compared with placebo among men and women free of CVD who had LDLc <130 mg/dl and elevated high-sensitivity CRP. The post hoc analysis compared CV events in 3267 patients with moderate CKD at study entry and 14 528 with normal eGFR. After a median follow-up of 1.9 years, statin-treated CKD patients had a 45% reduction in the primary endpoint and a 44% reduction in all-cause mortality. Additionally, in CKD patients there were no differences between statin therapy and placebo for adverse events. However, statin-treated CKD patients had a statistically significant but not clinically different higher HbA1c at 24 months, but no differences in fasting glucose were observed. Although results in CKD patients were not specifically discussed, in another post hoc analysis of the JUPITER trial, Ridker et al. found that treatment with statin therapy was associated with a fast time to diagnosis of diabetes [155].

Statins and Diabetes Risk

A number of meta-analyses have summarized statin trials in evaluating risk of incident diabetes and found statin treatment was significantly associated with an increased risk [156–160]. The magnitude of risk may differ depending on diabetes definition, statin dose [158, 159, 161] duration of exposure to statin therapy [162], and statin type [160, 163] and may further be explained by bias in competing risk of mortality in placebo treated patients [164]. The mechanism of action by which statins increase the risk of incident diabetes is not clear, and several mechanisms have been postulated [165–168]. To date, no study has directly examined risk of diabetes incidence in statin-treated patients with CKD. Authors of the cited studies [156–160] agree that risk of diabetes incidence does not outweigh the benefits of CV risk protection and improved survival with statin therapy. However, the overall safety of statins (in particular high-dose statin) in CKD patients still needs to be addressed in future studies.

Nonstatin Lipid Lowering in CKD

Although statin therapy is the main course of treatment for dyslipidemia, a number of studies have evaluated the potential benefits of nonstatin lipid-lowering therapies in CKD. The nonstatin lipid-lowering medications include those targeted at lowering cholesterol (bile acid binding resins, ezetimibe, PCSK9 inhibitors) and those altering lowering triglyceride and/or elevating HDL levels (fibrates, niacin, omega (n–3) fatty acids).

Cholesterol

Bile Acid Binding Resins

Bile acid binding resins, including cholestyramine, colestipol, and colesevelam, are another cholesterol-lowering medication often given to statin-intolerant patients. They are less potent than statins at decreasing TC and LDLc, and have been associated with an increase in TG level [169]. The Lipid Research Clinics Coronary Primary Prevention Trial (LRC-CPPT) randomized 3806 men free of coronary artery disease with elevated LDLc (>175 mg/dl) to cholestyramine with an intended dose of 24 g/day versus placebo [170]. After 7.1 years there was a significant 19% reduction in the incidence of nonfatal MI or coronary death. The average serum creatinine in enrolled patients was 1.03 mg/dl and effect modification by CKD was not conducted.

The phosphate binder, sevelamer, used in CKD patients to lower serum phosphorous levels was shown to act as a bile acid binder in CKD patients and lowered LDLc as well as increasing HDLc [171]. Colestilan, a phosphate binder used in Japan, was shown to be equivalent to sevelamer in phosphate binding and LDLc lowering efficacy [172] and similar to simvastatin in LDLc lowering [173]. The benefit of sevelamer in reducing adverse outcomes in CKD patients has been demonstrated [174–176]. One small study compared sevelamer versus calcium acetate in atorvastatin-treated dialysis patients and found greater LDL lowering in sevelamer-treated patients, but no difference in coronary artery calcium progression between treatment arms after 1 year [177]. Whether bile acid resins, including sevelamer, confer CV benefit in CKD patients already on statin therapy needs to be further evaluated.

Ezetimibe

Ezetimibe is another cholesterol-lowering medication that acts similarly to bile acid resins by decreasing cholesterol absorption. When added to statin therapy, ezetimibe can reduce cholesterol levels by an additional 23–24% on average. The Improved Reduction of Outcomes: Vytorin Efficacy International Trial (IMPROVE-IT) [178] evaluated the effect of ezetimibe combined with simvastatin, as compared with simvastatin alone, in 18 144 patients who had an acute coronary syndrome and whose LDL cholesterol values were within guideline recommendations. Over a median follow-up of 6 years, patients on the combined therapy had significantly greater benefit of LDL lowering and lower risk of the composite endpoint of nonfatal MI, unstable angina requiring rehospitalization, coronary revascularization (≥30 days after randomization), or nonfatal stroke. A post hoc analysis of IMPROVE-IT evaluated associations across eGFR levels and found patients with normal eGFR had a 12% risk reduction, while those with moderate CKD had a 13% risk reduction of the primary endpoint [179]. The analysis found no difference in change in mean eGFR over the 7 years of follow-up between study arms, yet also found no excess of adverse risk in the combined therapy patients. The results of this post hoc analysis combined with the SHARP trial results demonstrate the benefits of the combined statin plus ezetimibe therapy without any concerns of added risk in CKD.

PCSK9 Inhibitors

PCSK9 inhibitors have shown remarkable results in LDL lowering and CV benefits [180, 181].

The Long-term Safety and Tolerability of Alirocumab in High Cardiovascular Risk Patients with Hypercholesterolemia Not Adequately Controlled with Their Modifying Therapy (ODYSSEY LONG TERM) study randomized patients with high risk of CV events, LDLc ≥70 mg/dl, and receiving

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

treatment with statins at the maximum tolerated dose to alirocumab versus placebo [181]. At week 24, the mean percentage change in LDLc from baseline for alirocumab versus placebo was 62%, and the treatment effect remained over the 78 weeks of follow-up. A post hoc analysis found that the rate of CV events (death from coronary heart disease, nonfatal MI, fatal or nonfatal ischemic stroke, or unstable angina requiring hospitalization) was 48% lower in alirocumab-treated patients versus placebo. Patients with eGFR <60 ml/min/1.73m^2 for 3 months or more at the screening visit were included in the study as having a high risk of CV events; however, patients with eGFR <30 ml/min/1.73m^2 were excluded. A larger trial called ODYSSEY OUTCOMES randomized 18 924 patients aged 40 years or older to alirocumab versus placebo if they had acute coronary syndrome (acute MI or unstable angina) within 12 months prior to randomization, were on high-intensity statin, and had an LDLc ≥70 mg/dl. Patients with eGFR <30 ml/min/1.73m^2 were again excluded. At 4 months, alirocumab patients had a 56% greater LDLc reduction, which was maintained after the remaining course of follow-up. Over a median follow-up of 2.8 years, alirocumab-treated patients had a 15% lower risk of the primary endpoint (coronary heart disease death, nonfatal MI, ischemic stroke, or unstable angina requiring hospitalization). Patients also had a lower risk of all-cause death, but not CVD or coronary heart disease death. The results of this trial were presented at the 2018 American Cardiology Conference [182]. A post hoc analysis included eight of the earlier phase 3 ODYSSEY trials and found that among 4629 hypercholesterolemic patients (including 10% with impaired renal function), LDLc lowering and safety were comparable in CKD and non-CKD patients [183]. To date, information comparing clinical outcomes across CKD stages have not been presented for alirocumab.

The Further Cardiovascular Outcomes Research with PCSK9 Inhibition in Subjects with Elevated Risk (FOURIER) trial then tested the impact of evolocumab when added to high-intensity or moderate-intensity statin therapy in 27 564 patients with clinically evident ASCVD and LDL ≥70 mg/dl [180]. At 48 weeks follow-up, the mean percentage reduction in LDLc with evolocumab, as compared with placebo, was 59% (95% CI: 0.58–0.60), with 87%, 67%, and 42% of patients in the evolocumab-treated group achieving LDLc <70, <40, and <25 mg/dl, respectively. After a median follow-up of 2.2 years, evolocumab versus placebo reduced the risk of the primary composite endpoint (CV death, MI, stroke, hospitalization for unstable angina, or coronary revascularization) by 15%. Patients with eGFR ≥20 ml/min/1.73m^2 were included in the study [184]. At the 2018 American Society of Nephrology Kidney Week Conference, Charytan et al. presented the results of a post hoc analysis comparing the efficacy and safety of evolocumab versus placebo across baseline CKD stages [185]. The analysis showed that the FOURIER trial was composed of 29%, 55%, and 16% of patients with eGFR ≥90, 60–89, and <60 ml/min/1.73m^2, respectively. LDLc reduction with evolocumab versus placebo at 48 weeks, relative risk of the primary endpoint, and adverse events including eGFR decline was similar across CKD groups. They also found that absolute relative risks for the secondary endpoint (composite of CV death, MI, or stroke) were larger among those with eGFR <60 ml/min/1.73m^2, as compared to patients with eGFR ≥90 ml/min/1.73m^2.

PCSK9 inhibitors may have a great future in treating dyslipidemia in patients with CKD, although concerns have been raised regarding the affordability of this drug. Further studies are needed, in particular in dialysis and renal transplant patients.

Triglyceride/HDL

Fibrates

CKD patients with elevated TG may need additional or other lipid-lowering therapy as statins have been shown to only modestly reduce TG. Fibrates (including gemfibrozil and fenofibrate) have been used in clinical practice to decrease TG levels, modestly improve HDL, and reduce CV events. The Helsinki Heart Study [186] and the Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT) [187] demonstrated a reduction in CV events (fatal and nonfatal MI, and nonfatal MI or death from coronary causes, respectively) in fibrate-treated patients compared to placebo. However, in the larger Fenofibrate Intervention and Event Lowering in Diabetes (FIELD) trial, which included 9795 patients, fenofibrate did not reduce the primary endpoint (coronary heart disease death or nonfatal MI) but did significantly reduce nonfatal MI by 24%, total CV disease events by 11%, and coronary revascularizations by 21% [188]. The authors of the trial speculated that higher rates of off-protocol initiation of statin therapy in placebo-allocated patients may have masked a moderately larger treatment benefit. A meta-analysis addressed data concerning patients with CKD enrolled in VA-HIT and FIELD as well as other studies (10 studies, 16 869 CKD patients) [189] and found fibrates improved lipid profiles and reduced major CV events and CV deaths but not all-cause mortality and stroke in patients with mild to moderate CKD. The analysis also reported fibrates reduced albuminuria and reversibly reduced serum creatinine; however, it found no clear effect of preventing progression to ESRD.

In clinical practice, fibrates are typically recommended in addition to statin therapy. The Action to Control CV Risk

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in Diabetes (ACCORD) study evaluated the added benefit of fenofibrate versus placebo to statin in 5518 type 2 diabetic patients being treated with open-label simvastatin and found no benefit for fibrates in reducing CV outcomes [190]. In a post hoc analysis, which included 1910 patients with mild to moderate CKD and 3554 with normal eGFR, fenofibrate conferred no benefit in patients with CKD for primary or secondary outcomes [191]. However, in the non-CKD patients alone, the fenofibrate patients had a 36% reduction of CV mortality and a 44% lower rate of fatal and nonfatal congestive heart failure. Some studies have cautioned that the combined therapy may lead to safety concerns, such as rhabdomyolysis [192], but pharmacokinetic studies failed to show any changes in statin kinetic parameters when fenofibrate was tested against each statin separately [193–195]. Current Kidney Disease: Improving Global Outcomes (KDIGO) guidelines suggest that combined statin and fibrate therapy should not be used in patients with renal impairment due to concerns of adverse events and statin should be prescribed if trying to choose between the two medication classes [196]. However, if indicated, Canadian guidelines suggest that fibrates alone may be used in patients with mild CKD at lower doses (one-third of the normal dose) [197]. Additional studies may be needed to further evaluate whether the potential benefit of fibrate added to statin therapy in CKD patients outweighs any potential risks.

Niacin

Similar to fibrates, niacin is used to increase HDLc and reduce TG concentration. Early trials demonstrated that niacin added to statin monotherapy resulted in a reduction of carotid intima thickness, a marker of atherosclerosis. However, clinical trials failed to show CV benefit and introduced concerns regarding niacin safety. The Atherothrombosis Intervention in Metabolic Syndrome with Low HDL/High Triglycerides and Impact on Global Health Outcomes (AIM-HIGH) study enrolled 3414 patients with coronary artery disease (men below 40 mg/dl and women below 50 mg/dl) and high TG (over 150 mg/dl) with LDLc lowered to 40–80 mg/dl with simvastatin and ezetimibe, and randomized them to additional niacin or placebo therapy [198]. The primary endpoint evaluated was the first event of the composite of death from coronary heart disease, nonfatal MI, ischemic stroke, hospitalization for an acute coronary syndrome, or symptom-driven coronary or cerebral revascularization. After 36 months of follow-up, despite lipid improvement, there was no clinical benefit in reducing the primary endpoint from the addition of niacin to statin therapy. However, a post hoc analysis identified a subgroup of 439 patients with elevated TG (>200 mg/dl) and lower HDL (<32 mg/dl) that had a significant decrease in primary events, suggesting more extreme thresholds for enrollment should be used for niacin therapy [199]. Another post hoc analysis evaluated the efficacy of niacin in patients with stage 3 CKD and found no benefit in CV outcomes and a higher all-cause mortality risk in niacin-treated patients [200].

The Treatment of HDL to Reduce the Incidence of Vascular Events (HPS-THRIVE) trial enrolled 25 673 statin-treated patients with ASCVD and randomized them to niacin/laropiprant versus placebo [201, 202]. The study failed to show any benefit of the niacin therapy in reducing major CV events. Moreover, patients in the niacin therapy group had a higher risk of adverse events, including disturbances in diabetes control, diabetes incidence, and adverse events related to gastrointestinal and musculo-skeletal systems, skin, infection, and bleeding. Of note, the study included patients with a wide range of lipid levels who may not be indicated for niacin therapy, including over 49% of trial patients with an HDL ≥43 mg/dl and 74% with TG levels of <151 mg/dl.

Although a small pharmacokinetic study demonstrated that niacin may not need dose adjustments in patients with CKD [203], current KDIGO guidelines have stipulated that nicotinic acid has not been well enough studied in CKD, and given the risks of toxicity, it is currently not recommended for treatment of high TG [196]. Two review articles have summarized the beneficial properties of niacin, including anti-inflammatory properties, reducing serum phosphorous levels, and preventing HDL dysfunctionality [204, 205]. This suggests potential benefit of niacin therapy in patients with CKD, although further studies are needed.

Omega (n-3) Fatty Acids

Omega-3 fatty acids have also been used to target lowering of TG levels. The active ingredients include eicosapentanoic acid (EPA) and docosahexaenoic acid (DHA). In addition to dietary recommendations to consume fish rich in omega-3 fatty acids, there are two prescription strength medications on the US market: Lovaza, containing 375 mg DHA and 465 mg EPA, and Vascepa, containing 1 g purified EPA. A study found that the EPA-only Vascepa decreased LDLc, while the DHA-containing Lovaza increased it [206].

Clinical trials of omega-3 fatty acids for CV endpoints have yielded mixed results. The Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarto Miocardico-Prevenzione (GISSI-Prevenzione) study enrolled 11 324 survivors of MI and randomized them to Lovaza 1 g/day versus placebo [207, 208]. After 3.5 years, there was a significant 15% reduction in the combined endpoint of death,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nonfatal MI, and stroke. Similar results were observed in a study of over 6000 heart failure patients [209]. However, additional studies that examined the clinical benefit of omega 3-fatty acids as an add-on therapy to statins failed to show clinical benefit in patients with a history of MI [210–212]. The Japan EPA Lipid Intervention Study (JELIS) randomized 18 645 patients with or without pre-existing coronary artery disease and a serum cholesterol >250 mg/dl to statin plus either 1800 mg EPA or placebo [213]. After 4.6 years, there was a significant reduction in the risk of major coronary events and nonfatal coronary events (19% each), a 28% decrease in the risk of unstable angina, and a 20% reduction in stroke in treated patients [214, 215]. Renal patients were excluded from the study. A more recent trial randomized 8179 statin-treated patients with established CVD, diabetes, or other risk factors and a fasting TG of 135–499 mg/dl and LDLc of 41–100 mg/dl to Vascepa or placebo. The study found that EPA-treated patients had a 25% lower risk of the primary endpoint (CV death, nonfatal MI, nonfatal stroke, coronary revascularization, or unstable angina) [216]. Patients with CKD, except those requiring dialysis, were included in the trial and stratification by eGFR showed no heterogeneity of effect.

Hemodialysis patients have markedly lower levels of plasma EPA and DHA when compared with NDD-CKD patients [217]. DHA has been shown to be an independent predictor of all-cause mortality [218] and of sudden cardiac death [219] in hemodialysis patients. A small trial randomized 206 hemodialysis patients to low-dose omega-3 fatty acids versus placebo, and found a small but significant reduction in the number of MIs (four versus 13, $P = 0.036$) in the treated versus placebo arms [220]. The Fish Oil Inhibition of Stenosis in Hemodialysis Grafts (FISH) study enrolled 201 patients and randomized them to fish oil (four 1 g pills per day) versus placebo for 12 months. In the fish oil group, there were half as many thromboses, fewer corrective interventions, and improved CV event-free survival [221].

Although the benefits of omega-3 fatty acids are promising in CKD and dialysis patients, further studies in larger trials are needed.

Guidelines

Guidelines advising on dyslipidemia slightly differ whether approaching from a nephrology angle using KDIGO guidelines [196] or a cardiology angle using ACC/AHA guidelines (Table 34.1). According to the 2018 ACC/AHA guidelines, CKD with an eGFR <60 ml/min/1.73m^2 is considered a risk-enhancing factor, and thereby adults aged 40–75 years with LDLc 70–189 mg/dl who are at 10-year ASCVD risk of 7.5% or higher should be treated with a moderate intensity statin with possible combination with ezetimibe [3]. For patients transitioning to dialysis, continuation of statin therapy is recommended. However, because the trials failed to show benefit of statin initiation in dialysis patients, initiation of statin in dialysis is not recommended. This is an update from previous guidelines, which did not have a recommendation regarding initiating or continuing statins in hemodialysis patients [222]. Similar to the current ACC/AHA guidelines, KDIGO guidelines recommend initiation of statin treatment with a statin or statin/ezetimibe combination in adults aged ≥50 years with eGFR <60 ml/min/1.73m^2, but not treated with chronic dialysis or kidney transplantation. Statin initiation is also recommended in NDD-CKD non-transplanted adult patients aged 18–49 years if they have known coronary disease, diabetes mellitus, prior ischemic stroke of >10% estimated 10-year risk of coronary death, or nonfatal MI. Similar to the ACC/AHA guidelines, KDIGO guidelines also suggest statins not be initiated, but should be continued in dialysis-dependent CKD. They also suggest treatment with statin in adult kidney transplant recipients. Current ACC/AHA guidelines do not have suggestions for renal transplant recipients. For statin therapy dosing in CKD patients, where statins are recommended, KDIGO guidelines provide a table which has dosing recommendations per statin type that corresponds with ACC/AHA guidelines of moderate statin doses. The ACC/AHA guidelines indicate there is a need for randomized control trials testing the efficacy of higher dose versus moderate dose statins in patients with risk-enhancing factors, which includes CKD. A recent cohort study in US veterans demonstrated no difference in the association of statin dose with mortality outcomes across stages of NDD-CKD [223].

For TG lowering, the KDIGO guidelines advise therapeutic lifestyle changes, and caution against the use of statins in combination with fibrates in CKD patients due to increased risk of adverse events. The 2013 ACC/AHA guidelines state that gemfibrozil should not be used in combination with statin, and for TG lowering a fenofibrate can be prescribed with dose alterations according to CKD stage: not to exceed 54 mg/day in patients with eGFR 30–59 ml/min/1.73m^2 and to discontinue when eGFR is persistently <30 ml/min/1.73m^2. Although there is currently a lack of data to support any guideline recommendation, niacin and omega-3 fatty acids may be used in place of fibrates, with monitoring of potential adverse reactions; however, further studies in CKD patients are needed.

Conclusion

The lipoprotein profile in CKD patients is variable depending on CKD stage, other patient characteristics including nutritional status, and management of the patient including

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 34.1 Recommendations for treatment of dyslipidemia.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Statins for NDD-CKD patients, age <80 years	All NDD-CKD patients aged 50–80 years should be treated with a high-dose statin or a moderate dose statin ± ezetimibe irrespective of serum cholesterol. Younger patients should be treated if they have documented ASCVD, diabetes, or estimated 10-year risk of coronary death or nonfatal MI >10%.	High for total mortality, CV mortality, and MACE	Strong. Level A Class I.
Statins for hemodialysis patients	Statins should not be initiated in hemodialysis patients. Statins should be continued in transition to hemodialysis for predialysis patients.	High for noninitiation; low for continuation of statins	Strong for noninitiation. Level A Class III, no benefit. Weak for continuation. Level B Class IIa.
Statins for peritoneal dialysis patients	Statins may be initiated in peritoneal dialysis patients when cholesterol is elevated (>225 mg/dl).	Weak and only for total mortality	Weak for total mortality. Level C Class IIb.
Statins for renal transplant patients	Statins should be initiated in renal transplant patients, although there are increased risks due to drug interactions.	Weak for initiation and only for MACE; high for drug interaction	Weak for initiation. Level C Class IIa.
Statins for patients age >80 years	Statin initiation or continuation could be considered if the patient or family agrees and the long-term benefit exceeds the risks. Informed consent discussion is necessary.	Weak for initiation or continuation	Weak evidence. Level C Class IIa.
Fibrates	Fibrates are considered not effective as an add-on to statins in CKD patients unless triglycerides are >500 mg/dl.	Weak for use with triglycerides >500 mg/dl	Weak evidence. Level C Class IIb.
Niacin	Niacin should not be used for treatment of dyslipidemia in CKD patients.	Moderate for mortality	Moderate evidence. Level C Class III no benefit/harm.
Omega-3 fatty acids	EPA should be used in NDD-CKD patients with stage 3 CKD in addition to statin therapy if triglycerides are >135 mg/dl	Moderate for total and CV mortality and MACE	Moderate evidence. Level B Class I.
Ezetimibe	Ezetimibe should be added to statin therapy in CKD patients if the LDL cholesterol was not decreased by 50% and/or if LDL cholesterol is not at goal.	High for CV mortality and MACE	Strong evidence. Level A Class I.
Bile acid binding resins	Bile acid binding resins should not be used for dyslipidemia in CKD patients.	Weak	Low evidence. Class C Level III possible harm.
PCSK9 inhibitors	PCSK9 inhibitors should be used in patients with stage 3 CKD and ASCVD who have a LDL cholesterol >70 mg/dl on maximum tolerated dose of statin + ezetimibe.	Strong for CV mortality and MACE	Strong evidence. Class A Level I.

ASCVD, atherosclerotic cardiovascular disease; CKD, chronic kidney disease; CV, cardiovascular; EPA, eicosapentanoic acid; LDL, low-density lipoprotein; MACE, major adverse cardiovascular event; MI, myocardial infarction; NDD-CKD, nondialysis dependent chronic kidney disease; PCSK9, proprotein convertase subtilisin/kexin type 9.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. type of dialysis and drugs aimed at prevention of graft rejection. Consequently, the ability of the different lipoproteins to predict adverse outcomes is limited. Interpretation of the levels should be individualized. Moderate dose statins should be initiated in patients with NDD-CKD and continued after patients transition to dialysis. The clinical benefit of statin currently outweighs the risk of adverse events in CKD patients. Further study is needed to ascertain the efficacy and possible risk of higher dose statins or nonstatin lipid-altering medications in CKD patients.

Chronic Kidney Disease and Hypertension

Branko Braam

Division of Nephrology, Department of Medicine, University of Alberta, Canada

Introduction

Hypertension (HTN) is not only highly prevalent in patients with chronic kidney disease (CKD), it is also one of the most prevalent causes of progressive kidney injury and end-stage kidney disease (ESKD). This makes HTN a central issue in the treatment of the patient with CKD. Although it is clear that the renin angiotensin system (RAS), the sympathetic nervous system (SNS), and extracellular fluid volume (ECFV) expansion play a pivotal role in the pathophysiology of HTN in CKD, HTN remains uncontrolled in many patients. Clinically, blood pressure (BP) measurements in CKD are more complex than in essential hypertension because of the frequently disturbed diurnal rhythms. Angiotensin converting enzyme inhibitors (ACEis) and angiotensin receptor blockers (ARBs) are mainstay therapies for HTN in CKD to prevent progression of kidney failure. Diuretics are underutilized but can substantially contribute to better BP control in CKD. It is not clear whether newer therapies like baroreceptor stimulation and kidney denervation have utility in CKD. We propose an approach to the treatment of HTN in CKD based on the pathophysiology of HTN in CKD. For information about management of HTN in transplant recipients, and patients on hemodialysis or peritoneal dialysis, refer to Chapters 22 and 42.

Epidemiology

In this chapter, HTN in CKD is defined as having a BP of >130/80 mmHg or being on antihypertensive treatment [1]. This threshold is based on the recent literature, as discussed below, with the revision of several guidelines as a consequence. With increasing severity of kidney disease, the prevalence of HTN becomes progressively higher such that most patients with end-stage renal disease (ESRD) will become hypertensive.

Besides uncontrolled HTN, it seems relevant to consider resistant HTN (rHTN) [2]. Several definitions are relevant here. The term "apparent treatment-resistant hypertension" is defined as BP not at goal when the patient is prescribed ≥3 classes of antihypertensive medication or at goal after prescription of ≥4 classes. Of note, the most recent position paper on rHTN by the American Heart Association does not mention an actual BP level, but defines rHTN as the BP of a hypertensive patient that remains elevated "above goal" [3]. It is quite likely that over the next few years the BP level for defining rHTN could be adjusted as a result of the new insights about HTN appearing in the literature (see below).

The prevalence of apparent treatment-rHTN amounts to 2–10% in the general population [4, 5]. Data from the Chronic Renal Insufficiency Cohort (CRIC) study indicate that the prevalence is substantially higher in patients with CKD [6]. In the study, 40% of participants had apparent treatment-rHTN, with half of them not at target BP on ≥3 medications and the other half at target BP on ≥4 medications. This leads to questioning how many patients have "true" rHTN. Judd and Calhoun defined true rHTN as "a properly measured office BP >140/90 mmHg with a mean 24-hour ambulatory BP >130/80 mmHg in a patient confirmed to be taking ≥3 antihypertensive medications" [7]. The difference with the definition of apparent resistant hypertension is that here, BP is "properly measured" and not derived from sources where the assessment of BP is ill

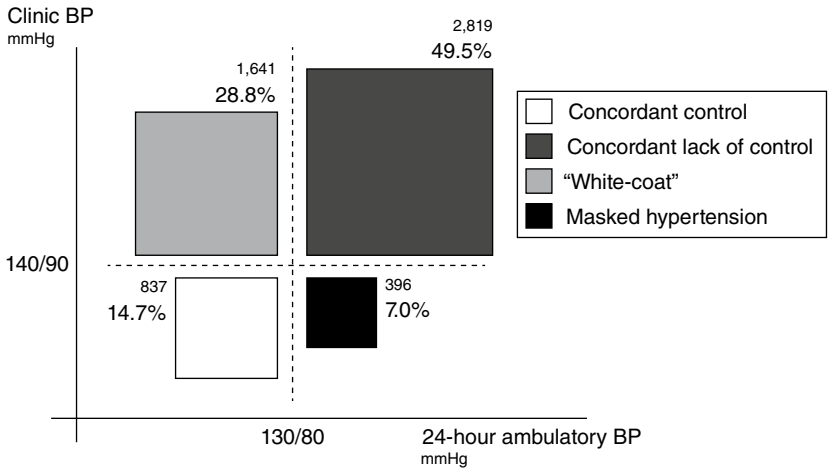

Figure 35.1 Prevalence of masked and white-coat hypertension in hypertensive patients with chronic kidney disease. *Source:* Reproduced with permission [13]. On the *x* axis, patients are divided into two groups: blood pressure (BP) <130/80 mmHg with 24-hour ambulatory BP or ≥130/80 mmHg. On the *y* axis, patients are also divided into two groups: clinic BP <140/90 mmHg and ≥140/90 mmHg. There are two groups where 24-hour ambulatory BP and clinic BP are discordant. One is the well-known white-coat hypertension: patients with normal BP at home (assessed with the 24-hour ambulatory BP assessment) and elevated in the clinic (assessed with the clinic BP). Less well recognized is masked hypertension: patients with normal BP in the clinic and elevated BP at home. *Source:* Gorostidi et al. [13]. © 2013, Elsevier.

defined, and that medication is "confirmed" and not "prescribed." While CKD is identified as a reason for true rHTN, it is currently not clear whether the prevalence of true rHTN is higher or lower than in people without CKD. It does not take away the relevance to investigate adherence if BP targets are not achieved with ≥3 antihypertensive medications.

A last issue is masked HTN, which is HTN that is present when the patient is at home, but is not measured as such in the office. The prevalence of masked HTN is estimated to be about 7–42% of hypertensive patients [8, 9] and is associated with an elevated cardiovascular risk [10]. By its nature, masked HTN can only be detected by ambulatory or home BP measurements. In a recent study with CKD patients, Agarwal defined masked HTN as having controlled HTN in the office (BP <140/90 mmHg), with elevated BP at home. Assessed by ambulatory BP measurements >135/80 mmHg during daytime, >130/80 mmHg during the entire day, or >120/70 mmHg during the night, overall prevalence of masked uncontrolled HTN was 56%. Assessed using average weeklong home BP measurements >135/85 mmHg, prevalence was similarly high at 51% [11]. A recent study from Europe reported a lower prevalence of 19% using ambulatory BP measurements [12]. These studies strongly emphasize the importance of home and ambulatory measurements. This is further illustrated in Figure 35.1.

Assessment of Blood Pressure

In the context of clinical evaluation of the patient with CKD, four different assessments of BP are being used: in-office manual, multiple in-office automated, home, and ambulatory measurements. Unfortunately, the level of BP is still often only derived from in-office manual measurements. These are notorious for inaccurate assessment of BP for a number of reasons, including white coat HTN (i.e. stress associated with a clinic visit), as well as the inability to diagnose masked or nighttime HTN. Multiple in-office automated measurements, if done appropriately with at least five measurements with the patient left alone seated in the right position in a quiet room, do resemble daytime ambulatory BP measurements. Although obviously more preferably than a single in-office measurement, it takes more time in the clinic, and masked or nighttime HTN still cannot be diagnosed. Since both masked and nighttime HTN are more prevalent in CKD patients [8, 9], this is obviously relevant. Home BP measurements have a number of benefits, including the possibility to have multiple measurements over the day and during work and weekend days. This facilitates the assessment of BP variability, including potential weaning of medication actions during some time of the day (e.g. becoming hypertensive before taking medications in the morning), and it enables the diagnosis of masked, but not nighttime hypertension. Furthermore, it engages patients in their care.

Performing ambulatory BP measurements is more labor intensive, can be psychologically troubling for the patient, or even a bit painful, yet it provides day- and nighttime BP measurements, shows variations, allows coupling BP to symptoms, and avoids patient selection. Given the high prevalence of HTN in CKD, a strong call is being made to use ambulatory BP measurements more frequently in the assessment of BP in the CKD patient because of the issues with high prevalence of white coat, masked, nighttime, and variable hypertension. The pros and cons of different BP assessments are summarized in Table 35.1.

Table 35.1 Pros and cons of different approaches to assess blood pressure.

Issue	Office BP	Automated office BP	Home BP	ABPM
Affected by white-coat phenomenon	Yes	Possible	No	No
Able to detect white-coat hypertension	No	No	Yes[a]	Yes[a]
Able to detect masked hypertension	No	No	Yes[a]	Yes[a]
Easily available	Yes	Possible	Yes	Possible
Low cost	Yes	No	Yes	No

[a] When office measurements are also available.
BP, blood pressure; ABPM, ambulatory blood pressure measurements.

Pathophysiology

Three key mechanisms form an important basis for HTN in CKD: activation of the RAS and the SNS, and ECFV expansion. In addition, there are dozens of other BP modulating systems involved in the pathophysiology of HTN in CKD. Studies from the 1970s demonstrated elegantly that when renin levels are related to volume status, the baroreceptor curve is shifted upward: at any level of ECFV, renin is higher in CKD patients compared to controls. This activated RAS is more prominent in polycystic kidney disease [14], kidney involvement in scleroderma [15], as well as renovascular disease. The mechanisms by which angiotensin II leads to HTN are not only the classically described vasoconstriction and increase in aldosterone release but also encompass direct increases in proximal tubular reabsorption [16] and a number of indirect effects like increased oxidative stress with all its consequences and activation of the SNS. It has been nicely demonstrated that in CKD patients, ACE inhibition partly corrects the left shift of the baroreceptor curve.

Volume overload is the consequence of a too excessive sodium intake and the impaired ability of the kidney to excrete sodium at normal arterial pressures. Sodium intake to a certain extent is modifiable, yet in advanced kidney disease normotension cannot be maintained even at very low levels of sodium intake [17]. Effectively the pressure natriuresis curve has shifted to the right. At a tubular level, the activated RAS will enhance sodium reabsorption and the nephron is meanwhile unable to suppress its fractional reabsorption sufficiently. If glomerular filtration rate (GFR) decreases to 10% of normal, fractional sodium excretion would need to increase from about 1% to 10% to achieve sodium balance. It has become clear that volume overload is prevalent in CKD and hemodialysis patients now that reliable bio-impedance assessments are widely available [18, 19].

SNS activity is increased in CKD and ESRD. Initial observations by Converse demonstrated that nephrectomy diminished the activation of the SNS, as assessed by muscle sympathetic nerve activity [20]. Since then, sympathetic hyperactivity has been shown in nonproteinuric CKD as well as polycystic kidney disease. The hyperreactivity depends at least in part on the RAS, since in CKD patients ACE inhibition leads to normalization of sympathetic activity [21]. Surgical renal denervation has been shown to reduced BP in experimental CKD as well as in humans [22]. Denervation using an intravascular device has been less successful; however, technique improvements could resolve this [23]. Of note, sympathetic activation not only affects BP control but is also involved in a large number of processes, including glucose metabolism and insulin resistance, endothelial dysfunction and vascular stiffness, and immune modulation [24].

Besides this classical triad of mechanisms for HTN, CKD, and ESRD come with several other disturbances affecting BP regulation. Structural changes to the vasculature, including the classical Monkenberg media sclerosis, lead to increased vascular stiffness and peripheral resistance. This will affect both the BP and the pulse wave propagation and reflection, leading to increased cardiac afterload. Accumulation of the endogenous inhibitor of nitric oxide synthase (i.e. asymmetric dimethyl arginine [ADMA]), due to diminished breakdown, has been identified as a functional issue leading to high BP [25]. Functional abnormalities are also suspected in many BP-regulating systems, including the sensitivity to and handling of, among other factors, natriuretic peptides, eiconasoids, and endothelin. None of these potential mechanisms have currently been translated into therapy backed up by solid clinical investigation.

Differential Diagnosis

A conundrum in the evaluation of the patient with HTN and CKD is that once CKD has developed, renal parenchymal HTN can obscure other forms of secondary HTN. This is difficult to decipher; however, it remains important if one wants to treat the HTN effectively and decrease the progression of kidney failure. For example, if a primary hyperaldosteronism has led to long-standing HTN and target organ damage including CKD, it is important that this is diagnosed and treated accordingly. However, diagnostic algorithms for primary hyperaldosteronism in moderate to advanced CKD do not have a solid evidence base, so one falls back on clinical evaluation and judgment: (relative) hypokalemia, alkalosis, and treatment resistance. If strongly elevated, a Plasma Renin activity (PRA) level might be helpful. Visualization of the adrenal glands and adrenal vein sampling will require an open discussion between care provider and patient.

Renal artery stenosis also leads to diagnostic and therapeutic dilemmas. Following the negative results of the STAR, ASTRAL, and CORAL trials about angioplasty and stent placement regarding treatment BP regulation and renal function [26–28], there is a strong reluctance to assess whether renal artery stenosis is present. If there is a suspicion of renal artery stenosis, there are at least three reasons to do additional investigations toward confirmation, despite these trials. First, fibromuscular dysplasia can present with impaired renal function and HTN, and is potentially resolvable [29]. Second, the three trials did not address whether patients with a rapid deterioration of renal function or with flash pulmonary edema could benefit from angioplasty and stent placement. Third, performing additional investigations could be performed if the kidney failure is unexplained. Although not very common, renal artery stenosis can present with a nephrotic range proteinuria. If kidney function is stable and BP is controllable, however, the three trials provide strong evidence not to do additional diagnostic testing or an intervention.

Table 35.2 lists a number of diagnoses that should be considered before HTN in a patient with CKD is labeled as renal parenchymal HTN.

Goals of Treatment of Hypertension in the Patient with CKD

Prevention of progression of CKD by HTN is one goal in the treatment of the HTN. There has been overwhelming evidence accumulated over the last 25 years supporting that fact that BP control reduces the progression of CKD.

A strong body of evidence supports the use of antihypertensive therapy, specifically with ACEi or ARBs, in patients with diabetic nephropathy (Table 35.3**)**. In 1993, the first large randomized control trial (RCT) to support this compared captopril versus placebo in preventing doubling of creatinine or reaching ESRD as primary outcome in patients with diabetic nephropathy [30]. The study demonstrated a decrease of 48% in reaching the outcome over the 3 years of follow-up. This study was followed by the Irbesartan in Diabetic Nephropathy Trial (IDNT) studying patients with type 2 diabetes, which demonstrated a better protection by Irbesartan for kidney disease progression than placebo or amlodipine [34] for a composite endpoint of doubling of creatinine or all-cause mortality. Similar findings were reported in the Reduction of Endpoints in NIDDM with the Angiotensin II Antagonist Losartan (RENAAL) trial; here, a 16% reduction in risk to reach a composite renal outcome (doubling of creatinine or reaching ESKD) and death was observed in patients with diabetic nephropathy treated with losartan versus placebo [35]. A post hoc analysis of the RENAAL trial for renal outcomes separately indicated a benefit for patients with a high pulse pressure but was not straightforward in its interpretation [38].

Regarding nondiabetic nephropathy, there is also evidence that BP lowering slows progression of kidney disease. The aim of the African American Study of Kidney Disease and Hypertension (AASK) trial was to compare intensive versus less intensive BP lowering in African Americans with hypertensive kidney injury [36]. While the trial could not conclude that more intensive BP lowering had additional benefit to prevent the major outcomes (rate change of eGFR and progression of CKD or all-cause mortality), this trial concluded that there was specific benefit of an ACEi above a beta-blocker or calcium channel

Table 35.2 Secondary causes of hypertension to be considered in the patient with CKD.

System	Cause
Vascular	Atherosclerotic renal artery stenosis
	Fibromuscular dysplasia
	Aortic coarctation
Endocrine	Primary hyperaldosteronism
	Secondary hyperaldosteronism
	Cushing's syndrome
	Congenital adrenal hyperplasia
Tubular transport	Liddle's syndrome
	Gordon's syndrome
Other	Obstructive sleep apnea
	Severe obesity

Table 35.3 Major trials on hypertension treatment in patients with CKD.

Study	Number of randomized patients	Primary aim	Study population	Study design	Outcomes evaluated	Duration of follow-up	Results	References
The effect of angiotensin-converting enzyme inhibition on diabetic nephropathy	409	To determine whether captopril has kidney-protecting properties independent of its effect on BP in diabetic nephropathy	Age: 18–49; IDDM for at least 7 years; serum creatinine ≤2.5 mg/dl; urine protein excretion ≥500 mg/24 h	DBRCT in 30 centers; captopril 25 mg PO TID ($n = 207$), placebo ($n = 202$); goal SBP <140 mmHg, DBP <90 mmHg	Primary: doubling of baseline serum creatinine to at least 2.0 mg/dl Secondary: length of time to the combined endpoints of death, dialysis, and transplantation and changes in kidney function	Median: 3 yr	Risk reduction for the primary endpoint was 48% in the captopril group Risk reduction was 50% for the combined endpoint in the captopril group	[30]
The effects of dietary protein restriction and BP control on the progression of CKD (MDRD)	Study 1:585; Study 2:255	To test whether restricting protein and controlling HTN delay the progression of kidney disease	Age: 18–70; serum creatinine (M) 1.4–7.0, (F) 1.2–7.0 mg/dl; MAP ≤125 mmHg; Study 1–GFR 25–55 ml/min, Study 2–GFR 13–24 ml/min Insulin-requiring diabetics and those with proteinuria >10 g/day were excluded	RCT in 15 centers Groups: usual (≤107 mmHg) or low MAP (≤92 mmHg); usual or low-protein diet (Study 1) and low and very low protein diet (Study 2) groups	Primary outcome: decline in GFR measured by I-iothalamate clearance, stratified by BP and proteinuria	Mean: 2.2 years	No difference in decline in GFR in both studies Among patients with higher baseline proteinuria, the low-BP group had a significantly slower rate of GFR decline in both studies	[31]
Effect of ramipril on decline in GFR and risk of terminal kidney failure in proteinuric, nondiabetic nephropathy (REIN)	352	To test the hypothesis that glomerular protein traffic, and its modification by an ACEi, influences kidney disease progression	Age: 18–70; Cr Cl 20–70 ml/min with variation <30% in previous 3 months; urine protein excretion >1 g/24 h for at least 3 months; no ACEi for at least 2 months before study	DBRCT Stratum 1: urine protein 1–2.9 g/24 h ($n = 186$) Stratum 2: urine protein ≥3 g/24 h ($n = 166$) Randomized to ramipril (1.25 mg) or placebo Dose increased every 2 weeks for a goal DBP <90 mmHg Other agents used as needed to achieve goal BP	Primary outcome: rate of GFR decline measured by iohexol clearance Secondary outcomes: urinary protein excretion and serum creatinine concentration Intention-to-treat analyses	Stratum 1: Median: 31 mo Stratum 2: Mean: 16 mo	Stratum 1: GFR decline per month not significantly different; significant reduction in proteinuria and progression to ESRD in the ramipril group Stratum 2: Decrease in the GFR decline per month was significantly lower in the ramipril than the placebo group (0.53 vs. 0.88 ml/min, $P = 0.03$) Significant reduction in proteinuria in the ramipril group that correlated inversely with GFR decline	[32, 33]

Table 35.3 (Continued)

Study	Number of randomized patients	Primary aim	Study population	Study design	Outcomes evaluated	Duration of follow-up	Results	References
Renoprotective effect of irbesartan in patients with nephropathy due to type 2 diabetes (IDNT)	1715	To determine whether the use of an ARB or a CCB would provide protection against the progression of nephropathy due to type 2 diabetes beyond that attributable to the lowering of BP	Age: 30–70; type 2 diabetes; HTN–BP >135/85 or use of antihypertensive agents; urinary protein excretion of at least 900 mg/24 h; serum creatinine: (M) 1.2–3.0 mg/dl, (F) 1–3 mg/dl	DBRCT in 210 clinical centers; randomized to irbesartan ($n = 579$, dose titration 75–300 mg/day); amlodipine ($n = 567$, dose titration 2.5–10 mg/day); or placebo ($n = 569$)	Primary endpoint: composite of a doubling of the baseline serum creatinine, onset of ESRD, or death Secondary outcome: combined cardiovascular endpoint	Mean: 2.6 years	Risk of the primary composite endpoint in the irbesartan group was 20% and 23% lower than the placebo ($P = 0.02$) and amlodipine ($P = 0.006$) groups respectively No significant differences in death rates from any cause or the CV composite endpoint	[34]
Effects of BP level on progression of diabetic nephropathy (RENAAL)	1513	To assess the role of the angiotensin-II-receptor antagonist losartan in patients with type 2 diabetes and nephropathy	Age: 31–70, type 2 diabetes and nephropathy (urine albumin/creatinine ratio of ≥300 mg/g or proteinuria of ≥0.5 g/day); serum creatinine 1.3–3.0 mg/dl	DBRCT, multinational study, randomized to losartan (50–100 mg daily) or placebo, stratified by baseline proteinuria (urine albumin-to-creatinine ratio <2000 mg/g or ≥2000 mg/g) Additional open-label agents used as needed for goal BP <140/90 mmHg	Primary composite endpoint: time to doubling of serum creatinine, ESRD, or death, whichever occurred first Secondary endpoints: composite of morbidity and mortality from cardiovascular causes, proteinuria, and the rate of progression of kidney disease	Mean: 3.4 years	The losartan group had a 16% risk reduction in the primary endpoint (P=0.02 vs. placebo). Similar rates of death and cardiovascular morbidity and mortality in the two groups Losartan had a 35% reduction in proteinuria ($P < 0.001$, compared to placebo)	[35]
Effect of BP lowering and antihypertensive drug class on progression of hypertensive kidney disease (AASK)	1094	To compare effects of two levels of BP control and three antihypertensive drug classes on GFR decline in African Americans with HTN	Age: 17–80; African Americans; HTN; GFR 20–65 ml/min; nondiabetics	3 × 2 factorial design; randomized to usual (102–107 mmHg) or lower (<92 mmHg) MAP goal Treatment with metoprolol, 50–200 mg/day; ramipril, 2.5–10 mg/day; or amlodipine, 5–10 mg/day assigned in 2 : 2 : 1 ratio Additional open-labeled agents added sequentially	Primary endpoint: rate of change in GFR (GFR slope–acute and chronic) Secondary clinical composite outcome: GFR reduction by 50% or by 25 ml/min from baseline, ESRD, or death Other secondary outcomes: urine protein excretion, all CVE	3–6.4 years	There was no significant difference in mean GFR slope from baseline through 4 years in the two BP groups and the drug group comparisons The secondary clinical composite outcome was similar in the two BP groups, but the ramipril group had a 22% reduction compared to the other drug groups	[36, 37]

Effects of BP level on progression of diabetic nephropathy (post hoc analyses of RENAAL)	1513	To evaluate the impact of baseline and treated SBP, DBP, and PP to assess the specific effect of losartan and the implications of dihyropyridine calcium channel blockers as concurrent therapy on composite and individual outcomes in patients with type 2 diabetes and nephropathy	Age: 31–70; type 2 diabetes and nephropathy (urine albumin/creatinine ratio of ≥300 mg/g or proteinuria of ≥0.5 g/day); serum creatinine 1.3–3.0 mg/dayl	DBRCT, multinational study, randomized to losartan (50–100 mg daily) or placebo, stratified by baseline proteinuria (urine albumin-to-creatinine ratio <2000 mg/g or ≥2000 mg/g) Additional open-label agents used as needed for goal BP <140/90 mmHg	Primary composite endpoint: time to doubling of serum creatinine, ESRD, or death, whichever occurred first	Mean: 3.4 years	Baseline SBP of 140-159 mmHg, compared to SBP <130 mmHg, increased risk for ESRD or death by 38% ($P = 0.05$) Patients randomized to the losartan group with a baseline PP >90 mmHg had a 35.5% risk reduction for ESRD or death ($P = 0.02$) compared to the placebo group	[38]
BP control for renoprotection in patients with nondiabetic chronic kidney disease (REIN -2)	338	To assess the effect of intensified vs. conventional BP control on progression to ESRD in patients with nondiabetic proteinuric nephropathies	Age: 18–70; nondiabetic nephropathy with persistent proteinuria (>1 g/24 h for at least 3 months); proteinuria of 1-3 g if Cr Cl <45 ml/min, and proteinuria ≥3 g if Cr Cl <70 ml/min	Multicenter RCT All received background ACEi therapy with ramipril Randomized to conventional (DBP <90 mmHg) or intensified (BP <130/80 mmHg) BP control Add-on therapy with felodipine in the intensified BP group	Primary outcome: time to ESRD over 36 months follow-up Secondary outcome: to compare the effects of two different levels of BP control on GFR decline, residual proteinuria, and fatal and nonfatal CVE	Median: 19 months	No significant difference in the progression to ESRD in the two BP groups ($P = 0.99$) No difference in the secondary outcomes between the two groups	[39]
Kidney outcomes in high-risk hypertensive patients treated with an ACEi or a CCB vs. a diuretic (ALLHAT post hoc analyses)	33 357	To determine whether, in high-risk hypertensive patients with a reduced GFR, treatment with a CCB or an ACEi lowers the incidence of kidney disease outcomes compared with treatment with a diuretic	Age: ≥55; stage 1 or 2 HTN with at least one other CAD risk factor; serum creatinine <2 mg/dl	DBRCT, post hoc analyses, randomized to receive chlorthalidone (12.5–25 mg/day), amlodipine (2.5–10 mg/day), or lisinopril (10–40 mg/day) in a 1.7 : 1 : 1 ratio Goal BP <140/90 in each arm by adding open-label agents as needed Stratified by baseline eGFR	Clinical kidney outcomes: development of ESRD or death from kidney disease Composite endpoint of ESRD or ≥50% decline in GFR from baseline; mean GFR during study follow-up	Mean: 4.9 years	No significant difference in the outcomes in patients taking chlorthalidone compared to those who received lisinopril or amlodipine, irrespective of the baseline GFR	[40]

Table 35.3 (Continued)

Study	Number of randomized patients	Primary aim	Study population	Study design	Outcomes evaluated	Duration of follow-up	Results	References
Effect of a lower target BP on the progression of kidney disease: long-term follow-up of the MDRD study (post hoc analyses)	840	To assess the effects of a low target BP on kidney failure and all-cause mortality	Age: 18–70; serum creatinine (M) 1.4–7.0, (F) 1.2–7.0 mg/dl; MAP ≤125 mmHg; Study A: GFR 25–55 ml/min, Study B: GFR 13–24 ml/min	Long term follow-up of patients from 1993 to 2000 after the MDRD study ended (see above for MDRD study design)	Outcomes: kidney failure and a composite outcome of kidney failure or all-cause mortality, through extended follow-up	Approx. 7 years (1993–2000)	The adjusted hazard ratios in the low compared with the usual target BP group were 0.68 and 0.77 for development of kidney failure and the composite outcome, respectively	[41]
In the Action to Control Cardiovascular Risk in Diabetes blood pressure trial (ACCORD-BP); kidney subgrou p analysis	4678	Intense vs. standard therapy in patients with type 2 diabetes	Type 2 diabetes mellitus; hemoglobin A1C ≥7.5% Age ≥ 40 years with CVD; age ≥ 55 years with any of the following: atherosclerosis, albuminuria, LVH, ≥2 CV risk factors (dyslipidemia, HTN, smoking, or obesity) Exclusion criteria: BMI >45 kg/m^2; creatinine >1.5 mg/dl (132.6 umol/l)	Selection of the 2 × 2 design of the ACCORD study: standard (SBP <140 mmHg) vs. intense BP (SBP <120 mmHg) control; standard intense diabetes control	Primary outcome: composite endpoint, including both nonfatal and fatal CVD events (first occurrence of nonfatal myocardial infarction, nonfatal stroke, and cardiovascular death)	Mean follow-up: 4.7 years	No clear cardiovascular benefit of intense vs. standard therapy could be demonstrated, although the risk of stroke was reduced by 38% (HR 0.623, 95% CI 0.361-1.074)	[42]
Systolic Blood Pressure Intervention Trial (SPRINT)	9361	Intensive treatment (SBP <120 mmHg) vs. standard (SBP <140 mmHg) treatment	Age: >50 years; SBP ≥130 mmHg and increased cardiovascular risk, but without diabetes	Open-label RCT in 201 sites	Primary outcome: composite outcome of myocardial infarction, acute coronary syndrome not resulting in myocardial infarction, stroke, acute decompensated heart failure, or death from cardiovascular causes Kidney outcome in participants with CKD at baseline: composite of a decrease in the eGFR of 50% or more (confirmed by a subsequent laboratory test) or the development of ESRD	Median follow-up: 3.26 years	SBP of less than 120 mmHg, as compared with less than 140 mmHg, resulted in lower rates of fatal and nonfatal major cardiovascular events and death from any cause, although significantly higher rates of some adverse events were observed in the intensive-treatment group No difference in kidney outcome in intense BP treatment vs. standard group	[43]

ACEi: angiotensin-converting enzyme inhibitor; BMI: body mass index; BP: blood pressure; CCB: calcium channel blocker; CKD; CrCl: creatinine clearance; (also cr cl); CV: cardiovascular; CVD: cardiovascular disease; CVE: cardiovascular event; DBP: diastolic blood pressure; DBRTC: double-blind randomized controlled trial; ESRD: end-stage renal disease; GFR: glomerular filtration rate; (also eGFR: estimated glomerular filtration rate;); HTN: hypertension; IDDM: insulin dependent diabetes mellitus; M/F: male/female; MAP: mean arterial pressure; PP: pulse pressure; RCT: randomized controlled trial; SBP: systolic blood pressure.

blocker in this setting. The smaller Ramipril Efficacy In Nephropathy (REIN) study addressed a similar question in proteinuric, nondiabetic nephropathy [32]. It studied whether BP lowering with an ACEi or with other therapy had comparable effect on proteinuria, slowing down kidney disease progression and preventing ESRD at the same level of BP control. Again, ACEi more so than other therapy decreased progression and prevented ESRD in the group with the lower level of proteinuria (the group with the higher level of proteinuria was discontinued because of strong benefit of ACEi during an interim analysis). In the patients receiving the ACEi, the percentage reduction in proteinuria was inversely correlated with decline in GFR. This review of trials is not exhaustive and more trials can be found in the literature, all stressing the importance of BP control to prevent CKD progression.

The other very important goal of treatment of HTN is the prevention of cardiovascular disease. In the Atherosclerosis Risk in Communities (ARIC) study cohort, progressive cardiovascular risk was reported in patients with mild to severe kidney disease that was independent from a large number of other cardiovascular risk factors [44]. That this is competing with the risk to reach ESRD was demonstrated in an epidemiological study showing that 1% of >11 000 patients with CKD stage 3 reached kidney replacement therapy, meanwhile 24% of the cohort passed away from cardiovascular disease; for CKD stage 4 these numbers were 18 and 46%, respectively [45]. This very clearly underscores the need to take both renal and cardiovascular protection into consideration for treatment. As mentioned, the IDNT and RENAAL trials support treatment of HTN for a composite renal and all-cause mortality outcome, the latter mainly being cardiovascular mortality.

The Action to Control Cardiovascular Risk in Diabetes-Blood Pressure (ACCORD-BP) trial investigated the effect of intense versus standard therapy in patients with type 2 diabetes, but it excluded patients with a serum creatinine level of more than 1.5 mg per deciliter (132.6 μmol/l). In the trial patients with mild to moderate CKD (stages 1–3B, $n = 4678$) no clear cardiovascular benefit of intense versus standard therapy could be demonstrated, although the risk of stroke was reduced by 38% (HR 0.623; 95% CI 0.361–1.074). The authors concluded that, given that the trial was not designed and powered to this purpose, an effect of intense BP control in patients with CKD could not be excluded [42].

In the Systolic Blood Pressure Intervention Trial (SPRINT), more than 9000 patients were randomized to intensive versus less intensive BP treatment where average systolic BP of 121 and 136 mmHg, respectively, were achieved [43]. When the trial was stopped early, more intensive treatment was associated with a significantly lower incidence of the composite outcome (defined as myocardial infarction, other acute coronary syndromes, stroke, heart failure, or death from cardiovascular causes). The hazard ratio with intensive treatment was 0.75 (95% CI 0.64–0.89). A post hoc analysis revealed that in about 2000 patients with CKD stages 3–4 the decrease in cardiovascular outcome was similar, with a hazard ratio of 0.72 (95% CI 0.63–1.05), and the hazard ratio for all-cause mortality was 0.72 (95% CI 0.53–0.99) [46]. This was not accompanied by more adverse events. Regarding the renal outcome, the composite of ≥50% decrease in eGFR from baseline or ESRD was not different between the intensive and less intensive groups (HR 0.90; 95% CI 0.44–1.83). As expected because of the larger drop in BP, the intensive group had a slightly higher rate of change in eGFR at 6 months into the study (−0.47 vs. −0.32 ml/min per 1.73 m^2 per year, $P < 0.03$). So, in this hallmark trial, more intensive treatment of patients with cardiovascular risk and CKD for more intensive BP lowering led to lower cardiovascular events, was not associated with higher adverse events, and was similar in kidney outcome. In light of the above, for cardiovascular more than kidney treatment goals, a lower BP target in CKD patients seems preferable.

Lifestyle Changes and Blood Pressure Control in CKD

Dietary Sodium

Despite the fact that ECFV expansion due to high sodium intake and impaired sodium handling by the kidneys in CKD are considered key factors in the pathogenesis of HTN in CKD patients, information on the role of sodium intake both in the progression of kidney disease and on cardiovascular event rate in CKD patients is limited. Regarding progression of kidney disease, Lambers Heerspink et al. demonstrated in an analysis of data pooled from the RENAAL and IDNT trials that a low sodium intake potentiated on the effect of angiotensin blocker not only to slow CKD progression but also to decrease cardiovascular events [47]. Further to cardiovascular outcomes, Mills et al. demonstrated that the higher urinary sodium excretion from multiple 24-hour urine collections in the CRIC study was associated with increased risk of cardiovascular events (composite of congestive heart failure, stroke, and myocardial infarction) [48]. There are no large-scale RCTs on the influence of dietary sodium restriction specifically aimed at CKD patients. It is necessary to mention the Dietary Approaches to Stop Hypertension (DASH) study since it provides solid evidence on the effect of dietary sodium restriction to lower BP; however, this study was not targeted to assess progression of CKD [49]. In 2015, a Cochrane review was published summarizing the effects of dietary sodium restriction on renal sodium excretion (to

Table 35.4 Lifestyle management in the treatment of hypertension in chronic kidney disease (KDIGO Clinical Practice Guidelines).

Management	Recommendation	Certainty of evidence	Strength of recommendation
Lifestyle modification Sodium/salt	Lower or maintain salt intake to <90 mmol/day (equivalent to <2 g sodium/day or < 5 g sodium chloride/day)	C, low	1
Weight loss	Achieve or maintain a healthy weight (BMI 20–25)	D, very low	1
Exercise	Aim to exercise for at least 30 minutes five times per week	D, very low	1

evaluate whether the intervention was successful) and on kidney function [50]. Included in the analysis were eight studies, mostly nonrandomized, with the number of subjects ranging from 14 to 52 per arm. The three short-term (<4 weeks) and four out of the five long-term (≥4 weeks) studies indeed showed a significant decrease in urinary sodium excretion. Regarding kidney function, low dietary sodium did not decrease eGFR ($n = 2$ studies), creatinine clearance ($n = 3$), renal plasma flow ($n = 1$), or filtration fraction ($n = 1$); obviously the number of studies is very limited. BP and protein excretion were reduced by dietary sodium restriction. Only one study measured a decrease (0.8 l) in ECFV by reduction of sodium intake [51]; unfortunately, no changes in creatinine or eGFR were reported, so changes in volume status could not be related to changes in renal function. Although the data is lacking to strongly support that dietary sodium restriction in patients with CKD leads to a decrease in CKD progression and cardiovascular events, the lack of evidence should not be considered as evidence that such intervention could not be useful (table 35.4).

Obesity and Weight Loss

There are numerous studies in the literature about weight loss and its effects on BP, whether by dietary or pharmacological intervention or by bariatric surgery. There is also quite some evidence to support that obesity can affect the function of the kidney [52]. Nevertheless, there is no solid evidence supporting that weight loss has a beneficial effect on kidney disease progression in CKD patients. Regarding diabetic kidney disease, our current knowledge falls short on how lifestyle, medical, and surgical interventions can decrease CKD progression and whether there is a threshold weight loss required for benefit [53] (table 35.4).

Exercise

Exercise can lower BP, reportedly to a similar extent as a normal dose of an antihypertensive medication. However, adequately powered RCTs reporting the independent effects of exercise to slow down progression of kidney disease are lacking. One small trial ($n = 30$) randomized CKD patients to daily, 30-minute, aerobic exercise or usual care but failed to show that this slowed down progression of CKD [54]. Another observational study showed a 2.8% difference in eGFR decline between physically active people versus those who were sedentary [55]. This illustrates the need for adequately powered trials with sufficient follow-up to determine the potential benefits of exercise to slow down progression of CKD. Of note, exercise has been shown to decrease cardiovascular event rates in numerous other patient populations with cardiovascular risk.

A comprehensive review of lifestyle changes for the treatment of BP can be found elsewhere [56] (table 35.4).

ACEi and ARBs versus Other Medication in Hypertension in CKD

There is abundant literature about the actions of angiotensin II, besides intrinsic renal autoregulation, to maintain glomerular pressure when kidney perfusion pressure is decreased. This is achieved by preferential efferent arteriolar vasoconstriction. Conversely, blockade of angiotensin II action by ACE inhibition or AT1 receptor antagonists can decrease glomerular pressure by a decrease in BP, but also by a preferential efferent vasodilation. In addition, blockade of angiotensin II can decrease the glomerular ultrafiltration coefficient. Not surprisingly, it has been shown that angiotensin in many different models of kidney failure can decrease kidney damage and proteinuria more so than other agents, particularly calcium antagonists [57].

It is therefore rather surprising that clinical data on kidney protection of RAS inhibitors versus other agents is conflicting. There are several trial results suggesting that RAS inhibitors are more effective in decreasing progression of nondiabetic and diabetic proteinuric and nonproteinuric kidney disease compared to calcium channel blockers.

There are several considerations around this issue of effectiveness of RAS inhibitors versus other drugs. First,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

RAS inhibitors if dosed appropriately lead to an acute decrease in glomerular filtration, due to the mechanism explained above, and the absence of good autoregulation to offset the drop in BP in CKD patients. Administration of calcium antagonists has the opposite effect as they lead to an increase in glomerular filtration. If progression of CKD is studied, one should either study the changes in GFR after the initial changes in BP and glomerular filtration, or one should study the GFR after discontinuation of the study drugs. This is nicely illustrated in the report by Bakris, where he demonstrated a clear increase in GFR after discontinuation of the ACEi [58]. A related problem is that the exact same BP was not achieved in all studies. While in the IDNT study, for example, the difference was not more 2 mmHg [34], one cannot exclude that this explains (the absence) of differences between two study drugs. A third issue is whether other medications were allowed to be changed to control BP, which could introduce a confounder. Altogether the consensus seems to be that in diabetic and nondiabetic proteinuric kidney disease blockade of the RAS is the preferred first-line approach, whereas in nonproteinuric disease this is less conclusive.

Blood Pressure Target

No definitive conclusion can be reached about the best BP target for patients with CKD. On the one hand, there are no studies that have reached a solid conclusion about the best BP level to prevent the progression of proteinuric and nonproteinuric CKD. As mentioned, the SPRINT post hoc assessment of the effect of BP level on the progression of CKD did not reveal any benefit of lower BP goals [46]. That said, the trial was not powered to identify any benefit for specific etiologies of kidney failure. Similarly, the AASK trial could not demonstrate an additional benefit of intense versus standard treatment of BP in African Americans with nondiabetic hypertensive kidney injury [36]. The ACCORD-BP trial was unable to show this in patients with CKD stage 1–3B with diabetes [42]. Although there is no RCT comparing standard versus strict BP control to slow progression of CKD induced by IgA nephropathy, several observational studies support this [59, 60]. The Halt Progression of Polycystic Kidney Disease (HALT-PKD) trial compared strict versus standard BP control in autosomal dominant polycystic kidney disease (ADPKD) patients ($n = 558$). Intense BP control did not affect the primary outcome, percentage change in kidney volume, but it decreased the progression of CKD [61]. The clear observations from the SPRINT study have triggered a large dispute about the BP targets in patients with CKD. This has led to lowering of the target to 130/80 mmHg in the American College of Cardiology/American Heart Association guidelines for the management of HTN [62]. The most recent European Society of Hypertension/European Society of Cardiology guidelines now advise a target of 130–139 mmHg for systolic BP but do not mention a target for diastolic BP [63]. The debate about the right BP target is ongoing.

A Therapeutic Approach to Treatment of Hypertension in CKD

Although a physiology-based approach for more individually targeted treatment of HTN is not currently standard of care, such an approach may be considered in the management of patients who are identified as having truly resistant and difficult-to-control HTN. To effectively target a specific pathophysiological system, it is necessary to first demonstrate that the system is activated (using plasma hormone levels, physiologic measurements, or function tests). To date, key regulatory systems are not fully delineated and a comprehensive panel of "probes" is not yet available. With these limitations, assessment and targeting of several major regulatory pathways in HTN development is considered in this section.

Measurement of plasma renin activity or measuring the acute fall in BP after captopril administration may be used to predict BP response to RAS blockade [64]. Beyond the use of standard diuretic agents at standard doses, evaluation of volume status and urinary salt excretion could be used to assess a particular patient's salt-avidity and individual response to a diuretic agent and dosage. Evaluation of volume status and salt intake and excretion is not routinely performed and is technically difficult. Application of objective estimates of volume status using methods such as bioimpedance may be a consideration. Measurement of hemodynamic parameters and volume status using thoracic bio-impedance has been demonstrated to be an effective approach to improve BP control in several small trials [65]. A next important step would be to monitor salt intake and excretion by 24-hour urine sampling. Alternatively, a "salt calculator" has been developed, which consists of a survey of ~25 questions and provides an estimate of daily salt intake [66]. There is a body of evidence supporting the importance of increased activity of the SNS as one of the key factors in HTN in general and in hypertensive kidney disease in particular [21, 67]. Unfortunately, the activity of the SNS cannot be easily measured. Methods such as heart rate variability, plasma norepinephrine and catecholamines [68], and muscle sympathetic nerve activity [21] are not suitable for daily practice, and it is unclear whether these methods can reliably predict response to therapy.

BP responses to mineralocorticoid receptor inhibition reportedly are not related to plasma aldosterone concentrations or aldosterone-to-renin ratios in patients already treated for hypertension [69, 70]. Only in untreated patients was response to mineralocorticoid receptor inhibition linked

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. to plasma aldosterone levels [71] and inversely to plasma renin activity [72]. Regarding patients with rHTN, plasma aldosterone, aldosterone-to-renin ratios, and 24-hour urine aldosterone levels were higher in those with rHTN versus controls [65]. Moreover, another study reported decreases in BP after addition of a low dose of spironolactone in patients with rHTN of 16.6/7.0, 23.9/9.7, and 26.0/10.7 mmHg at 1, 3, and 6 months after starting the drug [73].

Figure 35.2 illustrates an algorithm that can be followed to assess the effectiveness of targeted therapy for the

physiological driving forces of BP as discussed. Until more evidence becomes available to support the use of such techniques in clinical practice, the proposed approaches can be considered in cases of individual patients with resistant and difficult-to-treat HTN to maximize targeted BP therapy.

Conclusion

Hypertension is not only prevalent in patients with CKD, it is also a key factor to control cardiovascular events in patients with CKD and to prevent progression of CKD itself. BP assessment is more complicated and needs special attention in patents with CKD. Since CKD by itself is an important determinant of disturbed BP control, secondary causes of HTN can easily be overlooked in this group. Inhibition of the RAS and volume control are key to BP management, next to lifestyle measures. Last but not least, BP treatment of the hypertensive CKD patient could benefit from a physiology-based approach.

Introduction

Chronic kidney disease-mineral and bone disorder (CKD-MBD) is commonly encountered in the later stages of CKD. CKD-MBD is a systemic disorder manifest by abnormal calcium, phosphorus, parathyroid hormone (PTH), and vitamin D metabolism; abnormal bone turnover, mineralization, volume, growth, or strength; and vascular and soft tissue calcification. Clinical features of CKD-MBD, such as accelerated cardiovascular disease and skeletal pain and deformity, are associated with premature mortality and impaired health-related quality of life (QoL) and symptoms. Recipients of a kidney transplant experience changes in bone metabolism and bone quality related to drug effects, particularly corticosteroid therapy.

A range of treatments are used to correct the metabolic abnormalities observed with CKD-MBD. These include phosphate binding agents, vitamin D compounds and analogs, calcimimetics, dietary restriction, parathyroidectomy, and bisphosphonates. Although CKD-MBD is central to the care of moderate to severe CKD (stages 3b-5), much of the rationale for treatment has been based on biological reasoning rather than empiric evidence. The prevailing rationale for treatment has been that correcting abnormalities in bone and parathyroid metabolism can prevent complications (specifically, vascular calcification and skeletal fragility and deformity) and thereby improve patient survival and QoL. CKD-MBD is associated with bone demineralization and, more importantly, with skeletal symptoms and nonosseous calcification, including calcification of the vasculature. The latter is thought to contribute to the increased premature cardiovascular mortality that is observed in CKD.

The therapeutic approach to CKD-MBD that considers treatment of abnormal serum PTH and phosphorus levels, and that maintains serum calcium levels to prevent skeletal and cardiovascular morbidity, is based principally on observational studies. High-quality evidence arising from randomized controlled trials (RCTs) to inform clinical decision-making for CKD-MBD and transplant-related bone disease is limited. Treatment efficacy is generally evaluated based on surrogate biomarkers of bone metabolism, strength, and density, and serum biochemical markers. Current therapies for CKD-MBD rely on a combination of approaches, including hormone replacement where hormone deficiencies are present (e.g. 25-hydroxy-vitamin D and 1,25 dihydroxy-vitamin D) and suppression where excesses occur (e.g. PTH and phosphorus) and direct modulation of serum and/or whole-body phosphorus and calcium.

Treatment recommendations regarding CKD-MBD in CKD stages 1–4 have been based on expert opinion and the extrapolation of evidence from stage CKD 5D Table 36.1. There are also no well-designed clinical trials in CKD of any stage that have evaluated concurrent modulation of combination therapies (e.g. phosphate binders along with vitamin D and calcimimetics) on the long-term outcomes of mortality and nonbone-related morbidity, particularly cardiovascular complications. Short-term trials of combination therapy with vitamin D and cinacalcet are available for surrogate outcomes such as serum PTH.

Recent systematic reviews of trials have shown that there is often low or very low certainty that treatment of CKD-MBD makes a difference to the outcomes that directly impact on patients including cardiovascular complications,

Table 36.1 Treatment for CKD-MBD.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Vitamin D	We suggest vitamin D compounds can be used to lower serum parathyroid hormone levels for patients with CKD. Patients with CKD (any stage) may reasonably choose not to receive vitamin D compounds based on the very low certainty that treatment makes a difference to longer term outcomes, including quality of life, skeletal symptoms, growth and bone deformities, and cardiovascular morbidity and mortality.	*Low or very low* (mortality, cardiovascular events, skeletal symptoms, quality of life) *Moderate* (serum parathyroid hormone levels)	Weak [1, 2]
Calcimimetic therapy	We suggest calcimimetic agents can be used to lower serum parathyroid hormone levels or prevent parathyroidectomy for patients treated with dialysis. Patients with CKD (any stage) may reasonably choose not to receive calcimimetic therapy as treatment makes no difference to mortality and causes gastrointestinal side-effects and hypocalcemia.	*High* (mortality, hypocalcaemia, parathyroidectomy in patients treated with dialysis) *Moderate* (nausea in patients treated with dialysis) *Low or very low* (CKD stages 3–5)	Weak [3]
Phosphate binders	We suggest phosphate binder therapy may be used to lower serum phosphorus levels in patients with CKD. Patients with CKD (any stage) may reasonably choose not to receive phosphate binder therapy based on the very low certainty that treatment makes a difference to skeletal, cardiovascular, or quality of life outcomes. The specific choice of phosphate binder may be determined by patient preferences for avoidance of specific adverse effects.	*Moderate* (gastrointestinal side-effects and hypercalcemia) *Low or very low* (mortality, cardiovascular events, skeletal symptoms, parathyroidectomy, quality of life)	Weak [4, 5]
Dietary restrictions	We suggest dietary phosphorus restriction may be used in patients with CKD to lower serum phosphorus levels. Patients with CKD may reasonably choose not to restrict dietary phosphorus based on the very low certainty that dietary modification makes any difference to mortality, cardiovascular events, or skeletal complications.	*Very low*	Weak [6]
Serum biochemical targets	We suggest that treatment of mineral and bone disorder is not guided by specific serum levels of parathyroid hormone, phosphorus, or calcium by phosphorus product based on the very low certainty that this approach makes a difference to longer term outcomes, including quality of life, skeletal symptoms, growth and bone deformities, and cardiovascular complications and mortality.	*Very low*	Weak [7]
Transplant bone disease	We suggest that bisphosphonates may be used to prevent fracture and bone pain. Patients with a kidney transplant may reasonably choose not to receive bisphosphonate therapy based on the low certainty that treatment makes any difference to skeletal complications and low certainty of safety information.	*Low*	Weak [8]

GRADE assessment of the certainty of the evidence [9]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

skeletal symptoms and deformity, growth in children, and QoL. Based on these findings, the choice of treatment should be based on patient preferences for improvement of specific outcomes and the avoidance of side effects, together with treatment availability and cost.

This chapter examines the evidence for management of CKD-MBD in adults, including transplant-related bone disease.

Definition

CKD-MBD is a systemic disorder of mineral and bone metabolism caused by impaired kidney function with one or more of the following abnormalities: dysregulated calcium, phosphorus, PTH, or vitamin D metabolism; altered bone turnover, mineralization, volume, linear growth or strength; or vascular or other soft tissue calcification [10].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

CKD-MBD usually develops over several years, with an asymptomatic phase that is manifest by hormone and serum abnormalities, including progressive increases in serum phosphorus and PTH. As the condition becomes symptomatic, patients can experience bone fragility causing pain or fracture, disability and impaired QoL, and vascular and valvular calcification causing cardiovascular complications, hospital admissions, and premature death.

In clinical practice during the 1980s and 1990s, disorders of bone and mineral metabolism caused by CKD were considered to be largely limited to bone abnormalities, hence the term "renal osteodystrophy." Renal osteodystrophy describes the pathological changes in bone morphology associated with CKD and is characterized by bone histomorphometry changes based on bone biopsy. Renal osteodystrophy includes a range of bone disorders including osteitis fibrosis cystica (high turnover with mineralization defect and normal bone volume), adynamic bone disease (low turnover with normal mineralization and low or normal bone volume), osteomalacia (low turnover with abnormal mineralization and low to medium bone volume), and mixed uremic osteodystrophy (high turnover with mineralization defect and normal bone volume).

The broader term, CKD-MBD, was developed by a consensus workshop in 2005 to recognize the diverse range of systemic manifestations of altered mineral metabolism [11]. As a result of this conference, the term renal osteodystrophy was recommended as a term used exclusively to define alterations in bone morphology associated with CKD, with reporting on histomorphometry based on a unified classification system including parameters of bone turnover, mineralization, and volume (TMV). The term CKD-MBD was recommended to describe the broader clinical syndrome manifest by abnormal bone and mineral metabolism and/or skeletal calcification.

For each patient, the clinical manifestations of CKD-MBD are varied and change over time. The variable phenotypic expression of CKD-MBD leads to the challenge of identifying and using a single and reproducible measure to define CKD-MBD and assess response to treatment.

Epidemiology

The heterogeneity in clinical and biochemical abnormalities of CKD-MBD makes it difficult to determine its exact prevalence in patients with CKD. The prevalence also depends both on the clinical characteristic used to identify the presence of the syndrome and the stage and duration of CKD.

Serum calcium and phosphorus levels tend to remain within normal physiological limits (>2.1 mmol/l and <1.5 mmol/l, respectively) until the glomerular filtration rate (GFR) is below 30 ml/min [12]. Approximately 40% of patients with a GFR <20 ml/min experience abnormal serum phosphorus and levels while 15–20% of such patients experience abnormal serum calcium levels. Serum PTH levels increase with decreasing GFR levels. High serum levels (>7.4 pmol/l) are present in 12% of those with GFR>80 ml/min, 17% of those with GFR 70 and 79 ml/min, 21% of those with GFR between 60 and 69 ml/min, and 56% of those with GFR <60 ml/min [12]. Serum 1,25-dihydroxy-vitamin D_3 concentrations tend to increase in parallel with decreases in GFR, with levels of 22 pg/ml experienced by approximately half of patients with a GFR between 20 and 29 ml/min.

Determining the prevalence of bone morphology changes caused by CKD is more challenging to assess than serum biomarkers due to the invasive nature of the bone biopsy, potential coexistence of osteopenia or osteoporosis in older patients, and the range of treatments used to manage CKD-MBD. Abnormal bone metabolism is observed in nearly all patients with CKD stage 5D (requiring dialysis) and most patients with CKD stages 3–5. Adynamic bone disease, in which low bone turnover with normal mineralization occurs (with diminished osteoblast activity, bone formation, and activation) is present in 10–71% of patients with CKD stage 5D and 5–49% of patients with CKD stages 3–4 [13]. Due to secular trends in treatment of CKD-MBD and increasing comorbidity associated with CKD, the prevalence of adynamic bone disease appears to be increasing.

Medial vascular calcification is highly prevalent in patients with CKD and inversely correlates with GFR [14]. In young patients treated with dialysis, coronary artery calcification, measured by electron beam computed tomography, was present in 80% of patients between 20 and 30 years old, and nearly doubled over a period of 20 months [15]. In a small study in 48 patients with a GFR between 17 and 55 ml/min, 90% of patients demonstrated aortic vascular calcification, suggesting the majority of patients with CKD stages 3–5 have arterial calcific changes [16].

Recipients of a kidney transplant lose bone rapidly and early after transplantation from body sites rich in trabecular bone [17]. Bone mineral density may decline by 4–10% in the first 6 months, with further decreases of 0.4–4.5% between 6 and 12 months [18, 19]. Devolution of parathyroid gland overactivity decreases after transplantation, but PTH levels may remain elevated in 45% of kidney transplantation recipients for up to 2 years [20]. Bone histomorphometry shows increased trabecular separation and reduced number, delayed mineralization and lower mineralizing surface, and higher osteoid surfaces with lower bone volume [21].

This figure 36.1 illustrates some of the complex relationships between calcium, phosphorus, vitamin D, and PTH that determine normal mineral metabolism and some of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ways in which these relationships may be altered in CKD leading to the development of CKD-MBD. Two processes mediate the early events in the pathogenesis of CKD-MBD in early CKD: the renal and systemic responses to excess phosphorus and the fall in active 1,25 dihydroxy-vitamin D levels. The number of functioning nephron units declines as kidney function worsens. The maintenance of normal serum phosphorus levels in the presence of CKD is dependent on an increase in phosphate excretion per nephron. High PTH and low active vitamin D levels inhibit tubular phosphate transport by decreasing sodium-dependent phosphate cotransporter activity. Fibroblast growth factor (FGF)-23 and the FGF-23 FGFR-Klotho complex may be important modulators of renal phosphate excretion. In addition, FGF-23 appears to reduce $1,25(OH)_2$ vitamin D in part by decreased 1-α-hydroxylase activity. The fall in 1-α-hydroxylase activity in CKD is most likely secondary to multiple mechanisms. Active vitamin D is also reduced in many patients because of insufficient 25 hydroxyvitamin D. Low levels of active vitamin D reduce calcium absorption from the gastrointestinal tract and stimulate secretion of PTH. Additionally, low calcium levels stimulate PTH secretion. Consequently, calcium levels are partially restored by release of calcium from the bone. Excess PTH, hyperphosphatemia, and vitamin D deficiency each appear to contribute to the development of the systemic and vascular manifestations of CKD-MBD.

Pathophysiology

Renal osteodystrophy was recognized as a significant and progressive disease in patients with CKD stage 5 soon after effective renal replacement therapy became generally available in North America, Europe, and Asia. The disease state was recognized principally as a demineralizing and debilitating bone disease leading to gross skeletal deformation, hypocalcemia, and hyperphosphatemia. It was observed to be more prevalent in patients with prolonged kidney failure, and especially among those with chronic diseases of the renal tubulo-interstitium [22]. Bone biopsy studies demonstrated that the degree of disordered bone architecture was associated directly with the degree of hyperparathyroidism and that the latter correlated in some studies to 25(OH)-vitamin D deficiency or to $1,25(OH)_2$-vitamin D deficiency [23–26].

Abnormalities of bone and mineral metabolism start to occur in CKD stages 2 and 3 when the GFR is between 40 and 70 ml/min. Even before clinical changes are observed in serum phosphorus levels, injury to kidney tissue stimulates circulating signals that modify osteocyte function. An overview of the pathogenesis of CKD-MBD is shown in Figure 36.1.

A progressive increase in fibroblast growth factor 23 (FGF23) occurs as GFR falls due to increased secretion by

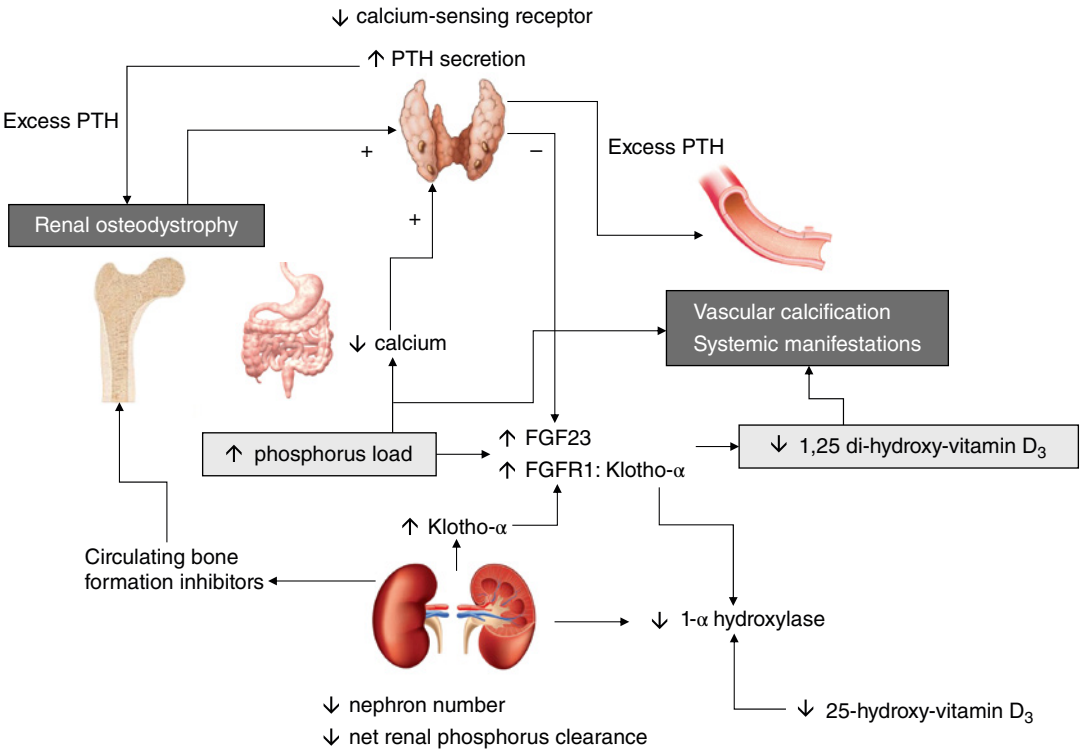

Figure 36.1 Pathogenesis of secondary hyperparathyroidism and CKD-MBD.

osteocytes and osteoblasts, loss of secretory inhibition, and impaired renal excretion [27]. FGF23 acts together with a coreceptor, the transmembrane protein Klotho-α, to suppress PTH gene expression and secretion [28]. Klotho-α is also expressed in the proximal renal tubule, acting to regulate tubular phosphorus transport, together with modulation of 1α-hydroxylase and 24-hydroxylase, involved in the activation steps of vitamin D_3 [29]. The maintenance of normal serum phosphorus levels in the presence of CKD is dependent on an increase in the fraction of filtered phosphate reabsorbed per nephron. High PTH and low active vitamin D levels inhibit tubular phosphate transport by decreasing sodium-dependent phosphate cotransporter activity and increasing phosphate excretion per nephron. In addition, FGF-23 appears to reduce $1,25(OH)_2$ vitamin D_3 in part via decreased 1-α-hydroxylase activity.

The fall in 1-α-hydroxylase activity in CKD is most likely secondary to multiple mechanisms. Active vitamin D is lower in many patients because of insufficient 25-hydroxy-vitamin D. 25-hydroxy-vitamin D (calcidiol) is the substrate for 1-α hydroxylase action and can be reduced in CKD due to lower sun exposures, lower skin synthesis of cholecalciferol with uremic-pigmentation, and dietary restrictions. Low levels of active vitamin D (1,25-dihydroxy-vitamin D_3) result in reduced calcium absorption through the gastrointestinal tract and stimulate secretion of PTH. Additionally, low serum calcium levels lead to increases in PTH secretion through exocytosis due to lower activation of the calcium-sensing receptor. In response, serum calcium levels are partially restored by release of calcium from the bone.

The progressive decrease in 1,25-hydroxylation of vitamin D_3 through decreasing 1-α hydroxylase activity in kidney tissue, mediated in part by the counter-regulatory actions of FGF-23, is an important factor in the development of CKD-MBD [30]. Decreasing 1,25-hydroxy-vitamin D_3 levels and the consequent hypocalcemia are key stimulants of PTH secretion. A complex interplay between vitamin D deficiencies, low serum calcium, high serum phosphorus, elevated FGF-23 levels which reduce calcitriol activity, together with impaired intestinal absorption of dietary and supplemental vitamin D, and altered dietary patterns caused by uremia, are the hallmarks of CKD-MBD.

Abnormalities in bone due to CKD include changes in bone turnover, mineralization, and volume (Figure 36.2), leading to pain, fracture, and deformity.

Excessive circulating PTH increases bone turnover. Disordered osteoblast function results in impaired collagen release and the generation of woven bone structure. Fibrosis occurs in the peritrabecular and marrow contours due to

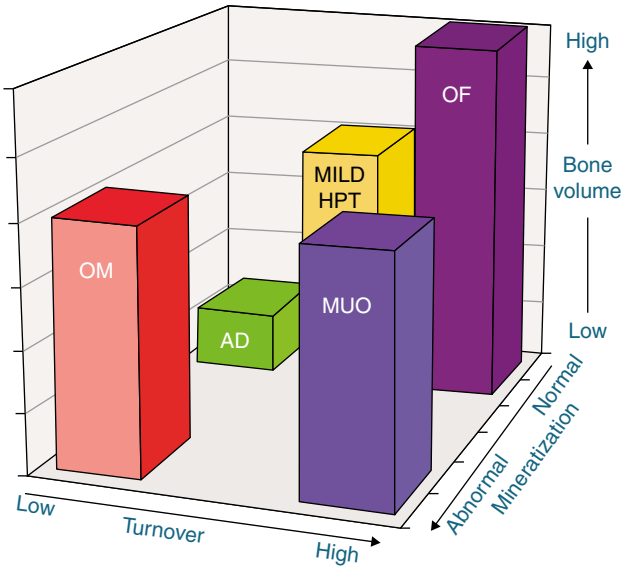

Figure 36.2 Changes in bone architecture and metabolism in CKD-MBD. AD, adynamic bone disease. HPT, hyperparathyroidism. MUO, mixed uremic osteodystrophy. OM, osteomalacia. (Permissions needed from [11]). *Source:* Moe S et al. [11]. © 2006, Elsevier.

collagen deposition from fibroblastic osteoprogenitors. Osteoid, the nonmineralized structure within bone, is expanded, resulting in loss of the usual three-dimensional structure of bone architecture. Mineralization of bone is accelerated, leading to altered bone strength and form. This process of abnormal and increased bone osteoid generation and mineralization is known as high bone turnover renal osteodystrophy (or osteitis fibrosa). Low-bone turnover disease is marked by reduced bone turnover, suppressed bone formation, and impaired bone mineralization, leading to accumulated nonmineralized bone matrix and increased osteoid volume. A mixed osteodystrophy results from high PTH levels together with impaired mineralization. Bone formation is variable and can be high or low. Increased number and activity of osteoclasts is seen together with accumulated woven osteoid, and variable mineralization depending on the presence of woven or lamellar bone. Vascular smooth muscle cells are located in the media of vessel walls and contract to regulate vascular tone.

In the presence of uremic serum and inorganic phosphate, high glucose, oxidized lipids, and cytokines, vascular smooth muscle cells can dedifferentiate into osteocytic-like cells. This osteogenic phenotype increases expression of bone-forming transcription factors and matrix proteins [31]. The transformed vascular smooth muscle cells secrete collagen and noncollagenous proteins within the vessel intima and media. Incorporation of calcium and phosphorus within matrix vesicles initiates mineralization, leading to vascular calcification [32].

Figure 36.2 shows the prevalence of combinations of bone volume, turnover and mineralization. Clusters of characteristics can identify commonly encountered discrete pathological abnormalities that occur in CKD-MBD. For example, high bone volume, with normal mineralization and high bone turnover, characterizes osteitis fibrosa (OF) or advanced hyperparathyroid bone disease.

Transplant bone disease is characterized by pre-existing CKD-MBD, persistent hyperparathyroidism despite normalization of kidney function, hypovitaminosis D, and immunosuppression effects, particularly glucocorticoid treatment [33].

Diagnostic Tests

As CKD-MBD has protean manifestations that can be specific to the individual patients and vary based on severity of kidney disease and treatment, none of the diagnostic tests used for clinical decision-making measure all aspects of CKD-MBD. The diagnostic approach can be based on specific clinical probability of abnormalities and as a guide to treatment. The diagnostic tests to evaluate CKD-MBD are outlined in Table 36.2. In general, diagnosis and assessment involve evaluation of biochemical abnormalities and bone and vascular involvement. To date, there are no systematic summaries of diagnostic test performances of clinical methods used to evaluate CKD-MBD.

Biochemical Abnormalities

Clinical practice guidelines recommend biochemical markers including serum PTH, calcium, phosphorus, and bone-specific alkaline phosphatase to guide management and provide indirect information about high and low bone turnover [10]. Biochemical markers are not diagnostic of the clinical complications of CKD-MBD (bone disease, vascular occlusion, and symptoms) but are simple to obtain and can indicate responses to therapeutic interventions.

Serum PTH

Serum PTH rises progressively as kidney function declines and is often elevated above the normal range (1.1–7.4 pmol/l) in stages 3 and 4 CKD. PTH is the most commonly used biochemical marker to indicate likely bone turnover. A specific target range has not been identified at which clinical outcomes are reduced, and clinical practice guidelines suggest a broad range of appropriate values, consistent with this lack of evidence. High PTH levels (>91.2 pmol/l) combined with complications including refractory itch, skeletal pain or malformation, persistent hypercalcemia, and extraskeletal calcification may prompt consideration of surgical parathyroidectomy. Serum PTH levels may be poorly predictive of bone histological changes, although values at the extremes of the range can be specific for high and low bone turnover. In a retrospective study, the best cut-point to discriminate low from high bone turnover was an intact PTH <11.8 pmol/l while the best cut-point to discriminate high from low bone turnover was >36 pmol/l [39]. There may be some utility in serial measures of PTH to detect a rising concentration that might prompt identification of reversible causes including high dietary phosphorus, low dialysis dose, or vitamin D deficiency, or indicate the need to consider parathyroidectomy if symptoms arise.

Serum Phosphorus, Calcium, and Vitamin D

Serum phosphorus and calcium are commonly measured at regular intervals in clinical care. The serum levels are not diagnostic of a specific process and should be interpreted in the context of other findings (including symptoms, treatment, and serum PTH levels). Measurement of 25-hydroxy-vitamin D_3 may identify vitamin D deficiency (<50 nmol/l) or insufficiency (50–75 nmol/l). Circulating levels do not necessarily correlate with kidney function.

Bone

Bone tissue in CKD-MBD has abnormal turnover (balance between production and resorption), mineralization, and volume. A variety of measures have been used to assess for renal osteodystrophy and vary in terms of specificity, the range of information provided about bone turnover, mineralization, and volume, and the availability of diagnostic tests within routine clinical practice.

Bone-specific Alkaline Phosphatase

Alkaline phosphatase (ALP) circulates as several isoforms, including liver-specific and bone-specific ALP. Nearly all (95%) of circulating ALP is either bone- or liver-derived in equal ratios. Bone-specific ALP above 20 ng/ml has high sensitivity and specificity for identifying patients with high bone turnover and excluding those with low bone turnover [36]. Total ALP (including liver isoforms) has lower specificity for high (specificity 90%) and low (specificity 50%) bone turnover at a cut-point of 200 IU/l.

Biomarkers of Collagen and Bone Metabolism and Activity

Serum biomarkers such as osteocalcin, osteoprotegerin, TRAP-5b, pyridinoline, deoxypyridinoline, procollagen type 1 amino-terminal extension peptides, and C-terminal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 36.2 Summary of diagnostic tests in CKD-MBD.

Test	What does it measure?	Comments
Biochemical		
Parathyroid hormone	• Measures circulating intact parathyroid hormone • Normal 1.1–7.4 pmol/l • PTH fragments accumulate in CKD and may interfere with some assays	• Optimal level unknown in CKD • Rising level can prompt for assessment of high phosphate levels or intake, hypocalcemia, and/or vitamin D deficiency • Low levels may indicate risk of low bone turnover • Serum PTH levels poorly predict bone histology • High PTH levels together with symptoms (high serum calcium, symptomatic bone disease, refractory pruritus, extraskeletal calcification or calciphylaxis, unexplained myopathy) may prompt consideration of surgical parathyroidectomy
Calcium	• Measures circulating calcium concentrations but not ionized levels • Needs adjustment for serum albumin • Not indicative of total body calcium burden	• Can be low due to decreased 1,25-di-hydroxy-vitamin D_3 levels, phosphatemia, and blunted bone response to PTH • Can be elevated secondary to treatment and/or tertiary hyperparathyroidism • Low levels associated with tetany and cardiac arrhythmias; high levels associated with kidney stones, mood disorders, acute kidney injury, and consitpation
Phosphorus	• Measures circulating serum phosphorus concentrations. • Influenced by food intake, adherence to and timing of medication, and interval from last dialysis • Serial measures most appropriate to guide therapy	• Optimal level unknown in CKD • Interpretation in context of other biomarkers and patient's treatment and symptomatic state is appropriate
25-hydroxy-vitamin D_3	• Identifies vitamin D deficiency (<50 nmol/l) or insufficiency (50–75 nmol/l) [34]	• Not directly correlated with GFR • 10–50% of patients with CKD stages 3 and 4% have levels >75 nmol/l • Can guide therapeutic replacement although high certainty evidence of improved clinical outcomes not available
Bone		
Alkaline phosphatase	• 95% of serum alkaline phosphatase (ALP) in healthy adults is either bone ALP or liver ALP isoforms in approximately equal parts [35] • Testing for bone-specific ALP isoform can provide predictive information for bone histology and activity	• Lower biological variability than PTH • Markedly high or low levels of bone-specific may predict bone turnover • Elevated bone-specific ALP (20 μg/l) and PTH (>22 pmol/l) has 100% sensitivity and 80% specificity for high turnover bone disease [36] • Combining bone-specific ALP <20 μg/l and PTH <22 pmol/l provides 100% sensitivity and 100% specificity for low turnover bone disease [36]
Bone-derived turnover markers of collagen synthesis and breakdown	• Includes markers of synthesis (procollagen type I C-terminal propeptide) and breakdown (type I collagen cross-linked telopeptide, pyridinoline, deoxypyridinoline)	• Uncertain diagnostic utility in CKD • Variable renal clearances and undefined reference ranges for CKD mean these tests are not currently recommended in routine diagnostic work-up for CKD-MBD

Table 36.2 (Continued)

Test	What does it measure?	Comments
Bone biopsy	• Measures bone microarchitecture, turnover, and mineralization • Considered gold-standard for assessment of renal osteodystrophy	• Invasive, requires expertise to perform, process, and interpret; rarely performed in clinical care • Limited usefulness for monitoring treatment response due to invasiveness
Dual-energy X-ray absorptiometry (DXA)	• Measures bone mineral density (BMD) in grams per square centimeter	• Inexpensive, noninvasive, and low radiation exposure • Limited information about bone quality or turnover • Low bone mineral density may predict fracture in any stage of CKD [37, 38]
High-resolution peripheral quantitative computed tomography (HR-pQCT)	• Measures three-dimensional microstructure of cortical and trabecular bone to generate microstructural analysis • Evaluates bone mechanical competence • Evaluates distal tibia and radius • Measures volumetric bone mineral density	• Low radiation • Requires specific scanner, not available in many clinical settings • Limited standardized reference data • Limited evidence of validation against bone histomorphometry • Not in routine clinical care
High-resolution magnetic resonance imaging (HR-MRI)	• Measures bone microarchitecture • Evaluates distal tibia, radius, femur	• No ionizing radiation • Routine scanning equipment • Limited evidence of validation against bone histomorphometry • Complex post-processing analysis • Not in routine clinical care
Cardiovascular		
Lateral X-ray lumbar abdominal aorta	• Semi-quantitative estimation of calcification of abdominal aorta	• Sensitivity 62%, specificity 78% for coronary artery calcification if X-ray score >7 • Simplicity
Computed tomography	• Electron bean (EBCT) and multislice (MSCT) • Coronary artery calcification measured as Agatston score is calculated as the product of a calcified plaque area by a coefficient related to the peak CT density measured within the same plaque	• Radiation • Not able to differentiate between intimal and medial calification • Limited information about severity of obstructive coronary artery disease
Echocardiogram	• Identification of valvular abnormalities	• Readily available • Functional cardiac information • No radiation

crosslinks have no role in clinical care due to their lack of diagnostic evidence and renal elimination, leading to difficult interpretation of their diagnostic test performance in the presence of CKD [11].

Bone Structure and Quality

Diagnostic tests for renal osteodystrophy would ideally examine the essential properties of bone: strength for load-bearing, flexibility to absorb energy, compression, and tension without fracture, and volume and weight to facilitate mobility [40]. Assessing the quality of bone structure to bear mechanical load without injury is limited as diagnostic tests measure indirect markers of bone metabolism or turnover, density, or structural composition. Routinely used diagnostic approaches for CKD-MBD would optimally identify specific functional or structural bone abnormalities that can be ameliorated by therapy to prevent adverse patient outcomes. However, not all fractures or bone symptoms have the same pathogenesis and CKD-MBD is characterized by highly heterogeneous changes to bone density, architecture, mineralization, and volume. Standard diagnostic approaches to fracture risk secondary to osteoporosis may have different diagnostic utility in the present of CKD.

In this section, the diagnostic strategies to examine bone density and bone structure and quality are discussed.

Bone Imaging

Bone Mineral Density

A key purpose of diagnostic evaluation of renal bone disease is to predict and guide management based on patient-relevant outcomes, including risks of skeletal deformity, loss of height, bone pain, and low trauma fracture. Assessing bone mineral density (BMD) is recommended by the United States Preventive Task Force [41] as a component of screening for osteoporosis in women older than 65 years and younger women at higher risk of fracture. The role of BMD assessment to guide management in CKD-MBD is more uncertain.

Hyperparathyroidism may lead to sclerosis and thickening of trabecular bone (and increased BMD) with concurrent accelerated resorption of cortical bone (with reduced BMD). Consequently, BMD may poorly predict fracture risk and lead to administration of anti-osteoporotic therapy that adversely impacts on bone metabolism.

A previous consensus workshop on the definition and evaluation of CKD-MBD in 2006 cited a study in 70 patients treated with hemodialysis, in which mid-radius but not femoral neck and lumbar spine BMD was decreased and correlated with time on dialysis [42]. While BMD at all sites (mid-radius, femoral neck, lumbar) was negatively correlated with bone-specific ALP and serum-intact PTH, there was no association with fracture occurrence, suggesting BMD may have limited utility in CKD-MBD.

BMD measurement using dual-energy X-ray absorptiometry (DXA) is suggested by the 2017 updated Kidney Disease: Improving Global Outcomes (KDIGO) guidelines for patients in whom knowledge of fracture risk will inform decision-making [10]. This is consistent with findings in a longitudinal cohort study involving 131 patients with CKD stage 5 treated with hemodialysis [43]. A BMD T-score ≤−2.5 at the total hip had a sensitivity of 88.5% and specificity of 65.6% for incident low trauma fractures or morphometric spine fractures, while the diagnostic test performance of lumbar spine BMD was somewhat lower (81.3 and 68.6%). In a second study of 485 hemodialyzed patients who were followed for 5 years for radiographic spine or any clinical fracture, the sensitivity and specificity for any fracture was highest for total hip BMD T score ≤−2.7 (66.7% and 84.9%) for patients with a serum PTH <23.3 pmol/l, and had lower predictive utility in those patients with a serum PTH above the same cut-point [37].

There are no high-quality studies evaluating the performance of DXA for BMD to predict clinical bone outcomes after kidney transplantation.

Quantitative Computed Tomography

In addition to DXA, BMD can be quantified using quantitative computed tomography (QCT), which provides a volumetric assessment of bone density, differentiates between cortical and trabecular bone, and is less prone to interference from bone deformity and overlying nonosseus calcification. QCT can assess BMD at the hip and vertebra peripheral body sites, and involves high radiation exposure. Peripheral QCT (pQCT) is an application of QCT that can evaluate BMD at distal sites, such as the radius or tibia.

High-resolution (HR) peripheral QCT (HR-pQCT) is similar to QCT, although higher spatial resolution allows HR-pQCT to measure BMD in the distal extremities (specifically the radius and tibia). In patients with stage 5D, HR-pQCT at the radius measuring cortical bone structures (area, density, and thickness) provided the highest AUCs (0.73, 0.72, and 0.72, respectively) to predict any incident radiological spinal or low trauma fracture [43]. The predictive value of trabecular bone parameters derived from HR-pQCT was lower than for cortical bone. In a study comparing vertebral bone density obtained by QCT with bone histomorphometry in 26 patients treated with hemodialysis, vertebral BMD by QCT was correlated with trabecular bone volume, while QCT for vertebral BMD had an AUC of 0.76 for bone volume by bone biopsy [44].

In addition to measurement of BMD in distal sites, HR-pQCT can provide information about bone microstructure including cortical density, area, and thickness, and trabecular number and architecture. In 91 patients with CKD (32 with fracture and 59 without fracture), HR-pQCT of the radius in those with fracture demonstrated lower cortical area and thickness, and lower trabecular number and greater trabecular separation [45]. The discrimination for fracture by HR-pQCT parameters varied by duration of CKD.

Magnetic Resonance Imaging

High-resolution MRI (HR-MRI) and micro-MRI provide 3D information of bone morphology and trabecular structures at peripheral body regions and avoids the need for ionizing radiation [46]. These tools may provide noninvasive evaluation of renal osteodystrophy, but remain largely limited to research settings.

Bone Biopsy

The bone biopsy remains the gold standard for detailed information about bone metabolism, but remains limited in clinical practice due to the invasive nature of the procedure and the expertise required to conduct, process, and analyze the information provided. The bone biopsy can allow the direct visualization of bone to evaluate bone turnover, mineralization, and volume, according to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a standardized nomenclature based on these components (turnover/mineralization/volume; TMV) [11]. Unlike biochemical markers, bone biopsy can distinguish high turnover bone disease from other forms of bone disease, including mixed osteodystrophy, low bone turnover (adynamic bone disease, osteomalacia), and bone pathologies caused by specific etiologies.

The bone biopsy has not been recommended for routine care, but may assist specific management in the presence of inconsistency among diagnostic tests, unexplained fracture or bone pain, severe progressive vascular calcification, unexplained hypercalcemia, possible aluminum toxicity, definitive histological diagnosis before parathyroidectomy, and prior to bisphosphonate treatment.

Bone biopsy after kidney transplantation may identify patients who have low bone turnover, for whom antiresorptive therapies may increase risks of complications, although there are no studies evaluating the diagnostic test performance of bone histomorphometry in the setting of kidney transplantation [33].

Fracture Risk Assessment

The Fracture Risk Assessment Tool (FRAX) incorporates demographic variables (age, sex), clinical factors (weight, height), and risk factors for factor (previous facture, smoking, glucocorticoids, rheumatoid arthritis, alcohol intake, secondary osteoporosis) with or without BMD to estimate a ten-year probability of fracture [47].

Evidence supporting FRAX as a predictive tool in CKD is limited. The performance of the FRAX score has been tested in a Canadian multicenter study of patients over 40 years with CKD stage 3 [48]. FRAX with BMD has moderate–low discriminatory power to predict fracture (AUC 0.69). In a study involving recipients 1-year on average after kidney transplantation, the FRAX score with bone mineral density had limited predictive utility for major fracture (AUC 0.62) [49].

Vascular Calcification

Diagnostic tests for vascular calcification in patients with CKD include assessment for abdominal aortic and valvular calcification.

Plain Radiography

Abdominal aortic calcification can be identified by a lateral abdominal radiograph (to avoid the overlay of the aorta and the vertebral structures). X-rays can be assessed for the presence of vascular calcification. Plain radiography is a simpler, cheaper test for calcification that limits radiation exposure compared with computed tomography. In addition, semiquantitative measures of severity can be applied to provide a calcification score (range 0–24) [50]. In a study of 275 adults treated with hemodialysis, 77.8% had abdominal aortic calcification with a median score of 6 [51]. Evidence for the diagnostic utility of abdominal X-ray to predict clinically relevant disease in CKD is sparse. In 90 patients treated with hemodialysis, a cut-off vascular calcification score of 6.5 on abdominal radiography had a sensitivity of 85% and specificity of 57% for coronary artery disease [52].

Computed Tomography

Computed tomography (electron beam [Electron Beam Computed Tomography] or multislice [Multi-slice computed tomography]) provides quantitative assessment of coronary artery calcification. The degree of coronary artery calcification can be calculated using the Agatston score, calculated by multiplying the area of each calcified lesion by the pixel intensity of the lesion [53]. The scores for each lesion are then summed to provide an overall score, reflecting burden and intensity of calcification. Calcification scores in adults of 0–10, 11–100, >100, and >400 represent low, intermediate, progression from intermediate to high, and highest risk, respectively [54]. Patients treated with dialysis have coronary artery calcification scores 10-fold higher (approximately 4000 on average) than age-matched patients [55].

In a study of young patients with CKD stage 5 (ages 7 to 30 years), nearly all (88%) patients older than 20 years of age had evidence of coronary calcification with EBCT, compared with 5% of similarly aged people without CKD stage 5 [15]. In a small study in 29 patients with CKD stage 5, a CT-based coronary artery calcium score >500 had sensitivity and specificity of 50% and 80% for detecting coronary artery stenosis ≥50% luminal narrowing on percutaneous angiography. This suggests that CT calcification has a low detection rate for coronary artery stenosis, but may have moderate test performance for exclusion of coronary artery narrowing [56]. The current role of coronary artery calcification scores to detect luminal coronary artery occlusion or for clinical-decision making is uncertain [57].

Echocardiography

There are limited data on the diagnostic utility of echocardiography for clinical decision-making about cardiac valvular calcification specific to the setting of CKD.

Prognosis

Skeletal Complications (Fracture, Pain, Deformity)

Several large-scale studies have demonstrated increased risks of fracture for patients with CKD stage 5D. Hip fractures measured using ICD-9 codes occur at an incidence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

8 per 1000 person-years for men and 14 per 1000 person-years for women, suggesting a relative risk approximately fourfold that of the general population [58]. Prior kidney transplantation increases fracture risk, which becomes attenuated over time after surgery, while among transplant recipients fracture risk is higher among those with a prolonged duration of dialysis prior to transplantation. The incidence of fracture is higher among those with low or high serum PTH levels and for those receiving psychoactive or corticosteroid medications [59, 60].

In nearly two million community-living adults, and using diagnostic and procedure codes to evaluate fracture risk during 4.4 years of follow-up, there appears to be no increased risk of hip, wrist, or vertebral fracture among those with an estimated GFR below 60 ml/min per 1.73 m^2 [61]. It is possible that evidence of higher fracture risk associated with CKD is due to confounding by comorbidity, including inflammation and BMD [62].

Risks of fracture after kidney transplantation are highly heterogeneous, ranging from 3 to 100 fractures for every 1000 person-years [63]. Differences between studies are likely to relate to study population differences, type of fracture, and duration of dialysis before transplantation. Overall, the 10-year cumulative incidence of hip fracture for kidney transplantation is 1.7%, while the 3-year nonvertebral fracture incidence (1.6%) may be lower than the general population with a previous nonvertebral fracture (2.3%) [64].

The incidence of bone pain and skeletal deformity with CKD is less frequently reported than fracture, likely due to the availability of diagnostic and procedural codes to capture fracture-related events for longitudinal analyses compared with the challenge of systematic collection of symptoms and patient-reported outcome measures. In a community cross-sectional study among 1118 patients with CKD, bone and joint pain was the most frequently experienced symptom [65], although this has not been a consistent finding in the literature [66, 67]. Similarly, there are insufficient systematic data recorded on skeletal pain or deformity for recipients of a kidney transplant.

Mortality and Cardiovascular Events

The protean manifestations of CKD-MBD, including biochemical abnormalities, vascular calcification, and fracture, are associated with mortality, hospitalization, and cardiovascular events. The rationale for therapeutic control of serum PTH and phosphorus levels has been, in part, evidence of the "dose-dependent" association between higher serum phosphorus and PTH concentrations with all-cause mortality, as demonstrated in two seminal studies by Block et al. [68, 69]. However, in a systematic review of 47 cohort studies, while there is evidence that the risk of death increases by 18% for every 1 mg/dl increase in serum phosphorus (0.32 mmol/l), there is little evidence that serum levels of calcium and PTH are associated with all-cause or cardiovascular mortality [7]. Similarly, there are no robust cohort data to show that alterations in serum concentrations over time are linked to clinical outcomes, or that therapeutic modulation of serum phosphorus levels improve clinical outcomes.

Bone-related abnormalities including altered bone mineral density, fracture, high or low bone turnover diseases and extra-osseus calcification are all associated with worse clinical outcomes, including cardiovascular events, hospitalization, and death. As with serum parameters, evidence that treatment modification or prevention improves QoL or survival is awaited, while associations with clinical outcomes may represent confounding due to kidney function and comorbidity that cannot be accounted for by statistical adjustment [70].

Treatment

Historically, treatment of CKD-MBD focused on management of renal osteodystrophy and secondary hyperparathyroidism. The goals of therapy were to prevent symptoms or provide symptom relief, and control the mineral abnormalities of high serum phosphorus, low serum calcium, and progressive increases in serum PTH. More recently, due to the recognition that serum calcium, phosphorus and PTH level, and vascular calcification are associated with mortality and premature cardiovascular events, treatment goals were expanded to preventing premature death and cardiovascular complications. Treatment to correct abnormal serum levels of calcium and phosphorus has demonstrated efficacy across many randomized trials, while evidence of high certainty that such treatment makes a difference to clinical outcomes including fracture, mortality and cardiovascular events has remained elusive despite a wealth of clinical research.

Phosphate Lowering

Phosphate binders reduce phosphorus absorption from dietary content through binding within the gut (Box 36.1). Given the strong association between elevated serum phosphorus that occurs in the later stages of CKD with vascular and metastatic calcification, phosphate binders have been universally adopted into routine care and were recommended in early guidelines [71], despite there being no high-quality evidence that these agents prevent symptoms or bone and cardiovascular complications of CKD.

Box 36.1 Agents used as Phosphate Binders

Mineral salts
- Calcium carbonate
- Calcium acetate
- Calcium citrate
- Magnesium hydroxide
- Magnesium carbonate

Metal-based compounds
- Aluminum hydroxide
- Lanthanum carbonate
- Iron salts

Nonabsorbed polymers and resins
- Sevelamer hydrochloride
- Sevelamer carbonate

Aluminum

Aluminum hydroxide came into widespread use in the mid- to late 1970s, although subsequently drew concern because of case series that associated aluminum accumulation with neurotoxicity and other tissue toxicities, well-studied disease outbreaks associated with parenteral aluminum from dialysate, experimental models of aluminum toxicity, and the observation that chelation therapy appeared to modify the natural history of toxicity in cases attributed to oral aluminum exposure [72–78]. Evidence supporting the view that aluminum salts may be harmful and less effective than calcium-based binders infer that there is not a level of aluminum exposure that is safe during long-term use [78, 79].

Nonaluminum Phosphate Binders

Numerous RCTs of phosphate binders have been conducted, although most evaluate therapy for a few weeks or months and compare newer phosphate binders against calcium-containing salts [80]. Placebo-controlled trials have small sample sizes and are designed to prove the efficacy of therapy to lower serum phosphorus.

A network meta-analysis of RCTs evaluating phosphate binders, except for aluminum salts, provides evidence for comparative efficacy and safety against other phosphate binder classes or placebo or standard therapy in the absence of head-to-head trials (Table 36.3) [7]. Compared with placebo, all phosphate binder classes lower serum phosphorus, and iron-based binders lead to greater reductions than sevelamer, lanthanum, and calcium. Despite this, it is very uncertain whether phosphate binders prevent death, fracture, or need for parathyroidectomy when compared with either calcium-based binders or placebo. Sevelamer (carbonate or hydrochloride) may prevent death compared with calcium-based binders, although confidence in this evidence is low due to important methodological limitations in the available trials. It is also uncertain whether sevelamer lowers mortality, calcium biners increase mortality, both, or neither.

Sevelamer and lanthanum binder classes probably incur less hypercalcemia than calcium-based binders. The longer-term consequences of less hypercalcemia and calcium exposure with noncalcium binders is not deducible from randomized trials.

Adverse effects appear specific to specific phosphate binder classes. Sevelamer ranks as the highest probability of causing constipation, while lanthanum ranks highest for nausea and iron binders rank highest for diarrhea. Phosphate binders account for one-half of the daily pill burden for patients treated with dialysis, which is associated with lower health-related QoL [81].

Magnesium carbonate, magnesium hydroxide, and other magnesium salts bind phosphorus. In a short-term study magnesium carbonate lowered calcium ingestion from phosphate binding agents [82]. In a network meta-analysis, there was little or no high-quality evidence pertaining to patient-centered outcomes for magnesium-based binders [5].

It remains uncertain when, along the spectrum of CKD, phosphate binders should be initiated, what level of serum phosphorus should be targeted to improve outcomes, and whether all phosphate binders are equivalent in terms of long-term outcomes. There is currently no evidence based on randomized trials that specific target levels of serum phosphorus improve clinical endpoints. In a trial involving patients with CKD (stages 3b and 4) increases in coronary calcification artery calcium volume particularly among patients at caution may be needed for the use of phosphate-binding therapy for patients with normal serum phosphorus levels [83].

Dietary Modification

Clinical practice guidelines suggest lowering dietary intake of phosphorus to control serum phosphorus [10]. A Cochrane review identified there is low-quality evidence that dietary phosphorus restriction makes any difference to clinical outcomes, although dietary modification did lower serum phosphorus by 0.18 mmol/l on average [84]. In uncontrolled studies, there is no evidence of an association between phosphate intake (as estimated by 24-hour excretion) and serum phosphorus [85] or cardiovascular disease and mortality [86].

Dialysis Duration and Frequency

Frequent or longer hours dialysis lowers serum phosphorus levels. In the Frequent Hemodialysis Network (FHN)

Table 36.3 Summary of findings: phosphate binder therapy.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% confidence interval)	Certainty of the evidence (GRADE)	Conclusion
Sevelamer versus calcium-based binder					
All-cause mortality	6376 (20)	122 fewer (158 to 52 fewer)	0.39 (0.21 to 0.74)	Low ●○○○	Sevelamer may prevent death
Cardiovascular death	2712 (4)	100 fewer (138 fewer to 61 more)	0.33 (0.08 to 1.41)	Very low ○○○○	It is uncertain whether sevelamer makes any difference to cardiovascular mortality
Fracture	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of sevelamer on fracture
Parathyroidectomy	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of sevelamer on parathyroidectomy
Constipation	7862 (27)	12 more (0 to 38 more)	2.12 (1.01 –4.45)	Moderate ●●○○	Sevelamer probably leads to constipation compared with calcium-based binders
Nausea	7265 (26)	2 fewer (10 fewer to 16 more)	0.84 (0.34–2.08)	Low ●○○○	It is uncertain whether sevelamer leads to nausea
Hypercalcemia	5159 (21)	76 fewer (82–62 fewer)	0.14 (0.07 –0.29)	Moderate ●●○○	Sevelamer probably leads to less frequent hypercalcemia than calcium-based binders
Lanthanum versus calcium-based binder					
All-cause mortality	6376 (20)	Not estimable	0.78 (0.16–3.72)	Very low ○○○○	It is uncertain whether lanthanum decreases mortality
Cardiovascular death	- (—)	—	No studies	Absent	No studies were found that studied the impact of lanthanum on cardiovascular mortality
Fracture	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of lanthanum on fracture
Parathyroidectomy	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of lanthanum on parathyroidectomy
Constipation	7862 (27)	18 fewer (38 fewer to 18 more)	0.70 (0.37–1.30)	Low ●○○○	It is uncertain whether lanthanum leads to constipation
Nausea	7265 (26)	144 more (0 to 456 more)	2.18 (1.00–4.74)	Low ●○○○	Lanthanum may lead to nausea
Hypercalcemia	5159 (21)	109 fewer (116–90 fewer)	0.09 (0.03–0.25)	Moderate ●●○○	Lanthanum probably leads to less frequent hypercalcemia than calcium-based binders

Daily Trial, dialysis six times per week lowered serum phosphorus by 0.18 mmol/l compared with dialysis three times per week [87]. Similarly, frequent nocturnal hemodialysis lowered serum phosphorus levels by 0.45 mmol/l compared with conventional hemodialysis [88]. However, whether these changes in serum phosphorus translate into improved clinical outcomes is uncertain.

In summary, these data suggest phosphate binder therapy may be used to lower serum phosphorus levels in patients with CKD. Patients with CKD (any stage) may reasonably choose not to receive phosphate binder therapy based on the very low certainty that treatment makes a difference to skeletal, cardiovascular, or QoL outcomes. There is limited evidence dietary modification or higher dose dialysis to lower serum phosphorus improves clinical endpoints. The specific choice of phosphate binder may be determined by patient preferences for the avoidance of specific adverse effects together with considerations of drug availability and cost.

Lowering Serum Parathyroid Hormone and Maintaining Serum Calcium

There are five principal modalities of treatment to treat elevated serum PTH levels and maintain serum calcium levels. These include (i) vitamin D compounds and synthetic analogs, (ii) calcimimetic agents, (iii) combinations of pharmacological interventions (vitamin D plus calcimimetic), (iv) lowering dialysate calcium, and (v) surgical parathyroidectomy Box 36.2.

Vitamin D

The natural history of untreated CKD-MBD is characterized by marked skeletal disability and hypocalcemia causing tetany. Early studies demonstrated that 25-hydroxy-cholecalciferol and calcitriol increased serum calcium, suppressed PTH, and stabilized bone histology [89–93], but promptly incurred hypercalcemia, elevated renal calcium excretion, and accelerated progression of kidney failure in a dose-dependent manner [94, 95]. Lower calcitriol doses suppressed PTH with lower risks of a hypercalcemic response [96, 97]. Much of the evidence supporting vitamin D treatment derives from these proof-of-concept studies and longitudinal cohort studies demonstrating an association between vitamin D therapy and lower mortality, although this observation has been questioned on the basis that a survival advantage with treatment may reflect unmeasured confounding related to treatment selection and indication [98–101].

Box 36.2 Vitamin D Agents

Cholecalciferol (vitamin D_3)
Ergocalciferol (vitamin D_2)
Calcifediol (25-hydroxy-vitamin D_3)
24,25-dihydroxy-vitamin D_3
Calcitriol (1,25-dihydroxy-vitamin D_3)
Alfacalcidol (1-hydroxy-vitamin D_3)
Paricalcitol (19-nor-1,25-dihydroxy-vitamin D_2)
Maxacalcitol (22-oxa-calcitriol)
Doxercalciferol (1-alpha-hydroxy-vitamin D_2)
Falecalcitriol (26,27-hexfluoro-calcitriol)

In 2009, two Cochrane reviews summarized the evidence for vitamin D therapy for patients with CKD stages 1–5 not requiring dialysis [1] and those with CKD stage 5D [2] (summarized in Table 36.4), respectively. Evidence for beneficial effects of vitamin D therapy is restricted to effects on bone histology and serum PTH, as trials do not have sufficient statistical power to provide definitive evidence on clinical outcomes.

In patients with CKD stages 1–5 and stage 5D, there is very low certainty that vitamin D therapy makes any difference to mortality, commencement of dialysis, need for parathyroidectomy, bone pain, or fracture. Vitamin D therapy lowers PTH by 5.6 pmol/l for patients with CKD stages 1 to 4 and 22 pmol/l, for those with stage 5D, while incurring hypercalcemia. Two randomized trials have demonstrated oral activated vitamin D does not improve cardiac function for patients with CKD stages 3–5 during 1 year of treatment [102, 103].

Vitamin D Analogs

Vitamin D therapy is limited by hypercalcemia and hyperphosphatemia, leading to the development of structurally modified derivatives with altered affinity for vitamin D binding proteins and vitamin D receptor to ameliorate treatment-related adverse effects on calcium and phosphorus. These include paricalcitol, 22-oxacalcitriol, doxercalciferol, and falecalcitriol. Based on a systematic review of randomized trials, there is limited evidence of different effects of vitamin D analogs on hypercalcemia, hyperphosphatemia, PTH levels, or clinical outcomes including bone pain, parathyroidectomy, or mortality compared with calcitriol or other vitamin D compounds [104].

Nutritional Vitamin D

Vitamin D_3 (cholecalciferol) is synthesized in the skin from cholesterol through a chemical reaction dependent on UVB radiation derived from sunlight. Vitamin D_2 is synthesized from radiation of ergosterol, a compound derived from the mold, ergot. In a systematic review of RCTs in 2010, five trials of cholecalciferol for 6 months on average in patients with all stages of CKD were identified [105]. In low to moderate quality evidence, cholecalciferol (20 000 IU

weekly to 25 000 IU once monthly) reduces serum PTH levels to some extent (3.5 pmol/l), without evidence of increases in serum calcium or phosphorus. Calcifediol (25-hydroxy-vitamin D_3) is converted to calcitriol by 1α-hydroxylase predominantly in the kidney, remaining under feedback regulation. In evidence from two short-term randomized trials (26 weeks or less), calcifediol lowers serum PTH levels in a dose-dependent manner for patients with hyperparathyroidism and vitamin D insufficiency [106, 107]. The effects of nutritional vitamin D supplementation for patients with CKD is unknown.

In summary, vitamin D compounds can be used to lower serum PTH levels for patients with CKD. Patients with CKD (any stage) may reasonably choose not to receive vitamin D compounds based on the very low certainty that treatment makes a difference to longer term outcomes including skeletal symptoms, bone deformities and symptoms, or cardiovascular complications and mortality.

Calcimimetic Therapy

Calcimimetic therapy mimcs the action of calcium on the calcium-sensing receptor in parathyroid tissue and suppresses PTH release. Two calcimimetic agents are approved for use in the USA by the US Food and Drug Administration (FDA) for treatment of secondary hyperparathyroidism in CKD stage 5D: oral cinacalcet and parenteral etelcalcitide. Cinacalcet is approved for marketing authorization in Europe [108]. Randomized trials have demonstrated cinacalcet lowers elevated PTH levels by 33 pmol/l on average for patients with CKD [109–111] Box 36.3.

A meta-analysis of RCTs comparing cinacalcet with placebo was published in 2013 involving 18 studies in 7446 adults with CKD (predominantly CKD Stage 5D) [112]. A summary of the findings is shown in Table 36.5. Given at 30–180 mg per day for a median of 6.5 months, there is high certainty that cinacalcet makes no difference to all-cause mortality for patients with CKD stage 5D and has uncertain effects on cardiovascular death. For patients with CKD stages 3–5, evidence for mortality was of low certainty. It is uncertain whether cinacalcet prevents fracture in CKD stage 5D and this outcome has not been evaluated in people with earlier stages of CKD. Cinacalcet leads to slightly fewer parathyroidectomy operations for people with CKD stage 5D.

Cinacalcet causes hypocalcemia for 60 patients in every 1000 treated for 1 year, and 150 more patients probably experience nausea. Additional prespecified subgroup analyses are reported from the Evaluation of Cinacalcet Hydrochloride Therapy to Lower Cardiovascular Events (EVOLVE) trial, in which cinacalcet was evaluated against placebo in nearly 4000 patients with CKD stage 5D [113]. A treatment-age interaction led to speculation that cinacalcet may be efficacious among older adults over 65 years of age, although caution is needed with this interpretation, as the EVOLVE study was not specifically designed to test this hypothesis [114]. Further trials are specifically needed among older patients to determine whether cinacalcet lowers mortality in CKD stage 5D.

Evidence for parenteral etelcalcetide in CKD is limited to a phase 2 dose-escalation trial [115], pooled data from two placebo-controlled randomized clinical trials [116], and a noninferiority trial comparing etelcalcetide with cinacalcet [117], all involving hemodialysis patients. Etelcalcetide suppresses PTH levels, while leading to some patients experiencing muscle spasm, nausea, or vomiting during 26 weeks of treatment. Etelcalcetide probably decreases serum PTH levels to a similar extent to cinacalcet. Effects of etelcalcitide on patient-level outcomes are uncertain.

The single-arm BONAFIDE study has characterized the bone response to cinacalcet therapy in 77 patients with CKD stage 5D, serum PTH >33 pmol/l, and biopsy-proven high bone turnover, after 6–12 months of cinacalcet treatment [118]. Cinacalcet may normalize bone metabolism, although two participants developed adynamic bone disease concomitant with lower PTH levels (<16.5 pmol/l) and one patient with hypophosphatemia developed osteomalacia. Similarly, Lien et al. evaluated the effects of cinacalcet on BMD over 26 weeks in 14 patients randomly assigned to conventional therapy or cinacalcet [119]. Cinacalcet may slightly increase BMD at the proximal femur. Although these two studies raise the hypothesis that cinacalcet may improve bone histology, a high-quality trial of clinical bone outcomes such as fracture, deformity, or disability is needed to provide evidence for clinical decision-making.

Box 36.3 Calcimimetic Agents

Cinacalcet
Etelcalcitide

Surgical Parathyroidectomy

Numerous case series and cohort studies have demonstrated that surgical parathyroidectomy reduces PTH levels in dialysis patients with secondary hyperparathyroidism. Prospective surgical cohorts have also described the rate of complications, the "optimal" surgical technique to increase the probability of maintaining target PTH levels postoperatively, and the effects of parathyroidectomy on the bone component of CKD-MBD, on postoperative serum calcium levels, and the need for vitamin D supplementation [120–124].

Surgical parathyroidectomy has been advocated principally as a means of controlling severe hyperparathyroidism in CKD stage 5D who are refractory to medical management. There have been, to date, no long-term RCTs comparing parathyroidectomy to other modalities of controlling PTH in end-stage kidney disease (ESKD) patients with respect to mortality and significant morbidities, including pathologic fractures and cardiovascular events.

Parathyroidectomy has not been evaluated either with observational studies or with an RCT as a modality of treatment for secondary hyperparathyroidism in patients with CKD stages 3–5 not treated with dialysis. Surgical parathyroidectomy has not been evaluated long-term in comparison to medical approaches such as the use of calcimimetics, although the latter medical approach has displaced surgical parathyroidectomy in some areas of the world.

Dialysate Calcium

It was recognized more than four decades ago that elevations in serum calcium levels in dialysis-dependent patients reduced PTH levels. This led to adoption of higher dialysate calcium concentrations as the standard of care. In the 1970s, dialysate calcium levels increased from 2.5 mEq/l (and roughly equivalent to the normal serum calcium level) to 1.50–1.75 mmol/l to assist management of hypocalcemia, elevated serum PTH levels, and bone disease. As calcium salts replaced aluminum to bind phosphorus and maintain serum calcium, together with the introduction of vitamin D compounds, higher dialysate calcium concentrations were linked to hypercalcemia and dialysate calcium concentrations were lowered.

More recently, attention has been directed toward the risks associated with an increased exogenous calcium

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

burden, principally based on low-quality observational data, including the oversuppression of parathyroid function and the development of low-turnover bone disease, as well as vascular calcification. Increasing dialysate calcium has been associated with mortality across 307 facilities and 17 236 patients in the Dialysis Outcomes and Practice Patterns Study (DOPPS) [125].

The KDIGO guideline for management of CKD-MBD suggests a dialysate calcium concentration between 1.25 and 1.50 mmol/l is used [10]. Emerging nonrandomized evidence indicates lower dialysate calcium concentrations (<1.25 mmol/l) are associated with hospitalization for heart failure, hypocalcemia, and intradialytic hypotension [126]. In addition, lower dialysate calcium is associated with lower serum calcium, increased serum phosphorus and PTH levels, and increased use of phosphate binders, vitamin D, and calcimimetics, indicating that low dialysate calcium may aggravate secondary hyperparathyroidism. Observational data also indicate that higher dialysate calcium concentrations (>1.75 mmol/l) are associated with higher mortality [127].

In a small RCT, low dialysate calcium (1.3 mmol/l) may slightly lower serum calcium levels (by 0.12 mmol/l) and increase serum PTH levels (by 16 pmol/l) and prescribing of calcimimetics and vitamin D therapies compared with high dialysate calcium (1.6 or 1.75 mmol/l). It is uncertain whether low dialysate calcium makes any difference to vascular calcification, left ventricular mass, or bone mineral density [128]. In a second randomized clinical trial in 225 patients treated with hemodialysis and with serum PTH levels ≤33 pmol/l, it was uncertain whether a dialysate calcium of 1.25 mmol/l made any difference to coronary artery calcification, bone histomorphometry, or adverse events compared with a dialysate calcium of 1.75 mmol/l [129].

Low Bone Mineral Density

Adults with CKD experience an increased risk of fractures due to altered bone strength. The incidence of hip fracture is approximately 7 per 1000 person-years among men and nearly 14 per 1000 person-years among women, representing a relative risk that is fourfold that of the general population for both sexes [58]. As in the general population, hip fracture is associated with high rates of death and hospitalization [130]. In patients with CKD, the degree of demineralization is correlated with the degree (stage) and/or duration of CKD [131, 132]. Additionally, demineralization may be accelerated in patients who have CKD caused by pathologies typically treated with steroids (e.g. glomerulonephrititis, lupus nephritis, etc.) and those characterized by chronic metabolic acidosis associated with renal tubular acidosis [133].

The presence of a fragility fracture or low BMD in a person with CKD can be due to osteoporosis or CKD-MBD (or combination). Therefore, it can be challenging to decide on the most appropriate clinical management of fractures in the presence of CKD, as treatment will depend on the underlying predominant pathology that may include osteoporosis, osteomalacia, high bone turnover, or adynamic bone disease. The likely etiology of a fragility fracture or low BMD is related with estimated GFR. For patients in an estimated GFR above 30 ml/min per 1.73 m^2, the predominant pathology, in the absence of elevated serum phosphorus or PTH levels, is likely to be osteoporosis. For patients in an estimated GFR below 30 ml/min per 1.73 m^2, other bone disorders may predominate and CKD-MBD should be excluded before a diagnosis of osteoporosis is probable.

Evidence is emerging for the effects of antiresorptive medications on BMD and fracture risk in CKD stages 3–5D, although the evidence of impact on patient-centered outcomes is very low quality. Possible treatments include bisphosphonates, receptor activator of nuclear factor-κB ligand (RANKL) inhibition (denusomab) and selective estrogen receptor modulators (SERM). Post hoc analyses of treatment effects in people with CKD enrolled in studies in the wider population and trials specifically evaluating therapy in the setting of CKD have become available.

Bisphosphonates

Bisphosphonates are used widely for the treatment and/or prevention of osteoporosis and its complications in the general population (Box 36.4).

These agents are eliminated via renal excretion [134, 135]. The efficacy of these agents in the treatment of osteoporosis in people without CKD is confirmed with high-certainty evidence within multiple trials [136]. The use of bisphosphonates in individuals with CKD is less well studied, resulting in low certainty evidence, and largely limited to prevention of BMD loss for recipients of a kidney transplant [137]. There is no evidence of high certainty that bisphosphonates modify clinical outcomes such as fracture or safety for people with CKD.

Box 36.4 Bisphosphonates (shown in ascending order of potency [potency relative to etidronate])

Etidronate [1]
- Clodronate [10]
- Pamidronate [100]
- Alendronate [500]
- Ibandronate [1000]
- Risedronate [2000]
- Zolendronate [10000]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The effects of alendronate on BMD for women enrolled in the Fracture Intervention Trial (FIT) were examined post hoc in participants with CKD [138]. Women with an estimated GFR < 45 ml/min per 1.73 m^2 experienced increases in BMD (5.6%, 95% CI 4.8–6.5%) and may have experienced fewer fractures. There are no trials specifically designed to evaluate adverse events or risk of adynamic bone disease with bisphosphonates in CKD (any stage). In a pooled analysis of nine trials evaluating risedronate 5 mg daily to prevent or treat osteoporosis or steroid-induced bone disease, patients with CKD stages 3 and 4 were identified post hoc. Risedronate has uncertain effects on adverse events, kidney function, or rates of low bone turnover [139].

In a small RCT, patients treated with dialysis receiving etidronate (a low potency bisphosphonate) for 24 weeks experienced retardation of coronary artery calcification and lower aortic calcification compared with standard therapy [140]. In contrast, alendronate therapy for adults with CKD stages 3 and 4 has uncertain effects on aortic vascular calcification and kidney function [141].

Bisphosphonates have been reported to cause acute kidney injury, which may occur after some delay and is not always fully reversible [142, 143].

Denusomab

Denusomab is a human monoclonal antibody that binds and inhibits the actions of receptor RANKL, which is expressed by osteoblastic cells and mediates osteclastic bone resorption. Denusomab increases BMD [144] and prevents fracture [145] in older women with low bone density. Preliminary studies indicate that the pharmacokinetics of denusomab are not affected by kidney function, although in a single-dose study among 55 people with CKD stages 1–5D treatment was complicated by low serum calcium levels and sometimes required hospitalization for parenteral calcium supplementation [145].

At present, there are no prospective randomized trials designed to evaluate the benefits and harms of denusomab in people with CKD and low BMD. In a post hoc analysis of the FREEDOM trial, denosumab may prevent vertebral fractures in women with CKD stage 3, but treatment effectiveness was very uncertain among women with CKD stage 4 [146]. Although the authors concluded that adverse events were not increased, there was no information given about individual adverse events, particularly low serum calcium levels.

Raloxifene

Raloxifene is an oral SERM that increases BMDs Three trials provide information about raloxifene for women with low bone density and CKD, but evidence is limited by uncertainty of effects on in nonvertebral bone, and very low certainty about safety and fracture endpoints. In 50 women on dialysis and osteoporosis or severe osteopenia, raloxifene 60 mg daily may increase lumbar spine BMD [147]. Similarly, in a trial involving 60 women with CKD stage 5 and 5D, raloxifene treatment for 8 months may increase BMD significantly at the lumbar spine [148]. In a post hoc analysis of a multicenter randomized placebo-controlled trial, raloxifene may increase vertebral BMD, but has uncertain effects on fracture and adverse events among women with an estimated GFR below 60 ml/min per 1.73 m^2 [149]. Thus, there is no high-quality evidence that antiresorptive treatment strategies, including raloxifene, are effective or safe in people with CKD and low bone mineral density.

In summary, these data do not lead to a recommendation about treatment for low BMD for patients with CKD.

Target Levels of Serum Parathyroid Hormone, Phosphorus, and Calcium

Although specific target ranges for serum phosphorus and PTH have been previously suggested by clinical practice guidelines [71], there are no RCTs that evaluate whether these serum targets make any difference to clinical outcomes [7]. Accordingly, the KDIGO guidelines provide weak recommendations based on low-quality evidence (Box 36.5).

In summary, these data do not allow a recommendation that treatment for CKD-MBD should include specific serum targets for phosphorus or PTH.

Box 36.5 Target serum levels of parathyroid hormone, phosphorus, and calcium suggested in clinical practice guidelines

Serum biochemical parameter	CKD stage	Kidney Disease: Improving Global Outcomes (KDIGO) (2017) [10]
Phosphorus	3 and 4	Toward normal range (*2C*)
	5D	Toward normal range (*2C*)
Calcium	3 and 4	Avoid hypercalcemia (*2C*)
	5D	Avoid hypercalcemia (*2C*)
Intact parathyroid hormone	3	Optimal level is not known Patients should be assessed when levels above upper limit of normal (*2C*)
	4	Optimal level is not known Patients should be assessed when levels above upper limit of normal (*2C*)
	5D	Optimal level is not known Patients should be assessed when levels above upper limit of normal (*2C*)

Grade for strength of recommendation: level 1, strong' level 2, weak. Grade for quality of evidence: A, high, B, moderate, C, low, D, very low.

Bone Disease After Kidney Transplantation

In a recently updated Cochrane review, 50 randomized trials have evaluated bisphosphonates, vitamin D, teriparatide (synthetic PTH), denusomab, cinacalcet, parathyroidectomy, and calcitonin [150]. Bisphosphonates are the most commonly assessed treatment approach for prevention of fracture after kidney transplantation (Table 36.6).

Evidence for treatment of bone disease after kidney transplantation is generally of low or very low certainty based on the methodological limitations in randomized trials. As the rates of fracture are low in available trials and existing trials involve small numbers of participants, existing research studies lack statistical power to provide high-quality evidence that treatment makes a difference to bone-related patient outcomes.

Table 36.6 Summary of findings: treatments for bone disease after kidney transplantation.

Outcomes	No. of participants (no. of studies)	Absolute effect (per 1000 patients treated for 1 year)	Relative effect (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Bisphosphonates					
Fracture	765 (13)	38 fewer (61 fewer to 1 more)	0.62 (0.38–1.01)	Low ●○○○	Bisphosphonates may prevent bone fracture for recipients of a kidney transplant
Bone pain	153 (3)	133 fewer (160–12 fewer)	0.20 (0.04–0.93)	Low ●○○○	Bisphosphonates may prevent bone pain for recipients of a kidney transplant
Spinal deformity	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of bisphosphonate therapy on spinal deformity
Graft loss	332 (6)	Not estimable	1.01 (0.42 to 2.44)	Very low ○○○○	It is very uncertain whether bisphosphonate therapy makes any difference to graft loss
All-cause mortality	606 (10)	Not estimable	0.62 (0.23 to 1.63)	Very low ○○○○	It is very uncertain whether bisphosphonate therapy makes any difference to all-cause mortality
Nausea	- (—)	—	No studies	Absent	One study was found that evaluated nausea with bisphosphonate therapy
Hypocalcemia	207 (4)	Not estimable	5.59 (1.00–31.1)	Very low ○○○○	Bisphosphonate therapy may incur hypocalcemia
Vitamin D					
Fracture	299 (5)	Not estimable	0.96 (0.10–8.94)	Very low ○○○○	It is very uncertain whether vitamin D therapy makes any difference to fracture
Bone pain	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of vitamin D therapy on bone pain
Spinal deformity	- (—)	—	No studies	Absent	No studies were found that evaluated the impact of vitamin D therapy on spinal deformity
Graft loss	- (—)	—	No studies	Absent	One study was found that evaluated graft loss with vitamin D therapy
All-cause mortality	232 (3)	Not estimable	0.49 (0.03–9.22)	Very low ○○○○	It is very uncertain whether vitamin D therapy makes any difference to mortality
Nausea	- (—)	—	No studies	Absent	No studies were found that evaluated whether vitamin D therapy leads to nausea
Hypercalcemia	465 (7)	66 more (15 fewer to 300 more)	2.09 (0.84–5.22)	Very low ○○○○	It is very uncertain whether vitamin D therapy leads to hypercalcemia

CI: confidence interval. Evidence is drawn from a 2017 Cochrane review update (in peer review) [150]. GRADE assessment of the certainty of the evidence [9]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Systematic radiological assessment for vertebral fracture is the predominant fracture-related outcome in existing randomized trials of bone therapies in kidney transplantation. Treatment in randomized trials is commenced at the time of transplantation in about half of all trials and within the first 3 years in the remaining trials. Based on 13 studies, involving 765 patients and reporting fracture events for 58 participants, bisphosphonates given for about 12 months may prevent fracture (spinal or low trauma) and bone pain. The safety profile of bisphosphonate treatment and the efficacy and safety of vitamin D for bone protection among kidney transplant recipients is very uncertain [150]. Evidence for denosumab, teriparatide, and cinacalcet is currently insufficient to inform decision-making.

In summary, these data do not allow one to recommend specific treatments for bone disease after kidney transplantation.

Patient and Caregiver Treatment Preferences

Currently, there are no studies evaluating patient and caregiver preferences for treatment or outcomes specifically in CKD-MBD. In a national workshop involving stakeholders including patients, caregivers, health providers, and researchers, lifestyle interventions and those interventions that can improve long-term transplant outcomes, prevention, and QoL were research priorities in CKD [151]. There is currently insufficient data to recommend lifestyle or exercise interventions for CKD-MBD-related outcomes [152].

Conclusion

CKD-MBD is a frequent complication for patients with moderate to severe CKD and is a central component of specialist nephrology care. In addition, bone loss occurs rapidly in the first few months after kidney transplantation.

No RCTs or large cohort studies have provided evidence of high certainty to support practices of monitoring serum biochemical markers, bone disease or vascular and non-vascular calcification. At this time, there is insufficient high-quality evidence that treatments improve patient-centered outcomes. At present, treatment for CKD-MBD can be guided by shared decision-making based on patient preferences and therapeutic safety and cost.

Introduction

Nutritional status is one of the main modifiable factors that affect the prognosis and evolution of patients with acute and chronic kidney disease (CKD) (Table 37.1). In CKD, dietary factors may have an influence on important clinical outcomes, including disease progression, quality of life, morbidity, and mortality. Due to the kidney's unique role in nutrient metabolism, patients with kidney failure are unable to maintain adequate nutrient homeostasis. As kidney disease progresses, there is a reduction in the excretion of solutes, which results in sodium and volume overload, hyperkaliemia, hyperphosphatemia, and metabolic acidosis. In addition, uremic toxins accumulation leads to reduced appetite with increased risk for suboptimal energy and nutrient intake, altered hormone regulation, and inflammation, all together exacerbating the risk for the so-called protein-energy wasting (PEW) syndrome. This syndrome is defined as a state in which there is a decrease in protein and energy stores, usually associated with a lower functional ability to adapt to stress situations and worse patient survival [18–22].

Many factors contribute to the nutritional status of the CKD patient, such that there is no definitive marker to diagnose PEW nor a single treatment to reverse this state. In the CKD patient, PEW can be produced both by undernutrition and by other factors unrelated to nutrient intake, such as the appearance of intercurrent catabolic processes, the loss of nutrients through urine or dialysate, metabolic acidosis, and endocrine alterations (e.g. growth hormone [GH] and insulin-like growth factor 1 [IGF-1] deficiencies, hyperinsulinism, hyperparathyroidism) [23–37].

Nutritional interventions should be a cornerstone strategy in the management of CKD patients, both as a renoprotective antiproteinuric measure in the predialysis stage, and to prevent overweight and malnutrition in all stages of CKD, the latter especially in later stages. Given the number of factors involved in the nutritional and metabolic status of the CKD patient, adequate dietary management will require a combination of therapeutic measures that minimize energy-protein depletion and favor the anabolic stimulus. Many of these measures, such as the correction of acidosis and the modification of renal replacement therapy, go beyond simple caloric or dietary support [38, 39].

The optimal approach to nutrition is not well known, and randomized controlled trials (RCTs) are lacking and have yielded conflicting results. This chapter examines the evidence for management of nutrition in adults with CKD stages 3–5, including dialysis and transplant patients, focusing mainly on CKD progression and PEW treatment. Evidence for nutritional interventions for CKD mineral and bone disorders (CKD-MBD), and for children with kidney failure is discussed in Chapters 36 and 38, respectively.

Nutritional Requirements for Patients with Kidney Disease

Because a "kidney diet" can have many restrictions, adherence to such a diet can be difficult and troublesome. In addition, the optimal diet for CKD patients varies depending

Table 37.1 Nutritional interventions for CKD.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Dietary interventions, including dietary patterns and nutritional counseling	We suggest dietary interventions can be used to improve health-related quality of life, blood pressure control, eGFR, and nutritional status assessed by albumin levels. Patients with CKD (any stage) may reasonably choose not to receive dietary interventions based on the very low certainty that treatment makes a difference to longer term outcomes including survival, cardiovascular morbidity, and development of ESRD.	High (blood pressure control) Moderate (serum albumin levels) Low (health-related quality of life, eGFR) Very low (mortality, cardiovascular events, progression to ESRD)	Weak [1]
Dietary protein restriction, including LPD and VLPD	We suggest dietary protein restriction can be used to reduce the risk for development of ESRD in both nondiabetic and diabetic patients with CKD stages 3–5, and to reduce both mortality and risk for development of ESRD in type 1 diabetic patients with ND-CKD. Patients with CKD may reasonably choose not to receive dietary protein restriction as treatment makes no difference to mortality or PEW development.	High (mortality) Moderate (development of ESRD) Very low (development of PEW)	Weak [2–5]
Dietary salt restriction	We suggest dietary salt restriction can be used to reduce blood pressure, antihypertensive medication dosage, proteinuria, and edema for patients with CKD. Patients with CKD may reasonably choose not to receive dietary salt restriction based on the very low certainty that treatment makes a difference to longer term outcomes including health-related quality of life, survival, cardiovascular morbidity, and the development of ESRD.	High (blood pressure, proteinuria) Very low (mortality, cardiovascular morbidity, development of ESRD)	Weak [6, 7]
Dietary caloric restriction to reduce weight	We suggest dietary caloric restriction can be used to reduce proteinuria and blood pressure, as well as hyperfiltration in ND-CKD patients. Patients with CKD may reasonably choose not to receive dietary caloric restriction based on the very low certainty that treatment makes a difference to the development of ESRD.	Moderate (blood pressure, proteinuria) Very low (development of ESRD)	Weak [8]
Probiotics supplementation	We suggest probiotics supplementation may be used to reduce p-cresyl sulfate levels. Patients with CKD may reasonably choose not to receive probiotics supplementation based on the very low certainty that treatment makes a difference to longer term outcomes including health-related quality of life, survival, cardiovascular morbidity, and the development of ESRD.	Very low	Weak [9]
Oral nutritional supplements	We suggest oral nutritional supplements may be used to improve nutritional status by increasing serum albumin levels and body mass index in dialysis patients, without influence on serum potassium and phosphorus levels. Patients with CKD (any stage) may reasonably choose not to receive probiotics supplementation based on the very low certainty that treatment makes a difference to survival.	Very low	Weak [10]
Intradialytic parenteral nutrition	We suggest intradialytic parenteral nutrition may be tested to improve nutritional status in hemodialysis patients with PEW if nutrient requirements can be achieved in combination with oral intake. Hemodialysis patients with PEW may reasonably choose not to receive intradialytic parenteral nutrition based on the very low certainty that treatment makes a difference to longer term outcomes including survival and morbidity.	Very low	Weak [11]

Megestrol acetate	We suggest megestrol acetate may be tested in dialysis patients to reverse poor appetite and improve nutritional status if other treatment options are unavailable and for less than 24 weeks. Dialysis patients with poor appetite may reasonably choose not to receive megestrol acetate based on safety concerns and the very low certainty that treatment makes a difference to longer term outcomes including health-related quality of life, survival, and morbidity.	Very low	Weak [12]
Fish oil supplements	We suggest fish oil supplements may be used in dialysis patients to alleviate chronic inflammation status, depression symptoms, and hypertriglyceridemia, and reduce cardiovascular events and the risk of arterio-venous-graft events. Dialysis patients may reasonably choose not to receive fish oil supplements based on the very low certainty that treatment makes a difference to longer term outcomes including health-related quality of life and survival.	High (hypertriglyceridemia) Moderate (C-reactive protein levels) Low (depression symptoms, cardiovascular events, arterio-venous-graft events) Very low (health-related quality of life, mortality, ND-CKD)	Weak [13]
L-Carnitine supplementation	We suggest L-carnitine supplements may be tested in dialysis patients to alleviate chronic inflammation status. Dialysis patients may reasonably choose not to receive L-carnitine supplements based on the very low certainty that treatment makes a difference to longer term outcomes including health-related quality of life, survival, and comorbidity.	Very low	Weak [14, 15]
Statins	We suggest statins may be used in dialysis patients to alleviate chronic inflammation status and reduce cholesterol levels. Dialysis patients may reasonably choose not to receive statins based on the moderate to very low certainty that treatment makes a difference to longer term outcomes including health-related quality of life, survival, and cardiovascular events.	High (C-reactive protein levels, cholesterol levels) Moderate (survival and cardiovascular events) Very low (health-related quality of life, ND-CKD)	Weak [16]

CKD, chronic kidney disease; LPD, low protein diet; VLPD, very low protein diet; eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; ND-CKD, nondialysis chronic kidney disease.

GRADE assessment of the certainty of the evidence [17]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.

upon their nutritional needs, the CKD stage, the type of renal replacement therapy, and the presence of other comorbidities such as PEW, obesity, hypertension, proteinuria, or heart failure. Patient preferences, their cultural eating habits, and their economic status are additional factors to be kept in mind for improving their compliance with dietary recommendations, which should be monitored regularly.

Need for Individualization

Too many restrictions should be avoided as they may result in a reduced nutrient intake. Dietary modifications are seldom required for patients with estimated glomerular filtration rate (eGFR) ≥60 ml/min/1.73 m^2. Such patients should be advised to implement the same dietary recommendations as for the general population, consisting of low sodium and refined sugar, avoidance of red and processed meats, and high content of fruits, vegetables, legumes, fish, poultry, and whole grains. In later stages of CKD, however, the diet needs to be modified (Figure 37.1) [40]. Historically, research and guideline recommendations have been focused mainly on modifying single micro- or macronutrients intake, such as protein, sodium, potassium, or phosphate. Providing specific nutrients may prevent and treat PEW, whereas limiting the intake of certain nutrients may prevent obesity, hypertension, and proteinuria, reducing the risk of cardiovascular disease and CKD progression as well as ameliorating uremic symptoms [41]. However, the nutrient content of each type of diet tends to be steady and constant, and individual dietary habits usually remain unchanged over time, therefore the overall dietary pattern may be more decisive for patient outcomes than an excess or deficiency of specific nutrients [42].

Overall Recommendations

The current Kidney Disease Outcomes Quality Initiative (K/DOQI) guidelines recommend a protein intake ranging from 0.6 to 1.2 g/kg body weight per day according to CKD stage, of which more than half should be of high biological value. The recommended energy intake is 35 kcal/kg body weight per day for those who are younger than 60 years of age, and 30–35 kcal/kg/day for individuals who are 60 years or older [43]. These guidelines do not refer to the recommended intake of carbohydrates, lipids, or most micronutrients, with the exception of recommendations for calcium and phosphorus intake. The European guidelines give recommendations regarding the intake of vitamins, minerals, and trace elements, although they recognize that in the absence of RCTs such recommendations cannot be considered true clinical guidelines, but rather reflect only the opinion of experts [44]. Overall, many of the nutritional requirements indicated for the CKD population are simple extrapolations based on the recommendations made for the general population, with the added classic limitations

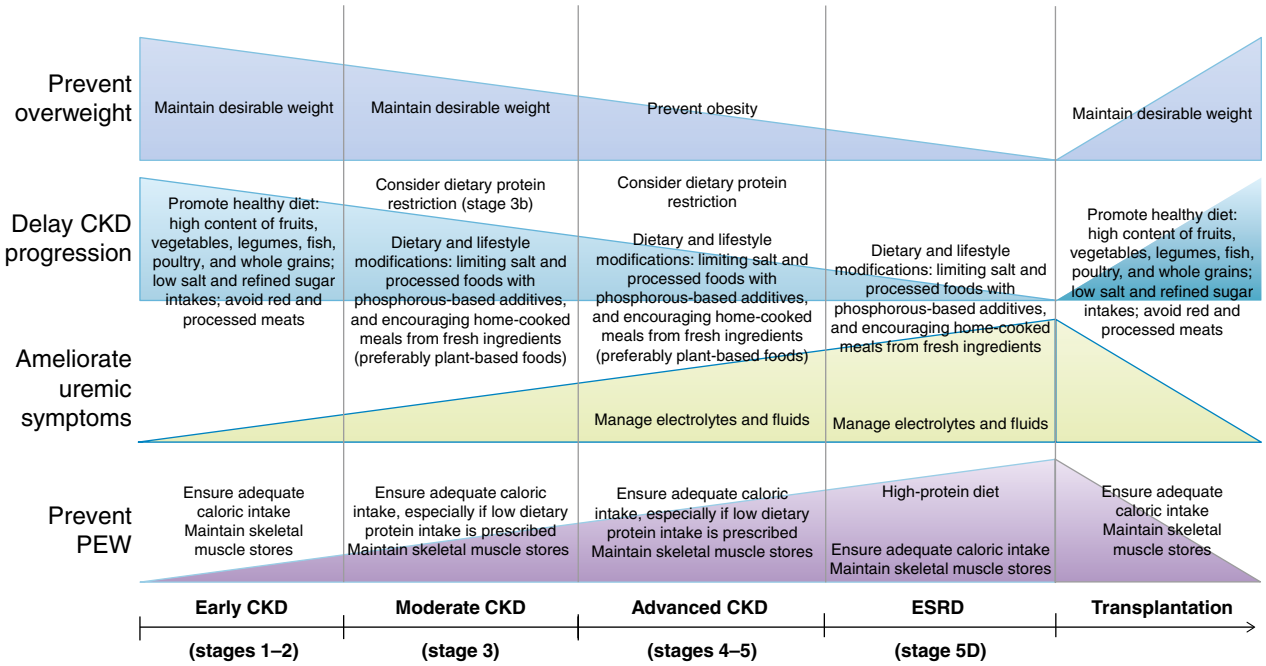

Figure 37.1 Schematic representation of the relative importance of each of the main nutritional goals across the CKD stages, including preventing overweight, delaying the development of ESRD, decreasing uremic symptoms, and preventing PEW. CKD, chronic kidney disease; PEW, protein-energy wasting.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. in potassium intake, sodium, and phosphorus, which have prevailed for more than 40 years in patients on dialysis.

However, many of these classic recommendations, which include restricting the intake of fruits, vegetables, or dairy products, are probably not adequate for current patient characteristics (i.e. old and fragile) and treatments, which range from conservative management to more intensive dialysis regimens, including nocturnal or short-daily hemodialysis (HD) [45]. Conversely, what has recently been proposed is an increase in the intake of fiber, antioxidants, and phytochemicals, which could have a very positive impact on the nutritional and cardiovascular status of CKD patients [46, 47]. In this sense, recommendations should not only be based on the quantity but also on the quality of each food, so that the choice, for example, of unprocessed foods may allow us to abandon unnecessary restrictions that can affect the quality of life of patients [45].

In addition, stable patients with precise dietary indications, both those with CKD and those on dialysis or transplanted, can develop an intercurrent acute process that requires substantially increasing their energy and protein requirements.

Table 37.2 shows the nutritional requirements for adult patients with nondialysis CKD (ND-CKD), HD, peritoneal dialysis (PD), and transplant, according to the main clinical guidelines and consensus papers [43, 44, 48–55].

Energy Requirements

Adequate caloric intake – by avoiding processed carbohydrates and saturated fat intake, and by increasing complex carbohydrates and mono- and polyunsaturated fats – must be maintained to avoid malnutrition, and conversely to prevent overweight and obesity, given their contribution to the cardiovascular risk and kidney disease progression. Due to the increased resting energy expenditure (REE) secondary to inflammation and comorbidities linked to CKD, as well as for preserving a neutral or positive nitrogen balance, current guidelines recommend a caloric intake of 30–35 kcal/kg/day, which is higher than for the general population. However, this general recommendation should be individualized according to the patient's profile, including age, lean body mass (which is the primary determinant of energy expenditure), physical activity, and the type of kidney disease [56–58].

- In ND-CKD patients under a low protein diet (LPD), an energy intake of 35 kcal/kg/day may be recommended to ensure a neutral nitrogen balance. By contrast, in sedentary, elderly, and obese patients the energy contribution should provide around 30 kcal/kg/day.
- In PD patients, about 300 kcal may be provided in each glucose-based exchange, contributing up to 30% of the total daily energy intake [59]. This additional source of calories should be taken into consideration when assessing energy intake in this population.
- In kidney transplant patients, the caloric intake should be adapted to individual needs according to physical activity and presence of low weight or obesity.
- Any intercurrent catabolic episode may require increasing energy (and protein intake) independently of CKD stage or renal replacement therapy (Table 37.2).

Protein Requirements and Source of Protein Intake

For ND-CKD stable patients, the recommended protein intake is 0.6–0.8 g/kg/day, of which at least half should be of high biological value [43, 48]. This restriction is generally well tolerated, limiting waste-product accumulation while simultaneously preserving nutrition. Benefits of lower protein diets include slowing CKD progression and reducing uremic symptoms [56, 58, 60]. Reduced protein intake is also associated with favorable laboratory and metabolic effects, including reduction of uremic toxins and acid load, with better control of hyperkalemia and hyperphosphatemia [61, 62]. Figure 37.2 summarizes the potential benefits of dietary protein restriction.

Nevertheless, the optimal degree of protein restriction remains unclear, and there is no consensus on the recommended level of protein restriction according to the degree of kidney dysfunction. There are basically two alternatives: the so-called low protein diet (LPD, 0.6–0.8 g/kg/day) and the very low protein diet (VLPD, 0.3–0.4 g/kg/day) supplemented with 7–15 g/day of ketoanalogs and essential amino acids. In both cases, patients should be carefully monitored for adequate caloric intake (30–35 kcal/kg/day) that allows a positive nitrogen balance and so that proteins are not used as a caloric source. [41, 62] The 2012 Kidney Disease, Improving Global Outcomes (KDIGO) guidelines for the management of CKD recommended lowering dietary protein intake to 0.8 g/kg/day in CKD stage 4–5 subjects with diabetes (grade 2C recommendation) and without diabetes (grade 2B recommendation), and avoiding a high protein intake (>1.3 g/kg/day) in adults with CKD at risk of progression (recommendation grade 2C). It considers the restriction of 0.6 g/kg/day nutritionally adequate given that it facilitates better control of uremic complications [63, 64].

There is no consensus on whether the source of proteins differently impacts on CKD progression risk. Although recent observational studies have suggested that plant proteins may have more reno-protective effects than animal proteins [41], confounding factors inherent to a diet rich in protein from plant sources (i.e. a higher intake of vitamins and antioxidants) make it difficult to draw conclusions [42].

Table 37.2 Summary of nutritional requirements for patients with kidney failure.

	Early CKD (stages1–2)	CKD stages 3–5	Hemodialysis	Peritoneal dialysis	Transplantation
Energy (kcal/kg/day)[a]	30–35	30–35	30–35	30–35 (including kcal from dialysate)	30–35
Protein (g/kg/day)[b]	0.8 1.0 if intercurrent catabolic episode 0.8 (+1 g/day of high biological value protein for each g/day of urinary protein loss) if nephrotic syndrome	0.6–0.8 0.3–0.4 in selective patients with CKD 5 and conservative treatment Keto/amino acid supplementation may be considered together with dietitian support 1.0 if intercurrent catabolic episode	≥1.2 if IHD ≥1.5 if intercurrent catabolic episode 1.7 if CRRT	≥1.2 ≥1.5 if peritonitis	0.8 ≥1.4 for the first 4 weeks after transplantation or if high dose of prednisone is required 0.6–0.8 if CKD stages 3–5T
Fiber (g/day)	25–38	25–38	25–38	25–38	25–38
Sodium (mg/day)	<2.0–2.4	<2.0–2.4	<2.0–2.4	<2–2.4	<2–2.4
Potassium (mEq/day)[c]	No potassium restriction	51–102 Potassium restriction should be prescribed based on serum potassium levels	40–70 If long interdialytic interval restriction must be mandatory	Does not usually need restriction Patients with hypokalemia should increase their potassium intake	Potassium restriction should be prescribed based on the serum potassium levels
Vitamin D (IU/day)	600–800	600–800	600–800	600–800	600–800
Calcium (g/day)	≤800–1000	≤800–1000	≤800–1000	≤800–1000	≤800–1000
Phosphorus (mg/day)[d]	800–1000	800–1000	<800	<800	800–1300
Magnesium (mg/day)	200–300	200–300	200–300	200–300	200–300
Iron (mg/day)[e]	10–18	10–18	10–18	10–18	10–18
Zinc (mg/day)[f]	15	15	15	15	15

CKD, chronic kidney disease; IHD, intermittent hemodialysis; CRRT, continuous renal replacement therapy; T, transplant.

[a] Carbohydrates, which provide 40–60% of the daily energy intake, should be natural (nonrefined) and complex with a high-fiber content; 35 kcal/kg ideal body weight/day for those who are less than 60 years of age and 30–35 kcal/kg ideal body weight/day for individuals 60 years or older and sedentary people.

[b] At least 50% of dietary protein should be of high biological value.

[c] First avoid high-potassium foods with poor nutritional value and correct other causes of hyperkaliemia such as metabolic acidosis or renin-angiotensin-aldosterone system inhibitors before restricting healthy foods.

[d] Limiting processed foods with phosphorous-based additives and encouraging home-cooked meals from fresh ingredients (preferably plant-based foods) should be the first-line interventions for phosphorus restriction; the next-line strategy may be to exclude that dietary protein intake is higher than recommended, and limiting foods with high phosphorus to protein ratios.

[e] 10 mg/day for males and nonmenstruating females; supplementary iron should be given to all hemodialysis patients treated with an erythropoiesis-stimulating agent (ESA) to maintain adequate serum transferrin and serum ferritin levels, aimed to achieve a target hemoglobin (Hb), except for those receiving the iron intravenously.

[f] Zinc supplementation of 50 mg zinc element per day for 3–6 months should be considered in hemodialysis patients with a chronic inadequate protein/energy intake and symptoms evoking zinc deficiency (impaired taste or smell, skin fragility, impotence, peripheral neuropathy).

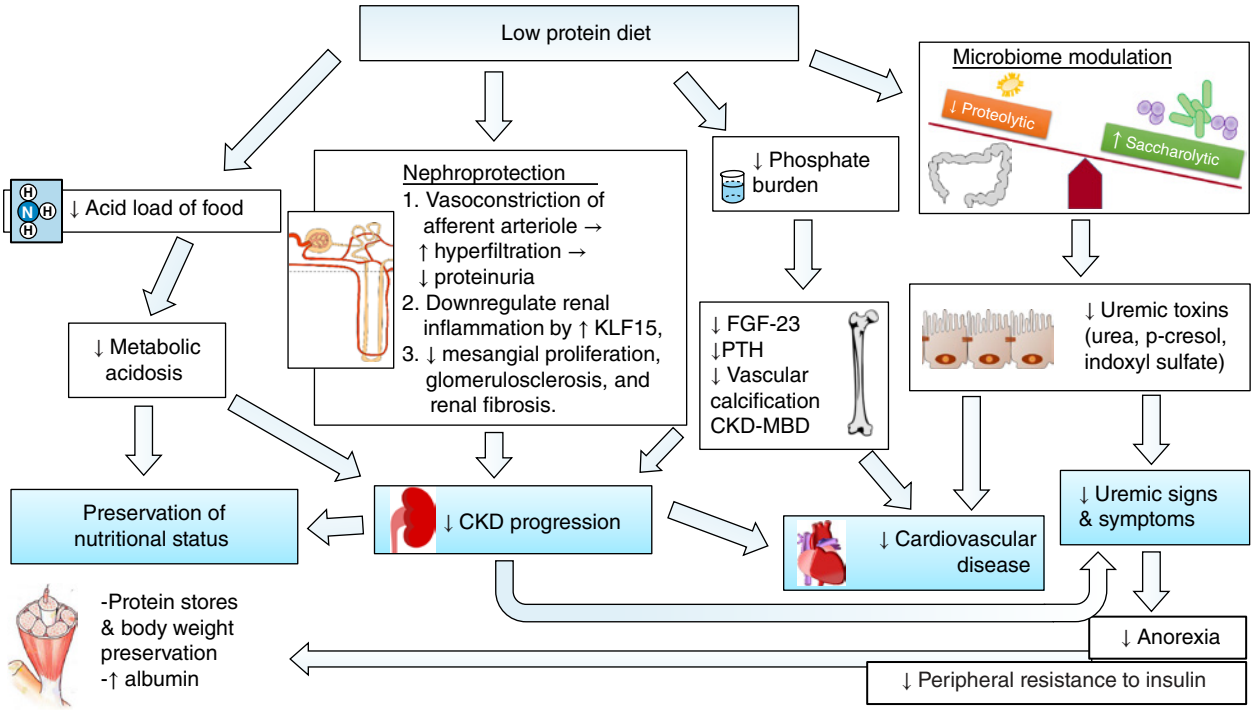

Figure 37.2 Potential benefits of low protein diet. CKD, chronic kidney disease; CKD-MBD, chronic kidney disease-mineral and bone disorder; KLF15, Kruppel-like factor-15; FGF-23, fibroblast growth factor-23; PTH, parathyroid hormone. *Source:* Adapted from: Wang et al. [60] and Chan et al. [58].

Patients transitioning to dialysis therapy with incremental dialysis, and especially those on prevalent dialysis, should increase their protein intake to 1.2–1.4 g/kg/day to prevent PEW [60]. Protein losses into the dialysate, increased energy expenditure, and inflammation related to the dialysis procedure are the main reasons for this higher protein requirement [20, 59]. Patients in any CKD stage with existing or imminent PEW due to intercurrent catabolic episodes may require an increase in protein intake (Table 37.2). For kidney transplant recipients, during the first 4 weeks after transplantation and whenever high doses of steroids are used, a protein intake of at least 1.4 g/kg/day is recommended. Due to the lack of available studies in this group of patients, it has been suggested those with normal kidney function should follow similar recommendations to the general population. In transplant patients with chronic graft dysfunction, it is recommended to provide the same protein restriction diet as in patients with ND-CKD [54].

Sodium Intake and Fluid Balance

A modest sodium restriction (<2.0–2.4 g/day of Na ≈ <5–6 g/day of NaCl) is recommended for the management of CKD patients [44, 62]. The benefits of salt restriction may include lower blood pressure (BP) and proteinuria, improved cardiovascular outcomes, and slower CKD progression [62]. For dialysis patients, it may help to decrease thirst, avoiding an excessive interdialytic weight gain and fluid overload, which are closely related to cardiovascular events and survival [65, 66].

Potassium Intake Recommendations

Most CKD patients do not require aggressive dietary potassium restriction until advanced stages. K/DOQI guidelines recommend no potassium restriction for patients with CKD stages 1–2, while a limited intake from 2 to 4 g/day (51–102 mEq/day) is recommended for patients with CKD stages 3–4 [43]. However, given that potassium is associated in the general population with lower systolic BP, lower risk of stroke, and better bone mineral density, dietary potassium restriction should be prescribed based on serum potassium levels [67–69]. Moreover, it has been suggested that high potassium foods with poor nutritional value (i.e. bran products, chocolate, or salt substitutes) should be voided and other causes of hyperkaliemia, such as metabolic acidosis or renin-angiotensin-aldosterone system inhibitors, corrected before restricting healthy foods such as fruits and vegetables [64]. For ND-CKD patients with chronic hyperkalemia, obtaining a 24-hour urine for potassium may help to determine whether decreased kidney excretion or excessive potassium intake is the cause of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

hyperkalemia. If the urine potassium content is much higher than 50 mEq/24 h, reducing potassium intake should be effective for controlling high potassium levels.

For HD patients, the long interdialytic interval may be a particularly critical period for severe hyperkalemia appearance, and potassium intake restriction may be mandatory, given the association of hyperkalemia with arrhythmia and higher mortality in this population [70].

Calcium, Phosphorus, and Vitamin D Intake Recommendations

Although K/DOQI guidelines suggest limiting total calcium intake to 1500 mg/day, including medication sources [43], there have been concerns about the safety of this recommendation, which may lead to a marked positive calcium balance and the potential development of cardiovascular calcifications [71]. Several experts recommend limiting total calcium intake to 800–1000 mg/day or less [64].

Given the role of serum phosphate in the pathogenesis of vascular calcification and the link between phosphate levels and survival in both the general and CKD populations, clinical practice guidelines suggest limiting dietary phosphate intake in the treatment of hyperphosphatemia (grade 2D recommendation) [72], with a maximum dietary phosphate intake of 800–1000 mg/day [43, 44]. Limiting processed foods with phosphorous-based additives and encouraging home-cooked meals from fresh ingredients (preferably plant-based foods) should be the first-line interventions for phosphorus restriction [64]. The next-line strategy may be to exclude excessive dietary protein intake, as well as limiting foods with high phosphorus to protein ratios [41].

The optimal dietary vitamin D intake and the optimal levels of 25-hydroxyvitamin D for CKD patients remain controversial [72, 73]. Based on the recommendations made for the general population, vitamin D intake for CKD patients is recommended at 600–800 IU/day [44, 64]. Although some interventional studies have showed some benefits of vitamin D supplementations in proteinuria and nutritional status in CKD patients, no definite conclusions can be drawn yet from this emerging evidence [74, 75]. Moreover, to date no clear benefit on skeletal outcomes can be concluded from the vitamin D administration in CKD populations [73, 75].

Fiber Intake Recommendations

Although the recommended dietary fiber intake for CKD patients is not even discussed in current nutritional guidelines, recent data suggest that fiber intake seems to provide similar [76–78], if no greater [79], benefits to those demonstrated in the general population, including improved survival, lower systemic inflammation, and less rapid CKD progression. A daily fiber intake of 25–30 g/day or more for CKD patients may be suggested, as this amount is similar to the recommendation for the general population [62]. Because of potassium restriction in advanced CKD, fruits and vegetables intake tends to be low, and dietary fiber intake is often very low [80]. Plant-based foods, with special attention to fruits and vegetables that are low in potassium, are an important source of dietary fiber that should be recommended in moderation to CKD patients, as long as the potassium levels allow [62].

Definition of Protein-energy Wasting

In the uremic milieu, a state of hypercatabolism, inflammation, and undernutrition leads to the development of PEW syndrome. This syndrome represents a maladaptive metabolic state characterized by a decrease in both protein deposits and energy reserves that appears in patients with acute or chronic kidney failure as part of a mechanism of defense of the body in response to a stress situation. PEW is a consequence of various factors that usually appear as kidney function decreases, including a spontaneous decrease in nutrient intake and various metabolic and hormonal alterations that lead to a depletion of proteins (especially skeletal muscle), and that does not recover only with diet. Table 37.3 shows the diagnostic categories defined by the International Society of Renal Nutrition and Metabolism for diagnosing PEW, including biochemical criteria, low body mass, reduced muscle mass, and low protein or energy intakes [20]. One diagnostic criterion needs to be met in at least three of the four categories for the diagnosis of PEW, so no single marker can diagnose the syndrome.

Epidemiology of Protein-energy Wasting

PEW is a common phenomenon across the spectrum of acute kidney injury (AKI) and CKD; prevalence increases in patients on dialysis and the longer they remain on dialysis [81]. However, the exact evaluation of the prevalence of PEW in the kidney population has been historically hampered by several factors, including the lack of a standardized definition for malnutrition, the variability of existing evaluation tools, the limited sample sizes of most of the studies, and the different prevalence of malnutrition in the general population reflecting economic and social disparities between different geographical regions [82]. In a recent meta-analysis from contemporary studies (2000–2014) including more than 50 subjects with kidney disease, the prevalence of PEW by Subjective Global Assessment (SGA) or Malnutrition-Inflammation Score (MIS) was estimated to range from 60% to 82%, 11% to 54%, 28% to 54%, and 28% to 54% for AKI, CKD stages 3–5, dialysis, and transplant

Table 37.3 The ISRNM criteria for diagnosing PEW.

Criteria		Comments
Serum chemistry		
	Serum albumin <3.8 g/dl	Nonspecific. It may be influenced by fluid status, inflammation, proteinuria, dialysis procedure, intercurrent illnesses, liver disease, etc.
	Serum prealbumin (transthyretin) <30 g/dl	Only appropriate for maintenance dialysis patients (levels may vary according to GFR level for patients with nondialysis CKD).
	Serum cholesterol <100 mg/dl	It may be influenced by lipid-lowering medication.
Body mass		
	BMI <23 kg/m^2	Weight is influenced by fluid overload and does not distinguish fat from muscle.
	Unintentional nonedematous weight loss over time: 5% over 3 months or 10% over 6 months	
	Total body fat percentage <10%	
Muscle mass		
	Muscle wasting: reduced muscle mass of 5% over 3 months or 10% over 6 months	
	Reduced mid-arm muscle circumference area (reduction >10% in relation to 50th percentile of reference population)	Measurement must be performed by a trained anthropometrist.
	Creatinine appearance	May be influenced by both muscle mass and meat intake.
Dietary intake		
	Unintentional low DPI <0.8 g/kg/day for at least 2 months for dialysis patients or <0.6 g/kg/day for patients with CKD stages 2–5	Can be assessed by dietary diaries and interviews, or by calculation of nPCR or nPNA.
	Unintentional low DEI <25 kcal/kg/day for at least 2 months	Can be assessed by dietary diaries and interviews.

BMI, body mass index; CKD, chronic kidney disease; DEI, dietary energy intake; DPI, dietary protein intake; GFR, glomerular filtration rate; ISRNM, International Society of Renal Nutrition and Metabolism; nPCR, normalized protein catabolic rate; nPNA, normalized protein nitrogen appearance.
Note: At least one measure from at least three of the criteria should be met in order to classify a patient as having PEW. *Source:* Adapted from: Fouque D, Kalantar-Zadeh K, Kopple J, et al. A proposed nomenclature and diagnostic criteria for protein-energy wasting in acute and chronic kidney disease. Kidney Int 2008; 73: 391–398.

patients, respectively (Figure 37.3) [83]. Another recent study using the four PEW diagnostic criteria showed a prevalence of more than 50% of moderate or severe PEW in the HD population [84].

Pathophysiology

Nutritional Disorders in CKD

The kidney functions in maintaining nutrient homeostasis and the nutritional disorders that appear in CKD are depicted in Figure 37.4. During the course of CKD, the kidneys progressively lose their ability to maintain nutrient homeostasis, with a resulting reduction in the excretion of solutes and subsequent accumulation of toxic products (including protein waste products, phosphate, sodium) and water. This leads to acidemia, hyper-azotemia, hyperphosphatemia, and fluid retention. The kidneys attempt to compensate for damage through hyperfunction (hyperfiltration) of the remaining functional nephrons, and activation of several compensative mechanisms, such as secondary hyperparathyroidism (SHPT) or volume expansion, which may be harmful for the body. As a result of all these changes, several nutrient disorders arise as kidney function declines, including metabolic acidosis, systemic inflammation, and hormonal dysregulation that have been attributed to the development of hypercatabolism and risk for negative nitrogen balance [85].

Causes of Protein-energy Wasting

Several factors contribute to the deterioration of nutritional status in CKD patients. PEW can occur due to inadequate nutrient intake, as well as other factors not related to diet, such as comorbidities, appearance of intercurrent catabolic processes, metabolic acidosis, and several endocrine disorders associated with CKD, such as deficit of GH and IGF-1, hyperinsulinism, SHPT, or hyperglucagonemia (Figure 37.5) [37]. Although clearance of uremic toxins by dialysis is able to partially reverse anorexia related to uremic syndrome, the dialysis technique itself can contribute to PEW due both to the forced loss of nutrients by the dialysate and to direct catabolic and inflammatory effects [27]. The consequences of PEW are reduction of muscle mass, increased risk of infection, and cardiovascular disease, which results in lower quality of life and survival of CKD patients [37].

Decreased Protein and Energy Intake

Uremic syndrome is associated with loss of appetite and various gastrointestinal disorders that lead to a decrease in nutrient intake. The progressive accumulation of uremic toxins, enteric hormones, adipokines (leptin, visfatin), and inflammatory cytokines that appear as kidney disease progresses are the main factors that have been related to decreased appetite [86, 87]. Underdialysis is an additional factor that contributes to anorexia and dysgeusia, so adequate dialysis is essential to preserve the nutritional status of HD patients. Several RCTs have shown that an increase in the dose of diffusive or convective dialysis allows an increase in nutrient intake. In a randomized study, an increase in the dialysis dose from Kt/V 0.8 to 1.3 increased the protein intake (estimated by the rate of normalized protein catabolic rate [nPCR]) at 3 months, whereas the control group did not show changes in Kt/V and nPCR [88]. In another trial comparing high-flux HD with on-line hemodiafiltration, the administration of a convective volume of 23.6 l allowed an increase in protein intake with a tendency to increase appetite [89]. Similar results have been observed with other more intensive dialysis regimens, such as short-daily dialysis or long nocturnal dialysis [90, 91].

The usual dietary restrictions in CKD patients, the recommendations for cooking foods to reduce the content of

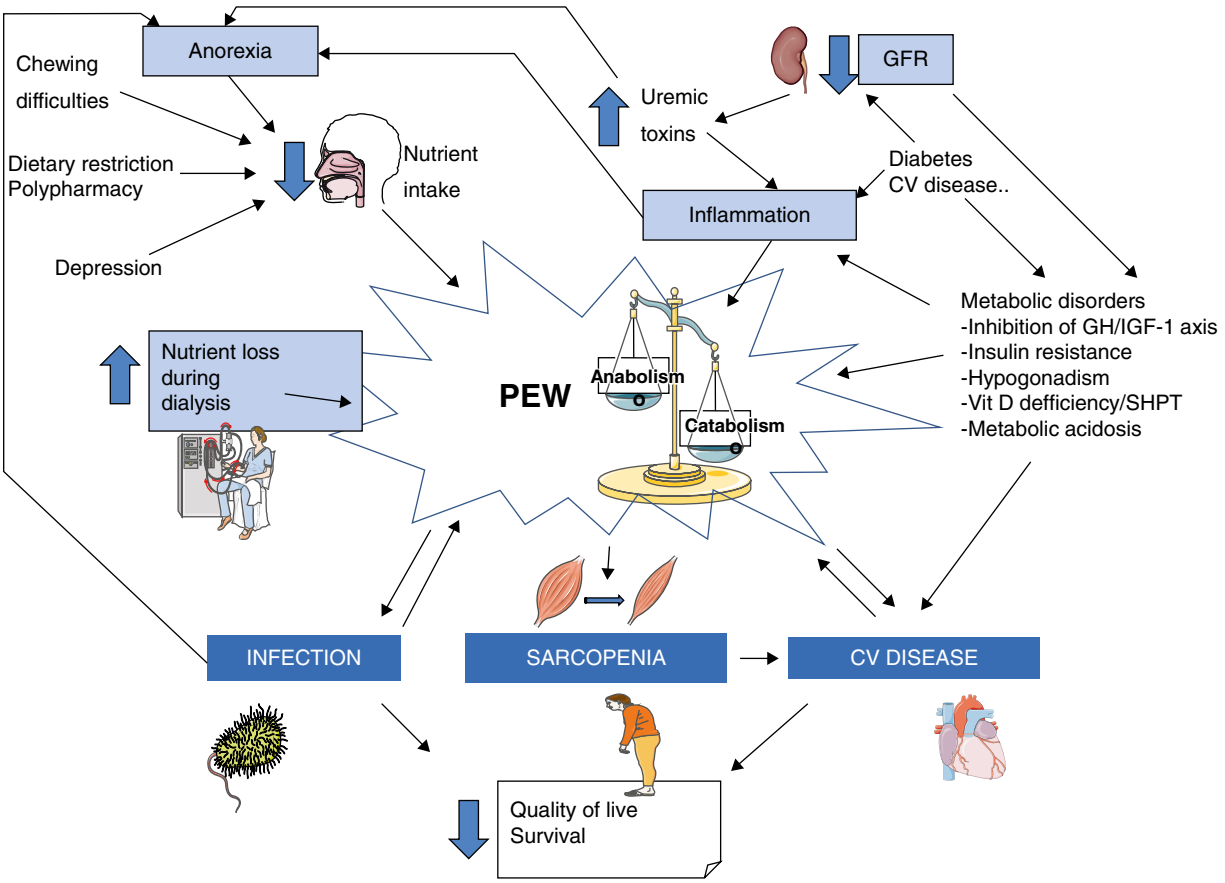

Figure 37.5 Pathophysiology of PEW. CV, cardiovascular; GFR, glomerular filtration rate; GH, growth hormone; IGF-1, insulin-like growth factor 1; PEW, protein-energy wasting; SHPT, secondary hyperparathyroidism. *Source:* Adapted from: Carrero et al. [37].

electrolytes, as well as the use of phosphate binders during meals alter the palatability of food and its absorption, which contributes to undernutrition of this population. Even restricting fluids to reduce interdialytic weight gain in dialysis patients can decrease caloric intake, since many solid foods have a high water content.

Oral and gastrointestinal tract problems modify the quantity and quality of the food ingested. Some of these factors are very frequent, such as dry mucous membranes, glossitis, mucosal inflammation, and palatability problems; these can create difficulties in swallowing and food perception. Periodontitis and lack of teeth can make chewing difficult, forcing the patient to choose foods that are easy to chew and possibly of poor nutritional value, especially fiber [92].

Finally, psychological and social aspects such as depression, loneliness, or limited ability to perform activities of daily living also contribute to potential anorexia or difficulty in ensuring food availability [37].

Catabolic Effect of Uremia, Decreased Anabolism, and Comorbidities of the CKD Patient

Hypercatabolism is the other main component of PEW [20, 37]. Potential causes of its occurrence include the accumulation of uremic toxins, microinflammation, and metabolic alterations associated with the uremic milieu and the patient's comorbidities. Systemic inflammation contributes to PEW syndrome in CKD patients through multiple mechanisms (Figure 37.6) [93–95]. In addition to inducing reduced appetite, inflammation generates increased energy expenditure and exerts direct and indirect catabolic effects. Tumor necrosis factor alpha (TNFα) promotes the loss of lean mass through the promotion of catabolic pathways, such as nuclear factor kappa B (NF-kB) and the ubiquitin-proteasome system. Indirectly, interleukin-6 (IL-6) promotes muscle catabolism by contributing to the inhibition and resistance of anabolic pathways.

The inhibition of the GH/IGF-1 axis (due to a lower expression of IGF-1 receptors in the muscle and negative hypothalamic feedback secondary to the retention of GH, IGF-1, and its carrier protein), the resistance to insulin, and the inhibition of testosterone synthesis are the main altered anabolic pathways in CKD patients, which generates a reduction in muscle mass and strength [96, 97]. Metabolic acidosis contributes to protein hypercatabolism, mainly by activating the ubiquitin–proteasome system and other muscle proteolytic pathways, decreasing hepatic synthesis of albumin, and increasing insulin resistance, which in kidney failure is preferentially muscular, favoring the onset of sarcopenic obesity [98, 99]. Finally, the typical comorbidity of the CKD patient also contributes to hypercatabolism through several factors including anemia, water overload, cardiovascular disease, or SHPT (Figure 37.7) [37]. The coexistence of diabetes is especially relevant, given

that it is associated with gastroparesis, obesity, and muscle loss with relative preservation of fat mass.

Loss of Nutrients and Catabolic Effects of Dialysis

The loss of nutrients and the inflammatory stimulus produced during dialysis contribute to the appearance of PEW. The dialysis procedure is a perfect example of the integration of malnutrition and catabolism and how PEW is carried out (Figure 37.8). Amino acids, peptides, and proteins are lost through the dialysate in both HD and PD. Plasma amino acid concentrations are reduced approximately 20% on average after a single HD session, which decreases the availability of substrate for the synthesis of muscle proteins. All this, along with the decrease in nutrient intake, leads to a lower availability of nutrients, which generates undernutrition and an increase in protein catabolism with the breakdown of muscle proteins to compensate for these losses, which contributes to the appearance of PEW [27, 37, 101–104].

Patients undergoing PD have additional characteristics inherent to the technique that modify their nutritional status, including forced absorption of glucose, which provides 300–600 kcal/day, greater protein losses by the dialysate than in HD, which can contribute to development of sarcopenic obesity, and difficult gastric emptying, which may limit the intake of food and supplements due to early satiety [105–108].

The dialysis procedure produces an inflammatory stimulus with cytokine activation, which increases muscle degradation and PEW, especially if the microbiological quality of the dialysate is low, if the membrane is bioincompatible, or if the filters are reused. Finally, patients on HD are at greater risk of loss of residual renal function, especially if high ultrafiltration rate is prescribed, which is associated with decreased appetite and an increase in basal metabolism and inflammation, aggravating PEW [37]. Both volume and a high ultrafiltration rate may also generate intestinal hypoxia by a mechanism similar to that which occurs with intradialytic myocardial stunning. This hypoxia increases the permeability of the intestinal mucosa to bacterial lipo-saccharides, favoring its translocation into the enterocyte and increasing the inflammatory state [109, 110].

The combination of hypermetabolism and undernutrition may explain why standard HD does not prevent the appearance of PEW. Although initially HD improves the appetite of the incident patients and a progressive increase

in dry weight can be observed, this increase in weight is due to the increase in fat deposits, while the muscle mass decreases progressively as the patient remains in this modality of renal replacement therapy [111].

Diagnosis: Assessment of Nutritional Status

The nutritional assessment of CKD patients requires combining different dietary, anthropometric, and biochemical criteria. Due to the lack of reference values of many of these nutritional markers for this population, it is advisable to make repeated measurements of the different markers to assess their trend over time and to be able to detect subtle changes in nutritional status. Overhydration is another issue for assessment of nutritional status, as it increases the intra- and interindividual variability of these measures [20].

To date, there are no systematic summaries of screening and diagnostic tests to evaluate nutritional status among CKD patients.

Patient Interview

The clinical history allows collection of key information related to nutritional status, including: the presence of symptoms such as nausea, vomiting, or involuntary weight loss, which are associated with high risk for PEW, treatments that can affect nutritional status, such as phosphate binders or the use of corticosteroids, and the comorbidities and the socioeconomic status of the patient [112]. In addition, the presence of proteinuria, the residual renal function, and the type of dialysis are factors that may affect the nutritional status of CKD patients.

Measures that can be routinely collected under daily practice conditions are included in the so-called screening tools. Questions that are common to all screening tools include asking about appetite and involuntary body weight changes within a given time frame. Screening tools are inexpensive and quick and easy to use, so they can be performed by any healthcare professional with the result of identifying patients who are at risk for poor nutritional status and may require further assessment [112]. Typical screening tools are the Nutrition Screening Tool, Mini-Nutrition Assessment, and Malnutrition Universal Screening Tool/Malnutrition Screening Tool. There are a few studies that have assessed their reliability in CKD patients, observing a moderate sensitivity [113, 114]. Overall, evidence for recommending the use of screening tools among CKD populations is very limited.

Anthropometry and Body Composition

Weight and Body Mass Index

These measures have the advantages of simplicity and low cost, but they do not distinguish the different body

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

components (water, muscle, or fat). For HD patients, weight should always be assessed post-dialysis, taking into account the possible overhydration of the patient [115].

Mid-arm Circumference

This measure is simple to perform, correlating well with lean mass [116].

Skinfold Thickness

Subcutaneous fat evaluation by skinfold thickness of tricipital or bicipital and subscapular folds allows estimating the fat mass in adults with CKD stages 1–5 and post-transplant with a high correlation with dual energy X-ray absorptiometry (DEXA). Therefore, it is postulated as the method of choice for evaluating body fat among CKD populations [117, 118].

Bioelectrical Impedance Analysis

Bioelectrical impedance analysis (BIA) determines the electrical impedance or the resistance to the flow of an electrical current through the tissues of the body. Due to its water and electrolyte content, lean tissue is a good electrical conductor, while fat, bone, and skin are very poor conductors and offer a high resistance to electric currents. Using algorithms, BIA can calculate body water, body fat, and fat-free mass. Advantages include its ease of use and portability, as well as its sensitivity to detect changes in the short-term; it is highly recommended that BIA be available in all dialysis units. However, consideration must be given to limitations due to the state of hydration of the patient; overhydration, so frequent in CKD patients, overestimates lean mass and underestimates fat mass. Thus, repeated measures should be taken at a constant time post-dialysis to obtain a more reliable assessment of body composition with BIA [112, 119].

Handgrip Strength

This measure is a surrogate marker of lean body mass and is an indicator of superior strength of the body muscle. It has higher correlations with nutritional status and inflammatory markers, and was more predictive of mortality than muscle mass measured by DEXA. Its limitations are the lack of standardized protocols (with respect to body posture, selection/position of the hand) and the lack of reference measurements in the CKD population [116, 120, 121].

Nutritional Assessment Scores

Subjective Global Assessment

Subjective Global Assessment (SGA) is the most used nutritional questionnaire in CKD patients, and combines subjective clinical findings and objectives of the clinical history and physical examination to obtain a score that classifies the nutritional status of the patient from well-nourished to very malnourished. It collects information on weight changes, dietary intake, persistent gastrointestinal symptoms, functional capacity, nutritional needs, and physical examination [104]. It takes 15 minutes to complete by a health professional who has been trained to perform it. Several studies have demonstrated the validity and reliability of the 7-point SGA score among CKD patients (including ND-CKD, HD, and PD) and its correlation with other measures of nutritional status, including lean body mass and serum albumin levels [122–125].

Malnutrition-Inflammation Score

Malnutrition-Inflammation Score (MIS) is a modified version of the SGA, and incorporates three new objective parameters: body mass index (BMI), serum albumin, and transferrin or iron binding capacity. It was designed in an attempt to reduce the subjectivity of the SGA by using a quantitative scoring system. Each of the referred items are scored from 0 to 3. A MIS score of 0–5 is considered normal, 6–17 represents mild/moderate malnutrition, and 18–30 indicates severe malnutrition. MIS was designed specifically for the HD population [126], although it has also been validated in ND-CKD, PD, and kidney transplant patients [127–129].

Biochemistry

Albumin

Serum albumin concentration is the most used nutritional parameter in CKD patients due to its reproducibility and low cost, as well as its capacity to respond to nutritional interventions [130]. Several studies have supported that serum albumin concentration is a sensitive measure of nutritional status, being associated with other common nutritional status markers in CKD. Although evidence suggests that it is a strong predictor of mortality, it has a half-life of 20 days, which means that its response to acute changes in nutrient intake is delayed. Another limitation is its low specificity, since albumin is influenced by inflammation, stress, and overhydration [131–135]. An albumin level below 3.8 g/dl is suggestive of PEW [20].

Prealbumin

The main advantage of prealbumin (or transthyretin) is its half-life of 2 days, which makes it more sensitive to short-term changes in nutritional status and/or acute response to nutritional therapy than albumin. However, levels are affected by kidney function, inflammatory status, and intercurrent diseases [131]. Prealbumin levels below 30 mg/dl are suggestive of PEW [20].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Serum Creatinine

This may be an adequate surrogate measure of muscle mass in dialysis patients as long as residual kidney function is minimal or absent. There are no defined cut-off points, so longitudinal assessment is suggested for each patient, with the advantage that it is useful for detecting individual changes in the short term [130, 133]. In addition, serum creatinine determination allows for the calculation of the creatinine index [135].

Creatinine Index

If bioimpedance testing is not available, lean mass can be estimated using the kinetic model of creatinine, which is a reliable method to monitor muscle mass and protein nutritional status in dialysis patients. It is based on the principle that the generation of creatinine is proportional to muscle mass in stable patients in steady state. The creatinine index is defined as the normalized creatinine production rate, which is equal to the sum of the creatinine excretion rate (creatinine in the dialysate + urinary creatinine) and the rate of metabolism of creatinine in a state of metabolic equilibrium. To avoid post-dialysis determination of blood creatinine and dialysate, different formulas have been developed to calculate the creatinine index from baseline creatinine levels, Kt/V, age, and sex [135].

Cholesterol

Although a blood cholesterol level of less than 100 mg/dl is a criterion for PEW [3], its use as a nutritional marker is limited given that it is negatively influenced by lipid-lowering treatment and positively influenced by proteinuria [130].

C-Reactive Protein

Although not a nutritional parameter, the determination of serum levels of C-reactive protein (CRP) allows monitoring of the inflammatory state in the CKD patient in a reproducible way. Given the great variability of CRP, repeated testing is required to assess its trend in each patient [130].

Protein Equivalent of Nitrogen Appearance

The kinetic model of urea has been used to estimate protein intake in HD patients in a steady state [133]. The protein equivalent of nitrogen appearance (PNA or nPCR) is calculated based on the increase of nitrogen in the interdialysis period. Catabolic or anabolic processes may overestimate or underestimate, respectively, the measurement of protein intake by this method. If the patient has residual kidney function, the urea lost in the urine should be taken into account [130]. For ND-CKD patients, protein intake may be estimated from urinary urea excretion with Maroni's formula [136].

Assessment of Food Intake

There are three methods to assess the food intake of proteins, calories, and nutrients in CKD patients. This should be done periodically and/or whenever PEW is suspected.

Twenty-four-hour Dietary Recalls

Through an interview, the patient is asked to recall food intake during the previous 24 hours. The main limitation of this method is that it extrapolates the intake of a day as the habitual intake of the patient, together with the high risk of bias, especially when the patient may have cognitive disorders or is not cooperative. The main advantages are the speed of its execution (it can even be done by telephone) and the lack of need for record-keeping by the patient [137–139].

Food Diaries and Records

The patient (or caregiver) is required to record food intake for 3 or 7 days, including a day of HD if this is the case and a weekend day. From this, a dietitian estimates the patient's food intake from food composition tables with the help of computer programs [140]. The most important limitations are food intake not recorded completely or accurately, and the impossibility of detecting seasonal variations in intake [137].

Food Frequency Questionnaires

In these, a series of questions ask about the frequency and amount of consumption of several common foods during the last 6–12 months; calculation of the amount of food ingested is done by multiplying the frequency by the specific amount for the measure provided. With questions such as "How many times a week do you eat fruit?", it may be easier to perform than the 3- or 7-day food diary, although it is not as reliable as such records [140]. One advantage is that it gives a view of food intake over a longer period of time, which is why it is especially useful in epidemiological studies. However, it is of little use at the individual level or when analyzing small groups of patients [137].

Assessment of Resting Energy Expenditure

Knowledge concerning energy requirements of CKD patients is imperative to providing a sufficient amount of energy to maintain adequate nutritional status [141]. Although indirect calorimetry is the most accurate method for measuring resting energy expenditure (REE), it is not usually available in the clinical routine [142]. In the absence of indirect calorimetry, several predictive energy equations based on simple bedside parameters have been

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

proposed. However, it must be noted that prediction equations used in normal individuals (i.e. Harris and Benedict's equation) overestimate REE in the ND-CKD population, although the errors may be minimized in the presence of comorbidities [142]. Conversely, several equations have been specifically developed for dialysis patients and validated in this population [143].

Prognosis: Consequences of PEW in Mortality, Morbidity, and Quality of Life

Multiple observational studies have shown that PEW markers are independently associated with worse survival [39, 144–146], decreased quality of life [147], increased risk of infections, and complications related to cardiovascular disease, with greater risk of hospitalization and healthcare costs [148, 149]. Moreover, the consequences of PEW are so rapid and negative in the prognosis of CKD patients that this modifies the usual and logical relationship between risk factors and poor evolution [150]. A clear example is the association between surrogates of overnutrition (i.e. obesity or hyperlipidemia) and mortality. In dialysis patients, obesity (versus normal weight) is associated with better survival, whereas the opposite effect is observed in the general population. The most likely explanation is that patients undergoing dialysis usually die from the short-term consequences of PEW and do not live long enough to die of cardiovascular disease associated with obesity. Additionally, increased fat deposits could protect the PEW patient for longer [151].

Although RCTs demonstrating the causal association between undernutrition and hypermetabolism with adverse patient outcomes in CKD patients are lacking, several epidemiological studies have explored this issue, showing that nutritional interventions in hypoalbuminemic HD patients may be effective in reducing hospitalizations rates and mortality [152–154]. All these data support the hypothesis that PEW is not only a risk factor, but also a treatable etiological factor in preventing mortality and morbidity, so that nutritional therapy can result in multiple improved clinical outcomes throughout the spectrum of CKD.

Treatment

People with kidney disease represent an extremely heterogeneous group of patients in whom nutritional recommendations may differ greatly depending on the type of nephropathy, its form of onset (acute or chronic), and the therapeutic goals being pursued, as, for example slowing down progression in the patient with ND-CKD, alleviating the protein hypercatabolism associated with the uremic milieu in the dialysis patient, or controlling the hyperkalemia in the patient under conservative treatment.

Although extensive literature has shown that high mortality risk in CKD patients is related in part to the nutritional derangements linked to kidney failure, there is not enough evidence to address the exact role of different dietary interventions in the prognosis of the CKD population. Whereas undernutrition may increase the risk for PEW, overnutrition may lead to sodium and volume overload, high BP, hyperkalemia, hyperphosphatemia, and accumulation of toxic metabolites of protein degradation. Treatment to decrease proteinuria and BP and improve several markers of PEW, such as serum albumin levels, have demonstrated efficacy across many RCTs, while evidence to hard clinical outcomes including survival, cardiovascular events, or CKD progression remains inconclusive. However, this lack of evidence does not necessarily indicate that nutritional interventions have no effect on CKD outcomes. Moreover, given that nutritional therapy including dietary counseling and supplements is safe and cost-effective, it should be considered to improve the poor prognosis of CKD patients.

Dietary Interventions for Survival, Quality of Life, and Overall Health of Adults with CKD

Dietary interventions are routinely recommended in CKD patients given the potential ability to influence clinical outcomes in this population. On the basis of evidence from nonrandomized studies in CKD patients, and especially from randomized studies in the general population, it has been suggested that healthy dietary patterns may prevent hard outcomes, including survival, cardiovascular events, and health-related quality of life [155].

However, the optimal approach to nutrition in CKD patients is not well known, and the few RCTs conducted in this population have yielded conflicting results. In 2017, a Cochrane review evaluated the benefits and harms of dietary interventions in CKD patients, including dietary patterns and nutritional counseling, with all-cause mortality, major adverse cardiovascular events, and health-related quality of life being the primary outcomes [1]. The review evaluated 17 RCTs with 1639 adult CKD patients, including 10 studies with 1130 people with ND-CKD stages 1–5, three studies with 341 dialysis patients, and four studies with 168 kidney transplant recipients (summarized in Table 37.4). Eleven studies ($n = 900$) evaluated dietary counseling and six studies evaluated dietary patterns ($n = 739$), including the Mediterranean diet (two studies, $n = 355$), a carbohydrate-restricted, low-iron, polyphenol-enriched diet

Table 37.4 Summary of findings: dietary interventions for overall health of adults with CKD.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for one year (95% CI)	Relative effect (95% CI)[a]	Certainty of the evidence (GRADE)	Conclusion
Primary outcomes					
Death (all causes): dietary counseling	371 (4)	Not estimable	1.59 (0.60–4.21)	Very low ●○○○	It is uncertain whether dietary counseling impacts on all-cause mortality
Death (all causes): CR-LIPE diet	170 (1)	Not estimable	0.50 (0.22–1.12)	Very low ●○○○	It is uncertain whether CR-LIPE diet impacts on all-cause mortality
Major adverse cardiovascular events: dietary counseling	62 (1)	Not estimable	6.58 (0.35–122.21)	Very low ●○○○	It is uncertain whether dietary counseling impacts on major adverse cardiovascular events
Health-related quality of life: dietary counseling	119 (2)	—	The MD in SF-36 score was 11.46 higher (7.73 higher to 15.18 higher) in the intervention groups compared to control	Low ●●○○	Dietary counseling may have clinically important increases in the SF-36 quality of life score
Secondary outcomes					
ESRD: dietary counseling and CR-LIPE diet	232 (2)	0.3 fewer (1 person in every 3000 treated for one year avoiding ESRD)	0.53 (0.26–1.07)	Very low ●○○○	It is uncertain whether dietary interventions impact on risks of ESRD
Worsening nutrition (subjective global assessment): dietary counseling	230 (2)	Not estimable	0.40 (0.05–3.37)	Very low ●○○○	It is uncertain whether dietary counseling impacts on risks of worsening nutrition as measured by subjective global assessment
eGFR: dietary counseling, Mediterranean diet, and fruits and vegetables	219 (5)	—	The SMD in eGFR was 1.08 higher (0.20 higher to 1.97 higher) with dietary intervention compared to standard care	Very low ●○○○	Dietary interventions may increase eGFR
Serum creatinine: dietary counseling and Mediterranean diet	112 (3)	—	The MD in creatinine was 0.83 μmol/l higher (−16.57 lower to 18.23 higher) with dietary intervention compared to standard care	Very low ●○○○	It is uncertain whether dietary interventions impact on creatinine levels
Systolic blood pressure: dietary counseling and fruits and vegetables	167 (3)	—	The MD in systolic BP was −9.26 mmHg lower (−13.48 lower to −5.04 lower) with dietary intervention compared to standard care	Moderate ●●●○	Dietary interventions probably reduce systolic BP

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Diastolic blood pressure: dietary counseling	95 (2)	—	The MD in diastolic BP was −8.95 mmHg lower (−10.69 lower to −7.21 lower) with dietary intervention compared to standard care	Moderate ●●●○	Dietary counseling probably reduces diastolic BP
Energy intake: dietary counseling	340 (4)	—	The SMD in energy intake was 1.54 higher (−0.87 lower to 3.95 higher) with dietary intervention compared to standard care	Very low ●○○○	It is uncertain whether dietary counseling impacts on energy intake
Energy intake: Mediterranean diet	40 (1)	—	The SMD in energy intake was 1.86 higher (1.11 higher to 2.61 higher) with Mediterranean diet compared to standard care	Very low ●○○○	Mediterranean diet may increase energy intake
Energy intake: high nitrogen and low carbohydrate diet	12 (1)	—	The SMD in energy intake was −0.65 lower (−1.82 lower to 0.53 higher) with high nitrogen and low carbohydrate diet compared to standard care	Very low ●○○○	It is uncertain whether high nitrogen and low carbohydrate diet impacts on energy intake
Body weight: dietary counseling, fruits and vegetables, CR-LIPE, and high nitrogen and low carbohydrate diet	454 (6)	—	The MD in body weight was −0.44 kg lower (−1.46 lower to 0.58 higher) with dietary intervention compared to standard care	Very low ●○○○	It is uncertain whether dietary interventions impact on body weight
BMI: dietary counseling	119 (2)	—	The MD in BMI was −1.70 kg/m^2 lower (−5.23 lower to 1.82 higher) with dietary intervention compared to standard care	Very low ●○○○	It is uncertain whether dietary counseling impacts on BMI
Arm circumference: dietary counseling	149 (2)	—	The MD in arm circumference was 0.37 higher (−0.39 lower to 1.12 higher) with dietary intervention compared to standard care	Very low ●○○○	It is uncertain whether dietary counseling impacts on arm circumference
Serum albumin: dietary counseling, Mediterranean diet, and CR-LIPE	541 (6)	—	The MD for the effect of serum albumin levels was 0.16 mg/dl higher (0.07 higher to 0.24 higher) with dietary intervention compared to control or standard care	Low ●●○○	Dietary interventions may increase albumin levels

BMI, body mass index; BP, blood pressure; CR-LIPE, carbohydrate-restricted, low-iron-available, polyphenol-enriched; eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; SF-36, short-form 36-item health survey.

Treatment estimates are drawn from a Cochrane review [1]. GRADE assessment of the certainty of the evidence [17]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.

[a] Effects are reported as the relative risk (RR) and 95% confidence interval (CI) for binary outcomes and mean difference (MD) and 95% CI for continuous outcomes (standardized mean difference [SMD] if different scales were used).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. (one study, $n = 191$), increased fruit and vegetable intake (two studies, $n = 181$), and a high protein/low carbohydrate diet (one study, $n = 12$). Studies related to dietary management of specific dietary factors such as protein, sodium, or phosphate were excluded. According to this systematic review, dietary interventions have uncertain effects on mortality and cardiovascular events among CKD patients as studies were not designed to examine these outcomes. In very-low-quality evidence, dietary interventions had uncertain effects on the development of end-stage renal disease (ESRD). Conversely, dietary interventions may increase health-related quality of life, eGFR, and serum albumin, and reduce several risks factors for cardiovascular events such as BP and serum LDL cholesterol levels. Whether these favorable effects on these surrogate endpoints would improve clinical outcomes for CKD patients remains uncertain [1].

Nutritional Interventions to Slow Progression of CKD

Dietary Protein Restriction

According to the hyperfiltration theory, the amount of protein intake in current diets, which is generally higher than our daily needs, could explain the appearance of glomerular sclerosis that accompanies aging (0.75–1.5 ml/min/year from the age of 40) [156–159]. Conversely, dietary protein restriction may protect against CKD progression by hemodynamic-mediated mechanisms, including intraglomerular pressure reduction, as well as by changes in cytokine expression and matrix synthesis (Figure 37.2) [62].

Nearly 20 RCTs have assessed the effects of protein restriction on kidney outcomes of interest, including CKD progression and the need for maintenance dialysis, proteinuria, phosphate levels, acidemia, and BP. These studies have been summarized in several meta-analyses [2–5, 160–165]. Most of these have been conducted recently [2–4], which indicates there remains great interest regarding protein restriction in CKD patients [62, 166, 167].

Several practical approaches have been described for protein restriction, with 0.6–0.8 g/kg of weight per day (LPD) being most frequently recommended for ND-CKD patients stages 3–5. However, a greater restriction of less than 0.6 g/kg/day (VLPD) supplemented with essential amino acids or their ketoacids has also been tested. The safety and implementation of protein restriction diets should be accompanied by ensuring adequate energy intake (30–35 kcal/kg/day) and regular nutritional checks. Overall, the balance of evidence suggests a benefit of dietary protein restriction (summarized in Table 37.5).

However, results of some RCTs have not consistently demonstrated that protein restriction would be beneficial in CKD progression. The primary results of the largest trial to date, the Modification of Diet in Renal Disease (MDRD), which analyzed the effect of protein restriction and intensive control of BP on the rate of loss of GFR (measured by iothalamate clearance) in 840 ND-CKD patients, did not support the hypothesis of benefit of protein restriction on the progression of kidney failure [168]. It is possible that the MDRD study duration was too short to fully appreciate the effect of protein restriction; this and other limitations could have allowed classifying this RCT as inconclusive rather than negative [169]. Indeed, subsequent secondary analyses performed by some of the MDRD investigators concluded that the balance of evidence was more consistent with the hypothesis of beneficial effect from the reduction of the proteins in the diet rather than with the hypothesis of nonbenefit, with this benefit being additive to that obtained by the BP control. The restriction of proteins slowed the deterioration of GFR, mainly in more advanced stages and in those cases of more rapid loss of renal function. These findings would justify the recommendation of an LPD in ND-CKD patients, and its safety, when accompanied by nutritional advice and systematic monitoring, is also supported by the evidence [169, 170].

In 2007 and 2018, two Cochrane reviews summarized the evidence for protein restriction for diabetic and nondiabetic kidney diseases, respectively [3, 5]. A summary of the findings is shown in Table 37.6. Evidence for beneficial effects of protein restriction for nondiabetic patients with ND-CKD stages 3–5 is restricted to effects of VLPD on progression to ESRD. Conversely, when LPDs were compared with normal protein diets, there was little or no difference in the number of people who progressed to dialysis. LPDs or VLPDs probably do not influence death; however, there are limited data on other adverse effects such as weight differences and PEW. Most studies reported that adherence to diet was satisfactory, but quality of life was not formally assessed in any studies. The authors encouraged conduct of new studies evaluating the adverse effects and the impact on quality of life of dietary protein restriction before these dietary approaches be recommended for widespread use [3].

Restricted protein intake appeared to slow progression of diabetic kidney disease, but not by much on average. Only one study explored all-cause mortality and ESRD as endpoints in type 1 diabetic patients, showing a relative risk (RR) of 0.23 for patients assigned to LPD. However, pooling of the seven RCTs of patients with type 1 diabetes resulted in a nonsignificant reduction in the decline of GFR of 0.1 ml/min/month (95% confidence interval [CI] −0.1 to 0.3) in the LPD group. For type 2 diabetes, one trial showed a small insignificant improvement in the rate of decline of GFR in the protein-restricted group and a second found a

Table 37.5 Meta-analyses and systematic reviews of diet protein restriction for kidney outcomes (RCTs only).

Author	No. of studies	Sample	Outcome measures	Methods	Conclusions
Fouque et al. [160]	6	$n = 890$ ND-CKD with varying degrees of renal failure	No. of deaths due to renal cause or need to initiate hemodialysis treatment	Difference in protein intake >0.2 g/kg/day in both groups Follow-up of at least 1 year	LPDs slowed progression to ESRD.
Pedrini et al. [161]	5	$n = 1413$ ND-CKD with moderate degree of renal failure	Calculation of RR of progression of renal disease	LPD of 0.4–0.6 g/kg/day Follow-up for 18–36 months	Protein restriction slowed progression of renal disease in diabetic and nondiabetic patients
Kasiske et al. [162]	13	$n = 1919$ ND-CKD (degree of renal failure was unreported)	Differences in rate of fall of GFR or creatinine clearance between control groups and groups treated with LPDs	Measurement of protein intake with urea excretion and nitrogen Analysis of results by intent-to-treat Measurement of disease progression by GFR or creatinine clearance Follow-up for 6–36 months	Protein restriction reduced the rate of decline in eGFR, although the magnitude of effects was weak [by only 0.53 ml/min/year (95% CI 0.08–0.98 ml/min/year)] The effect of dietary protein restriction was relatively greater among diabetic versus nondiabetic patients (5.4 ml/min/year, 95% CI 0.3–10.5 ml/min/year, $P < 0.05$)
Fouque et al. [163]	7	$n = 1494$ ND-CKD stages 3–5 Only nondiabetic patients	Renal death (death of any cause, requirement to start dialysis, or kidney transplant)	In theory, difference in protein intake between higher and restricted protein intake groups was approximately 0.35 g/kg/day in almost all the studies. However, based on urinary collection of protein waste products, the actual reduction in protein intake between groups in each study was less than expected (between 0.2 and 0.35 g/kg/day). Follow-up of at least 1 year	Reducing protein intake overall reduced renal deaths by about 39% ($P = 0.006$) To spare one extra renal death, 17 patients need to be treated with a low protein diet for approximately 2 years A subgroup analysis of the "start of dialysis" event was also highly significant, with an OR of 0.56 in favor of a restricted protein intake ($P < 0.01$)
Robertson et al. [5]	12 (nine RCTs, three before and after studies)	$n = 585$ Only diabetic patients (type 1 : 322; type 2 : 263) with nephropathy (UAER ≥300 mg/day)	Biochemistry (GFR), ESRD (all-cause mortality, nutritional status, health-related QOL, and costs were also analyzed)	Actual protein intake in the intervention groups ranged from 0.7 to 1.1 g/kg/day Interventions of reduced or modified protein intake ≥4 months	The RR of ESRD or death was 0.23 (95% CI 0.07–0.72) for patients assigned to an LPD Pooling of the seven RCTs in patients with type 1 diabetes resulted in a nonsignificant reduction in the decline of GFR of 0.1 ml/min/months (95% CI −0.1 to 0.3) in the LPD group For type 2 diabetes, one trial showed a small insignificant improvement in the rate of decline of GFR in the protein-restricted group and a second found a similar decline in both the intervention and control groups A specific recommendation of the necessary protein level to achieve this outcome was not possible

Table 37.5 (Continued)

Author	No. of studies	Sample	Outcome measures	Methods	Conclusions
Fouque et al. [165]	10 (also included three crossover studies)	$n = 1494$ CKD stages 3–5 Only nondiabetic patients	Renal death (death of any cause, requirement to start dialysis, or kidney transplant)	Protein intake (≥0.8 g/kg/day) vs. moderate (0.6 g/kg/day) to severe protein restriction (0.3 g/kg/day) regardless of supplementation with amino acids or keto-acids	Reducing protein intake overall reduced renal deaths by about 32% ($P = 0.0002$) Subanalysis (seven studies) found that reduced protein intakes between 0.3 and 0.6 g/kg/day compared to higher/free protein intakes resulted in a significant reduction in renal deaths (37%, $P = 0.0009$) The optimal level of protein intake cannot be determined based on this review
Rughooputh et al. [166]	15	$n = 1965$ CKD stages 1–5	Change in mean GFR	The assessment of protein intake was based on reported urinary indices Pooling the mean values for all studies, the achieved protein intake was 0.83 (0.15) g/kg/day in the experimental arm and 1.07 (0.17) g/kg/day in the control arm, based solely on urinary indices Follow-up of at least 1 year	Moderate protein diet restriction slowed CKD progression in nondiabetic and type 1 diabetic patients (−1.50 ml/min/1.73 m^2/year, 95% CI −2.73 to 0.26, $P = 0.0175$), but not in type 2 diabetic patients (−0.17 ml/min/1.73 m^2/year, 95% CI −1.88 to 1.55, $P = 0.85$)
Rhee et al. [2]	16 (RCTs with less than 30 participants were excluded)	$n = 2771$ CKD stages 3–5 (one study with 60 new ESRD patients on peritoneal dialysis with residual kidney function was also included)	Rate of progression to ESRD (all-cause mortality, nutritional status, and bicarbonate and phosphorus levels were also analyzed)	LPD (<0.8 g/kg/day) vs. higher protein diets (>0.8 g/kg/day) VLPD (<0.4 mg/kg/day) vs. LPD (0.4–0.8 mg/kg/day)	Risk of progression to ESRD was 4% lower in those who received LPD LPD (<0.8 g/kg/day) was also associated with higher serum bicarbonate levels, lower phosphorus levels, lower azotemia, and a trend toward lower rates of all-cause mortality VLPDs (protein intake <0.4 g/kg/day) were associated with greater preservation of kidney function and reduction in the rate of progression to ESRD Safety and adherence to a LPD was not inferior to a normal protein diet, and there was no difference in the rate of malnutrition or protein-energy wasting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Hahn et al. [3]	17	$n = 2996$ ND-CKD stages 3–5	End or change in GFR, ESRD (all-cause mortality and nutritional status were also analyzed)	LPD (0.5–0.6 g/kg/day) compared with a normal protein intake (≥0.8 g/kg/day) VLPD (0.3–0.4 g/kg/day) compared with LPD (0.5–0.6 g/kg/day) Follow-up of at least 1 year	LPD compared with a normal protein intake did not impact on the incidence of ESRD (RR 1.05, 95% CI 0.73–1.53) and on the outcome of final or change in GFR (SMD −0.18, 95% CI −0.75 to 0.38) VLPD comparted with LPD reduced the number who reach ESRD (RR 0.65, 95% CI 0.49–0.85) with no influence on the final or change in GFR (SMD 0.12, 95% CI −0.27 to 0.52) It was uncertain whether LPD or VLPD alter survival Twelve studies reported no evidence of protein-energy wasting in their study participants, while three studies reported small numbers of participants in each group with protein-energy wasting. It was uncertain whether LPD or VLPD alter final body weight. Most studies reported that adherence to diet was satisfactory Quality of life was not formally assessed in any studies
Yan et al. [4]	19	$n = 2492$ CKD stages 1–5 (two studies with 78 and 60 peritoneal dialysis patients were also included)	Kidney failure events, rate of change in eGFR per year, and changes in proteinuria (all-cause mortality, nutritional status, and phosphorus levels were also analyzed)	The difference in protein intake between protein restriction and control groups was at least 0.2 g/kg/day Follow-up of at least 24 weeks	LPD reduced the risk of kidney failure (OR = 0.59, 95% CI 0.41–0.85) and ESRD (OR = 0.64, 95% CI 0.43–0.96), but did not produce a clear beneficial effect for all-cause death events (OR = 1.17, 95% CI 0.67–2.06) The change in the MD for the rate of decline in the eGFR was significant (MD −1.85, $P = 0.001$), and for the proteinuria reduction (MD −0.44, $P = 0.02$) LPD also reduced the serum phosphorus concentration (MD −0.37, 95% CI −0.5 to −0.24) and BMI (MD −0.61, 95% CI −1.05 to −0.17). However, the change in albumin presented no significant difference between two groups (MD 0.23, 95% CI −0.51 to 0.97).

BMI, body mass index; CI, confidence interval; CKD, chronic kidney disease, ESRD, end-stage renal disease; eGFR, estimated glomerular filtration rate; LPD, low protein diet; MD, mean difference; ND-CKD, nondialysis chronic kidney disease; OR, odds ratio; QOL, quality of life; RCT, randomized controlled trial; RR, relative risk; SMD, standardized mean difference; UAER, urinary albumin excretion rate; VLDP, very-low protein diet. *Source:* Hahn D, Hodson EM, Fouque D (2018); Robertson L, Waugh N, Robertson A.(2007); Hultcrantz M et al.(2017).

Table 37.6 Summary of findings: dietary protein restriction for adults with CKD.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for one year (95% CI)	Relative effect (95% CI)[a]	Certainty of the evidence (GRADE)	Conclusion
Low protein diet versus normal protein diet for nondiabetic adults with CKD stages 3–4					
Death (all causes)	1680 (5)	13 fewer (27 fewer to 10 more)	0.77 (0.51–1.18)	Moderate ●●●○	LPD probably does not influence death
ESRD	1814 (6)	7 more (39 fewer to 76 more)	1.05 (0.73–1.53)	Low ●●○○	LPD may make little difference to the number of people who progress to ESRD
End of study or change in GFR	1680 (8)	Not estimable	The SMD for end or change in GFR was 0.18 lower (0.75 lower to 0.38 higher) with LPD compared to normal protein diet	Very low ●○○○	It is uncertain whether LPD impacts on the outcome of final or change in GFR
End of study body weight	223 (2)	Not estimable	The MD for end body weight was 3.09 kg lower (5.02 lower to 1.16 lower) with LPD compared to normal protein diet	Very low ●○○○	It is uncertain whether LPD impacts on final body weight
Quality of life	—(−)	Not estimable	Not estimable	Absent	No studies were found that evaluated quality of life
Very low protein diet versus low or normal protein diet for nondiabetic adults with CKD stages 4–5					
Death (all causes)	681 (6)	10 more (15 fewer to 60 more)	1.26 (0.62–2.54)	Moderate ●●●○	VLPD compared with LPD probably makes little or no difference to death
ESRD	1010 (10)	165 fewer (69–233 fewer)	0.65 (0.49–0.85)	Moderate ●●●○	VLPD probably reduces number of people who progress to ESRD
End of study or change in GFR	456 (6)	Not estimable	The SMD for end or change in GFR was 0.12 higher (0.27 lower to 0.52 higher) with VLPD compared to LPD	Very low ●○○○	It is uncertain whether VLPD compared with LPD impacts on the outcome of final or change in GFR
End of study body weight	291 (4)	Not estimable	The MD for end body weight was 1.40 kg higher (3.40 lower to 6.21 higher) with VLPD compared to LPD	Very low ●○○○	It is uncertain whether VLPD impacts on final body weight
Development of PEW	2373 (15)	Not estimable	1.31 (0.42–4.13)	Low ●●○○	Protein restriction may make little difference to the number of people who develop PEW
Quality of life	— (−)	Not estimable	Not estimable	Absent	No studies were found that evaluated quality of life

Low protein diet versus normal protein diet for diabetic renal disease					
Death (all causes) or ESRD: LPD vs. normal protein diet in type 1 diabetic patients	84 (1)	Not estimable	0.23 (0.07–0.72)	Low ●●○○	LPD may prevent death or progression to ESRD in type 1 diabetic patients
Change in GFR: LPD vs. normal protein diet in type 1 diabetic patients	222 (7)	Not estimable	There was a nonsignificant improvement in GFR of 0.1 ml/min/month (95% CI −0.1 to 0.3) in the LPD group	Low ●●○○	LPD may make little difference to the change in GFR in type 1 diabetic patients
Change in GFR: LPD vs. normal protein diet in type 2 diabetic patients	83 (2)	Not estimable	Not estimable	Very low ●○○○	It is uncertain whether LPD impacts on change in GFR in type 2 diabetic patients
Quality of life	— (−)	Not estimable	Not estimable	Absent	No studies were found that evaluated quality of life

CKD, chronic kidney disease; ESRD, end-stage renal disease; GFR, glomerular filtration rate; LPD, low protein diet; VLDP, very-low protein diet; PEW, protein-energy wasting.
Treatment estimates are drawn from two Cochrane reviews [3, 5]. GRADE assessment of the certainty of the evidence [17]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.
[a] Effects are reported as the relative risk (RR) and 95% confidence interval (CI) for binary outcomes and mean difference (MD) and 95% CI for continuous outcomes (standardized mean difference [SMD] if different scales were used).

similar decline in both the intervention and control groups. No data on the effects of LPDs on health-related quality of life in this population were found. According to the authors, and due to the variability amongst patients, there might perhaps be a 6-month therapeutic trial of protein restriction in all individuals with diabetic kidney disease, with continuation only in those who responded best [5].

Dietary Salt Restriction

The restriction of salt in the diet reduces BP and reduces proteinuria (independently of the effect on the BP) by a direct effect on the renin-angiotensin-aldosterone system, potentially improving cardiovascular outcomes and CKD progression to ESRD. However, the lack of long-term RCTs assessing the effectiveness and safety of dietary salt restriction on CKD progression and survival precludes any firm conclusions [62].

A 2015 Cochrane review summarized the evidence for salt restriction from eight RCTs of 258 adults with CKD (including six studies with ND-CKD patients, one with dialysis patients, and one with kidney transplant recipients) that compared two or more levels of salt intake [6]. Unfortunately, the short follow-up of the included studies (1–26 weeks) did not allow for establishing the effect of sodium intake on primary endpoints such as cardiovascular and all-cause mortality, cardiovascular events, or CKD progression. However, low salt interventions were associated with significant reduction in 24-hour sodium excretion (range 52–141 mmol) (eight studies, 258 patients, mean difference [MD] −105.86 mmol/day, 95% CI −119.20 to −92.51), systolic BP (eight studies, 258 patients, MD −8.75 mmHg, 95% CI −11.33 to −6.16), and diastolic BP (eight studies, 258 patients, MD −3.70 mmHg, 95% CI −5.09 to −2.30), allowing a significant reduction in antihypertensive treatment dosage (two studies, 52 patients, RR 5.48, 95% CI 1.27–23.66). Although data regarding urinary protein excretion was not able to be meta-analyzed, a significant reduction in proteinuria in relation to a low salt diet was noted in all the RCTs that reported this outcome [171–174]. Salt restriction significantly increased plasma renin activity and serum aldosterone, whereas one study reported a 56% reduction in the risk of edema [171]. There was no significant change in eGFR (two studies, 68 patients, MD −1.14 ml/min/1.73 m^2, 95% CI −4.38 to 2.11) or creatinine clearance (three studies, 85 patients, MD −4.60 ml/min, 95% CI −11.78 to 2.57) in relation to low salt interventions.

The effect of moderate salt restriction for lowering BP and proteinuria was confirmed in a 2018 meta-analysis of RCTs comparing the effect of low versus high salt intake, which involved 11 studies of 738 patients with ND-CKD stages 1–4 [7].

Dietary Caloric Restriction

Among both the general population and ND-CKD patients, an extensive body of evidence from epidemiological studies indicates that obesity and central fat distribution are independent risk factors for CKD progression and the development of ESRD [175, 176]. Insulin resistance, obesity-mediated hypertension, glomerular hyperfiltration, renin-angiotensin-aldosterone system activation, glomerular hypertrophy, and inflammation are the potential mechanisms by which obesity may increase CKD progression [177]. This excess risk associated with obesity may be reversible by achieving sustained weight loss through diet or bariatric surgery in the general population [178–180]. However, clear evidence on the harms and benefits of avoiding excessive caloric intake and reducing weight in obese people with ND-CKD is still lacking.

Nonrandomized evidence in obese patients with CKD has suggested that weight loss may lead to better BP control and reduction of the obesity-related glomerular hyperfiltration and proteinuria [180, 181]. Similar data were shown in two RCTs assessing the effect of hypocaloric diet in 17 obese patients and 30 overweight patients, respectively, with proteinuric nephropathies [182, 183]. Meta-analysis of both RCTs showed a significant overall reduction in urinary protein excretion of −1.65 g/24 h (95% CI −3.21 to −0.08), whereas eGFR remained stable during follow-up [8].

In summary, although there is limited evidence of the potential reversibility of the harmful hemodynamic effects, proteinuria, and progression of kidney disease related to obesity, weight reduction through diet and lifestyle modifications could be considered as a component of the therapeutic regimen of obese patients with ND-CKD [177].

Fiber Intake and Probiotics

Evidence is emerging for the effects of fiber intake on CKD progression and mortality in CKD stages 3–5, although only a few small interventional uncontrolled studies have addressed the effects of fiber intake in renal outcomes. In a single-blind crossover study of 13 ND-CKD patients with an eGFR less than 50 ml/min/1.73 m^2, supplementing the diet with fiber significantly reduced p-cresol levels and improved stool frequency [184]. In another uncontrolled trial, the addition of 23 g/day of fiber incorporated into the usual diets of 13 ND-CKD patients was associated with a significant reduction in blood urea nitrogen and creatinine levels, increasing the eGFR from 29.6 ± 3.5 to 32.5 ± 3.6 ml/min/1.73 m^2 after 4 weeks of fiber intervention [78]. These studies suggest with very-low-quality evidence that consuming a highly fermentable fiber, such as inulin, might reduce uremic toxins generation, potentially through the inhibition of proteolytic and enhancement of saccharolytic microbiome.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Supporting this is a placebo-controlled RCT involving 30 patients with CKD stages 3–4 where total plasma p-cresol concentration was reduced by 40% after taking a synbiotic for 4 weeks [185]. It remains uncertain if increasing fiber intake to normalize intestinal microflora could delay CKD progression to ESRD; even probiotics supplementation has not shown evidence of reducing CKD progression, according to a recent meta-analysis involving eight studies of 261 patients with CKD stages 3–5D (summarized in Table 37.7). However, this therapy may reduce the levels of p-cresol sulfate and elevate the levels of IL-6, thereby protecting the intestinal epithelial barrier of patients with CKD [9].

Dietary Patterns and CKD Progression

Although nutritional management in patients with CKD has been focused on limiting or supplementing the amounts of specific nutrients, epidemiologic and observational evidence suggests that overall dietary pattern might be more protective against CKD progression than excess or deficiency of an isolated nutrient [186–188]. Whereas the so-called Western diet (a high saturated fat diet, rich in red and processed meat and sweets) has been associated with increased risk of CKD progression and albuminuria [186], the Mediterranean diet has been linked to slower kidney function decline and favorable effects on cardiovascular morbidity and mortality [187]. In kidney transplant recipients, the Dietary Approach to Stop Hypertension (DASH) diet has been associated with lower risk of both kidney function decline and all-cause mortality [188]. A lower load and bioavailability of phosphorus (vegetable protein), reduction of the burden of uremic toxins and salt, better control of BP and other cardiovascular risk factors, and reduction of oxidative stress and inflammation are putative mechanisms which could explain the benefits derived from the Mediterranean diet [47]. However, in a systematic review of seven cohort studies involving 15 282 patients, six studies did not show an independent association between healthy dietary patterns (defined as generally consistent with higher intake of fruits and vegetables, fish, legumes, cereals, whole grains, and fiber, and lower in red meat, salt, and refined sugars) and risk of ESRD [155].

There is very limited evidence from interventional studies that adherence to healthy dietary patterns might have effects on CKD progression. In one RCT, 40 ND-CKD patients were randomly assigned to nutritional advice adapted from a Mediterranean diet or to standard care. After 3 months of follow-up, eGFR and creatinine and urea levels remained unchanged in both groups, although it may be argued that the intervention time was too short to assess CKD progression [189]. Conversely, another RCT involving 108 patients with CKD stage 3 followed for 3 years showed a slower progression of kidney disease in the group of patients allocated to dietary alkali treatment with base-producing fruits and vegetables or bicarbonate versus usual care [190].

In summary, it is uncertain whether healthy dietary patterns (independent of other healthy lifestyles) make any difference in preventing the development of ESRD among patients with CKD, although long-term RCTs are warranted [1].

Treatment of PEW in CKD

Prevention and early detection of PEW seems to be essential for the optimal treatment of the syndrome [48, 166, 191]. Important to the prevention of PEW is periodic screening for malnutrition, which must be performed at each patient visit to the clinic or hospital. Through an adequate patient interview, a guided physical examination, and a basic biochemical analysis that includes blood levels of albumin, urea, creatinine, and CRP, the suspected presence of PEW may be determined and a more detailed assessment of the nutritional status should follow, as well as early referral to the dietitian. Symptoms and warning signs include loss of appetite, changes in bowel habits, the appearance of edema, or involuntary weight loss. The routine determination of albumin and CRP allows objective monitoring of the visceral protein deposits and the inflammatory state of patients. Through the urea clearance (otherwise needed for controlling the dialysis dose in patients on dialysis), changes in protein intake can be quantified. In each clinical review, other preventive measures to preserve the nutritional status should be reinforced, including control of the dialysis dose and metabolic acidosis, continuous nutritional counseling, and supportive messaging about the benefits of adequate physical exercise tailored to each patient [48]. Table 37.8 shows a protocol used to monitor nutritional status and treat PEW in CKD patients.

With a frequency that usually ranges between 4 weeks and 4 months, depending on the CKD stage (the more advanced the stage, the more frequent the nutritional assessment), and whenever PEW is suspected in CKD patients, a more detailed assessment of nutritional status should be conducted. Recommendations for this assessment include an SGA score to provide a more detailed collection of the signs and symptoms of malnutrition, the determination of prealbumin and transferrin levels, which can reflect changes in nutritional status earlier than albumin, performance of bioimpedance if available (otherwise, the determination of the mid-arm circumference as a marker of muscle mass), and measurement of muscle strength by hand dynamometry.

Table 37.7 Summary of findings: probiotics supplementation for adults with CKD.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for one year (95% CI)	Relative effect (95% CI)[a]	Certainty of the evidence (GRADE)	Conclusion
Serum creatinine	250 (5)	Not estimable	The MD for serum creatinine was 0.08 mg/dl higher (0.13 lower to 0.28 higher) with probiotics compared to placebo	Very low ●○○○	It is uncertain whether probiotics supplementation impacts on serum creatinine levels compared to placebo
Blood urea	164 (3)	Not estimable	The MD for blood urea was 1.38 mg/dl lower (9.26 lower to 6.15 higher) with probiotics compared to placebo	Very low ●○○○	It is uncertain whether probiotics supplementation impacts on blood urea levels compared to placebo
p-cresol sulfate	125 (3)	Not estimable	The SMD for p-cresyl sulfate was 0.57 lower (0.99 lower to 0.14 lower) with probiotics compared to placebo	Low ●●○○	Probiotics may slightly reduce p-cresyl sulfate levels of CKD patients compared to placebo
Hemoglobin	93 (3)	Not estimable	The MD for hemoglobin was 0.21 g/dl higher (0.48 lower to 0.91 higher) with probiotics compared to placebo	Low ●●○○	Probiotics may slightly improve hemoglobin levels of CKD patients compared to placebo
Interleukin-6	134 (3)	Not estimable	The SMD for interleukin-6 was 0.37 higher (0.03 higher to 0.72 higher) with probiotics compared to placebo	Very low ●○○○	It is uncertain whether probiotics supplementation impacts on interleukin-6 levels compared to placebo
C-reactive protein	106 (3)	Not estimable	The MD for C-reactive protein was 0.64 mg/dl higher (3.81 lower to 5.09 higher) with probiotics compared to placebo	Very low ●○○○	It is uncertain whether probiotics supplementation impacts on C-reactive protein levels compared to placebo

CKD, chronic kidney disease.
Treatment estimates are drawn from a Cochrane review [9]. GRADE assessment of the certainty of the evidence [17]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.
[a] Effects are reported as mean difference (MD) and 95% confidence interval (CI) for continuous outcomes (standardized mean difference [SMD] if different scales were used).

Table 37.8 Suggested strategies for early detection and treatment of PEW in CKD patients.

	Warning signs	Potential interventions
Periodic nutritional screening (in each clinical visit)		
Actual body weight and ideal weight	Unintentional weight loss >5% of ideal body weight or estimated dry weight or weight <85% of ideal weight	If PEW is suspected, a more detailed nutritional assessment and an early referral to the renal dietitian are mandatory
Dietary intake	Loss of appetite	Other preventive measures: 1) Dietary assessments to evaluate whether the intake provided with the diet is adequate in protein and caloric contents 2) Correction of metabolic acidosis 3) Achievement of adequate dialysis dose 4) Good oral hygiene 5) Treatment of digestive symptoms as needed (nausea/vomiting) 6) Adequate physical exercise (as tolerated) 7) Management of comorbidities (diabetes, chronic heart failure, etc.) 8) In-center meals (dialysis)
Serum albumin	<3.8 g/dl	
C-reactive protein	>10 mg/dl	
Urea clearance to estimate the protein intake (and calculate the dialysis dose)	<1.2 g/kg/day in dialysis <0.6 g/kg/day in nondialysis dependent CKD	
Creatinine levels to calculate the creatinine index in dialysis patients[a]	<20 g/kg/day or significant reduction	
Detailed assessment (at least two to four times/year or whenever PEW is suspected)		
Subjective global assessment	Score of B or C	• An etiopathogenic approach: 1) Treatment of inflammatory causes: intercurrent infections, nonfunctioning renal graft, use of central venous catheters 2) Uremic symptoms: optimize dialysis if needed 3) Pill burden reduction (i.e. phosphate binders): consider dose reduction or temporary discontinuation of treatment 4) Treatment for gastroparesis in diabetic patients • Dietary counseling • Oral nutritional supplements • Tube feeding or percutaneous endoscopic gastrostomy • Intradialysis parenteral nutrition (for hemodialysis patients) • Intraperitoneal nutrition (for peritoneal dialysis patients) • Total parenteral nutrition • Adjunct therapies: appetite stimulants; anabolic hormones (androgens, growth hormone); anti-inflammatory interventions (omega-3)
Prealbumin	<30 mg/dl or significative reduction	
Transferrin	<200 mg/dl or significative reduction	
Mid-arm circumference	Significative reduction	
Bioelectrical impedance	Loss of muscle mass or fat mass	
Hand dynamometry	Loss of strength	
Dietary intake assessment	Protein intake <1.2 g/kg/day in dialysis or <0.6 g/kg/day in nondialysis dependent CKD Energy intake <30–35 kcal/day	

CKD, chronic kidney disease; PEW, protein-energy wasting.

[a]The equation to estimate creatinine index (CI) was developed based on age, gender, predialysis serum creatinine concentrations, and spKt/V urea with the simplified equation from Cannaud et al. [135] [$16.21 + 1.12 \times (1\ si\ man; 0\ si\ female) - 0.06 \times \text{age (years)} - 0.08 \times \text{sp}Kt/V + 0.009 \times \text{Cr}_{pre}(\mu\text{mol/l})$]. To evaluate CI using plasma creatinine concentration in mg/dl, divide the creatinine concentration term by 88.4.

Dietary Counseling

In patients for whom preventive approaches to PEW have been insufficient, the first therapeutic step should be intervention by a nutritionist, who will carry out a dietary assessment to evaluate whether the dietary intake is adequate in protein and caloric contents. This intervention may support initiating therapy with oral nutritional supplements (ONS) [48].

The randomized evidence to determine whether providing individual nutrition counseling improves nutritional status in ND-CKD patients is limited to one RCT involving 56 patients with CKD stages 4–5 [192, 193]. Patients were randomly allocated to fortnightly, individualized counseling on a prescription of 0.75 g/kg/day of protein and 145 kJ/kg/day of energy versus written education material for 3 months. During the 12-week follow-up, the intervention group had less decrease in body cell mass, greater increase in energy intake, and greater improvement in SGA score compared with the control group.

Two RCTs have demonstrated dietary counseling may improve several nutritional parameters for patients with CKD stage 5D [194, 195]. In the largest trial to date, 180 HD patients with baseline albumin levels less than 3.7 g/dl were randomized to identify and intervene on specific modifiable nutritional barriers (i.e. low nutritional knowledge, decreased appetite, or gastrointestinal symptoms) versus usual care; results showed significant improvements in protein and energy intakes and albumin levels regardless of levels of inflammatory markers [193]. According to another, small RCT, intensive nutritional counseling might be of greater benefit than nutritional supplements alone in the management of PEW in HD patients [195].

Oral Nutritional Supplements

ONS can offer an additional source of protein (0.3–0.4 g/kg/day) and energy (7–10 kcal/kg/day) for achieving the recommended targets (Table 37.2) in CKD patients with a decreased spontaneous nutrient intake. ONS are usually recommended to be administered two or three times a day, always after meals ("as a dessert") to avoid losing appetite, or during the HD session [39]. The nutritional response to therapy is directly correlated with severity of PEW at baseline [48].

The efficacy of oral supplements to improve nutritional status in dialysis patients has been tested in a number of small RCTs, which have been meta-analyzed in a recent systematic review of 15 studies with 589 subjects (Table 37.9) [10]. Compared with placebo or routine care, provisions of ONS resulted in a significant increase in BMI and albumin levels, with no effects on phosphorus or potassium levels. Evidence for beneficial effects of ONS is restricted to effects on nutritional parameters, as RCTs did not have sufficient statistical power to allow meta-analysis of patient-centered outcomes, such as survival, quality of life, or cardiovascular events. Given the short follow-up and the small sample sizes of the studies, the quality of the evidence according to the meta-analysis was considered very low.

Only one RCT has assessed the effects of protein supplementation on mortality in the dialysis population as a primary endpoint [196]. However, it compared only oral protein supplement with intradialytic parenteral nutrition (IDPN) and did not include a usual care arm, probably because of the ethical implications of withholding nutritional therapy to malnourished patients. Body weight, serum albumin, and PNA increased in both groups. Similarly, there were no differences between the two groups regarding mortality.

The randomized evidence for ONS in PD patients is very limited and shows a higher rate of noncompliance and intolerance compared to HD patients [39, 197]. In an open-label RCT, 28 PD patients were allocated to an oral egg albumin-based supplement versus conventional nutritional counseling. During a 6-month follow-up, the treatment group had significantly improved serum albumin, calorie and protein intake, and nPNA [198]. In a 4-month RCT involving 100 PD patients with malnutrition, calcium caseinate versus usual care resulted in a significant increase in serum albumin levels [199]. Evidence for ONS in renal transplant and ND-CKD patients is absent, although ONS might help to prevent PEW in patients on LPD [200].

Altogether, very-low-quality evidence suggests that short-term oral energy or protein/amino acid supplements may improve nutritional status in dialysis patients, without influence on serum phosphorus or potassium levels.

In those patients with oral intolerance to ONS, nasogastric tubes, percutaneous endoscopic gastrostomy, or jejunostomy probes can be used. These nutritional treatments are usually reserved for patients with severe, postsurgical, critical anorexia or with problems swallowing due to neurological alterations or head and neck surgery. Randomized evidence for enteral tube feeding in the CKD population is absent [201].

Intradialytic Parenteral Nutrition in HD

Although the enteral route is the initial treatment of choice for nutritional supplementation, parenteral provision of nutrients during the HD session can be considered for patients who continue to be malnourished despite ONS or who are unable to tolerate oral supplementation (e.g. those with severe gastroparesis). Although the optimal duration of treatment is unknown, a trial of 3–6 months is recommended to assess the response to IDPN. IDPN is usually

Table 37.9 Summary of findings: oral nutritional supplements for adults with CKD on dialysis.

Outcomes	No. of participants (no. of studies)	Absolute number of patients affected per 1000 patients treated for one year (95% CI)	Relative effect (95% CI)[a]	Certainty of the evidence (GRADE)	Conclusion
Primary outcomes					
Death (all causes)	— (–)	—	No studies	Absent	No studies were found that evaluated the impact of ONS on survival
Cardiovascular events	— (–)	—	No studies	Absent	No studies were found that evaluated the impact of ONS on the appearance of cardiovascular events
Infectious events	— (–)	—	No studies	Absent	No studies were found that evaluated the impact of ONS on the appearance of infectious events
Health-related quality of life	— (–)	—	No studies	Absent	No studies were found that evaluated the impact of ONS on health-related quality of life
Secondary outcomes					
Body mass index	376 (9)	Not estimable	The MD for the effect of BMI was 0.40 kg/m^2 higher (0.10 higher to 0.71 higher) with ONS compared to control or standard care	Low ●●○○	ONS may increase body mass index
Serum albumin	507 (14)	Not estimable	The MD for the effect of serum albumin levels was 1.58 mg/dl higher (0.52 higher to 2.63 higher) with ONS compared to control or standard care	Moderate ●●●○	ONS probably increases serum albumin levels

BMI, body mass index; CKD, chronic kidney disease; ONS, oral nutritional supplements.
Treatment estimates are drawn from a Cochrane review [10]. GRADE assessment of the certainty of the evidence: [17] High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.
[a] Effects are reported as the relative risk (RR) and 95% confidence interval (CI) for binary outcomes and mean difference (MD) and 95% CI for continuous outcomes (standardized mean difference [SMD] if different scales were used).

administered only 3 days per week for 4 hours, thus it is not appropriate for severely malnourished patients, in whom total parenteral nutrition may be necessary to provide sufficient proteins and calories to treat PEW [48].

A 2010 systematic review of RCTs compared IDPN with usual diet, placebo, or ONS; it included three studies with 220 HD patients [202]. Unfortunately, there were insufficient data to undertake a meta-analysis of whether IDPN improves survival, quality of life, or nutritional status. In the largest trial in the review (and to date), 186 malnourished HD patients received ONS with or without 1 year of IDPN [196]. The study showed an improvement in nutritional markers in both groups, indicating that the addition of IDPN to ONS did not provide additional benefit over ONS alone; no differences in survival were noted. A 2017 RCT compared IDPN given three times weekly versus dietary counseling in 107 HD patients with PEW. IDPN for 16 weeks resulted in a significant increase in mean serum prealbumin, although without changes in SGA score or quality of life [203].

The conclusion then is that although IDPN might be used in highly selected patients with positive results, it is uncertain whether IDPN improves quality of life, decreases mortality, or prevents hospitalizations. This is in agreement with the results of a recently published systematic review that included both interventional and observational studies [11].

Intraperitoneal Infusion of Amino Acids in PD

Although use of amino acids in the dialysate may be an adequate nutritional intervention for malnourished PD patients who are unable to tolerate ONS, evidence in this regard is limited to one small RCT [204]. Improvements in overall protein balance (protein synthesis minus protein breakdown) was observed with the use of a dialysate that contained amino acids and glucose versus glucose as control dialysate in a crossover study of eight patients over 14 days. Whether this dialysis procedure may improve the nutritional status in malnourished PD patients remains uncertain.

Non-nutritional Interventions for PEW

In addition to correcting any nutritional deficiencies, treatment of malnourished CKD patients should always include an ethological approach to identify the causes involved in PEW [48]. Inflammation may be a cause of anorexia and increased energy expenditure, which increases the risk of developing PEW. This inflammation can be caused by a wide range of potentially treatable factors (Box 37.1). Although periodic determination of CRP to help assess the presence of underlying and treatable inflammatory processes would be beneficial [43, 48], this recommendation is based on epidemiological evidence linking inflammation to poor outcome in the CKD population [130]; there are no RCTs to suggest that outcomes are improved by nonspecific inflammation-reducing modalities.

The treatment of the different comorbidities could also help to correct PEW (i.e. adequate metabolic control for diabetes or antidepressants for mood disorders). Although the quality of evidence for the ethological approach to PEW is very low or absent, a few small randomized and quasi-randomized controlled trials have shown the benefits of increasing both solute diffusion and convection on the nutritional status of dialysis patients [88, 89]. Thus, improving dialysis adequacy, with interventions aimed at enhancing solute clearance, might impact positively on PEW, although quality evidence is lacking [48].

Other additional therapeutic measures to correct PEW, most of them considered as experimental, may include the use of appetite stimulants such as megestrol acetate, anti-inflammatory drugs, and exercise and anabolic agents [48].

Megestrol Acetate

Evidence for the use of megestrol acetate as orexigenic is restricted to dialysis patients. A systematic review of three RCTs and six observational studies assessing the efficacy and safety of megestrol acetate was published in 2016 [12].

Box 37.1 Nonspecific Inflammation-reducing Interventions for Protein-energy Wasting in Patients with Chronic Kidney Disease

Screen and treat occult infections:
- Urinary tract infections
- Diabetic foot ulcers
- Gut flora dysbiosis
- Tuberculosis

Assess for poor dental hygiene and periodontal disease

Routinely assess for volume overload

Screen and treat rheumatologic conditions:
- Vasculitis
- Systemic lupus relapses
- Rheumatoid arthritis

Screen for pericarditis

Embolize or remove nonfunctioning renal allografts

Optimize vascular access
- Replace central venous catheters with arteriovenous fistula
- Remove nonfunctioning arteriovenous grafts

Optimize hemodialysis prescription
- Replace standard dialysate fluid with ultrapure dialysate
- Replace bioincompatible membranes with biocompatible membranes
- Replace standard hemodialysis with on-line hemodiafiltration

All three RCTs were limited by small sample sizes (range 9–22 subjects), short duration (range 8–24 weeks), a high degree of bias, and absence of clinical outcomes such as quality of life or hospitalizations. Appetite, serum albumin, and body weight significantly increased in some but not all the studies. Altogether, it is uncertain whether megestrol acetate impacts on PEW. In addition, use of megestrol acetate was associated with significant adverse events, which were especially noted in the six observational studies, and there were no data regarding the safety of using megestrol acetate beyond 24 weeks [12].

Anti-inflammatory Agents

In addition to treating inflammation directly due to a specific identified source (e.g. an ongoing chronic infection), the use of anti-inflammatory agents in malnourished CKD patients has been tested in several RCTs. A meta-analysis of RCTs assessing the anti-inflammatory effects of fish oil containing omega-3 polyunsaturated fatty acids versus placebo or no treatment was published in 2016 [13]. It involved 13 studies with 916 patients with CKD stage 5D on HD, and showed that fish oil significantly reduced some CRP and high-sensitivity CRP but not all inflammatory markers. In addition, fish oil reduced the risk of arteriovenous (AV)-graft events and cardiovascular events and alleviated depression symptoms, although no effect on albumin levels was noted. In 2014, two meta-analyses examined the effects of L-carnitine supplementation in HD patients, with mixed results [14, 15]. Whereas in one meta-analysis (49 RCTs, 1734 participants) there was a significant decrease in CRP levels noted [14], the other review (25 studies, 1172 participants) indicated this therapy did not result in a significant reduction in CRP levels [15]. In a small uncontrolled trial, daily supplementation with Brazil nut (the richest known food source of selenium) for 3 months resulted in a significant decrease in cytokines and other inflammatory and oxidative markers [205].

Besides the anti-inflammatory effects related to some nutrient supplementation, some drugs may also exert the same effects in CKD populations. In 2012, a meta-analysis summarized the evidence for the effect of statin therapy on inflammatory and nutritional markers in dialysis patients. Nine RCTs involving 3098 patients were analyzed, with the resulting report of a significant decrease in CRP and high-sensitivity CRP levels but no effect on serum albumin levels [16]. In a small RCT of 108 HD patients, sevelamer hydrochloride versus calcium acetate lowered high-sensitivity CRP after a 1-year follow-up [206]. An uncontrolled trial of 24 HD patients noted a reduction in CRP and IL-6 after a 3-month intervention with *N*-acetylcysteine [207]. Pentoxifylline, anti-TNF agents, and recombinant IL-1 receptor antagonists have also been tested in the treatment of inflammation in patients with CKD.

Anabolic Agents

Anabolic agents including recombinant human GH and androgenic steroids may also be effective in CKD patients with PEW. In a 4-week follow-up RCT involving 17 malnourished dialysis patients, treatment with recombinant human GH, whose use is approved for pediatric patients with CKD and short stature, significantly increased weight gain and IGF-1 and transferrin levels, suggesting that short-term GH administration might be associated with an anabolic reaction in malnourished dialysis patients [208]. However, the long-term nutritional benefits of GH have been not demonstrated [209]. In an RCT involving 29 patients undergoing dialysis, treatment with nandrolone versus placebo for 6 months resulted in a significant increase in lean body mass associated with functional improvement, including a decrease in the time to complete the walking and stair-climbing test [210]. Despite this positive effect on protein stores, the long-term efficacy and risk for adverse effects of androgenic anabolic steroids remains unclear, thus limiting their role in medical practice.

Overall, evidence on the safety and effectiveness of anti-inflammatory drugs and anabolic agents in CKD patients is very low, hindered by small studies, with limited follow-up, and focused primarily on HD patients. Large-scale RCTs are needed to confirm these anti-inflammatory effects.

Lastly, although an aerobic and resistance exercise program in well-nourished CKD patients may improve physical capacity and quality of life [211], no data are available regarding the anabolic effect of exercise in CKD patients with PEW.

Conclusions

Attention to nutritional status is critical as it may impact on important clinical outcomes in patients with CKD, including CKD progression, quality of life, morbidity, and mortality. Although some interventional studies have shown that nutritional interventions may have reno-protective effects and improve surrogate markers of survival, high-quality evidence is still insufficient. However, this lack of evidence does not necessarily indicate that nutritional interventions have no effect on CKD outcomes. Given that nutritional therapy, including dietary counseling and supplements, is safe and cost-effective, it should be considered to improve the poor prognosis of CKD patients.

Introduction

Chronic kidney disease (CKD) is a progressive disorder associated with increased morbidity, cost of treatment, and mortality. When identified early, CKD progression to end-stage kidney disease (ESKD) can be delayed or halted. However, once CKD has significantly advanced (estimated glomerular filtration rate [eGFR] <30 ml/min/1.73 m^2), very little can be done to sufficiently delay progression of disease to avoid the need for renal replacement therapy (RRT) [1]. The number of people with advanced CKD is high globally. For instance, the United States Renal Data System (USRDS) 2018 annual report showed that the overall prevalence of CKD (stages 1–5) in the United States adult general population was 14.8% in 2013–2016 (CKD stage 3 was the most prevalent [6.4%]) [2]. Although RRT is often inaccessible to many across the world [3], in places where treatment is available it is important that patients are adequately prepared for treatment initiation. In many instances, however, patients with CKD will not be prepared for RRT, especially in developing countries where patients are often "crash-landers" requiring RRT at time of first contact with nephrologist [4, 5]. Preparation for dialysis, when carried out through a multidisciplinary process, has been shown to be associated with better patient survival [6] or slower decline in glomerular filtration rate (GFR) compared to patients receiving usual care [7]. Strategies for retarding progression of CKD and treating complications associated with CKD are discussed in detail in Chapters 31 to 37. This chapter focuses on the approach to dialysis modality selection, patient education, and preparation for specific modalities.

Epidemiology of ESKD and Dialysis Therapies

It is widely known and accepted that ESKD is a noncommunicable disease with global impact and public health importance. ESKD represents the final phase in the spectrum of CKD and is typified by the occurrence of worsened biochemical and metabolic profiles. Although a greater percentage of CKD patients are likely to die from cardiovascular-related causes rather than progress to ESKD [8, 9], those who do progress usually need the introduction of RRT, such as dialysis, for survival.

There has been a steep increase in the prevalence of ESKD since the first forms of RRT were instituted about six decades ago. In the United States, an increasing prevalence of ESKD continues to be observed despite plateauing incidence rates; a recent summary of the United States Renal Data System (USRDS) reports a yearly increase of about 21 000 ESKD prevalent cases per year [10]. A similar pattern of increase has been observed in Europe [11]. This epidemiologic trend has far-reaching implications with regards to the initiation and provision of RRT due to increasing need and resource implications. The global prevalence of ESKD is presently estimated at 0.1%, with known notable inter- and intra-regional differences in the availability and access to RRT. There will be a continued increase in the incidence and prevalence of ESKD and dialysis therapies due to increasing age, the increasing burden of chronic diseases such as diabetes mellitus and hypertension, as well as advances in the treatment of these diseases

which promote longevity. In addition, the contribution of chronic infectious disease-related ESKD, such as HIV-associated nephropathy and hepatitis B- and C- associated kidney disease, to this burden cannot be overlooked.

Maintenance dialysis modalities have become the more predominant forms of RRT; kidney transplantation remains an underutilized RRT option due to reasons such as organ scarcity and the unbearably high costs of setting up and running renal transplant programs, especially for many developing nations [12]. There were approximately 284 patients per million population (pmp) receiving maintenance dialysis in 2010 [13]. Incidence rates (i.e. initiation rates) of maintenance dialysis have been the highest in low- to middle-income countries due to improved access to dialysis therapies. Prevalence rates are on the increase globally; rates have increased, albeit disproportionately, by between 154% and 170%. Prevalence rates have been estimated at >2000 patients pmp, 750–1999 patients pmp, 10–99 patients pmp, and <0.1 patients pmp in North America, Europe (excluding Russia), Central Asia, and West Africa, respectively [13].

Timing of Nephrology Referral (Early vs. Late) and Outcomes

Although there is no consensus on the ideal timing for nephrology referral of the CKD patient, most societal/organizational guidelines recommend that CKD patients should be referred to a nephrologist when GFR is <30 ml/min/1.73 m^2 (i.e. stage 4). Early referral ensures that the choice of care (conservative or active, peritoneal dialysis [PD] or hemodialysis [HD]) can be a shared decision-making process rather than an option chosen out of dire necessity [14]. It also ensures that the discussion about ESKD care with respect to RRT options such as renal transplantation and the various alternatives of HD and PD therapies can be established. It has been demonstrated that the timing of nephrology referral influences the eventual dialysis modality selected and the creation of the required vascular access in the circumstances of hemodialytic therapies [15]. Early referral of the CKD patient to the nephrologist provides ample time for permanent access creation and the opportunity to address any complications that might occur before dialysis becomes needed (Table 38.1).

Table 38.1 Consequences of late referral and benefits of early referral of CKD patients to nephrologist.

Consequences of late referral[a] of patients with CKD	Benefits of early referral[b] of patients with CKD
• Inadequate control of diabetes, blood pressure, hyperlipidaemia, and malnutrition	• Prevention and management of modifiable risk factors of CKD
• Inadequate management of anemia and mineral bone disease	• Optimization of treatment of CKD
• Rapid deterioration of renal function	• Delayed progression of CKD
• Increased hospitalizations and duration of in-hospital stay	• Access to structured educational programs
• Increased cardiovascular morbidity and mortality	• Adaptation of CKD patient to RRT treatment
• Poor preparation for dialysis	• Preparation and creation of suitable dialysis access
• Inadequate psychological preparation and support	• Avoidance or lesser need for temporary vascular access
• Loss of opportunity to participate in shared decision-making on dialysis modality and initiation	• Training on selected modality of RRT
• Less chance of initiating RRT with PD	• Better compliance
• Increased chance of use of temporary access with associated complications	• Increased opportunity for pre-emptive kidney transplantation
• Increased need for urgent start of dialysis	• Reduction of cardiovascular morbidity and mortality
• Increased chance of poor compliance to treatment due to poor understanding	• Reduction of management costs due to better planning
• Lack of pre-transplant evaluation and loss of opportunity for pre-emptive kidney transplant	
• Excessive management costs	

CKD, chronic kidney disease; RRT, renal replacement therapy; PD, peritoneal dialysis.
[a] Referral of patients with CKD <3 months before initiation of dialysis.
[b] Primary healthcare physician should ideally refer patients with CKD at stage 1 if hematuria or significant proteinuria is present, at stage 2 if eGFR declines >4 ml/min/year, and at stage 3 for all patients with CKD where eGFR is <60 ml/min/1.73 m^2.

Importance of Patient Educational and Learning Programs

Management of patients with CKD can be complicated given that at early stages CKD is usually an asymptomatic condition. Explaining this diagnosis to a patient, who is expected to make major lifestyle changes, can pose significant challenges in the face of low public awareness of kidney diseases in general [16, 17]. Several studies have shown that awareness of kidney disease is low amongst patients. Tuot et al., using 1999–2008 National Health and Nutrition Examination Survey (NHANES) data in 1852 adults with eGFR <60 ml/min/1.73 m^2, assessed whether markers of kidney disease that should trigger CKD recognition among providers are associated with higher individual CKD awareness [18]. They reported that 90% of individuals with two to four markers of CKD and 84% of individuals with five or more markers of CKD were unaware of having CKD. Only those with albuminuria had greater odds of CKD awareness than those without (adjusted odds ratio 4.0, $P < 0.01$) [18].

Patient education is a process and should begin from the time when the physician reveals the diagnosis, which should be delivered at the patient's pace of understanding with empathy and conveyance of hope [19]. This initial message should be given in a quiet place that is free of interruptions, and preferably when the patient is accompanied by supportive family or friend or in the presence of supportive staff or care giver (e.g. nurse, counsellor, or social worker) [19, 20]. Potential dialysis patients need information not only about the mechanics of specific dialysis modalities but also the associated features of such therapy to help make informed choices. Predialysis CKD education should be individualized according to available resources and the level of knowledge of the patient, and should include tours of dialysis facilities, meeting patients who are undergoing treatment with different dialysis modalities, use of videos and written materials, and behavior-changing protocols with small-group problem-solving activities [21]. Other education program contents could include discussion of CKD risk factors, interpretation of kidney function tests, complications of CKD, interventions to slow loss of kidney function, dietary changes necessitated by disease state, different options for dialysis and their impact on the individual's lifestyle, travel and time commitments for in-center HD treatment, importance of preserving upper extremity veins for future dialysis access, timing of placement of dialysis access, renal transplantation, and financial costs and insurance coverage [22].

There is evidence that educational interventions can be a useful tool for improving knowledge on various aspects of CKD (including risk factors), patient self-management, and patient outcomes [23–26]. Lopez-Vargas et al. [27] in a systematic review of educational interventions in CKD patients that included 26 studies (12 trials, 14 observational studies involving 5403 participants) broadly categorized the primary outcomes of educational interventions into two groups: (i) patient-reported outcomes (e.g. quality of life, psychosocial function, knowledge, self-management, and lifestyle modification) [28–32] and (ii) clinical end points (eGFR, dialysis therapy commencement, survival, blood pressure, and biochemical markers) [26, 33–36]. They reported that the characteristics of effective interventions included those with interactive and practical skills teaching sessions (13/15 studies), integrated negotiated goal setting (10/13 studies), involved groups of patients (12/14 studies), their families (4/4 studies), and a multidisciplinary team (6/6 studies), and frequent participant/educator encounters (weekly [4/5 studies], monthly [7/7 studies]) [27]. Kurella Tamura et al. [37] evaluated the role of participation in a kidney disease screening and education program in improving ESKD preparation and survival in 595 adults who developed ESKD after participating in the National Kidney Foundation Kidney Early Evaluation Program (KEEP). They identified and selected non-KEEP patients from a national ESKD registry and matched them to KEEP participants based on demographic and clinical characteristics. KEEP participants were more likely to see a nephrologist before ESKD (76.0% vs. 69.3%, $P < 0.01$), more likely to use PD versus HD (10.3% vs. 6.4%, $P < 0.01$), more likely to be placed on the transplant waiting list before ESKD (24.2% vs. 17.1%, $P < 0.01$), and more likely to undergo transplantation (9.7% vs. 6.4%, $P < 0.01$), although they were not more likely to undergo pre-emptive transplantation (1.7% vs. 1.5%, $P = 0.7$). KEEP participants were slightly more likely to use an arteriovenous (AV) fistula or graft (23.4% vs. 20.1%, $P = 0.09$) at the first outpatient dialysis and slightly more likely to have a mature or maturing arteriovenous fistula or graft at the first outpatient dialysis (44.0% vs. 39.6%, $P = 0.06$).

Modality Selection and Timing of Dialysis Initiation

Modality Selection

Counseling CKD patients about RRT options for ESKD is a distinct educational process. Patients in late stage 3 and stage 4 CKD should be educated on a range of potential options, including home and in-center dialysis modalities, transplantation, and in appropriate cases where RRT cannot be offered, conservative care (Figure 38.1) [38]. In the United States, more than 90% of patients initiating RRT commence

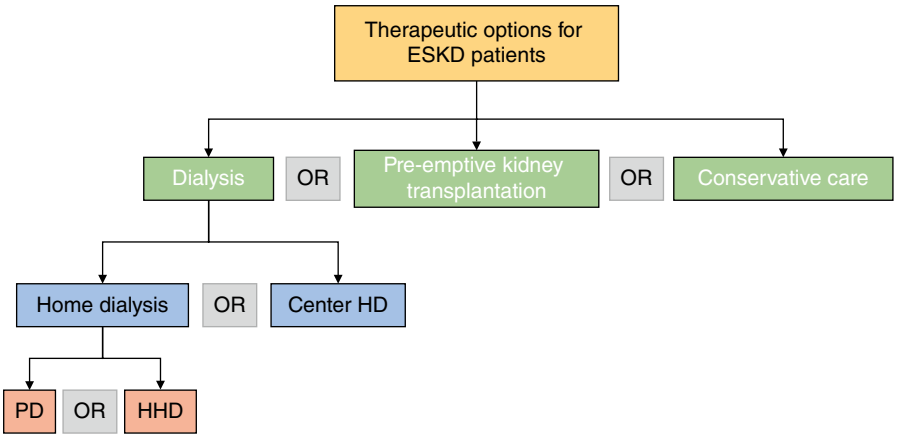

Figure 38.1 Treatment options for patients with end-stage kidney disease. HD, hemodialysis; HHD, home hemodialysis; PD, peritoneal dialysis.

therapy using in-center HD, with approximately 8.5% initiated on PD while the rest receive treatment through other modalities (home HD [<2%], conservative management [<1%], and pre-emptive kidney transplant [<1%]) [39]. There are geographic differences in the modality patients are likely to initiate RRT on depending on government policy and the country's economic status [40, 41]. Other factors like the patient's clinical (comorbid) conditions and the nephrologist's familiarity with each technique also play a role on modality selection; often, however, little attention is given to individual patient preferences [42].

Selecting a dialysis modality is a complex decision process for the patient. Murray et al. have shown that factors influencing a CKD patient's participation in the decision-making included interpersonal relationships; preservation of current well-being, normality, and quality of life, need for control, and personal importance on benefits and risks [43]. Patient involvement in modality selection through shared decision-making is advocated to support patients deciding on a modality of treatment suitable to their clinical condition, lifestyle, and social circumstances [44]. However, for shared decision-making to occur, the patient must be willing to be involved in their dialysis treatment decision. This is not always observed as studies have shown that up to 27% of patients may prefer a passive role in treatment decision-making [45–47]. Also, due to resource constraints, the choice of modality may be made only by physicians (e.g. in South Africa where RRT is rationed) [4]. Barriers to shared decision-making have been explored and include time needed to integrate shared decision-making in clinical practice, patients preference not to be involved in the process of decision-making, and disagreement amongst healthcare professionals on asking patients about their preference (some patients are information receivers and others are engagers) [48–50]. However, the shared decision-making model provides an ideal framework to involve patients in selection of the best treatment option suitable to them [44]. In the Empowering Patients on Choices for Renal Replacement Therapy (EPOCH-RRT) study, a cross-sectional study was designed to assess patients' perspectives at the time they choose a dialysis modality [51]. It included 180 patients with advanced CKD, either nondialysis dependent or on dialysis therapy (HD and PD) across the United States. Maintaining as much independence as possible, quality and quantity of life, and flexibility in daily schedule were the themes most often reported by patients as important for choice of modality. About half of the HD patients (47%) believed that the decision to be treated by HD had largely not been their choice; this was only reported by 3% of PD patients. The study findings supported the need for interventions to improve shared decision-making on dialysis treatment options, targeting both patients and clinicians.

Expected patient survival on dialysis is a major factor that influences choice of treatment modality. Several studies have assessed the relationship between dialysis modality and survival; most studies report an initial survival benefit on PD within the first 2 years of treatment initiation, but a less favorable long-term survival for PD compared with HD [52–54]. In a recent study that used data from 196 076 patients within the European Renal Association-European Dialysis and Transplant Association (ERA-EDTA) Registry who started RRT between 1993 and 2012, van de Luijtgaarden et al. reported a reduction of PD incidence and prevalence with time [55]. They also showed that there was a similar 5-year patient survival for PD versus HD in 1993–1997 (adjusted hazard ratio [HR] 1.02, 95% confidence interval [CI] 0.98–1.06), while patient survival was higher for PD patients in 2003–2007 (HR 0.91, 95% CI 0.88–0.95). Thus, although initiating RRT on PD was associated with favorable patient survival when compared with starting on HD treatment, PD was often not selected as initial dialysis modality.

Although home hemodialysis (HHD) is becoming an increasingly available RRT option, patient selection criteria may confound comparison with other RRT modalities. For instance, HHD patients in Australia and New Zealand are usually younger and have fewer comorbidities than patients undergoing PD and in-center HD [56, 57]. One study that included 10 710 patients on incident PD and 706 patients on incident HHD reported that treatment with HHD was associated with better patient survival than treatment with PD (5-year survival 85% vs. 44%, respectively, log-rank $P < 0.001$) [57]. Another study showed that home dialysis (home HD + PD) had a 13% lower mortality risk compared to facility HD, while PD showed a 20% lower mortality risk in the early period (<3 years) that is offset by a 33% greater mortality risk in the late period (>3 years), with no overall net effect [56]. When the attributes of dialysis care and the trade-offs that patients considered when making decisions about dialysis modalities was quantified, Walker et al. reported that patients preferred home dialysis over facility-based care when increased nursing support was available and when longer survival, wellbeing, and flexibility were expected. In addition, they showed that sociodemographic factors (age, ethnicity, and income) also influenced patients' choices [58].

Given that the presence of some comorbidities or patient features may be a relative or absolute contraindication to the desired dialysis modality (Table 38.2) [59], patients should be informed about this and guided toward other options. Patients should also understand that no care plan is completely inflexible, and modality switching can and should occur if an initial choice is deemed less than optimal by the patient and kidney care team.

Table 38.2 Contraindications to specific dialysis modalities.

Hemodialysis	
	Relative contraindications • Difficult vascular access – Severe peripheral arterial vascular disease – Central vein stenoses or occlusions • Desired home dialysis with lack of appropriate home environment or partner
Peritoneal dialysis	
	Absolute contraindications • Extensive abdominal adhesions • Hydrothorax or diaphragmatic defects • Loss of peritoneal membrane function (ultrafiltration, solute clearance) Relative contraindications • Morbid obesity • Severe protein calorie malnutrition • Loss of residual renal function • Bowel disease – Ischemic – Chronic inflammatory – Diverticulosis or diverticulitis

Timing of Dialysis Initiation

The optimal time to initiate maintenance dialysis is currently unknown; many patients are vulnerable during this transition period as it has been reported that the majority of patients are unprepared and ill-informed about commencing dialysis [42]. The factors surrounding timing of initiation of treatment are often multifaceted and are often different for patients and care providers. For instance, one study reported that patients based their choice on a "gut instinct," as well as the effects of commencing treatment on quality of life and survival, while care providers considered biomedical factors and an instinct to prolong life [60]. In the United States, provider characteristics such as graduating from a nondomestic medical school and greater experience (length of time of practice) have been linked with timing of initiation of treatment [61]. Various guidelines published after the Initiating Dialysis Early and Late (IDEAL) study [62] have generally recommended a late commencement of dialysis (eGFR <6–10 ml/min/1.73 m^2) and, importantly, for dialysis initiation to be guided by the patient's clinical status (presence of uremic symptoms, nutritional status, and daily life activities) (Table 38.3) [70–74].

The IDEAL study was specifically designed to evaluate whether the timing of the initiation of maintenance dialysis influenced survival among CKD patients [62]. Patients were randomly assigned to initiate dialysis early (eGFR 10–14 ml/min/1.73 m^2) or assigned to the late-start group (eGFR 5–7 ml/min/1.73 m^2). The primary outcome was all-cause mortality. During the follow-up period, 152 of 404 patients in the early-start group (37.6%) and 155 of 424 in the late-start group (36.6%) died (HR with early start group 1.04, 95% CI 0.83–1.30, $P = 0.75$). The time of dialysis did not influence secondary events (cardiovascular, infectious) or quality of life. The study concluded that planned early initiation of dialysis in patients with stage 5 CKD was not associated with an improvement in survival or clinical outcomes. Following publication of the IDEAL study, several observational studies have been published about timing of dialysis initiation [61, 75–77]; most did not show benefit with early initiation and some even reported harm when treatment was started early. This suggests that presence of comorbidities rather than level of eGFR at

Table 38.3 Guideline recommendations on vascular access.

Group	Year	Recommendation statements	Strength and evidence of recommendation
Canadian Society of Nephrology [63]	2006	**Planning for vascular access, access timing, placement, and maturation** • Preserve arm veins suitable for placement of vascular access. • Establish AVF when the patient has an eGFR of 15–20 ml/min and progressive kidney disease.	GRADE: D (opinion) GRADE: D (opinion)
		Preferred access type • The preferred type of vascular access is a radio-cephalic native vessel AVF.	GRADE: C
National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) [64]	2006	**Planning for vascular access, access timing, placement, and maturation** • In patients with CKD stage 4 or 5, forearm and upper-arm veins suitable for placement of vascular access should not be used for venipuncture or for the placement of intravenous catheters, subclavian catheters, or peripherally inserted central catheter lines. • A fistula should be placed at least 6 months before the anticipated start of HD treatments. This timing allows for access evaluation and additional time for revision to ensure a working fistula is available at initiation of dialysis therapy. • A graft should, in most cases, be placed at least 3–6 weeks before the anticipated start of HD therapy. Some newer graft materials may be cannulated immediately after placement.	GRADE: B
		Preferred access type • The access should be placed distally and in the upper extremities whenever possible. Options for fistula placement should be considered first, followed by prosthetic grafts if fistula placement is not possible. Catheters should be avoided for HD and used only when other options listed are not available.	Not graded
European Renal Best Practice Advisory Board (ERBP)/European Renal Association – European Dialysis and Transplant Association (ERA-EDTA) [65]	2007	**Planning for vascular access, access timing, placement, and maturation** • Potential chronic HD patients should be ideally referred to the nephrologist and/or surgeon for preparing vascular access when they reach stage 4 of their CKD (eGFR <30 ml/min/1.73 m^2) or earlier in case of rapidly progressive nephropathy or specific clinical conditions such as diabetes or severe peripheral vascular disease.	Evidence level: III
		Preferred access type • Autogenous AVF should be preferred over AVG and AVG should be preferred over catheters. • The upper extremity AV fistula should be the preferred access and should be placed as distal as possible.	Evidence level: III
The Society for Vascular Surgery [66]	2008	**Planning for vascular access, access timing, placement, and maturation** • We recommend that patients with advanced CKD disease (late stage 4, MDRD <20 to 25 ml/min) who have elected HD as their choice of renal replacement therapy be referred to an access surgeon in order to evaluate and plan construction of AV access.	GRADE 1 recommendation, very low-quality evidence
		Preferred access type • We recommend the placement of forearm autogenous AV access as the first choice for primary access for HD.	GRADE 1 recommendation, very low-quality evidence

Table 38.3 (Continued)

Group	Year	Recommendation statements	Strength and evidence of recommendation
Renal Association Clinical Practice Guideline on Vascular Access for Hemodialysis [67]	2015	**Planning for vascular access, access timing, placement, and maturation** • We suggest that all patients that may require HD should have education on forearm vein preservation. • We recommend that the exact timing of placement of vascular access will be determined by rate of decline of renal function, comorbidities, and by the surgical pathway.	GRADE 2 recommendation, low-quality evidence GRADE 1 recommendation, moderate quality evidence
		Preferred access type • We recommend that all patients with ESKD who commence HD or are on long-term HD should dialyze with an AVF as first choice, an AVG as second choice, a tunneled venous catheter as third choice, and a nontunneled temporary catheter as an option of necessity.	GRADE 1 recommendation, high-quality evidence
Japanese Society for Dialysis Therapy [68]	2011	**Planning for vascular access, access timing, placement, and maturation** • If HD has been selected as the treatment for ESKD, the nephrologist should explain the role and importance of vascular access in this treatment and refer the patient to an access surgeon as soon as possible. • Vascular access construction should be considered when eGFR is <15 ml/min/1.73 m^2 (CKD stages 4 and 5) as well as considering clinical conditions; in patients with diabetic nephropathy, who have a tendency to show overhydration, vascular access construction should be considered at a higher eGFR.	Opinion, not graded Opinion, not graded
		Preferred access type • AVF of the wrist or the anatomical snuff box would be the first choice, but the site of vascular access construction should eventually be determined by a comprehensive evaluation of the patient's background, general conditions, and local conditions.	GRADE 1 recommendation, moderate quality evidence
Clinical Practice Guidelines of the European Society for Vascular Surgery [69]	2018	**Planning for vascular access, access timing, placement, and maturation** • Referral of CKD patients to the nephrologist and/or surgeon for preparing vascular access is recommended when they reach stage 4 of CKD (eGFR <30 ml/min/1.73 m^2), especially in cases of rapidly progressing nephropathy. • A permanent vascular access should be created 3–6 months before the expected start of HD treatment.	GRADE 1 recommendation, very-low quality evidence GRADE 1 recommendation, moderate quality evidence
		Preferred access type • An autogenous AVF is recommended as the primary option for vascular access.	GRADE 1 recommendation, high quality evidence

initiation could be associated with patient outcomes [77–79]. Given that residual renal function is a key determinant of outcome and is better preserved with PD, some studies have assessed the effects of early-start compared with late-start dialysis on clinical outcomes in PD patients [80, 81]. In a cohort of 8047 incident PD patients who started dialysis therapy in 2001–2009 in Canada, Jain et al. reported that in comparison with the late-start group, the overall mortality rate was not higher for the early-start (adjusted HR 1.08, 95% CI 0.96–1.23) or mid-start (adjusted HR 0.96, 95% CI 0.86–1.09) groups [80]. Their study conclusion, that early initiation of PD therapy (eGFR >10.5 ml/min/1.73 m^2) is not associated with increased mortality, was divergent to most observational studies assessing HD.

Put together, it will be more beneficial if choice of dialysis modality and timing of commencement are determined on an individual basis that combines patient preference and lifestyle considerations while integrating medical factors and availability of resources and support, rather than comparison of survival outcomes [79].

Preparation for transplantation is addressed elsewhere in this textbook (Chapters 56 and 57). Unless there is absolute certainty about a patient's prospect for pre-emptive live donor kidney transplantation, it is preferable to provide dialysis preparation in parallel with or as an alternative to transplantation evaluation [59].

Preparation for Hemodialysis and Vascular Access

An integral component of dialysis is preparation and initiation. Hemodialysis as an extracorporeal form of RRT requires access to the circulatory system (i.e. vascular access) for blood to be circulated through the extracorporeal membrane (i.e. the dialysis membrane) (Table 38.3). Selection of the optimal type of vascular access can be challenging as there are various factors that need to be taken into consideration [82]. These elements include health-system associated factors, principal among which include the timing of referral of the CKD patient from primary care to the nephrologist or referral from nephrology care to the vascular access team, patient-related factors, such as the patient's preferred choice, age, and comorbidities (e.g. diabetes mellitus, obesity, peripheral vessel disease), and institutional availability/accessibility to the technical expertise required in creating and revising the vascular accesses should the need arise.

The timing of referral of the CKD patient to the nephrologist significantly influences the type of access incident HD patients commence therapy with. Clinical practice guidelines recommend that in preparing CKD patients for HD, arteriovenous (AV) access should be created well in advance of the anticipated start time of HD [63, 66, 67, 74, 83]. The guidelines also recommend that CKD patients be referred early, with the exact eGFR cut-offs varying among guidelines. They also advocate an even earlier referral for stage 4 CKD patients with known comorbidities as these may influence the outcome of access creation. There are three main vascular access options for HD, including (in order of preference) native arteriovenous fistulae (AVF), arteriovenous grafts (AVG), and central venous catheters (CVCs). AVFs remain the preferred initial option over AVGs, while CVCs are the least preferred except in special circumstances, for example high-risk of AV complications or the elderly with limited life expectancy or personal preference [84]. Arteriovenous access options (AVG or AVF) are preferred over CVCs as they have comparatively lower risks of infection, thrombosis, or stenosis of central veins [85]; in addition, they deliver superior blood flow rates which in turn contribute to better clearance of uremic wastes. For instance, an AVF provides blood flow rates of up to 500 ml/min with relatively low complication rates [86]. In addition, AVF is the most cost-effective vascular access option as it is associated with relatively lower infection rates and need for endovascular revision [87–89]. It is also recommended that AVFs should preferably be created using more proximal vessels with the aim of preserving the distal vessels for later use in the event of a failed proximal AVF (Table 38.3) [63–66, 68, 69]. Some have challenged the assertion that AVFs are superior or should be the preferred choice of access [90, 91]. They argue that various comparisons between access types are subject to high degrees of bias due to their observational design and suggest that such comparisons are unable to account for other patient factors which likely contribute to poor outcomes seen in patients treated with catheters [92, 93].

Although AVF is the preferred vascular access type, its use at dialysis initiation has shown marked global variability. Astor et al. in the Choices for Healthy Outcomes in Caring for End-Stage Renal Disease (CHOICE) study demonstrated that only about one-third of the proportion of patients referred early to their nephrology service within the prior 12 months started HD with an AV (AVF/AVG) access [94]. Data from the Dialysis Outcomes and Practice Patterns Study (DOPPS) [95] indicate that AVF use among incident dialysis patients is highest in Japan, where 84% of patients initiated dialysis with an AVF. This contrasts with 28% of patients in the United States and 19% in the Gulf Cooperation Council countries such as Kuwait and Bahrain; 50–60% of most European countries report dialysis initiation with an AVF [94]. The Fistula First Breakthrough Initiative (FFBI) of the Centers for Medicare and Medicaid Services (CMS), initiated in 2003, is a set of strategies based on the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) Clinical Practice Guidelines for Vascular Access with the aim of promoting more AV vascular access use among incident and prevalent HD patients. It has set a target of 50% AVF use among incident HD patients. One of the core strategies of the initiative in attaining this objective is the timely referral of the CKD patient to a vascular surgeon for AVF assessment and placement [66, 96].

As well-defined as the objective and benefits of establishing an autogenous vascular access route at dialysis initiation are, there are patients for whom such access may not be a preferred option, for example the elderly. As the global population of elderly CKD patients increases, the incidence rates of ESKD in the elderly population aged 65 years and above will likewise increase [2]. This translates to an older population of patients with a high burden of comorbidities,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

such as diabetes mellitus, peripheral vascular disease, and congestive heart failure, requiring the establishment of vascular access to initiate dialysis. Age and comorbidities are known negative determinants of autologous AV access maturation and functionality [77, 79, 97]. With an all-cause mortality rate of 31% per annum [98], death becomes a competing risk for fistula maturation and cost-effectiveness in the elderly [99]. There are no specific recommendations for vascular access type in the elderly; however, the suitability of the fistula first initiative has been questioned [100].

Preparation for Peritoneal Dialysis

As is the case with commencing HD, early referral is key to preparing the patient who has made the choice of PD. It is recommended that potential PD patients should be referred at the latest 4 months prior to the anticipated start of dialysis [101]. This period affords the opportunity for PD education and home visits by a home PD team to assess the suitability of the patient's living conditions for PD and the availability of adequate storage space for PD supplies. In situations where suitability of the home is suboptimal, necessary modifications may be made in time. In addition, early referral provides ample time to establish PD access and obviates the need for bridging HD therapy.

A functioning PD catheter is a crucial requirement to successfully starting PD. Current guidelines suggest that PD access be established at least 2 weeks before the start of dialysis [102, 103]. This time allows for the healing of the catheter insertion site, training of the patient on the peculiarities of the PD technique such as catheter handling and care, and carrying out supervised exchanges. For the patients whose catheter will not be used soon, it can be buried in the anterior abdominal wall until exteriorization at that time when PD is about to be commenced.

Conclusion

Early referral and involvement of the nephrologist are important to enable adequate preparation of CKD patients who progress to requiring dialysis. A multidisciplinary approach to patient preparation for dialysis is encouraged and should be individualized on a basis that combines patient preference and lifestyle considerations, while integrating medical factors and availability of resources and support. The approach should also include comprehensive patient education that allows for shared decision-making on choice of dialysis modality. Early referral also enables adequate time to prepare for successful creation and maturation of a native AVF (or other vascular access options) in patients who have opted for HD. Although guidelines published after the IDEAL study suggest that dialysis be initiated late, for patients who have opted to start treatment with PD or in places where PD is favored dialysis should be initiated at higher GFR when patients still have residual renal function as this have been shown to be associated with better patient outcomes.

Choice of Hemodialysis or Peritoneal Dialysis for Kidney Replacement Therapy

Marlies Noordzij[1] *and Raymond T. Krediet*[2]

[1] *Department of Medical Informatics, Amsterdam UMC, University of Amsterdam, Amsterdam, The Netherlands*
[2] *Division of Nephrology, Department of Medicine, Amsterdam UMC, University of Amsterdam, Amsterdam, The Netherlands*

Introduction

The issue of timing of initiation of dialysis was first raised by Bonomini et al. in the 1970s [1–3]. They reported the highest survival rate in hemodialysis (HD) patients with a residual kidney function (measured by creatinine clearance) between 15 and 21 ml/min. However, criteria for the selection of patients for dialysis based on residual kidney function were not provided. The issue of an "earlier" start, which means with a higher glomerular filtration rate (GFR) than the usual threshold of 5–10 ml/min/1.73 m^2, reappeared again in the late 1990s when the process of developing guidelines for dialysis was started.

The choice of dialysis modality at the initiation of kidney replacement therapy has also been studied and discussed extensively in recent decades. There is, however, still no final consensus on whether HD or peritoneal dialysis (PD) treatment modality gives the best results. Consequently, both options have to be weighed in individual patients according to their specific needs, preferences, and clinical characteristics, with the aim of providing a patient-tailored kidney replacement therapy.

In this chapter, an overview is given of the current literature on the optimal timing of dialysis initiation and on the best dialysis modality choice.

Early Start or Timely Referral for Dialysis Initiation

A distinction should be made between the timing of referral to a nephrologist and the timing of initiation of dialysis treatment. Failure to make this distinction has confused the discussion. It should be emphasized that all studies on late referral to a nephrologist are either retrospective studies, based on surveys, or prospective cohort studies; nevertheless, the results are strikingly similar. Late referral for maintenance dialysis is associated with increased mortality [4–12] and decreased quality of life (QoL) [13, 14]. The excess mortality associated with late referral was independent of demographic characteristics, socio-economic status, and comorbidity. Moreover, late referral influenced the dialysis modality choice; patients who obtained predialysis care had a stronger preference for PD than patients who did not, the so-called late referrals [15]. In addition, patients who were referred late and started with PD were more likely to switch to HD during the first 6 months compared with patients who were referred in a more timely manner [16]. Despite all the evidence pointing to a beneficial effect of timely referral to a nephrologist, almost one-fourth of patients were referred less than 1 month before the start of dialysis in a survey of eight different European countries [17].

Guidelines and Studies on When to Initiate Dialysis Treatment

The timing of initiation of dialysis has been the subject of many opinion-based guidelines. A summary of international guidelines is presented in Table 39.1. The US National Kidney Foundation Dialysis Outcomes Quality Initiative (K/DOQI) Workgroup on Peritoneal Dialysis published an opinion-based guideline on the initiation of chronic dialysis treatment in 1997 [22]. The workgroup advised that dialysis should be initiated when renal Kt/V_{urea}

Table 39.1 Guideline recommendations on the timing of initiation of maintenance dialysis in patients with end-stage kidney disease (ESKD), based on GRADE.

Group	Year	Recommendation statement	Strength and evidence of recommendation
European Renal Best Practice advisory board (ERBP)/European Renal Association – European Dialysis and Transplant Association (ERA-EDTA) [18]	2011	• In patients with eGFR <15 ml/min/1.73 m^2, dialysis should be considered when there is one or more of the following: symptoms or signs of uremia, inability to control hydration status or blood pressure or a progressive deterioration in nutritional status. It should be taken into account that the majority of patients will be symptomatic and need to start dialysis with eGFR in the range 9–6 ml/min/1.73 m^2.	Grade: strong recommendation, high-quality evidence
		• High-risk patients (e.g. diabetics and those whose renal function is deteriorating more rapidly than eGFR 4 ml/min//1.73 m^2 per year) require particularly close supervision. Where close supervision is not feasible and in patients whose uremic symptoms may be difficult to detect, a planned start to dialysis while still asymptomatic may be preferred.	Grade: strong recommendation, low-quality evidence
		• Asymptomatic patients presenting with advanced CKD may benefit from a delay in starting dialysis in order to allow preparation, planning, and permanent access creation rather than using temporary access.	Grade: weak recommendation, low-quality evidence
Kidney Disease Improving Global Outcomes (KDIGO) [19]	2012	We suggest that dialysis be initiated when one or more of the following are present: symptoms or signs attributable to kidney failure (serositis, acid-base or electrolyte abnormalities, pruritus); inability to control volume status or blood pressure; a progressive deterioration in nutritional status refractory to dietary intervention; or cognitive impairment. This often but not invariably occurs in the GFR range between 5 and 10 ml/min/1.73 m^2.	Grade: 2B
Canadian Society of Nephrology [20]	2014	For adults (aged >18 yr) with an eGFR of <15 ml/min/1.73 m^2, we recommend an "intent-to-defer" over an "intent-to-start-early" approach for the initiation of chronic dialysis. With the intent-to-defer strategy, patients with eGFR of <15 ml/min/1.73 m^2 are monitored closely by a nephrologist, and dialysis is initiated with the first onset of a clinical indication or a decline in the eGFR to 6 ml/min/1.73 m^2 or less, whichever of these should occur first. Clinical indications for the initiation of dialysis include the following: symptoms of uremia, fluid overload, refractory hyperkaliemia or acidemia, or other conditions or symptoms that are likely to be ameliorated by dialysis. In the absence of these factors, the eGFR should not serve as a sole criterion for the initiation of dialysis unless it is 6 ml/min/1.73 m^2 or less.	Grade: strong recommendation; moderate quality of evidence
Japanese Society for Dialysis Therapy [21]	2015	The judgment on the time to initiate HD is allowed when a residual renal function shows progressive deterioration and reaction to eGFR <15 ml/min/1.73 m^2 in spite of sufficient optimal conservative treatment. However, the decision of starting HD should be determined based on a comprehensive assessment of renal failure symptoms, daily life activities, and nutritional status, which are not relievable without HD treatment.	Grade: 1D
National Kidney Foundation Kidney Disease Outcomes Quality Initiative (NKF-KDOQI) [1]	2015	The decision to initiate maintenance dialysis in patients who choose to do so should be based primarily upon an assessment of signs and/or symptoms associated with uremia, evidence of protein-energy wasting, and the ability to safely manage metabolic abnormalities and/or volume overload with medical therapy rather than on a specific level of kidney function in the absence of such signs and symptoms.	Grade: not graded

CKD, chronic kidney disease; eGFR, estimated glomerular filtration rate; HD, hemodialysis.

has fallen to 2.0/week. For a 70-kg man this equals a urea clearance of 8 ml/min, a GFR of 10 ml/min/1.73 m^2, and a creatinine clearance of 12 ml/min. A lower Kt/V_{urea} would only be acceptable when the normalized protein equivalent of nitrogen appearance, an index of protein intake in stable patients, was at least 0.8 g/kg of body weight/day and the patient was in a good nutritional state. These recommendations were retained in the update published in 2001. The clinical practice guidelines of the Canadian Society of Nephrology for treatment of patients with chronic kidney disease, published in 1999, were not significantly different from the US guidelines but set the target for the initiation of dialysis at a GFR of 12 ml/min/1.73 m^2 when symptoms were present. In addition, these guidelines state that dialysis should be started before the GFR drops below 6 ml/min/1.73 m^2 [23]. The European Best Practice Guidelines for PD recommend consideration of initiation of dialysis when the GFR is below 15 ml/min/1.73 m^2 in combination with evidence of poorly controlled conservative treatment. An absolute minimum value was set at 6 ml/min/1.73 m^2 [24].

At the time these guidelines were published many patients typically started dialysis at much lower clearances. In one study from the UK, the mean urea clearance was 3.9 ml/min [25]. A study from the United States reported that 63% of the patients had an estimated GFR between 5 and 10 ml/min/1.73 m^2, and 23% had an estimated value below 5 [26]. Although the aforementioned guidelines are not evidence based and are far from current practice, they have caused a trend toward earlier initiation of dialysis treatment [27, 28].

Observational cohort studies on the initiation of dialysis suffer two potential problems. First, the method used for GFR determination and, second, the effect of lead-time. Many cohort studies, often retrospective, used an estimation of glomerular filtration rate (eGFR) based on plasma creatinine, age, gender, and race, similar to the modification of diet in renal disease (MDRD) formula [29]. All investigations using the MDRD formula for eGFR reported associations between a high MDRD and increased mortality, despite corrections for possible confounders [30–32]. The use of the reciprocal plasma creatinine value in these analyses, instead of the creatinine clearance, is the most likely explanation because plasma creatinine is dependent on muscle mass and on glomerular filtration. The relative contribution of muscle mass to plasma creatinine will therefore be higher in the presence of severely impaired kidney function. Indeed a relationship between muscle mass and eGFR has been described in end-stage kidney disease (ESKD) patients at the initiation of dialysis, while follow-up confirmed the association between high eGFR values and mortality [33]. The obvious solution to avoid or diminish the effects of muscle mass on plasma creatinine is the use of creatinine clearance requiring timed urine collections or the use of a formula that includes an approximation of muscle mass, like the one developed by Cockcroft and Gault (C&G) in which body weight is included [34]. Using creatinine clearance, no effect of this parameter at the start of dialysis on mortality was found between patients who survived less than 1 year compared to those who survived more than 1 year on dialysis [35]. A comparison between 10-year patient survival after the start of dialysis between early (C&G >8 ml/min) and late (C&G <8 ml/min) starters showed a nonsignificant survival difference in favor of the early start group [36].

With the exception of Traynor et al. [36], none of the above-mentioned studies has taken lead-time bias into account. The lead-time is the period that late starters survive without dialysis, when compared with those who start earlier. When this difference is not taken into account, late starters will always have a survival disadvantage. The first study on the effect of lead-time bias was performed in 253 patients from the cohort of the Netherlands Cooperative Study on the Adequacy of Dialysis (NECOSAD) [37]. The patients who started dialysis according to the US guidelines [22] survived longer than those who started at a lower urea clearance, but this difference was no longer present after correction for the lead-time. This correction was performed using a program developed for patients with a malignancy. The other published studies on effects of the lead-time on survival used a simpler approach, that is, analyzing patients not from the time of dialysis initiation, but from a predefined GFR, for instance 20 ml/min/1.73 m^2 [36, 38–40]. No difference in mortality was found after correction for the lead-time bias in the studies from Scotland [36] and the United States [39]. A survival difference was present in the study from Hong Kong [38], but here a population starting dialysis with a GFR of 9 ml/min/1.73 m^2 was compared to one with a lower GFR, in which dialysis was initiated acutely due to the presence of severe uremic symptoms. The study from the Netherlands is interesting because effects of lead-time correction were analyzed in a large cohort of patients with GFR measurements (mGFR) and eGFR [40]. Results for eGFR without lead-time correction showed no difference between early and late starters, but after correction early starters had an increased risk of death. Without correction for lead-time, mGFR early starters had a somewhat lower risk of death than late starters, but the difference disappeared completely after lead-time correction.

The only randomized controlled trial comparing early initiation of dialysis with a late start based on GFR estimations [41] confirmed the results of the observational cohort studies discussed above, including when subgroups (e.g. presence or absence of diabetes mellitus) were analyzed

separately. It can therefore be concluded that no fixed GFR value to initiate dialysis can be identified, but that the value of clinical assessment cannot be underestimated. The development of severe uremic complaints should be avoided.

HD or PD as Initial Kidney Replacement Therapy

Dialysis modality choice at the initiation of kidney replacement therapy has been studied and discussed extensively in recent decades but still there is no final consensus on which treatment modality gives the best results. Consequently, both options have to be weighed in individual patients according to their specific needs, preferences, and clinical characteristics, with the aim of providing a patient-tailored kidney replacement therapy. Important outcomes for the evaluation of initial dialysis modality are patient survival, QoL, and values of biochemical parameters.

Patient Survival

The first study comparing continuous ambulatory PD with HD in incident patients was performed in the UK more than 30 years ago [42]. Using Kaplan–Meier analyses, the investigators showed that patient survival was not different between the two dialysis treatments during 3 years of follow-up. Since then, numerous survival comparisons between HD and PD treatment have been published, but their findings were inconsistent [43, 44]. Most studies performed in the last decade in Western countries showed either better survival for PD in the first period after the initiation of dialysis [45–49] or similar patient survival for both treatment groups [50–53]. In contrast, a large study performed in Korea showed higher mortality rates in PD patients than in HD patients [54]. Figures 39.1 and 39.2 show the dialysis "career" (including switches to other modalities and death) of patients who started either HD or PD in Europe between 1993 and 2007.

There are several factors that could potentially explain the differences in findings between these studies, including practice patterns, patient characteristics, and methodological issues.

Practice Patterns

Differences in dialysis modality-specific practice patterns between continents or countries may influence modality-specific patient survival. These practice patterns include general factors such as access to healthcare and organization of the healthcare system, but also more specific factors

that may contribute to the efficiency and quality of the dialysis offered, such as the HD treatment time and vascular access type, peritoneal catheters, and the dialysis fluids used. However, the results provided in most comparative studies do not allow evaluation of the extent to which HD and PD were performed in a state-of the-art manner. For example, in many survival comparisons the type of vascular access used for HD is not included in the analyses, whereas it was shown in a Canadian cohort that the type of vascular access plays an important role in the relationship between dialysis modality and mortality [55]. Starting HD with a central venous catheter largely explained the higher early mortality risk of HD in this study. Another example is the omission of the type of dialysis fluid in the comparison of patient survival. Based on data from the Taiwan health insurance database, it was demonstrated that the inclusion of one icodextrin-based PD fluid in the usual PD schedule could attenuate the survival disadvantage for PD relative to HD in diabetic patients, particularly for those who were elderly [56].

An additional factor that is usually not taken into account in survival comparisons of HD and PD is whether the start of dialysis was "planned" or "unplanned." It has been postulated that patients who need to start dialysis urgently are at a high risk of death, and as they are treated predominantly with HD this could induce selection bias into the comparison of mortality between HD and PD patients. A French cohort study showed there was a significant increase (50%) in mortality risk among elderly patients (≥75 years) with an unplanned start of HD when compared to those with a planned start, which suggests a comparison between the two dialysis modalities would be more balanced after removing the unplanned HD starts [57]. Two Canadian studies confirmed these findings. In 2011, Quinn et al. showed that HD and PD were associated with similar survival in incident patients starting dialysis electively as outpatients [52]. More recently, Wong et al. reported that HD and PD are associated with similar mortality among incident dialysis patients who are eligible for both modalities [53]. They claim that to better reflect the outcomes for patients who have the opportunity to choose between HD and PD in clinical practice, future comparisons of dialysis modality should be restricted to patients who are deemed eligible for both modalities. Finally, most recently more and more attention has been paid to home-based therapies, including both HD and PD. Data from the Australia and New Zealand Dialysis and Transplant Registry (ANZDATA) demonstrated that outcomes on dialysis therapy are improving with time, and this improvement is most marked with home dialysis modalities, especially home HD, when compared to conventional in-center HD [58, 59].

Patient Characteristics

Several studies from different parts of the world that found overall similar effects for PD and HD or a beneficial effect of PD over HD also showed that patient survival on PD was worse in specific subgroups of patients: those who were diabetic and who were older (mostly over 55 years). For example, investigators from the Canadian Organ Replacement Register who included data on more than 35 000 incident dialysis patients found that overall adjusted survival remained similar for HD and PD, even in the most contemporary cohort [60]. After stratification for diabetic status, age, and sex, they found that nondiabetic patients in the youngest age group (<45 years) showed survival benefits on PD treatment, while there was no difference in mortality in the older age groups. However, survival on PD was worse than on HD among patients with diabetes, in particular in those with higher age, which confirms the findings from previous studies from the United States, Asia, and Europe [48, 50, 51, 57, 61, 62].

In addition, patient characteristics related to ethnicity could partly explain different study findings across populations. In the United States, it was shown that dialysis patients who are Hispanic have better survival rates compared to those who are white, across all age categories [63]. This survival advantage is also present in African-American patients, although it is limited to patients older than 40 years of age.

To illustrate the variation in findings from different parts of the world, the results of a selection of large renal registry studies comparing patient survival between HD and PD treatment are summarized in Table 39.2.

Methodological Issues

Ideally, the decision on which dialysis modality gives the best outcomes should be based on results of randomized controlled trials in which the allocation of the dialysis modality is not influenced by attitudes or preferences of the nephrologist and the patient. The first randomized controlled trial comparing HD and PD as initial kidney replacement therapy was conducted in the Netherlands between 1997 and 2000 [64]. However, pre-existing opinions held by patients and physicians on the best treatment option were often reason for not including patients in the trial. As a result, the study was underpowered (only 38 patients could be included) and thus unsuccessful. Despite this result, a new trial started in China in 2011 (trial registration NCT01413074, http://clinicaltrials.gov); 5 years later, it also was terminated. Consequently, outcomes in HD and PD patients can only be compared based on large-scale observational studies.

Table 39.2 Comparison of mortality between HD and PD patients: a selection of recent large studies based on renal registry data.

Author, publication year (reference)	Country/region	Inclusion period	*N*	Effect
Asia				
Huang, 2008 [51]	Taiwan Renal Registry	1995–2002	48 629	Overall similar survival. PD better among nondiabetic patients and those ≤55 years; HD better among diabetic patients and those >55 years
Kim, 2014 [54]	Korean Health Insurance Review & Assessment Service database	2005–2008	32 280	Overall higher mortality on PD HD better among patients ≥55 years in all subgroups except those with no comorbidities and malignancy (similar survival regardless of age)
Europe				
Van de Luijtgaarden, 2016 [49]	European Renal Association-European Dialysis and Transplant Association (ERA-EDTA) Registry	1998–2006	196 076	Overall PD better in first years after starting dialysis Similar survival for diabetic patients and those ≥65 years
North America				
Mehrotra, 2011 [50]	United States Renal Data System (USRDS)	1996–2004	624 426	Overall similar survival in the most recent cohorts Over time greater improvement in survival among PD patients relative to HD at all follow-up periods
Yeates, 2012 [60]	Canadian Organ Replacement Register (CORR)	1991–2004	46 839	Overall similar survival; PD better in first 18 months, HD better after 36 months Women with diabetes aged ≥65 years higher risk on PD
Oceania				
McDonald, 2009 [46]	The Australia and New Zealand Dialysis and Transplant Registry (ANZDATA)	1991–2005	27 015	Overall PD better in the first 12 months after starting dialysis, thereafter HD better Younger patients without comorbidities had mortality advantage with PD treatment, but other groups did not

N, number; HD, hemodialysis; PD, peritoneal dialysis.

An important issue regarding treatment comparisons is the difficulty of making causal inference based on observational studies. The most important weakness of observational studies is that selection bias by the clinician – also called confounding by indication – may occur. There are several strategies to reduce the influence of such selection bias. Of these, multivariable adjustment for potential confounders during statistical analysis is most commonly applied. In recent years, more and more research groups have started to apply advanced statistical methods in addition to the conventional methods of survival analysis (i.e. Kaplan–Meier and standard Cox proportional hazards models) to assess the associations between dialysis modality and mortality risk [44]. Such methods include time-dependent Cox regression models (e.g. in [46, 49]), marginal structural models (e.g. in [46, 47]), and the use of treatment propensity scores in statistical models by means of adjustment, stratification, or matching (e.g. in [46, 49, 59, 62]). The fact that so many different statistical methods are being applied can partly explain the inconsistency in study results.

Mehrotra et al. applied several of these statistical methods to compare the survival of HD and PD patients from the United States Renal Data System (USRDS) [50]. They concluded that in the most recent cohort (2002–2004), there was no significant difference in the risk of death between patients who started on HD or PD. These findings were confirmed by investigators from the Canadian Organ Replacement Register who used a similar approach in comparing the data of their incident dialysis patient cohort [60].

Quality of Life and Biochemical Parameters

Although patient survival is an essential outcome, there are several other important outcomes that can and should be considered in the decision on which dialysis modality to choose. Many studies comparing all kinds of clinical outcomes between HD and PD have been performed. First of all, QoL is probably the most important outcome from the patient's perspective. However, only a few recent studies have compared the QoL between HD and PD patients. A meta-analysis published in 2017, in which only seven individual studies could be included, has not led to a unanimous conclusion [65]. Only some of the seven articles found significant differences between the two modalities; one showed a better QoL for PD patients, while two other studies found the best QoL in patients receiving HD.

In addition to QoL, there are many other outcomes that can be considered in the choice between the two dialysis modalities. One such outcome is the occurrence of renal anemia. A recent meta-analysis showed that both HD and PD have a similar effect on renal anemia in ESKD patients; the authors found no significant differences for levels of hemoglobin, ferritin, and transferrin saturation index between the two dialysis modalities [66]. A number of studies have shown advantages of PD, which were especially marked in the first years of treatment. These advantages include a better preservation of residual GFR [67–69] and better results after kidney transplantation with regard to delayed graft function [70, 71]. A systematic review and meta-analysis on the association between pre-transplant dialysis modality and transplant outcomes showed that patients who were treated with PD before their transplantation had a significantly lower incidence of delayed graft function and a better 5-year patient survival rate than those treated with HD before transplantation; there were no differences in the occurrence of acute rejection and graft survival [71].

Conclusion

Both for establishment of the optimal starting point for dialysis treatment and for dialysis modality comparison, the evidence base has needed to come from observational studies, despite their drawbacks, because as yet it has not been possible to perform randomized controlled trials. Up to now, these observational studies have indicated that no fixed GFR value to start dialysis can be identified. However, the value of clinical assessment cannot be underestimated and the development of severe uremic complaints should be avoided.

Overall, the treatment outcomes for HD and PD are very similar, even when sophisticated statistical methods are used. When specific patient subgroups were investigated, most studies showed that PD is associated with better survival for younger (mostly <55 years) and nondiabetic patients, but with worse survival for older and diabetic patient subgroups. These results indicate that both HD and PD can be considered as suitable initial kidney replacement therapy, depending on the patients' characteristics. Patients should be educated about potential advantages and disadvantages of both treatment modalities before the start of dialysis, so that they can make a well-informed choice together with their physician.

Preface

The synthesis of the totality of evidence in kidney disease was the original challenge we undertook when we conceived of the first edition of this evidence-based nephrology (EBN) textbook, thereby providing students of nephrology and practicing clinicians with a single convenient source of clinical evidence that had been passed through an evidence-based filter. More than 12 years have passed since the first edition, and so it is timely to revisit the challenge in the form of a second edition. The reasons for a second edition are principally three: the scale of new available data is substantial, newer methods of research synthesis have been developed, and there is a renewed focus on consumer engagement in general, including in the evaluation and management of kidney disease.

Scale of new data

Compared to the time of the first edition, the amount of new data is impressive. There are today more than 15 000 randomized controlled trials in nephrology published in approximately 30 000 reports, 11 300 more than in 2009, resulting in more confidence and precision around the estimates of intervention effects and new evidence in areas that were previously mostly evidence-free. These trials have also been summarized in systematic reviews, with over 6500 additional reviews in Medline since the first edition. Much of this new evidence is incorporated in three new sections of this textbook and multiple either new or entirely updated chapters.

Novel methods

Methods to assess the methodological quality of both systematic reviews and other study designs, including nonrandomized (case-control or cohort studies) and diagnostic test studies, have developed since the first edition. In addition, the number of syntheses of cohort studies has increased and the technique of network meta-analysis for comparing more than two interventions both directly (head to head) and indirectly (via a common comparator) has become more developed and is commonly encountered. These methods assist the summarizing and interpreting of evidence in key areas of decision-making, which is useful to patients, healthcare providers, and policy-makers.

Using these methods, organizations including the Cochrane Kidney and Transplant group and several guideline agencies have committed on a large scale to summarize the evidence and provide timely updates of established and emerging new evidence, making research findings more manageable and reliable for end users. Much of this work has been included in this edition of the textbook. We hope this will allow the end-user to both access best evidence from this diversity of resources as summarized by chapter authors and to become more familiar with how the newer techniques and resources contribute to a practice that is informed by best evidence.

Consumer engagement

Recently, there has been increasing recognition of the critical importance of engaging the end-users in research to ensure relevance and uptake. In particular there have been large-scale efforts to engage patients in all stages of research, including the evidence synthesis process and the dissemination of findings. For example, the Cochrane Kidney and Transplant group now has a patient editor, whose role includes translating scientific outputs into plain language summaries to simplify the "medical jargon" and make evidence easily accessible to people without a medical background, as well as prioritizing review topics. The Standardized Outcomes in Nephrology (SONG) initiative was launched in 2014 to establish the core outcomes to be reported in all trials in chronic kidney disease, based on a consensus among patients, caregivers, health professionals, and policy-makers. This initiative has emphasized patient-centered research and improved clinical outcomes in nephrology, ensuring that the outcomes measured and reported in clinical trials and other forms of research are relevant and meaningful to patients and increase the acceptability, transparency, and generalizability of the results in this population. New studies assessing these

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

outcomes are now being developed, with advancement of knowledge which could be incorporated into this edition of the textbook.

In short, compared to the previous version published in 2009, this updated textbook includes 20 new chapters and three new sections, covering supportive care and patient-centered care and outcomes. In addition, every chapter that was in the first edition has been extensively updated. Specifically, the new textbook covers epidemiology, acute kidney injury, primary diseases of the kidney, secondary diseases of the kidney, chronic kidney disease and complications, hemodialysis, chronic kidney disease stage 5, peritoneal dialysis, supportive care, transplantation, electrolytes and acid-base disorders, and patient-centered care and outcomes for both adult and pediatric patients. This effort was undertaken by existing and new authors and section editors, whom we would like to thank for their extensive work.

Giovanni Strippoli has joined as the third co-editor of *Evidence-based Nephrology*. Altogether, we hope that we have produced an even better evidence-based nephrology tool, where each chapter provides a clear foundation of the topic that is supported by the best current evidence.

We believe that this updated textbook more broadly covers available evidence and addresses crucial clinical questions regarding the treatment and care of people with all stages of chronic kidney disease, including people undergoing any form of dialysis (hemodialysis or peritoneal dialysis), those requiring kidney transplantation, and pediatric patients.

Inherently a textbook of this nature will always manifest potential limitations. We acknowledge that a textbook is unable to collect all new evidence in real time, and, like all of healthcare internationally, the COVID-19 pandemic did impact this book, specifically the publication timelines as contributors had to contend with major challenges. The inclusion of nonrandomized studies to maximize relevance and comprehensiveness has added complexity in the methods and may lead to residual uncertainty in the estimate of intervention effects. Finally, we focused on empiric evidence for management decisions and so pathophysiological mechanisms of chronic kidney disease and its treatment were not considered in detail. We have attempted to include economic evaluations where particularly relevant for national and international management guidelines.

In the true spirit of evidence-based medicine, we hope that this edition of *Evidence-based Nephrology* will continue to push the specialty toward greater reliance on the totality of evidence and the generation and utilization of evidence that is the least biased and the most precise to inform clinical decision making. To the material detailed in all the chapters we would expect that our readers will add, through their own judicious application of evidence-based medicine principles, their local context, and incorporate their patients values and preferences, given that objective evidence is rightly only one consideration in the delivery of true patient-centered care. Additionally, a textbook like this can at best be only one of several resources for the evidence-based medicine practitioner, and should be supplemented with current methodologically rigorous and transparent clinical practice guidelines. We hope this effort will provide a core resource for the evidence-based nephrology practitioner who is otherwise limited by time constraints from researching every question that may arise daily in the care of patients.

We certainly wish that students and evidence-based nephrology practitioners will benefit from this updated edition in the search for answers to questions that arise in daily care and their ambition to deliver the best care possible.

Modalities of Extracorporeal Therapy

Matthew J. Damasiewicz[1], Muh Geot Wong[2,4], and Peter G. Kerr[3]

[1] *Monash Health and Monash University, Clayton, Victoria, Australia*
[2] *Department of Renal Medicine, Concord Repatriation General Hospital, Concord, NSW, Australia*
[3] *Professor and Director of Nephrology, Monash Health and Monash University, Clayton, Victoria, Australia*
[4] *The University of Sydney, Sydney, NSW, Australia*

Introduction

Despite the complexity of hemodialysis (HD), the theoretical principles are relatively simple (Box 40.1). Blood and dialysis fluid are circulated on the opposite sides of a semipermeable membrane (the dialysis membrane), which permits the passage of water and smaller solutes, but restricts the passage of larger molecules. The provision of clinically adequate HD is for the most part dependent on water quality, dialysate composition, dialysis access, the presence and extent of treatment monitoring, and delivery and modality of blood purification.

Dialysis membranes are one of two key components that define the modality of blood purification, the other being the hydrostatic pressure gradient across the membrane itself (Table 40.1). The most important operating characteristic of dialysis membranes is their permeability to water. Low flux HD, high flux HD, and hemodiafiltration (HDF) are modalities characterized by increasing convective clearance of larger solutes in addition to the usual diffusive clearance of small solutes. The convective process relies on solvent drag by the passage of water across the membrane, and therefore greater membrane flux or permeability to water. Of note, the relative differences in clearance between all of these modalities of blood purification are large, although the absolute differences relative to native kidney function are small (Box 40.2).

The two other practiced forms of extracorporeal blood purification, hemofiltration and acetate-free biofiltration, are seldom used and will not be discussed in this chapter.

In this chapter, we summarize the published studies of hemodialysis membrane type and hemodialysis modality, and provide recommendations for nephrologists responsible for hemodialysis care.

Box 40.1 Dialysis Key Features

Dialysis modality	Membrane qualities	Solute removal
• Low-flux HD • High-flux HD • HDF	• Synthetic versus cellulosic • Low-flux, high-flux, super-flux	• Diffusion • Convection • Adsorption

HD, hemodialysis; HDF, hemodiafiltration.

Epidemiology

The origins of modern extracorporeal techniques for the treatment of end-stage kidney disease (ESKD) can be traced back to the early twentieth century, where rudimentary devices were used to remove fluid and solutes from blood in animal experiments. However, these early efforts were significantly limited by the insufficient effectiveness of the blood purification treatment. Modern efforts using HD became possible in the 1960s, with technological advances allowing improved dialysis membrane quality and mass production, along with improvements in anticoagulation and dialysis access.

Today HD is routinely applied to patients as an indefinite life-sustaining treatment for ESKD. Worldwide there are currently in excess of three million patients receiving HD and this number is projected to increase significantly, mostly due to the increased access to care in developing

Table 40.1 Membrane type and modality.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Hemodialysis (HD)	We suggest a synthetic, biocompatible, high-flux dialysis membrane can be used for hemodialysis rather than a low-flux membrane, to reduce cardiovascular mortality, although providers and patients may reasonably choose a low flux membrane due to the low certainty of effects on cardiovascular mortality and other outcomes.	Low	Weak
Hemodiafiltration (HDF)	We suggest HDF may be used rather than conventional HD to reduce cardiovascular mortality and reduce frequency of intradialytic hypotensive events, although patients may reasonably choose not to due to the low certainty evidence for improved clinical outcomes.	Low (cardiovascular mortality) or very low (dialysis-related hypotension)	Weak

GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.

Box 40.2 Relative Small and Large Solute Clearance for Different Stages of CKD and Dialysis

Native renal or RRT	Fluid control (%)[a]	Equivalent small uremic toxin clearance (EKRc)[b]	Equivalent large uremic toxin clearance (EKRc)[c]
Low-flux HD	5–10	10–15	3–3.5
High-flux HD	5–10	10–15	3.5–4
High-volume HDF	5–10	10–15	4–5
PD	100	8–12	1–2
Intensive HD	10–30	20–30	5–10
Severe CKD	100	15–30	15–30
Moderate CKD	100	30–60	30–60
Normal kidneys	100	> 60	> 60

CKD, chronic kidney disease; PD, peritoneal dialysis; RRT, renal replacement therapy.
[a] Hours per week of ultrafiltration as a percentage of 168.
[b] EKRc for urea, ml/min.
[c] EKRc for β2-microglobulin, ml/min.

nations. For most patients routine HD involves three treatment sessions per week, of 4–5 hours of treatment per session, although practice can and does vary considerably between countries. Most treatments are performed in hospital or free-standing community facilities, with a small percentage occurring as home-based HD.

Pathophysiology

Dialysis Membranes

Dialysis membranes permit the movement and removal of solutes and water during dialysis. Membranes have been generally classified based on their composition (cellulosic vs. synthetic) and permeability to water (high vs. low flux). Super-flux membranes, with markedly increased water permeability and middle molecule clearance, have become commercially available and are defined as medium cut-off (MCO) and high cut-off (HCO) membranes [1]. Dialysis membranes are not physiologically inert and make contact with the patient's blood, therefore they can elicit active biological responses in the patient. Although there is no formal definition of "bioincompatibility," such responses have long been recognized as device-related and clearly linked to adverse clinical outcomes.

The Evolution of Dialysis Membranes

The first modern HD membranes were cellulose based, thin-walled, and functionally classified as low flux. Despite their functionality, there were two significant disadvantages of these membranes. First, the natural, cellulosic fibers were immune-reactive mainly as a result of exposed hydroxyl groups [2, 3] activating inflammatory pathways such as complement and inducing inflammatory mediators. This resulted in a classical inflammatory response syndrome, reduced dialysis tolerance, and dialysis-related cachexia. Second, they only permitted the passage of small solutes (MW < 500 Da). This inability to remove larger molecules (in particular β2-microglobulin, MW 11 800 Da) was implicated in the subsequent development of dialysis-related amyloidosis, especially in very long-term HD patients [4].

The evolution of membranes in general occurred in two directions, first to improve "bioincompatibility" and second to improve flux. Development largely focused on the large-scale production of synthetic membranes made from polysulfone, polyamide, polyarylethersulfone, and polymethylmethacrylate [5]. Such plastics are generally, but not always, more biocompatible and less biologically active. They can be spun into fibers with more consistent pore size and geometry compared to cellulose, allowing more precise molecular weight (MW) cut-off and therefore more predictable clearance of larger molecules [6]. Early synthetic membranes were considerably thicker than low-flux membranes, causing a degree of impediment to diffusion-based clearance. However, modern synthetic membranes are thinner, with excellent operating characteristics.

High-flux membranes have increased clearance of middle molecules (nominally β2-microglobulin), which in turn has been associated with a reduced incidence of symptoms on dialysis and long-term complications such as dialysis-related amyloidosis [7]. Initial concerns about the excessive cost of high-flux membranes have been largely negated in developed countries with near-universal adoption. In addition, decreased dialyzer reuse has led to large volume production and further decreased costs. However, these remain pertinent issues in developing countries with comparatively nascent dialysis infrastructure. The routine use of endotoxin filters in modern dialysis circuits, and overall improvements in dialysis water quality and water purification technology have largely mitigated concerns about back-filtration of dialysate contaminants to the patient's blood [8].

The Clinical Relevance of "Flux"

Formally, "flux" is defined by the ultrafiltration coefficient (K_{uf}) of a dialysis membrane, defined as the rate at which water crosses the membrane at a given transmembrane pressure (defined in ml/h/mmHg). The importance of flux is not the permeability of the water per se, but the fact that greater flux of water across the membrane during the course of HD or HDF treatment results in greater passage of larger molecules (nominally β2-microglobulin) through the dialysis membrane by the process of solvent drag. Informally, both of these operating characteristics are now used to discriminate low- from high-flux membranes. However, thresholds that define degrees of "flux" remain somewhat arbitrary. In the HEMO study, a high-flux dialysis membrane was defined as $K_{uf} > 14$ ml/h/mmHg and β2-microglobulin clearance of >20 ml/min, whereas low-flux membranes were defined as β2-microglobulin clearance of <10 ml/min [9]. More recent definitions normalize the K_{uf} to the membrane surface area (expressed in ml//h/mmHg/m [1]) and define β2-microglobulin in terms of the sieving coefficient (SC), which is a ratio of the solute in the filtrate compared to its plasma concentration. The Membrane Permeability Outcome (MPO) study defined high-flux as β2-microglobulin SC >0.6 and $K_{uf} \geq 20$ ml/mmHg/h [10]. The European Dialysis (EUDIAL) Working Group felt that a characteristic of middle molecule clearance should be incorporated in a modern definition of "high flux" in addition to the ultrafiltration coefficient of a membrane.

The agreed EUDIAL definition of a high-flux membrane is based on the MPO study and is $K_{uf} = 20$ ml/h/mmHg/m [2] and β2-microglobulin SC > 0.6 [11]. It is important to note that most of the studies comparing high- and low-flux, and HD and HDF did not use this definition.

Middle Molecule Clearance and Super-flux Membranes

The chronic inflammatory response seen in maintenance HD patients has been linked to accelerated atherosclerosis, endothelial dysfunction, increased advanced glycosolation end-product levels, protein-energy wasting, cachexia, and secondary immune deficiency [12–19]. These in part mediate the increased all-cause and cardiovascular disease (CVD) mortality seen in ESKD patients when compared to age-matched individuals without kidney disease. This chronic inflammatory response is multifactorial and can be attributed to the plastic consumables used during dialysis, dialysis membranes, disinfecting solutions, and water quality as well as the presence of endotoxins and uremia. All of these can directly or indirectly induce pro-inflammatory cytokines, many of which are large-middle molecules (TNF-α, IL-6, and IL-10), themselves poorly cleared with conventional high-flux HD [20]. The contribution of a dialysis membrane to this process can be viewed in terms of its

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

contribution to inflammation (bioincompatibility) and potential for clearance of middle molecules during HD. The aim of increasing middle molecule clearance during HD has driven the development of super-flux membranes.

Middle molecules are a heterogeneous group of compounds broadly defined as having a MW of 500–60 000 D [21]. This includes the archetypal middle molecule marker β2-microglobulin and a plethora of other compounds that include cytokines, uremic toxins, growth factors, and hormones, which are generally further subclassified based on MW. Modern high-flux membranes are excellent at removing β2-microglobulin (MW 11800 D), but are poor at removing large-middle molecules (MW > 15 000 D) [22]. Therapies which combine convection with diffusion such as HDF (see below) have become an increasingly accepted method for increasing middle molecule clearance. Similarly, recent developments in membrane technology have enabled the development of super-flux membranes which are capable of clearing molecules with a MW of up to 50 000 D, which approximates and potentially surpasses the clearances provided by HDF [23, 24].

High cut-off membranes (HCO) were used clinically in the setting of kidney failure due to multiple myeloma to enhance the removal of kappa and lambda light chains (large-middle molecules) [25, 26]. These have a wide distribution of pore sizes and show variable clinical efficacy in the treatment of cast nephropathy. However, their use is associated with increased albumin loss and significant electrolyte abnormalities, e.g. hypophosphatemia. MCO membranes have been developed with a narrower range of distribution of pore sizes (Figure 40.1), below the MW of albumin (68 000 D). In theory these allow for more effective middle and large-middle molecule clearance, without excessive albumin loss [27]. What constitutes acceptable loss of albumin during HD remains unclear. Some albumin loss may in fact be beneficial due to the removal of protein-bound toxins. Super-flux membranes may provide us with a form of "enhanced" HD (when considered in terms of large-middle molecule clearance). The potential benefits of this new class of membranes, particularly when compared to existing convective therapies, requires further evaluation in clinical studies.

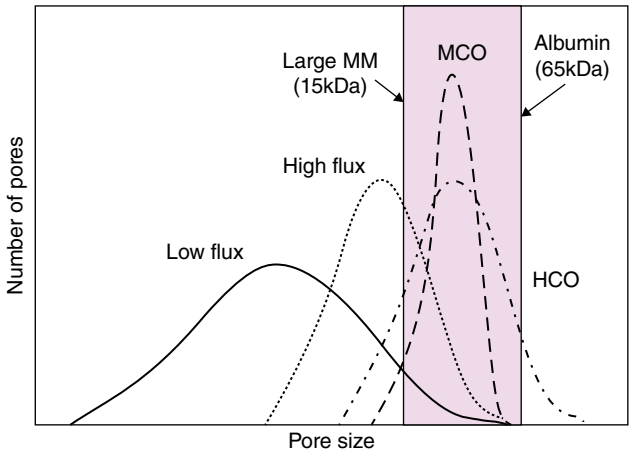

Figure 40.1 Schematic of pore size in dialysis membranes. MCO membranes (in pink) have been specifically designed to remove large middle molecule (compared to high-flux) membranes without excessive albumin loss (compared to HCO membranes). HCO, high cut-off; MCO, medium cut-off; MM: middle molecules. *Source:* From Wolley et al., CJASN 2018. ASN.

Dialysis Modality

HD is based on the diffusion of solutes across a semipermeable membrane and is highly effective at fluid removal, correcting acidosis and electrolyte disturbances, and removing small solutes and toxins. HD is less effective at removing middle and large-middle molecules, as effective diffusion is inversely related to MW. Convective therapies have been developed to overcome this problem by increasing the transport of larger molecules across dialysis membranes. HDF differs to conventional dialysis in that it involves the exchange of large volumes of fluid with the patient. Early convective therapies such as hemofiltration were subsequently combined with diffusion-based therapies in HDF, which is the most commonly used convective therapy across the world. Whilst HD remains the most commonly used dialysis modality worldwide, the uptake of HDF is increasing, particularly in Europe and Japan [28, 29].

Conventional HD

Conventional HD involves the use of a single-pump dialysis machine. Blood is drawn from the patient, passed through a semiporous hollow-fiber dialyzer of a given membrane type, and returned to the patient. At the same time, the dialysis solution (dialysate) is passed in a counter-current fashion through the dialyzer, on the other side of the dialysis membrane to the blood, in a single-pass fashion (meaning dialysate passes the membrane only once and then is discarded). The removal of excess extracellular fluid from the patient occurs by passage of the ultrafiltered extracellular fluid across the semiporous membrane from the blood compartment to the dialysate compartment. This is predominantly controlled by hydrostatic pressures but is also dependent on the porosity of the membrane and its ultrafiltration coefficient. High-flux membranes allow for the movement of more fluid than is desired, and this is balanced by back-filtration of dialysate back into the blood. In modern dialysis machines this is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. achieved with the use of ultrafiltration monitors which allow the setting of net fluid removal during each dialysis session. Solute removal is dependent on molecular size and weight, hydration radius, osmotic gradient, and electrical charge. Different dialyzer membranes, of different pore size and composition, will allow the passage of solutes at different rates, and more porous membranes allow the removal of larger molecules (see above). The predominant mechanism of removal, especially for smaller solutes, is movement through diffusion from blood into the dialysate. The other mechanism is convection, which occurs when dissolved solutes are removed as ultrafiltration occurs (also referred to as "solvent drag"). This latter mechanism is more important for larger molecules and is dependent on the porosity of the membrane. In conventional HD, most solute removal is by dialysis and ultrafiltration volumes are generally in the order of 6–8 l maximum (balanced by back-filtration within the dialyzer; Figure 40.2).

HDF

HDF differs from standard HD by incorporating a highly porous dialysis membrane that allows very high convective volumes. On-line HDF requires the use of a double-pump dialysis machine, utilizing a highly porous dialysis membrane that allows loss of high-volume ultrafiltrate into the dialysate compartment. The volume of ultrafiltrate lost is replaced by the infusion of ultrapure dialysate (UPD) into the patient's blood using the second, substitution fluid blood pump (Figure 40.3). The typical substitution volumes achieved in a standard post-dilution HDF should exceed 20 l, and any proposed benefit of HDF over high flux relies on effective convection volumes of at least 18–20 l. The European Dialysis Working Group (EUDIAL) has revised the definition of HDF incorporating both membrane properties (high flux as defined above) and convective volumes of least 20% of the total blood volume processed with fluid balance maintained by infusion of substitution fluid into the patient's blood [11].

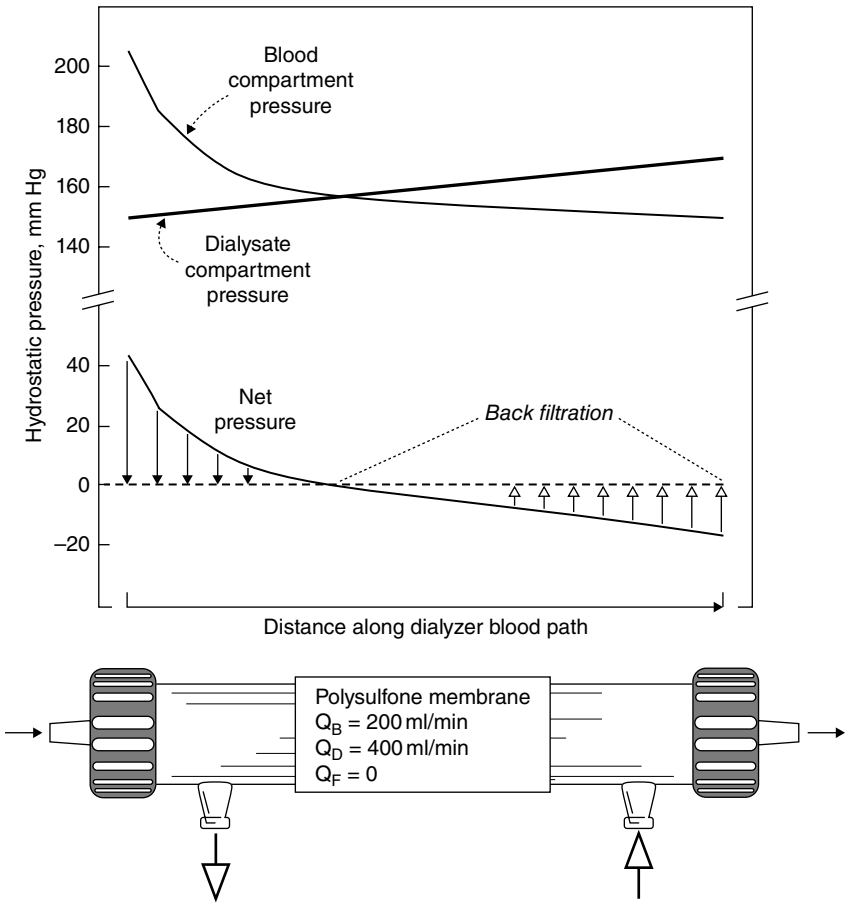

Figure 40.2 Schematic of fluid removal along a dialysis hollow fiber membrane. The net ultrafiltration volume is controlled by balancing the pressures, in effect by controlling negative pressure on the dialysate side of the membrane. *Source:* From Streicher, E., & Schneider, H. (n.d.). The Development of a Polysulfone Membrane. In Highly Permeable Membranes (pp. 1–13). © 1985, Karger Publishers.

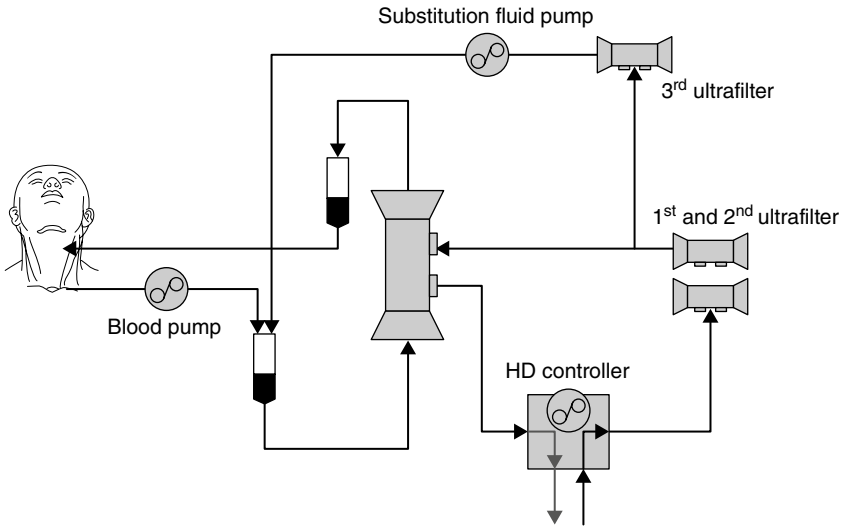

Figure 40.3 Schematic of the circuit used in HDF. This diagram represents predilution fluid replacement. Postdilution differs in the site of the entry of the replacement fluid (as the blood leaves the dialyzer, rather than prior to entry to the dialyzer).

The various types of HDF differ by the site of the dialysate replacement, which can be pre or post the dialyzer (or pre and post as "mixed" HDF), with differences around solute removal and the potential for excessive hemoconcentration. Predilution HDF (infusing the substitution fluid before the blood enters the dialyzer) dilutes the concentration gradient across the dialyzer, potentially decreasing small molecule clearance, but in clinical practice this is offset by greater ultrafiltration volumes (compared to postdilutional HDF), with the ensuing solvent drag resulting in similar clearances overall [30]. In post-dilution HDF the dialysate is infused downstream of the dialyzer (after dialysis has occurred), which optimizes the clearance of solutes through diffusion, and the high ultrafiltration rates limit the back-filtration that occurs in high-flux HD [31]. A limitation of this modality is that at high ultrafiltration rates there is excessive hemoconcentration within the dialyzer fibers, causing elevated transmembrane pressures, reduced clearances, and clotting of the dialysis circuit. To prevent this problem, the filtration fraction is generally limited to 20–25% of the total blood flow rate [32]. In modern dialysis machines, mixed dilution HDF allows for the infusion of dialysate both before and after the dialyzer, and the ratio of the infusion rates can be balanced to optimize clearances and minimize the adverse consequences of hemoconcentration. However, most observational and trial data are based on postdilution HDF.

The large convective component of HDF greatly enhances solute removal, but any improvement over conventional HD is mostly limited to middle and large-middle molecules.

As large volumes of dialysate are infused directly into blood lines, additional treatment monitoring considerations are needed. The first is the need for more accurate monitoring of fluid balance to ensure the balance of removed and replaced fluid equates with the desired fluid loss for the session. The second is the microbiological purity of the dialysate, with separate standards existing for HDF and HD, respectively.

Water Quality

Historically, poor water quality (from a variety of environmental, chemical, and microbiological factors) has been implicated in bio-incompatibility and adverse patient outcomes [33]. The quality of dialysis water has seen incremental improvements with advances in water purification, disinfection methods, and routine monitoring. The provision of high-quality dialysis fluids is now readily achievable in all modern dialysis units. The provision of high-quality dialysis water is arguably even more important in the provision of HDF, given the direct infusion of substitution fluid into the blood line. The advent of convective therapies has resulted in a new, more rigorous dialysis fluid quality standard, UPD, which is used for substitution fluids in HDF. The differences between standard and UPD dialysis fluids are defined by the International Organization for Standardization (ISO) in terms of terms of bacterial load, the total viable count in colony forming units per milliliter, and total the endotoxin load in endotoxin forming units per milliliter (Box 40.3).

Putative Benefits of HDF

It has been a long-standing supposition that the improved middle-molecule clearances (see above) observed with

HDF should translate to improved patient outcomes. Adding large convective volumes to standard (high-flux) HD improves the clearance of middle molecules, especially those in the 15 000–25 000 MW range, which includes a number of cytokines such as TNF-a, IL-1, IL-10, and IL-6 [34–36]. These have long been implicated in dialytic instability, bio-incompatibility, and poor dialysis outcomes, so their potential removal by HDF is an area of significant clinical interest. In the CONTRAST study, IL-6 and C-reactive protein (CRP) levels were lower in the HDF cohort compared to the conventional (low-flux) HD cohort [37]. However, in the FRENCHIE study there were no significant differences between HDF and high-flux HD over 24 months in serum levels of IL-6, IL-10, TNF-alpha, NT- N-terminal pro brain naturetic peptide (ProBNP), or high sensitivity cardiac troponin T (hs-cTNT) [38]. These results need further validation, and increased removal of cytokines may itself not be adequate if the stimulus for their induction is not addressed. Molecules in the large-middle molecule spectrum with MW 25 000–60 000 D remain poorly cleared by all HDF and high-flux HD therapies. The clearance of protein-bound solutes is generally not improved by HDF [39].

Cardiovascular instability remains a frequent clinical problem in patients on HD, and intradialytic hypotension has been increasingly associated with stunning of the myocardium and other vital organs such and the gut [40–43]. Anecdotally it appears that HDF may confer increased cardiovascular stability, but considerable debate continues as to whether this is indeed the case. Early observational and interventional studies provided mixed results with regards to cardiovascular stability and outcomes [44–46]. The results of two separate meta-analyses found that HDF reduces the incidence of symptomatic hypotension (compared to HD), with no significant difference in cardiovascular events or cardiovascular mortality [47, 48]. The recent FRENCHIE study, a randomized controlled trial (RCT) of older patients (>65 years), did not demonstrate a positive benefit for HDF over HD for the primary outcome of intradialytic tolerance. A small study using functional cardiac magnetic resonance imaging (MRI) studies during dialysis sessions found no difference in wall motion abnormalities and a number of cardiac parameters between high-flux HD and HDF [49]. The mechanisms underpinning any benefit for HDF have not been clearly elucidated but may relate to removal of cardioactive/vasoactive agents, such as interleukins and other vasoactive peptides. Alternatively, it may relate to thermal stability. This concept suggests that the large volume of infused dialysate prevents overheating during dialysis, thus preventing vasodilatation.

Treatment

High-flux Versus Low-flux on Cardiovascular Outcomes and Survival

A number of observational studies support an association between the use of high-flux membranes and improved survival outcomes in hemodialysis [50–53]. Three large RCTs were designed to provide further clinical evidence and these include the HEMO trial, MPO and the Multiple Interventions Related to Dialysis Procedures in Order to Reduce Cardiovascular Morbidity and Mortality in HD Patients (known as the EGE study) [10, 54, 55]. The details of these studies are outlined in Table 40.2.

A Cochrane meta-analysis pooled data from 33 randomized controlled trials and included 3820 participants. The results of the analysis are outlined in Table 40.3 [56]. Cardiovascular mortality was proportionally reduced by 17% in individuals receiving high-flux membrane dialysis compared to low flux dialysis (five studies, 2612 participants: risk ratio [RR] 0.83, 95% confidence interval [CI] 0.70 to 0.99) across a median follow up of 24 months. However, high-flux membranes did not reduce all-cause mortality, infection-related mortality, or hospital admissions compared to low-flux membranes. While the use of high-flux membranes reduced predialysis β2-microglobulin levels, insufficient data were available to reliably estimate the effects of membrane flux on carpal tunnel syndrome or amyloid-related arthropathy. In relation to surrogate outcomes, the data demonstrates that it is unlikely there is any

significant benefit for high -flux membranes compared to low-flux membranes in relation to urea clearance or serum lipid levels. The data suggest that if 1000 individuals with ESKD were treated with high-flux HD there would be no reduction in all-cause mortality or hospitalization rates, but 15 fewer deaths might occur attributed to cardiovascular disease (CVD) causes.

Super-flux Membranes

At present there is limited clinical experience with the use of MCO membranes. Evidence is limited to nonrandomized studies.

The putative benefits outlined above are offset by concerns of albumin loss and back-filtration, and both need further evaluation. Albumin losses during a MCO HD session can approximate 3 g, but no significant change in serum albumin levels has been demonstrated and at present the clinical significance of these findings remains unclear [57, 58]. Similarly, in vitro studies have shown no increase in back-filtration, but this may become apparent with the increased clinical use of MCO membranes [20]. The efficacy of MCO membranes has been shown in small studies, with improved clearance rates of complement factor D (MW 24 000 D), α1-microglobulin (MW 33 000 D), and the chitinase-like protein YKL-40 (MW 40 000 D) compared to high-flux HD [27]. Dialysis with MCO membranes has been associated with reduced activation of the renin-angiotensin system and decreased expression of proinflammatory cytokines (TNF-a and IL-6) [59, 60].

These findings need further evaluation in prospective studies and correlation with clinical outcomes. An early example of such a study is REMOVAL-HD [61]. This is a prospective, investigator-led, open-label study which aims to address the safety, efficacy, and impact on patient-centered outcomes with the use of MCO membranes in 85 prevalent HD patients. The primary endpoint is the change in predialysis concentrations of serum albumin, with additional biochemical and patient-centered secondary endpoints. The outcomes will inform the design of future clinical trials which need to compare MCO membranes not only to high-flux membranes, but perhaps more importantly to convective therapies.

International Society Guidelines: High Versus Low Flux

Guideline	Year	Recommendation
KDOQI [62]	2015	• We recommend the use of biocompatible, either high- or low-flux, hemodialysis membranes for intermittent hemodialysis. High-flux dialyzers should be used preferentially, but if there are cost restraints, patients with diabetes mellitus, low albumin, and longer dialysis vintage should be prioritized.
Japanese Society for Dialysis Therapy Clinical Guideline [63]	2015	• High-performance membrane dialyzers should be used. These were defined in 2005 as a β2-microglobulin clearance of at least 10 ml/min and updated in 2013 to include albumin permeability and adsorption capability.
CARI-KHA [64]	2013	• We recommend that high-flux membranes be used to remove molecules such as β2-microglobulin because they have been shown to achieve lower serum levels. • We suggest there are possible survival benefits from high-flux membranes for some groups, such as those on dialysis for more than 3.7 years, those with a serum albumin below 40 g/l, and diabetics
Renal Association Clinical Practice Guidelines [65]	2011	• We suggest that hemodialyzers with synthetic and modified cellulose membranes should be used instead of unmodified cellulose membranes. • We suggest that high-flux dialyzers should be used instead of low-flux dialyzers to provide HD. Evidence of improved patient survival with the use of high-flux membranes is restricted to incident patients, who have lower serum albumin concentrations (<40 g/l) or have diabetes mellitus, and prevalent patients, who have been on HD for more than 3.7 years.
European Best Practice Guidelines [66]	2010 Update to the 2007 Guidelines	• Synthetic high-flux membranes should be used to delay long-term complications of hemodialysis therapy in patients at high risk (serum albumin < 40 g/l) • In view of underlying practical considerations and the observation of a reduction of an intermediate marker (β2-microglobulin), synthetic high-flux membranes should be recommended even in low-risk patients.

The Canadian Society of Nephrology Clinical Practice Guidelines published in 2006 provide no clear recommendation. KDIGO does not provide guideline on dialysis prescription or membranes.

Discussion

The choice of dialysis membrane for HD remains a difficult question to answer based on hard evidence alone. Our preference reflects the default position in most higher-income countries, that of a high-flux, synthetic dialysis membrane. This is based on the putative benefits (improved biocompatibility, greater cardiovascular stability, and improved middle molecule clearance). The widespread uptake of synthetic membranes, along with reduced dialyzer reuse, have greatly reduced unit cost. Similarly, concerns about back-filtration and endotoxemia have been largely obviated by improvements in water quality. In countries where the availability of high-flux membranes remains limited, their use should be preferentially directed to patients with clinical characteristics that were associated with evidence of benefit, namely high cardiovascular risk. The choice between particular synthetic membranes is unlikely to be clinically significant, as any differences are probably small, and this has not been (or is likely to be) compared in head-to-head clinical trials. Finally, we await further clinical trial data pertaining to MCO membranes to assess any role in evidence-based clinical practice.

Evidence for HDF vs. HD

Much of the purported mortality benefit for HDF when compared to HD came from early observational studies [67–71]. These studies mostly compared postdilution HDF, albeit with variably defined effective convection volumes, to either low- or high-flux HD. The studies were heterogeneous in terms of the population studied as well as the type and quality of dialysis provided. As such these are particularly prone to the bias and confounding inherent to observational data, but the majority of these studies showed a mortality benefit for HDF when compared to conventional HD.

The four main RCTs comparing HDF to HD are summarized in Table 40.4 [37, 38, 72, 74]. These studies failed to provide clear answers, but in general did not demonstrate the mortality benefits hypothesized from the early observational trials. However, a consistent trend emerged from the secondary analyses, where a higher convection volume was associated with reduced all-cause and CVD mortality.

A 2015 Cochrane systematic review and meta-analysis included the three main RCTs (CONTRAST, ESHOL, and Turkish HDF), but also trials involving hemofiltration (HF) and acetate-free biofiltration [47] (Table 40.5). In general, the risk of bias was classified as high, resulting in a low level of confidence in the estimated treatment effects.

Convective dialysis probably did not decrease all-cause mortality (11 studies, 3396 participants, RR 0.87, 95% CI 0.72–1.05), although it probably reduced cardiovascular mortality (six studies, 2889 participants, RR 0.75, 95% CI 0.61–0.92). There was evidence that HDF reduced nonfatal cardiovascular mortality, infection related mortality or hospitalization. A reduction in dialysis-related hypotension with convective therapy was reported in one study (906 participants, RR 0.72, 95% CI 0.66–0.80). There was no significant benefit in terms of health-related quality of life, although the evidence was considered of very low quality. Convective therapies significantly reduced predialysis β2-microglobulin and increased dialysis dose (Kt/V urea), but results across the studies were heterogeneous and analysis limited to comparing HDF with HD yielded similar results. In absolute terms, it was suggested that convective therapies may prevent 25 cardiovascular deaths for every 1000 patients treated. In terms of surrogate outcomes there was a small reduction in predialysis β2-microglobulin levels (1813 participants, −5.55 mg/dl, 95% CI −9.11 to −1.98), however there was no evidence that HDF made any difference to predialysis blood pressure.

In a subsequent analysis, pooled individual participant data from the 4 major RCTs, which were designed to examine the effects of HDF on mortality endpoints, was used to study the effects of HDF on mortality outcomes in ESKD [73]. In the overall analysis HDF was associated with a proportional reduction in all-cause mortality by 14% (95% CI 1–24%) and cardiovascular mortality by 23% (95% CI 3–39%). There was no difference in subgroups, such as diabetics, but a closer scrutiny of convection volumes and mortality revealed that the benefit for HDF and all-cause mortality remained significant only in those patients who received convection volumes (>23 l/1.73 m per session [2]). Although this analysis has the advantage of a larger number of patients ($n = 2793$), the original trial issues remain, especially in regard to the differences in achieved convection volumes and HD type, and that these are non-randomized analyses. The major studies and meta-analyses all suggest a mortality benefit if higher convection volumes are achieved. However, the ability to "achieve" high convective volumes may simply reflect a well-functioning arterio-venous fistula, reasonably high blood flow rate, and the absence of major CVD disease. Therefore, patients achieving higher volumes may in fact be "better patients," biasing the high convective group to better outcomes.

Further trials are underway to further evaluate these questions. The CONVINCE trial, which is ongoing in Europe, is a randomized multicenter study involving 1800 patients comparing HDF to high-flux HD, with mortality as the primary endpoint (Netherlands Trial Registry, 7138). Careful attention is being paid to convection volumes, with a prespecified minimum of 23 l per session (body surface area [BSA] adjusted). In the meantime, the concept of "internal convection" has

Table 40.5 Summary of findings: HDF (convective therapies) versus HD (diffusive therapies).

	Hemodiafiltration (convective modalities) therapy versus conventional hemodialysis (diffusive modalities): outcomes of interest				
Outcomes	**No. of participants (studies)**	**Absolute number of patients affected per 1000 patients treated for 1 year (95% CI)**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
All-cause mortality	3396(11)	26 fewer (56 fewer to 10 more)	0.87 (0.72–1.05)	Low ●●○○	HDF has little or no effect on all-cause mortality
Infection-related mortality[a]	2793 (4)	Two fewer (eight fewer to seven more)	0.94 (0.68–1.30)	Very low ●○○○	It is uncertain whether HDF reduces infection-related mortality
Cardiovascular mortality	2889 (6)	25 fewer (39 to 8 fewer)	0.75 (0.61–0.92)	Low ●●○○	HDF may reduce cardiovascular mortality
Nonfatal cardiovascular events	714 (1)	18 more (18 fewer to 64 more)	1.14 (0.86–1.50)	Very low ●○○○	It is uncertain whether HDF reduces non-fatal cardiovascular events
All hospital admissions	1688 (2)	Not estimable	1.21 (0.12–12.05)	Very low ●○○○	It is uncertain whether HDF reduces hospital admissions
Dialysis-related hypotension[b]	906 (1)	Not estimable[c]	0.72 (0.66–0.80)	Low ●●○○	HDF probably reduces the risk of dialysis hypotension
Quality of life	988(8)	Not estimable	Not estimable	Very low ●○○○	HDF/convective therapies have uncertain effects on quality of life
Change in dialysis therapy	2919 (5)	Four fewer (19 fewer to 40 more)	0.87 (0.30–2.52)	Low ●●○○	It is uncertain whether HDF results is a lower cross-over to another dialysis therapy
Residual renal function (RRF)	. . .(..)	..(. . .)	No studies	Absent	No studies found that evaluated the impact of HDF on residual renal function
β2-microglobulin complication: carpal tunnel syndrome	67(1)	Not estimable	Not estimable	Very low ●○○○	It is uncertain whether HDF reduces carpal tunnel syndrome incidence
Adverse events and safety	. . .(..)	..(. . .)	No studies	Absent	No studies found that evaluated the impact of HDF on adverse events and safety

The results where possible are derived from the Cochrane systematic review, Nistor et al. [47]; for some outcomes other systematic reviews are referenced and indicated where relevant.
[a] Metrics from Peters [73], 2016 individual pooled meta-analysis.
[b] Metric described is from Nistor et al. (Cochrane systematic review), but in addition three of four aggregate study meta-analyses also showed a benefit (consistent across all meta-analyses).
[c] Estimate using Maduell et al. [72], events per 1000 patient years suggest a possible reduction by 2585 events per 1000 patient dialysis years (3188–1875 events fewer).

re-emerged with the development of MCO membranes with high K_{uf} values, with high obligatory ultrafiltration and therefore back-filtration rates when used in HD mode. This has some similarities to HDF, but all of the volume transfer occurs within the dialyzer (as ultrafiltration and back-filtration). It has been argued that this approach may well provide many of the benefits of HDF without the need for additional equipment. This of course remains as yet unproven.

International Society Guidelines

It is important to note the HDF is not practiced in the United States and the uptake of HDF has been led by parts of Europe and Japan. Being a comparably novel therapy HDF has not been considered in the Canadian Society of Nephrology Clinical Practice, KDIGO, KDOQI, and KHA-CARI guidelines.

Guideline	Year	Recommendation
Japanese Society for Dialysis Therapy Clinical Guideline [63]	2015	• HDF should enhance the removal of small proteins, reduce the production of inflammatory cytokines, and improve patients' prognoses. • HDF should be considered a therapy for nonspecific symptoms, including itching, joint pain, malaise, and poor appetite. Patients with dialysis hypotension should be considered for treatment with HD using a high-flux dialyzer and ultrapure dialysate.
Renal Association Clinical Practice Guidelines [65]	2011	• Both modalities are effective extracorporeal techniques for established renal failure but hemodiafiltration can provide higher rates of removal of small and middle molecules and may lower the risk of developing complications due to dialysis-related amyloidosis. • We suggest that high-flux HD using ultrapure water provides noninferior patient outcomes to hemodiafiltration.
European Best Practice Guidelines [75]	2007	• To exploit the high permeability of high-flux membranes, on-line HDF or HF should be considered. The exchange volumes should be as high as possible, with consideration of safety.

Conclusion

Despite the putative benefits of high-flux membranes such as improved middle molecule clearance and better biocompatibility, large RCT trails have failed to show a clear mortality benefit with the use of high-flux dialysis membranes. However, secondary analyses revealed a potential benefit in those with diabetes, low serum albumin, and longer dialysis vintage.

The increased adoption of high-flux membranes in the developed world has been driven in part by the presence of these clinical characteristics in many HD patients, as well as decreasing application of dialyzer reuse, which has resulted in a greater scale of manufacturing and decreased costs. Therefore, high-flux membranes are the default choice in most developed countries, but modified cellulosic membranes and low-flux membranes remain in use in many parts of the world and remain an appropriate choice in certain clinical situations.

The choice of dialysis modality remains a controversial topic, and the practice is highly variable across the world. The large treatment benefits of convective therapies seen in early observational studies were not confirmed by subsequent RCTs, although meta-analyses of intervention studies suggest there may be a benefit in relation to cardiovascular mortality and reducing the frequency of intradialytic hypotensive events. Moreover, the hypothesis-generating data suggesting higher convective volumes may be beneficial require further investigation in robust trials.

In summary, in modern dialysis units with ready availability of high-quality dialysis water, synthetic, high-flux dialysis membranes are now the accepted standard. The choice of dialysis modality remains less clear, and for most patients these therapies are likely to be of equivocal clinical benefit. Whilst we believe that HDF should not be routinely offered to all patients, it should be considered in patients with ongoing intradialytic instability and CVD, but only if adequate convection volumes can be achieved.

Introduction

Dialysis is a laborious and expensive process for both patients and healthcare providers. Naturally, all stakeholders are interested in knowing "How much is enough?" The definition of "adequacy" – the necessary amount of dialysis – continues to evolve as our understanding of the impact of dialysis on patient quality of life and survival advances. The initial approach of Scribner and colleagues was to provide sufficient dialysis to alleviate the patient's uremic symptoms [2]. Then, with the observation that urea clearance was associated with survival, the focus shifted to delivering sufficient dialysis to achieve urea clearance targets using a normalized urea clearance formula: Kt/V. More recently, as the limitations of a "urea-centric" approach have become apparent, there has been growing interest in dialysis frequency and duration, and in the preservation of residual renal function. Finally, with an aging dialysis population, in which multimorbidity is the norm, an appreciation of patient goals and quality of life is helping to add nuance to patient–clinician discussions such that they extend beyond biochemical targets and mortality. Our approach in this chapter will be to consider dialysis adequacy as a multidimensional concept, incorporating a comprehensive assessment of the patient's needs, symptoms, and goals, and within which minimum urea-clearance standards provide a useful, but far from definitive, benchmark.

Definition of Dialysis Adequacy: Meets Patient Needs

It is important to distinguish between the narrow definition of adequacy as the "minimum acceptable urea clearance" and the broader concept of the "quantum and quality of dialysis (and associated therapies) that the patient requires." The two are not interchangeable. The former measure – in the form of the urea-reduction ratio (URR) or its normalized derivation (Kt/V) – retains importance as a useful and easily interpretable reference point. The latter recognizes that dialysis performs many functions – clearance of solutes (ranging from 60 to 60,000 daltons in mass) and control of sodium, water balance, and blood pressure – and forms part of a broader suite of therapies that also aim to maintain bone and mineral homeostasis and red blood cell production. No single measurement can combine all of these parameters. Moreover, urea-based adequacy does not consider the broader impacts of dialysis therapy on quality of life or the potential for dialysis-related complications such as access dysfunction or reduction in residual renal function. A true definition of adequacy therefore has to be multidimensional and flexible enough to accommodate differing patient characteristics and goals of therapy.

We propose a hierarchy of needs for dialysis recipients ranging from basic physiological survival to achievement of the best possible quality of life and longevity. Inspired by Maslow [3], this approach places the needs of the patient on

Table 41.1 Assessment of level of evidence for intensity of hemodialysis therapy.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Minimum dialysis hours	If <4 h per session is prescribed in a three times per week schedule, we suggest a comprehensive assessment of adequacy, including rates of volume removal, is performed regularly to avoid under-dialysis.	*Very low*	Weak
Increased dialysis hours	We suggest increasing dialysis hours for willing patients based on evidence suggesting improvements in quality of life, hyperphosphatemia, pill burden, and blood pressure. We suggest that longer hours may also be a useful way to treat patients with high ultrafiltration rate requirements, uncontrolled hypertension, poor phosphate control, and/or to improve some aspects of quality of life.	*High* (hyperphosphatemia, pill burden) *Moderate* (left ventricular hypertrophy) *Low* (quality of life, blood pressure control)	Weak
Dialysis frequency	We suggest that more frequent dialysis sessions (four to six per week) be offered to patients wishing to improve blood pressure, improve serum phosphate or reduce pill burden. It may also be recommended in patients with left ventricular hypertrophy and may have small benefits for some aspects of quality of life. Patients taking on this therapy should be advised of the possible risks of increased vascular access events and more rapid loss of residual renal function.	*Moderate to high* (hyperphosphotaemia, pill burden) *Moderate* (blood pressure, left ventricular hypertrophy) *Low* (quality of life, vascular access events and residual renal function)	Weak
Targeting urea clearance	We recommend achieving at least an spKt/V of 1.2. We suggest that this *not* be used as the primary measure of dialysis adequacy.	*Low*	Weak
Limiting volume Removal	We suggest targeting ultrafiltration rates below 10 ml/h/kg.	*Very low*	Weak
Incremental dialysis	We suggest that incremental dialysis be undertaken only within a structured program including regular reassessment of residual renal function and dialysis adequacy.	*Very low*	Weak

GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

a continuum (Figure 41.1). Adequacy of dialysis therapy is then judged from the patient perspective in relation to the degree to which these needs are met. This schema aims to encourage clinicians to go beyond urea clearance by focusing on biological parameters known to be associated with improved patient outcome and on a patient-centered concept of wellbeing. In general, "more" dialysis – whether increased frequency or duration – may be helpful for many patients in achieving higher-level needs but cannot be considered "adequate" without reference to the individual patient.

Epidemiology

The number of individuals receiving renal replacement therapy is growing steadily, it is expected to reach 3.8 million in 2020 and rise to 5.4 million by 2030 [4]. This burden is not distributed equally and rates of dialysis and transplant uptake vary dramatically around the globe, from over 2000 per million population in Japan to as low as 2.8 per million population in Rwanda [5]. These figures are also likely to hide as many as 9.7 million individuals with ESKD who are unable to receive renal replacement therapy due to resource limitations [4]. For those fortunate enough to have access to dialysis, hemodialysis is the dominant modality, with the proportion of dialysis delivered as hemodialysis estimated to be 89% in 2013 [6]. This also varies from region to region, with the proportion on hemodialysis being as low as 20.6% in Hong Kong and greater than 99% in some countries [7].

Three sessions per week is near universal in high-income countries, with less than 5% of patients receiving

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Figure 41.1 Hierarchy of needs for the hemodialysis patient.

two or fewer sessions per week [8]. More frequent dialysis is also uncommon, although its prevalence varies from 14% in Sweden to <1% in the United States, Japan, and France [8]. In contrast, in 2011 up to 26% of patients in China were dialyzing twice weekly [9]. Although accurate data is lacking, twice-weekly dialysis is believed to be common practice in many low- and middle-income countries. Average session length also varies globally, with the mean value in most countries lying between 3.5 and 4 hours [8–10]. Other differences in dialysis delivery should be noted, with high-income countries typically providing high-flux dialysis with no dialyzer reuse. In contrast, low-flux dialysis and dialyzer reuse is common in many middle-income countries [11]. This is likely to contribute to poorer outcomes in these countries, although the relative impact of these practices on morbidity is not well described.

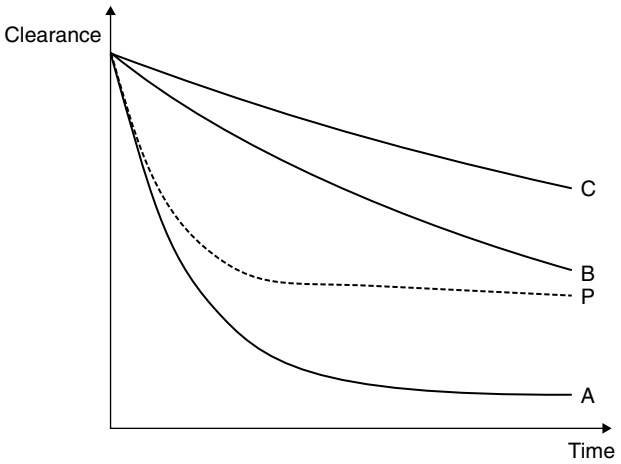

Figure 41.2 Clearance vs. time curves for solutes during a single dialysis session. A represents small solute clearance (e.g. urea). B and C represent larger solutes of varying weight (e.g. middle molecules). P (dashed line) represents clearance of a sequestered small solute (e.g. phosphate).

Pathophysiology

In high-income countries, where the use of high-efficiency and high-flux dialyzers is now standard, the question of dialysis adequacy is essentially a discussion of the relationship of solute and water clearance with dialysis time and frequency. Detailed discussion of dialyzer characteristics and the impact of blood and dialysate flow rates can be found elsewhere [12] and is beyond the scope of this chapter.

Figure 41.2 demonstrates the relationship between rate of solute clearance on dialysis and dialysis session time. It illustrates the three concepts central to understanding the prescription of dialysis time and frequency:

1) Solute clearance is greatest at the start of dialysis when the concentration gradients are highest [12]. For this reason, more frequent dialysis sessions (e.g. six vs. three times per week) allow more time on the steepest part of the removal curve, increasing small solute clearance even if total dialysis time remains the same [13].
2) As solute size increases, the rate of diffusion decreases. Thus, as solute size increases the concentration gradient

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

between blood and dialysate changes less rapidly, leading to greater "gain" in clearance from longer sessions. As a result, total dialysis time is more important than frequency for middle-molecule clearances.

3) "Sequestered" solutes display a biphasic clearance. Initially, the rate of clearance from the first compartment (blood or extracellular space) may decline relatively rapidly as the concentration gradient diminishes. This is followed by the mobilization of solute from secondary compartments which maintains the concentration gradient between blood and dialysate, and leads to a second phase of clearance in which the rate of clearance is maintained over the later hours of the dialysis session. The classic example of this phenomenon is phosphate. Up to four compartments have been proposed to adequately model intradialytic phosphate clearance [14, 15]. In all models, the initial clearance from the blood compartment is rapid, but beginning in the second hour of dialysis the rate of clearance plateaus as sequestered solute is mobilized from less accessible compartments. The result is that phosphate clearance can be improved with both increased session frequency (maximizing the time with rapid clearance) and increasing dialysis time (as clearance does not diminish over longer dialysis sessions).

Water "clearance" – i.e. ultrafiltration – is distinct from other parameters. The rate of ultrafiltration required to maintain euvolemia is determined by fluid intake, urine output, and the interaction between dialysis frequency and session length. More frequent sessions minimize fluctuations in volume status and longer sessions permit slower rates of ultrafiltration. Both large intradialytic weight gain and rapid ultrafiltration are associated with increased morbidity and mortality [16, 17]. Increasing session length (if frequency remains the same) tends to reduce the rate of ultrafiltration. Increasing session frequency (if total dialysis hours remains the same) may reduce the size of intradialytic weight gain (Figure 41.3).

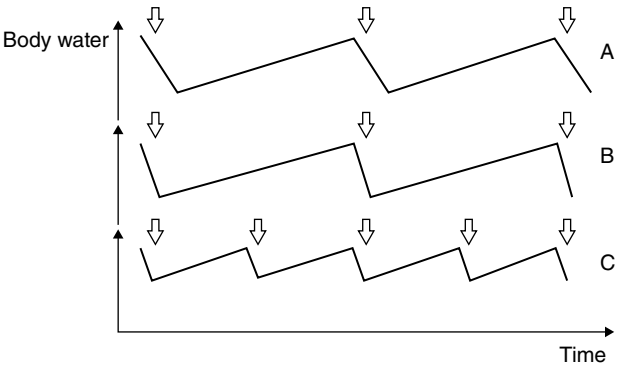

Figure 41.3 Pattern of volume changes with different dialysis schedules. (A) Thrice weekly 8 hours, (B) thrice weekly 4 hours, (C) frequent dialysis 2.4 hours × five sessions per week. Arrows indicate dialysis sessions.

Diagnosis

Dialysis therapy must be tailored to fit the patient. This requires a thorough exploration of the patient's symptoms, nutritional status, cardiovascular risk, and fluid status, bone, and metabolic health and, equally important, their goals, functional limitations and supports. Hence, assessment of adequacy requires a thorough clinical assessment *and* a frank discussion about patient expectations of treatment. We present here an indication of the information required to facilitate an adequacy assessment. An introduction to principles of urea kinetic modeling (UKM) is also provided as this remains a useful component of the adequacy assessment.

Comprehensive Clinical Assessment

The comprehensive clinical assessment should include the following:

1) Symptoms
   a) Uremic symptoms, such as nausea, poor appetite, pruritis, and restless leg syndrome.
   b) Symptoms of over- or under-hydration, including dyspnea, edema, thirst, and orthostatic dizziness.
   c) Adverse symptoms of dialysis, including cramps on dialysis and post-dialysis fatigue.
   d) Common comorbid symptoms, such as pain, disturbed sleep, and limitations to mobility
2) Physical examination
   a) Volume status and blood pressure
   b) Access assessment
3) Dialysis parameters
   a) Ideal body weight and interdialytic weight gain
   b) Pre- and postdialysis blood pressure
   c) Kt/V urea
4) Laboratory parameters
   a) Small solute clearance: urea, creatinine, potassium
   b) Anemia: hemoglobin, ferritin, and iron-binding capacity
   c) Volume status: sodium
   d) Nutrition: albumin, bicarbonate
   e) Bone and mineral disorder: phosphate, calcium, parathyroid hormone, alkaline phosphatase

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

5) Medication review
   a) Avoid overprescribing and consider pill burden
6) Cardiovascular assessment
   a) Consider screening for left ventricular hypertrophy
7) Functional status
   a) Multiple standardized measures of function and frailty exist, including the Karnovsky Performance Score or Clinical Frailty Scale [18]. Simple tests such as the Timed Up and Go may also be effective screening tools [13].
8) Social environment and supports
   a) Understand the patient's social environment and the demands on their time that may conflict with dialysis (e.g. employment, training, caregiver). Consider the needs of the patient's caregivers. Patient and caregiver responsibilities may heavily influence the choice of dialysis frequency and session length.
9) Goals and expectations
   a) What does the patient wish to achieve with dialysis therapy? What are their goals and how do they prioritize those goals? For instance, do they wish to receive a kidney transplant? Is dialysis aimed to extend life expectancy? To maximize their function? To spend time with family or friends? To enable travel and flexibility? Are their (and their family's or carer's) expectations of hemodialysis realistic?

Urea Kinetic Modeling

UKM refers to mathematical modeling that approximates the observed clearance of urea during one or more dialysis sessions by relating basic patient characteristics, such as urea generation and total body water, with parameters of dialysis therapy, such as time, dialysate flow rate, and dialyzer urea clearance. The field developed with the understanding that simply targeting low blood urea levels did not always result in better patient outcomes as low blood urea levels often reflected poor nutrition rather than adequate dialysis [19]. The details of modern UKM are beyond the scope of this chapter and quickly exhaust the patience of many physicians. Fortunately, as many excellent resources exist for those wanting a deeper understanding of the topic [7], we will focus attention mainly on the key concept of Kt/V_{urea} and the evidence supporting its current role in dialysis prescription.

Kt/V

The most commonly used marker of small molecule clearance is Kt/V, where:

K = dialyzer urea clearance (ml/min) (a function of dialyzer surface area and permeability, and blood and dialysate flow rates)

t = dialysis time (min) (hence, Kt represents the volume (ml) of plasma cleared of urea during the dialysis session)

V = postdialysis volume of distribution of urea (ml) (equivalent to total body water)

The advantage of this formula is that it is not dependent on absolute levels of blood urea, and therefore is independent of nutrition. Rather, as dialyzer urea clearance is a general surrogate for dialytic clearance of many small molecules, it represents a generalizable dialysis parameter. In choosing a dialyzer with known characteristics, dialysate and blood flow rates and treatment time, one can specify a desired Kt/V. UKM computer programs are available that facilitate this calculation.

In practice, owing to access recirculation and the error involved in the multiple assumptions underlying the model, prescribed Kt/V often differs substantially from the actual "delivered" Kt/V. Delivered Kt/V is therefore the key value to aid in adequacy assessments. Values below target should prompt titration of the variable parameters (for instance an increase in dialyzer size or session time) to increase clearance (consideration of access recirculation may also be warranted), with improvement confirmed by subsequent testing of the delivered Kt/V.

Single-pool *Kt/V*

In its simplest form, Kt/V is calculated assuming that urea is distributed evenly through one fluid compartment and is known as a single pool, or spKt/V. The most widely used equation to calculate delivered spKt/V is that of Daugirdas [12]:

$$\mathrm{sp}Kt/V = -\ln\left(U_{\mathrm{post}}/U_{\mathrm{pre}} - 0.008\times t\right) + \left(4 - 3.5\times U_{\mathrm{post}}/U_{\mathrm{pre}}\right) \times V_{\mathrm{uf}}/\mathrm{weight}$$

where U_{post}/U_{pre} is the ratio of postdialysis to predialysis urea, t is the treatment time in hours, Vuf is the ultrafiltration volume, weight is bodyweight in kilograms, and ln is the natural logarithm.

This equation has the advantage of including ultrafiltration volume (hence convective urea clearance) and intradialytic urea generation. It is validated between Kt/V values of 0.7 and 2.1 [20].

Equilibrated *Kt/V*

The assumption of a single pool of urea is an oversimplification, as demonstrated by the fact that blood urea levels rapidly rebound after dialysis is completed. This means that spKt/V overestimates urea clearance. To account for this, equilibrated, or eKt/V can be calculated, either by taking a second urea sample 35 minutes after the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

completion of the dialysis session or by modifying spKt/V using a conversion equation shown to reliably approximate measured eKt/V [8]:

$$\mathrm{e}Kt/V = \mathrm{sp}Kt/V \times \left(t/t+35\right)$$

where t is dialysis time in minutes.

Standard *Kt/V*

Standard Kt/V (stdKt/V) was devised to permit comparisons between dialysis regimens of different frequency or with peritoneal dialysis. The modeling equations utilize the pre- and postdialysis blood urea, and dialysis and patient parameters over a 1-week period to estimate the urea clearance required to maintain those values in a steady state. A number of different modeling equations are available to estimate stdKt/V, some of which incorporate residual renal function and/or convective urea clearance [9, 10]. StdKt/V is most important if patients receive incremental hemodialysis (less than three times per week) as an aid to the up-titration of dialysis in line with loss of residual renal function.

Urea Reduction Ratio

URR is the simple ratio of the change in urea during dialysis to the predialysis urea level (conventionally expressed as a percentage):

$$\mathrm{URR} = \left(U_{\mathrm{pre}} - U_{\mathrm{post}}\right)/U_{\mathrm{pre}} \times 100$$

(This is sometimes written as the equivalent formula URR = 1 – ($U_{\mathrm{post}}/U_{\mathrm{pre}}$).)

URR is related exponentially to Kt/V such that, as Kt/V rises, further large increases result in only small changes in URR. For example moving Kt/V from 1.5 to 2.0 results in an increase in URR from 73% to 82%. While simpler, it does not account for urea clearance due to ultrafiltration, nor the generation of urea during the dialysis session. Despite these limitations, observational evidence suggests that URR predicts outcomes similarly to Kt/V and it remains a part of current treatment guidelines [21].

Caveats in Interpreting *Kt/V*

It is important to be aware of the risk of under-dosing by Kt/V in smaller patients, such as women and children, in whom the lower value of V may lead to the prescription of shorter dialysis sessions, smaller dialyzers, or slower blood or dialysate flows. The risks of this were emphasized by in the HEMO trial, in which women randomized to the "standard" Kt/V target had a higher mortality than those in the "high" Kt/V arm [22]. Conversely, patients with higher body fat, in whom V overestimates total body water will tend to require increased dialysis dosing to achieve target Kt/V. This has been speculated to contribute to the observed survival benefits of higher body fat in hemodialysis recipients [23].

Conductivity-based measures of Kt/V are now available on many dialysis machines. These operate by manipulating the sodium concentration of the inflowing dialysate in a controlled fashion and measuring the resulting differences in electrical conductivity between the inflowing and outflowing dialysate. This provides a ready measure of small molecule clearance that can be used as a surrogate for urea clearance and therefore Kt/V. While correlated with urea-based Kt/V, conductivity measures tend to underestimate Kt/V and within-patient variation may be high [24, 25]. Given these limitations and the lack the clear observational and randomized controlled trial data to support their use, conductivity measures should be supplemented by periodic urea-based estimates of delivered Kt/V.

Assessment of Residual Kidney Function

Residual kidney function (RKF) is associated with quality of life [26] and lower mortality [27, 28]. This is thought to be due to the continuous provision of both small and middle molecular clearance and the beneficial impact on mineral metabolism and smoothing of fluid status fluctuations. Assessment of RKF typically plays little part in the prescription of hemodialysis, with most patients commencing a three times per week schedule from the initiation of dialysis [29]. This approach, essentially treating RKF as "bonus" clearance that does not require further consideration, has been challenged due to the observation that more frequent dialysis may be associated with more rapid loss of renal function [30].

Measurement of RKF is hampered by the fact that small solutes fluctuate with each dialysis session, that glomerular filtration is not constant in the interdialytic interval [31], and that extrarenal clearance (e.g. gastrointestinal) is not well-understood or quantified [32]. Optimal measurement demands urine collection over the entire (e.g. 44-hour) interdialytic interval. Creatinine-based measurements tend to overestimate RKF owing to tubular creatinine secretion, whereas urea-based measures underestimate it due to passive reabsorption of urea in the distal tubules.

Multiple methods of assessing RKF exist. Residual urea clearance (K_{ru}) can be reasonably approximated in a patient performing three sessions per week using a 24-hour urine collection commencing the day prior to a mid-week dialysis session using the following formula:

$$K_{\mathrm{ru}} = \frac{U_{\mathrm{urine}}}{U_{\mathrm{serum}} \times 0.9} \times \text{urine flow rate}\left(\mathrm{ml/min}\right)$$

where 0.9 is a factor that adjusts the predialysis serum urea value to approximate the mid-week mean [31].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

An alternative is to estimate RKF by the average of K_{ru} and K_{rCr} (residual creatinine clearance), utilizing the fact that the former underestimates and latter overestimates true RKF. Some authors, however, recommend relying only on K_{ru} on the understanding that the underestimate results in an assumed "buffer" providing a modicum of safety from under dialysis [33].

Prognosis

Longer treatment times are associated with longer life expectancy. Using data from 12 countries, Tentori et al. demonstrated an average reduction in risk of mortality of 6% for every 30 minute increase in session length [34]. The reasons for this finding are not clearly understood. Higher Kt/V may be one factor, but owing to the kinetics of small solute clearance the increase in Kt/V with increased time steadily diminishes as session length increases (c.f. Figure 41.2). Indeed, the observed mortality relationship is lost above Kt/V of approximately 1.3 [35]. Other factors are clearly important.

Observational studies have shown a dose-related increase in mortality with increasing ultrafiltration rates [16, 17]. For example, a 22% increase in mortality in those with rates >10 ml/h/kg (vs. ≤10 ml/h/kg) and a further 31% increase in those with rates >13 ml/h/kg (vs. 10–13 ml/h/kg) [36]. The benefits of slower ultrafiltration are hypothesized to stem from lower incidence of intradialytic hypotension and the myocardial strain associated with dialysis [37]. Other potential benefits include preservation of RKF, which in itself is clearly associated with improved prognosis [28]. Furthermore, increased session length is associated with lower phosphate levels, which are consistently associated with lower mortality [38].

Other prognostic factors that might impact on adequacy assessment are hypertension and fluid overload. The association with fluid overload is consistent. Studies utilizing bioimpedance spectroscopy have shown fluid overload (both pre- and postdialysis) to be positively associated with mortality [39, 40]. The relationship between hypertension and mortality in the ESKD population is the subject of substantial debate. Observational studies suggest a U-shaped association, with marked increases in mortality with low (<130/70 mmHg) predialysis systolic and diastolic blood pressure, and less pronounced increases with systolic blood pressure >180 mmHg [41]. Confounding by cardiovascular disease is likely to contribute to this phenomenon. Interdialytic blood pressure is poorly correlated with predialysis values and may display a different (more traditional) relationship with mortality. This uncertainty aside, current practice remains to treat hypertension in hemodialysis patients and the beneficial impact of improved fluid control and increased dialysis frequency or duration on blood pressure (see below) should be included in assessment of dialysis adequacy.

Treatment

Evidence Behind the Current Guidelines

Current guidelines are derived from the results of two pivotal clinical trials: the National Co-operative Dialysis Study (NCDS) and the HEMO study (Box 41.1). The NCDS, published in 1981, sought to determine if lower time-averaged urea levels were superior to higher, and if 3 vs. 4.5 hours was superior [42]. The time averaged urea (TAC_{urea}) targets of 50 vs. 100 mg/dl (18 vs. 36 mmol/l) were approximately equivalent to predialysis urea levels of 70 and 120 mg/dl (25 vs. 43 mmol/l). Patients with residual creatinine clearance greater than 3 ml/min were excluded. The study was terminated early as participants in the high TAC_{urea} arm had a higher incidence of death, withdrawal from dialysis, and hospitalization. There were no significant differences between those assigned to 3 vs. 4.5 hours of dialysis. Subsequent criticism of the study focused on the fact that the use of urea concentration as the treatment target was likely to have led to participants with a higher protein intake to be prescribed higher dialytic clearance compared to participants in the same arm of the study with a lower protein intake. This resulted in divergent outcomes depending on nutritional status, with little between-group separation in delivered dialysis clearance in those with low protein intake and a large difference for those with a higher protein intake. To account for this, Gotch and Sargent developed Kt/V as a way to measure dialysis dose independently of protein catabolic rate [19]. Their reanalysis of the NCDS data established that good clinical outcomes were associated with $Kt/V > 0.8$. Further work increased this cut-off value to 1.0 and observational data suggested that outcomes continued to improve above this value [43, 44]. The resulting uncertainty as to the optimal dose (based on Kt/V) led to the development of the HEMO study.

The HEMO study, published in 2002, randomized participants in a factorial design to high or low flux membrane and a higher or lower dialysis dose by Kt/V [22]. The low and high Kt/V arms achieved an spKt/V of 1.32 ± 0.09 (eKt/V 1.16 ± 0.08) and 1.71 ± 0.11 (eKt/V 1.53 ± 0.09), respectively; approximately equal to a URR of 65–75%. The study found no difference in mortality with dialysis dose (or flux): relative risk (high vs. standard) 0.96 (0.84–1.10, $P = 0.53$) and, for high vs. low flux, 0.92 (0.81–1.05, $P = 0.23$). Nor were there differences in hospital admissions. The

higher Kt/V was achieved not only by increasing treatment time (average 219 vs. 190 minutes) but also by a 20% increase in blood flow rates and small increases in dialyzer size and dialysate flow rates. As such, the results cannot be generalized to include increasing Kt/V while holding dialyzer size and flow rates the same, either by increased dialysis time or by increasing standardized Kt/V by increasing dialysis frequency. During screening, patients had to be able to achieve an eKt/V of at least 1.30 during a 4.5 hour session in order to enter the study. Due to the difficulty of achieving high Kt/V in large patients, only 3% of participants were greater than 100 kg, thus also limiting the generalizability to larger patients. The study also excluded those with a residual urea clearance of greater than 1.5 ml/min per 35 l urea volume and 67% of participants were anuric. Compared to the standard-dose group, women in the high-dose group had a 19% lower relative risk of mortality, but men had a 16% higher relative risk of mortality.[1] Differences in body size and composition have been postulated to explain these findings and no further randomized studies are available to clarify them.

Increased Dialysis Frequency and Session Length

The "un-physiological" nature of thrice weekly intermittent hemodialysis has always been recognized and is elegantly demonstrated by the clear peak in mortality at the end of the long 2-day break in patients on standard thrice weekly dialysis routines [45]. Yet, the randomized trials of different urea clearance targets have been limited to thrice weekly dialysis with session times reaching a maximum of 4.5 hours (the mean value in the high dose HEMO arm was 4 hours, 9 minutes) [22, 42].

Observational evidence clearly favors longer sessions. Dialysis times ≥4.5 hours and $Kt/V \geq 1.3$ are associated with lower mortality [46]. Saran et al. demonstrated that (after adjustment for confounders including Kt/V measured urea clearance) each 30 minute increase in dialysis time was associated with a 7% relative risk reduction in all-cause mortality [47]. They also observed a synergistic association between Kt/V and dialysis time, where the mortality benefit of increased Kt/V was amplified at longer dialysis times, although this interaction has not been observed in all studies [46]. A meta-analysis of observational studies concluded that, compared with conventional hemodialysis, home nocturnal dialysis (hazard ratio [HR] 0.46, 95% CI 0.38–0.55), in-center nocturnal dialysis (HR 0.73, 95% CI 0.60–0.90), and home short daily dialysis (HR 0.54, 95% CI 0.31–0.95) all provide substantial mortality benefits [48]. The observed benefits of longer dialysis times may be in part due to slower ultrafiltration, with ultrafiltration rates <10 ml/kg/h being associated with lower mortality and lower cardiovascular morbidity, presumably due in part to the deleterious effects of intradialytic hypotension [16, 36, 47]. Despite this, the possibility of residual confounding limits any conclusions regarding mortality based on observational data. Indeed, concern has been raised regarding frequent short daily in-center dialysis with an increased mortality seen in a propensity matched cohort study (HR 1.6, 95% CI 1.1–2.3) [49].

Between 2007 and 2017, a series of small, but important randomized trials of more frequent or extended hours dialysis (the findings of which are summarized in Table 41.2) have been published. The first three trials focused on dialysis frequency and compared five or six times per week to thrice weekly hemodialysis, with the Frequent Hemodialysis Network (FHN) Daily study utilizing short dialysis sessions (1.5–2.75 hours) [50] and the Culleton et al. [51] and the FHN Nocturnal [52] studies utilizing sessions of at least 6 hours in length. In contrast, the ACTIVE Dialysis trial compared total weekly dialysis hours of ≥24 hours (mostly delivered in three 8-hour sessions) to a standard regimen of ≤18 hours per week (delivered in three sessions) [53]. All studies were small (totaling 584 participants) and lasted no longer than 12 months. All demonstrated a reduction in left ventricular mass, although this was significant only in the Culleton et al. and FHN Daily studies. There were clear reductions in two important surrogate endpoints: serum phosphate and systolic blood pressure, with associated reductions in the need for phosphate binders and antihypertensives. Quality of life measurements were also stable or improved in the frequent or extended hours dialysis groups [50–52, 54].

Long term follow-up data is available for the FHN trials and provides conflicting signals. After a median follow-up of 3.6 years, the risk for mortality in the frequent in-center hemodialysis group of the FHN Daily trial was almost half that in the conventional group (HR 0.54 [95% CI 0.31 to 0.93, $P = 0.024$]) [55]. In contrast, in long-term follow-up of the 87 participants of the FHN Nocturnal trial, an increased risk of mortality was observed in the frequent home dialysis group (HR 3.88 [95% CI 1.27–11.79, $P = 0.01$]) [56]. Both results, the latter in particular, should be interpreted with caution owing to the small number of events in each arm. The potential harms of frequent dialysis could include an increase in dialysis-related myocardial stunning [37] or cerebral ischemia (which is not simply predictable from blood pressure and is associated with cognitive dysfunction) [57]. As such, the long-term impact of frequent dialysis remains unclear.

The FHN Daily trial identified a number of negative effects of frequent dialysis. A nonsignificant increase in the number of vascular access interventions (HR 1.35 [95% CI 0.84–2.18, $P = 0.22$]) was noted, which was significant when time to first access intervention was examined (HR 1.71, 95%CI 1.08–2.73) [50]. A similarly significant increase in the risk of vascular access failure or intervention was seen in the FHN Nocturnal trial (HR 1.88 [95% CI 0.97–3.64, $P = 0.06$]) [52]. No significant differences in vascular access complications were noted in the Culleton et al. or ACTIVE trials [51, 53]. The impact of frequent dialysis on residual renal function was examined in both the FHN Daily and Nocturnal trials with an increase in incident anuria (i.e. loss of residual renal function) seen in the Nocturnal trial (relative risk [RR] 1.83, $P = 0.06$) but not in the Daily trial (RR 1.11, $P = 0.99$) [30]. Caregiver burden also emerged as a consideration in the FHN Nocturnal trial, where a trend toward increased perceived caregiver burden (as measured by the Cousineau scale) was identified (6.1 [95% CI −0.8 to +13.1, $P = 0.08$]). No such trend was evident in the FHN Daily trial [58].

Incremental Dialysis

There is growing interest in a gradual approach to dialysis initiation. This is informed by the knowledge that RKF typically remains substantial when dialysis is initiated and the obvious corollary that patients might therefore require less dialysis in the early months and years after commencing dialysis. Moreover, observational studies suggest that twice-weekly dialysis is associated with preservation of RKF [59]. The hypothesis that more dialysis accelerates loss of RKF was strengthened by the results of the FHN trials in which participants assigned to frequent dialysis suffered a greater decline in RKF and/or urine volume [30]. When these observations are coupled to the well-described association between RKF and survival in hemodialysis patients [27, 28], the argument for incremental exposure to dialysis appears compelling.

However, the observational evidence (including both prospective and retrospective studies) has proven conflicting. While similar survival between twice weekly/incremental dialysis and standard thrice weekly has been demonstrated in multiple studies [60–63], residual confounding may explain many of these findings and an increase in mortality has also been observed in other studies. For example, a prospective study involving 685 participants found a fourfold increase in mortality in adjusted analysis among patients with RKF undergoing twice weekly dialysis compared to those undergoing three-times weekly dialysis (HR 4.20 [95% CI 1.02–17.32, $P = 0.04$]) [64]. A larger retrospective study in the United States compared 351 incremental dialysis patients to 8068 matched patients (including matching by RKF) and found equivalent mortality in those with baseline RKF > 3.0 ml/min/1.73 m^2 (HR 0.99, 95% CI 0.76–1.28) but increased mortality in those with ≤3.0 ml/min/1.73 m^2 (HR 1.61, 95% CI 1.07–2.44) [65]. These studies highlight the potential risks involved with incremental dialysis, especially in patients with minimal residual renal function (e.g. urea clearance <3 ml/min/1.73m^2, urine volume <600 ml/day) and emphasize that a well-structured program with clear patient understanding is necessary for such a program to be implemented. Future randomized controlled trials are required to ascertain the benefits and safety of this approach.

Summary of Findings

The evidence base for dialysis dosing is limited, with no high-quality systematic reviews published that include all

Box 41.1 Current Guideline Positions

The most recent Kidney Disease Outcomes Quality Initiative (KDOQI) guidelines for Hemodialysis Adequacy: 2015 Update [21] incorporate the long-term follow-up data from the FHN studies and the findings of the ACTIVE Dialysis trial.

KDOQI guidelines recommend a per session sp*Kt/V* target of 1.4 with a minimum delivered *Kt/V* of 1.2. For patients on more or less frequent dialysis the recommended target std*Kt/V* is 2.3 with a delivered std*Kt/V* of 2.1 (using an equation that considers ultrafiltration and residual renal function). A minimum time per session of 3 hours is recommended for those with minimal residual renal function. They also suggest that dialysis dose may be reduced in the presence of significant residual renal function, provided this is measured regularly (ungraded).

They suggest that patients be offered short frequent dialysis (<3 hours, five to seven sessions per week) or long duration dialysis (defined as 6–8 hours, three to six sessions per week) after considering individual patient preferences and the potential benefits of these therapies. It is recommended that the potential risks be discussed prior to commencing such therapies. Increased dialysis should be considered in the presence of difficulty controlling interdialytic weight gain, blood pressure, volume overload, or metabolic parameters such as hyperkalemia, hyperphosphatemia, or metabolic acidosis (ungraded).

recent studies. Observational evidence suggests that longer sessions and slower rates of ultrafiltration are associated with lower mortality. A single randomized trial has demonstrated that targeting a higher urea clearance (*Kt*/*V*) does not improve mortality, but this trial does not address the question of longer hours or more frequent sessions (than the standard 3.5–4 hours three times per week). A number of small studies demonstrate clear benefits of more frequent or extended hours on the surrogate endpoints of blood pressure and serum phosphate. They also suggest that such regimes may reduce left ventricular hypertrophy. Importantly, these gains were achieved while maintaining or improving quality of life. However, conflicting results have been observed on long-term mortality. Concern has been raised about loss of residual renal function with frequent dialysis and a possible increase in vascular access complications. No randomized trials are available to inform the use of RKF in dialysis prescription.

Conclusion

Dialysis adequacy must be assessed on an individual basis with patient needs being defined in line with patient goals and circumstances. We suggest that the KDOQI guidelines form part of an adequacy assessment, but emphasize that they are insufficient alone. We suggest, based on observational evidence, a minimum dialysis time of 4 hours for patients dialyzing three times per week. This is likely to be insufficient for many patients and increasing dialysis hours (or frequency) will typically be required to achieve patient needs. We recognize that important questions, such as the level of phosphate or blood pressure required to avoid death or morbidity, remain unanswered. Further research is required to define optimal surrogate endpoints (with reference to clinical events and patient-centered outcomes) as this will allow more informed goal-setting on the part of patients and clinicians.

Notes

1 This interaction was not significant after Bonferroni correction for multiple testing.
2 $N = 95$.
3 Effect estimates are adjusted for baseline characteristics (chosen as primary analysis by study authors).
4 Median change in frequent vs. standard groups ($P = 0.05$).

Introduction

The care of a hemodialysis (HD) patient is typically provided in a multidisciplinary setting that includes nurses, dieticians, pharmacists, social workers, and nephrologists. It traditionally focuses on the adequacy of small solute clearance (Chapter 41), vascular access (Chapter 44), anemia (Chapter 33), and mineral bone disorders (Chapter 36). This chapter is dedicated to other important issues related to the optimal care of hemodialysis patients, including potassium, acidosis, blood pressure control (hypertension [HTN] and intradialytic hypotension [IDH]), nutrition, and cardiovascular (CV) disease. It summarizes the available evidence relevant to these general aspects of the management of the HD patient.

Potassium Metabolism

The general principles of the assessment and treatment of disorders of potassium metabolism (hypokalemia and hyperkalemia) are detailed in Chapter 60. The specific problem of potassium as it relates to patients on HD is discussed in this chapter.

Prevalence and Outcomes of Hyperkalemia

Hyperkalemia is common among HD patients. In a prospective observational study from France, the proportion of patients with a serum potassium >5 mmol/l, >5.5 mmol/l, or >6 mmol/l at any time was 73.8%, 57.9%, and 34.5%, respectively. Not surprisingly, hyperkalemia is 2.0–2.4 times more prevalent on the day of the long interdialytic interval compared to short intervals due to dietary intake and impaired renal clearance despite enhanced gastrointestinal and salivary clearances in HD patients [1]. Higher dietary potassium intake is associated with increased mortality in dialysis patients even when adjusted for its association with increased energy and protein intake as well as other nutritional parameters. However, higher vegetable intake, often considered the primary source of potassium, was associated with lower mortality in a more recent, large study [2, 3]. Other contributors to hyperkalemia in HD include acidosis as well as several medications including renin-angiotensin-aldosterone system (RAAS) inhibitors, beta-blockers, heparin, and nonsteroidal anti-inflammatory drugs.

In chronic kidney disease (CKD), there is a U-shaped association between serum potassium and mortality [4]. In HD, hyperkalemia, defined as a serum potassium of 6–6.5 mmol/l compared to normal values, is associated with an increase in hospitalization and mortality regardless of the day of the week, while a serum potassium of 5.5–6 mmol/l is associated with adverse outcomes following the long dialytic interval [5]. In the analyses of the Dialysis Outcomes and Practice Patterns Study (DOPPS) data, sudden death due to arrhythmia, cardiac arrest or hyperkalemia was associated with lower dialysate potassium, including both <1.5 and 2–2.5 meq/l compared to >3 meq/l [6], suggesting that large intradialytic potassium shifts may be harmful from a CV perspective. However, a dialysate potassium of 1 meq/l in individuals with predialysis potassium >5.5 mmol/l was protective against mortality in an adjusted Cox proportional hazards model [7]. The heterogeneity of results across large observational studies challenges any determination of the

Table 42.1 General management of the hemodialysis patient.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Management of hyperkalaemia	We suggest adherence to a low potassium diet, ensuring adequate dialysis prescription, prescribing a dialysate potassium of 1–4 mmol/l depending on predialysis potassium levels, and correcting acidosis	Very low	Weak
Management of metabolic acidosis	We suggest using a dialysate bicarbonate of 22–24 mmol/l and using bicarbonate rather than acetate as the form of base delivery	Very low (bicarbonate dialysate concentration) and moderate (use of bicarbonate vs. acetate)	Weak (bicarbonate concentration) and weak (bicarbonate vs acetate)
Avoidance of intradialytic hypotension	We suggest that increasing dialysis session time may reduce the risk of intradialytic hypotension. In addition, cooled dialysate, prescription of midodrine, sodium profiling and the use of biofeedback may also be used.	Moderate (increasing session time) Low (cooled dialysate, sodium profiling, use of biofeedback) Prescription of midodrine (very low)	Weak
Hypertension measurement and targets	We suggest using self- home recorded BP or ambulatory BP monitoring to guide treatment rather than measures pre or post dialysis BP where possible, but it is difficult to recommend target BP in this population based on current evidence	Low	Weak
Hypertension treatment	We suggest reducing target weight and using antihypertensive agents, and that the selection of antihypertensive agents should be guided by other comorbidities and tolerance	Low	Weak
Lipid-lowering agents	We recommend not initiating lipid-lowering therapy with a statin or ezetimibe in patients receiving HD	High	Strong
Nutrition	We suggest assessing nutritional status by using a measure such as subjective global assessment and managing malnutrition by treating the underlying cause, ensuring adequate dialysis and increasing nutritional intake. We suggest generally using oral nutrition with or without supplements, but parenteral or intradialytic therapies may be considered.	Low	Weak

GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

degree to which hyperkalemia itself, rather than the numerous other behavioral and health issues correlated with hyperkalemia, is causative of increased mortality.

Management of Hyperkalemia

There is very little evidence guiding when and how to treat hyperkalemia to reduce the risk of death and the strength of current recommendations is weak (Table 42.1). Randomized controlled trials (RCTs) testing treatment strategies vary in terms of how they define hyperkalemia and rarely measure the degree to which treatments reduce the risk of mortality or other patient-important outcomes. Rather, this body of literature examines the degree and rapidity with which serum potassium is reduced. Whether and how urgently to institute treatment is largely guided by the degree of hyperkalemia and whether there are associated symptoms or signs (e.g. muscle weakness, paralysis, arrhythmias). It should be emphasized that although arrhythmias are considered the primary mechanism by which hyperkalemia causes death, the typical electrocardiogram (ECG) changes of hyperkalemia do not correlate strongly with serum potassium concentration nor do ECG findings associate strongly with the risk of death [8–10].

A 2005 systematic review for emergency interventions for hyperkalemia summarized the treatment for patients with hyperkalemia in general. For HD patients, the major difference is the availability and timing of hemodialysis. In symptomatic patients, maneuvers to stabilize the myocardium and shift serum potassium intracellularly should be

Table 42.2 Summary of findings: midodrine, cooled dialysate, sodium profiling, and biofeedback approaches to intradialytic hypotension (IDH).

	Midodrine vs. placebo [43]				
Outcomes	**No. of participants (studies)**	**Absolute number (95% CI) of patients affected per 1000 treated patients for 1 year**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
Intradialytic hypotension	Not estimated		Not estimable		
Nadir intradialytic systolic BP	79(6)		13.3 mmHg higher (95% CI 8.6–18.0)	Very low ●○○○	It is uncertain whether midodrine improves intradialytic systolic BP in hemodialysis
Nadir intradialytic diastolic BP	79(6)		5.9 mmHg higher (95% CI 2.7–9.1)	Very low ●○○○	It is uncertain whether midodrine improves intradialytic diastolic BP in hemodialysis
Post dialysis systolic BP	101(8)		12.4 mmHg higher (95% CI 7.5–17.7)	Very low ●○○○	It is uncertain whether midodrine improves post dialysis systolic BP in hemodialysis
Post-dialysis diastolic BP	101(8)		7.3 mmHg higher (95% CI 3.7–10.9)	Very low ●○○○	It is uncertain whether midodrine improves post dialysis diastolic BP in hemodialysis
Symptoms of IDH	Not estimated: (six studies)		Not estimable: generally, report improvement in symptoms	Very low ●○○○	It is uncertain whether midodrine improves symptoms related to IDH
Adverse events and safety	Not estimated		Not estimable: no serious adverse events reported	Very low ●○○○	It is uncertain whether midodrine is safe in patients receiving hemodialysis

	Cooled dialysate vs. standard temperature dialysate [54]				
Outcomes	**No. of participants (studies)**	**Absolute number (95% CI) of patients affected per 1000 treated patients for 1 year**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
Intradialytic hypotension	120 (11); 552 HD sessions	Not estimated	0.32 (0.18 to 0.56)	Low ●●○○	It is unclear whether or not using a lower dialysate temperature will reduce the frequency of intradialytic hypotension
BP changes during and after dialysis	(10)				
Dialysis adequacy	(seven studies)	Not estimated	Kt/V 0.-5 (−0.09 to −0.01)	Low ●●○○	It is unclear whether cooled dialysate reduces small solute clearance compared to standard temperature dialysate
Symptoms of discomfort	2547 dialysis sessions (nine trials)	Not estimated	2.95 (0.88 to 9.82)	Low ●●○○	Cooled dialysate may increase symptoms compared to standard temperature dialysate

Table 42.2 (Continued)

	Cooled dialysate vs. standard temperature dialysate [54]				
Outcomes	**No. of participants (studies)**	**Absolute number (95% CI) of patients affected per 1000 treated patients for 1 year**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
Sodium profiling vs. standard dialysis [56]					
Outcomes	No. of participants (studies)	Absolute number (95% CI) of patients affected per 1000 treated patients for 1 year	Relative effect (95% CI)	Quality of the evidence (GRADE)	Conclusion
Intradialytic Hypotension (IDH)	3600 dialysis sessions (13)	Not estimated	Pooled OR for all profiles 0.71 (0.60–0.85) Benefit varied with profile; benefit only evidence with stepwise profiling	Very low ●○○○	It is uncertain whether or not using sodium profiling compared to standard dialysis reduces the risk of IDH
Hemodialysis with biofeedback vs. standard dialysis [61]					
Outcomes	No. of participants (studies)	Absolute number (95% CI) of patients affected per 1000 treated patients for 1 year	Relative effect (95% CI)	Quality of the evidence (GRADE)	Conclusion
Intradialytic hypotension (IDH)	266 (6)	257 (from 92 fewer to 370 fewer episodes)	0.61 (0.44–0.86)	Low ●●○○	Biofeedback may reduce the frequency of IDH compared with standard hemodialysis
Predialysis systolic BP (SBP)	266 (6)	Not estimable	3 mmHg higher (2 lower to 7 higher)	Very low ●○○○	Biofeedback makes no difference to pre dialysis SBP compared with standard hemodialysis
Post-dialysis systolic BP (DBP)	266 (6)	Not estimable	7 mmHg higher (5 to 19 mmHg higher)	Very low ●○○○	Biofeedback may result in higher post dialysis DBP compared with standard hemodialysis
Quality of life outcomes	Uncertain (3)	Not estimable	No difference seen, not quantified	Very low ●○○○	It is uncertain whether biofeedback improves quality of life compared with standard hemodialysis
Mortality	104(2)	Not estimated	0.37 (0.07–2.01)	Very low ●○○○	It is uncertain whether biofeedback improves mortality compared with standard hemodialysis

considered while waiting to initiate hemodialysis. Additionally, the use of binding resins to enhance gastrointestinal elimination of potassium may be considered, although the risks and benefits are poorly delineated, particularly in dialysis patients.

New potassium binding resins are being investigated in addition to the widely available sodium polystyrene sulfonate. These include patiromer and sodium zirconium cyclosilicate (SZC). Although trials of the new agents have primarily involved nondialysis participants, a recent phase 3a trial has shown SZC to be safe, well tolerated, and effective in controlling serum potassium compared to placebo in the hemodialysis cohort in addition to usual hemodialysis. It is too early to propose how these new, expensive agents should be used in the hemodialysis cohort [11].

Dialytic Potassium Removal

Potassium removal during dialysis occurs by diffusion and convection; for diffusive therapies it is proportional to the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. gradient between serum and dialysate potassium concentrations. Once HD is initiated, serum potassium decreases approximately 1 mmol/l during the first hour of treatment and by a further 1 mmol/l over the next 2 hours and typically removes more than 100 mmol per 4-hour session but varies depending on the HD prescription [12]. Dialysate potassium concentrations typically range from 1 to 4 mmol/l based on the predialysis serum potassium values. The safety of using very low dialysate potassium concentrations, particularly potassium-free dialysate, in hemodialysis is questioned, although there is little evidence that the risk of serious hypokalemia is substantially higher with very low potassium dialysate. High bicarbonate dialysate may enhance the likelihood of restoring normokalemia by reducing acidosis and promoting an extracellular shift of potassium whereas high glucose dialysate can impair potassium removal due to insulin secretion and intracellular shifting [13].

For HD patients with recurrent hyperkalemia, adherence to dietary potassium restriction is the first step, and the dialysis prescription should be reviewed paying particular attention to adequacy, recirculation, dialysate potassium, and dialysate bicarbonate and performing a careful review and modification if possible of any contributing medications.

Management of Metabolic Acidosis

Metabolic acidosis is the most common acid-base abnormality in patients with CKD and in patients on dialysis but this abnormality may coexist with other acid-base disorders, including respiratory disorders [14]. Acid-base balance requires bicarbonate (HCO_3) reclamation in the proximal convoluted tubule and the renal excretion of nonvolatile acids (approximately 1 meq/kg of net acid production per day from dietary protein metabolism [15]) in the form of titratable acids (TA) and ammonium (NH_4). These mechanisms are dysfunctional in advanced CKD, leading to both a nonanion gap metabolic acidosis and an anion gap metabolic acidosis due the accumulation of phosphate, sulfate, urate, and hippurate. Metabolic acidosis increases as dietary protein intake increases acid generation, but is also affected by interdialytic weight gain (IDWG), dialysis schedule, dialysate bicarbonate concentration, and non-HCO_3 anion concentrations and adequacy.

Consequences of Acidosis

Metabolic acidosis in a hemodialysis patient may be associated with several consequences including:

- increased bone resorption, reduced bone mineral density, and hyperparathyroidism [16, 17]
- increased muscle protein catabolism and protein degradation [18, 19]
- hypoalbuminemia [20]
- impaired physical function [21]
- thyroid and growth hormone abnormalities [22]
- insulin resistance [23]
- hypertriglyceridemia [24]
- reduced respiratory reserve
- increased mortality [25, 26].

Base Delivery in Dialysis

The preferred form of base delivery to dialysis patients in the dialysate is in the form of bicarbonate (HCO_3) and potentially other anions, rather than acetate, as acetate is associated with hemodynamic instability [27] (Table 42.1). Observational studies suggest high bicarbonate dialysate increases predialysis serum bicarbonate, hyperparathyroidism, serum albumin, and triceps skin-fold thickness [28, 29]. The International Society of Renal Nutrition and Metabolism recommends targeting a predialysis HCO_3 of 22–24 mmol/l to avoid protein energy wasting and the Kidney Disease Outcome Quality Initiative (KDOQI) recommends maintaining a serum CO_2 > 22 meq/l in HD patients, but there are no RCTs to support alterations in dialysate or that adding oral bicarbonate improves patient-important outcomes [30, 31] (Table 42.1).

Intradialytic Hypotension

Introduction

IDH is a reduction in blood pressure during a dialysis treatment. The variety of definitions of IDH has resulted in broad estimates of frequency ranging between 10% and 55% of dialysis treatments [34, 36]. The potential importance of even IDH is due to its association with poor outcomes, particularly cardiovascular morbidity and mortality. Presumably this is due to repeated ischemic insults to vulnerable vascular beds. However, the association between IDH and clinical outcomes may primarily be due to residual confounding rather than a causal relationship.

Proposed causes of IDH include ultrafiltration (UF) rates that exceed intravascular refilling, an inappropriate target weight loss during HD treatment, intravascular osmolality reduction, autonomic dysfunction, and decreased cardiac reserve. Risk factors for IDH include dialysis vintage, female gender, lower predialysis blood pressure (BP), and hypoalbuminemia [32–34]. Studies of interventions to prevent IDH typically focus on changes in blood pressure and have insufficient power and duration to assess whether preventing IDH reduces patient-important outcomes such as cardiovascular events or mortality.

Definition

There is no consensus definition of IDH although a number of definitions are used in the literature [35]. These include definitions based on nadir BP, drop in BP from pre-HD level, symptoms associated with a drop in BP, a drop in BP prompting intervention, and combinations of the above. Systolic BP (SBP) nadir less than 90 mmHg in at least 30% of sessions has the most evidence showing a consistent association with mortality. There appeared to be a dose–response relationship, with more frequent IDH increasing risk for death. The addition of symptoms or intervention criteria did not increase the strength of this association. In the subset of patients with predialysis BP ≥160 mmHg, nadir BP less than 100 mmHg was strongly associated with mortality [36].

Prognosis/Pathogenesis

IDH is associated with poor outcomes, particularly cardiovascular morbidity and mortality [32, 36]. Repeated intradialytic ischemic insults to susceptible vascular beds induced by IDH are felt to be the mechanism by which IDH may cause cardiovascular events [37, 38]. Intradialytic myocardial stunning has been one marker of hemodynamic stress that has been studied. Higher ultrafiltration volumes and greater decreases in intradialytic systolic blood pressure are independent risk factors for the development of intradialytic myocardial stunning (Burton 2009). After 1 year of follow-up patients with myocardial stunning at baseline had a greater decrease in left ventricular ejection fraction and increased mortality [38]. Several interventions that lead to improvement in intradialytic hemodynamics have shown decreases in surrogate outcomes such as left ventricular mass index, intradialytic myocardial stunning, and brain white matter changes [37, 39–42].

Management

Several potential interventions exist to prevent IDH, including pharmacologic and dialysis-based interventions.

Pharmacologic interventions are not a well-studied area in the prevention of IDH. The most studied pharmacologic agent in the prevention of IDH is midodrine. Midodrine is a prodrug of desglymidodrine, an alpha-1 adrenergic receptor agonist. Midodrine is one of the most commonly used pharmacologic agents to prevent IDH. A systematic review conducted in 2004 found that midodrine as compared to control resulted in significant improvements in post-HD and nadir BP [43]. The studies were limited by small sample size, short duration, and high risk of bias. There were no RCTs of midodrine for IDH prevention. The two studies that assessed midodrine with cooled dialysate showed no effect compared to cooled dialysate alone [44, 45] (Table 42.2).

Dialysis-based interventions include longer HD session time, cooled dialysate, changes in dialysate sodium, and biofeedback dialysis.

Shorter weekly HD time, increased IDWG, and consequently higher ultrafiltration rates consistently show an association with poor outcomes, including cardiovascular morbidity and mortality [46–48]. Higher UF volume is an independent risk factor for myocardial stunning [38]. More frequent dialysis is associated with improved hemodynamic tolerability and less dialysis-induced myocardial stunning [42]. Both frequent hemodialysis network trials (frequent in-center HD and frequent nocturnal HD) demonstrated a decrease in the rate of hypotensive events requiring intervention in the frequent hemodialysis groups as compared to routine HD [49, 50]. The extended follow-up of the in-center HD trial showed decreased mortality in the more frequent HD group [51]. However, the extended follow-up of the nocturnal HD trial showed increased mortality in the more frequent HD group [52]. Whether increased dialysis frequency reduces mortality and whether any benefits are due to reducing IDH is uncertain.

Cooled dialysate compared to standard temperatures has been shown to decrease IDH, LV mass index, and myocardial stunning and protect against brain white matter changes [37, 39, 40, 53]. The reduction in IDH is mediated primarily through increased peripheral vascular resistance [40, 53]. A recent systematic review and meta-analysis of randomized trials on the topic of reduced temperature dialysate demonstrated a decrease in the rate of IDH by 70% (Table 42.2). There was a trend toward increased symptoms of discomfort in the cooled dialysate group that was not statistically significant. The trials were limited by short-term follow-up, lack of data on cardiovascular events and mortality, and low to very low quality of evidence [54]. A cluster-RCT of cooled vs. standard dialysate temperature and its effect on mortality and cardiovascular events will help to answer these questions (Major Cardiovascular and Other Patient-Important Outcomes With Personalized dialYsate TEMPerature, MY TEMP, http://ClinicalTrials.gov Identifier: NCT0262836).

Dialysate sodium concentrations affect the hemodynamic tolerability of HD. Increased dialysate sodium levels are felt to protect against a drop in serum osmolality and resultant fluid shifts out of the vascular compartment. The desire to improve the tolerability of HD by increasing dialysate sodium is tempered by the concerns over a positive sodium balance. The net positive sodium balance is thought to lead to increased thirst and IDWG, requiring increased UF rates and potentially increased IDH as a consequence. Data from the DOPPS showed an association between higher dialysate sodium and higher IDWG [55].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The same analysis of DOPPS data showed an inverse relationship between dialysate sodium and hospitalization as well as mortality. Studies on the effect of lowering dialysate sodium on IDH have had mixed results. Some have shown no effect and others an increase in the rate of IDH when dialysate sodium has been lowered (Hussein 2017). Thus far, there are no RCTs demonstrating an effect of dialysate sodium concentration on outcomes such as mortality, cardiovascular mortality, heart failure or other patient-important outcomes. A large cluster-RCT is being conducted to establish whether dialysate sodium of 137 mmol/l reduces important outcomes compared to a dialysate sodium of 140 mmol/l (Randomized Evaluation of Sodium Dialysate Levels on Vascular Events, RESOLVE, http://ClinicalTrials.gov Identifier: NCT02823821).

Sodium profiling, where dialysate sodium concentration is adjusted throughout the dialysis treatment, may decrease the risk of IDH. The dialysate sodium concentration is initially elevated, frequently to the supraphysiologic range, and is reduced based on any one of several possible profiles. A meta-analysis compared the effects of various sodium profiles on IDH [56]. A stepwise decrease in dialysate sodium was associated with a decrease in IDH. Linear profiling was not associated with a decrease in the incidence of IDH. Many of the included studies were limited by unclear allocation concealment and blinding [56].

Sodium profiles may result in a positive, negative, or neutral net sodium balance. There are concerns about net sodium gain and its associated consequences with sodium profiling. A small crossover study of IDH prone patients evaluated sodium balance positive or neutral profiles with or without simultaneous UF profiling [57]. Positive sodium balance profiles with or without UF profiling and neutral sodium balance profiles with UF profiling reduced the incidence of intradialytic discomfort, early session termination, UF failure, and inadequate dose (Kt/V) as compared to control and neutral sodium profiles without UF profiling (Table 42.2). Positive sodium balance sodium profiling was associated with increased IDWG and UF requirements. Sodium balance neutral sodium profiling combined with UF profiling was more likely to achieve target weight than positive sodium balance profiles. However, only positive sodium balance profiles significantly increased the nadir of systolic BP compared to control.

Biofeedback dialysis is an additional dialysis-based intervention that may involve adjustments in dialysate sodium and/or UF to reduce the incidence of IDH (Table 42.2). The most commonly used form of biofeedback dialysis is blood volume guided biofeedback dialysis. This method uses measures of relative blood volume to adjust UF rate and/or dialysate conductivity/sodium to maintain relative blood volume above an individualized critical value associated with the development of IDH.

Trials of biofeedback compared to dialysis without biofeedback demonstrated less intradialytic myocardial stunning and decreased rates of IDH [58–60]. A meta-analysis conducted in 2013 found biofeedback dialysis was associated with a reduced rate of IDH as compared to standard HD. The majority of included studies (6/8) used biofeedback dialysis with alterations in both UF rate and dialysate conductivity to maintain hemodynamic stability. The studies were limited by small sample size, short duration of follow-up, and low quality of evidence due to risk of bias from lack of blinding and potential for publication bias [61]. There is no high-quality evidence that biofeedback improves patient-important outcomes.

Trials of blood volume guided biofeedback dialysis where only UF rate is adjusted have not shown similar benefits. An early trial of blood volume guided HD with operator adjustments of UF rate showed an increased rate of hospitalization and mortality in the blood volume guided HD group and no decrease in the rate of IDH [62]. A recent crossover trial of biofeedback dialysis with UF rate adjustments alone in IDH prone patients did not find a significant decrease in the rate of IDH as compared to standard of care [63].

Summary

IDH is a common issue in chronic hemodialysis patients. It is associated with poor outcomes, including increased cardiovascular morbidity and mortality. While many interventions have been proposed to prevent IDH few have a solid evidence base. The literature is complicated by the fact that there have been a number of different definitions of IDH in use. There is a theoretical framework and biological plausibility potentially causally linking IDH to cardiovascular morbidity and mortality. However, critical evidence demonstrating that decreasing the incidence of IDH improves patient important outcomes such as cardiovascular events and mortality is lacking (Table 42.1).

Hypertension

Introduction

Blood pressures that meet the definition of hypertension for nondialysis patients are common in HD patients. However, whether similar definitions of hypertension are relevant to the hemodialysis patient population is uncertain and studies use heterogeneous definitions in hemodialysis. Differences arise between studies based

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

on definitions that vary in terms of blood pressure thresholds, timing of measurements (predialysis, during dialysis, post-dialysis, or on nondialysis days) and methods of measurement (e.g. at dialysis, home monitoring, ambulatory monitoring). For example, in study of 355 HD patients using thresholds of 140/90 for midweek, immediately predialysis BP, and 135/85 for 44-hour ambulatory blood pressure monitoring (ABPM), 35% or 47% had HTN which was associated with a hazard ratios for mortality of 1.87 (95% confidence interval [CI]) [64]. KDOQI guidelines define HTN in HD patients as predialysis BP >140/90 mmHg or postdialysis BP >130/80 mmHg [65]. European Renal Association–European Dialysis and Transplant Association (ERA-EDTA) guidelines use home BP >135/85 mmHg, ABPM>130/80, and midweek office BP >140/90 mmHg with no recommendation for blood pressure measured at dialysis treatments [66].

Pathophysiology

HTN often reflects inadequate volume control in HD patients. The removal of excess sodium by reducing dry weight can result in normalization of BP in many cases with a lag phenomenon supported by some [67] but not all studies [68]. BP is related to many factors, including volume status, which increases postdialysis linearly but with fluctuations [69], but also sympathetic nervous system activity, the RAAS, arteriosclerosis, and drugs (e.g. erythropoietin-stimulating agents).

Measurement and Outcomes

Options for monitoring BP include predialysis and postdialysis BP measurements, self-recorded home BP (SHBP) monitoring, and ABPM (Table 42.1). ABPM and SHBP monitoring correlate with outcomes while dialysis measurements do not appear to be as reliable with predialysis overestimating and postdialysis underestimating BP reading related to changes in volume status [70]. There is a J- or U-shaped curve for BP and mortality in the HD population but most studies are based on predialysis BP measurements [71] and do not distinguish between BP lowering by therapies (e.g. probing dry weight, antihypertensives) or confounders (e.g. infection, CV disease). For example, in a Cox regression model of 24 525 HD patients from DOPPS (excluding predialysis SBP < 110 and DBP < 50 suggestive of comorbid illness) adjusted for confounders, all-cause mortality was elevated with SBP 110–129 mmHg and lower with SBP 150–159 mmHg as compared to 130–139 mmHg. Mortality was elevated with DBP 50–59 mmHg compared to 80–90 mmHg [72].

Blood Pressure Targets

The optimal BP target is uncertain in HD, with no large RCTs evaluating intensive versus liberal BP targets in contrast to CKD and the general population. A pilot trial of dialysis patients with a predialysis SBP > 155 mmHg randomized participants to a target predialysis SBP 110–140 mmHg ($n = 62$) or 155–165 mmHg ($n = 64$) for 1 year. Dry weight probing, beta-blockers, and inhibitors of the RAAS were allowed [73]. SBP between the two groups differed by 12.9 mmHg and there was an excess of hospitalizations, vascular access thrombosis, and intradialytic hypotension in the lower target group.

Blood Pressuring Lowering Therapies

Nonpharmacologic therapies to lower BP include gradually reducing the dry weight to achieve euvolemia (e.g. no symptoms of signs of hypovolemia or hypervolemia) and sodium restriction to reduce interdialytic weight gain. Additional hemodialysis treatment time or sessions may be necessary to safely achieve euvolemia. Reducing the dialysate sodium may also reduce IDWG, volume status, and BP control [74]. In the DRIP trial, a RCT comparing ultrafiltration (weight loss of 0.1 kg/10 kg per dialysis until signs or symptoms of hypotension) ($n = 100$) to physician visits only ($n = 50$) without any changes in hypertensive therapy in HD patients with a mean interdialytic ABPM of 135/75 and a postdialysis weight reduction of 0.9 kg at 4 weeks resulted in SBP −6.9 mmHg (95% CI −12.4 to −1.3, $P = 0.016$) and DBP −3.3 mmHg (95% CI −12.2 to 1.0, $P = 0.048$) with similar changes at 8 weeks, which does not support the lag phenomenon [68].

The treatment of HTN with antihypertensive agents to lower BP decreased cardiovascular events and mortality [75, 76] (Table 42.1). In a meta-analysis of eight RCTs (1679 patients including both HD and peritoneal dialysis with varying inclusion criteria) for BP lowering in dialysis patients, the weighted mean SBP was 4.5 mmHg lower and diastolic blood pressure (DBP) 2.3 mmHg lower in actively treated patients compared to controls. Any BP lowering treatment (which included carvedilol, rampiril, fosinopril, telmisartan, candesartan, losartan, and amlodipine) reduced the risk of CV events (risk ratio [RR] 0.71, 95% CI 0.55–0.92, $P = 0.009$), CV mortality (RR 0.71, 95% CI 0.50–0.99, $P = 0.044$) and all-cause mortality (RR 0.80, 95% CI 0.66–0.96, $P = 0.014$) compared to control regimens [75].

Although the above meta-analysis suggests benefits to treatment with antihypertensives, whether classes of drugs differ importantly from one another was not clear. Small trials comparing classes of drugs do suggest differences in tolerability and adverse events. For example a RCT

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

compared lisonopril ($n = 100$) to atenolol ($n = 100$) in HD patients with HTN defined by ambulatory blood pressure > 135/85 and left ventricular hypertrophy (LVH). The trial was stopped early for potential excess harms in lisonopril-treated patients, including serious adverse events, hospitalization, HTN, and hyperkalemia [77]. However, excess harm was not seen in trials comparing other angiotensin blocking drugs to controls [78].

Selection of antihypertensives may be based on extrapolating evidence from the nondialysis population with specific indications (e.g. beta-blockers or RAAS inhibition for patients with reduced left ventricular function [79]). Options include beta-blockers with consideration of dialyzability [80], angiotensin converting enzyme (ACE) inhibitors or angiotensin receptor blocker (ARB) (reduction in LV mass but not CV events in a meta-analysis of five RCTs with BP 120–170/70–80), dihydropyridine calcium channel blockers, alpha-blockers, clonidine, mineralocorticoid receptor antagonists (BP lowering ranging from 1.7–11 vs. 2–5.2 in controls, RR CV mortality 0.40, 95% 0.15–0.75, RR mortality 0.40, 95% CI 0.23–0.69 [81]) and minoxidil. The use of RAAS inhibition was associated with less mortality in DOPPS with a hazard ratio of 0.89 (95% CI 0.80–0.99) and 0.94 (95% CI 0.90–0.99) in 11 241 incident and 37 124 prevalent HD patients [82]. However, in an RCT comparing olmesartan ($n = 235$) to control ($n = 234$) in HD patients with average pre-HD BP >140/90 targeting BP <140/90 did not show any difference in between the composite of death, nonfatal stroke, nonfatal myocardial infarction, and coronary vascularization. Thus, ideal targets and therapeutic agents remain uncertain.

Resistant Hypertension

Resistant hypertension in HD may be due to inadequate volume control or nonadherence in addition to other secondary causes of HTN. Paradoxical hypertension can occur during hemodialysis, possibly related the dialyzability of antihypertensives, neurohormonal activation, an altered balance of vasoactive substances, endothelial dysfunction, and hypervolemia [83]. The approach to these conditions is similar to that already outlined, including reducing dry weight, lowering sodium concentration in dialysate, and preferentially utilizing nondialyzable antihypertensives.

Statin Therapy in Patients on Hemodialysis

There have been a number of RCTs evaluating low-density lipoprotein (LDL) lowering with statin-based regimens in patients with end-stage renal disease (ESRD) to prevent vascular events. The major trials of statin use exclusively in patients with ESRD were the 4D [84] and AURORA [85] trials. Neither 4D nor ARORA demonstrated a statistical benefit of LDL lowering with statin-based regimens on their composite endpoint of cardiovascular death, nonfatal myocardial infraction (MI) or stroke. The 4D trial did show a benefit on the secondary endpoint of combined cardiac events (RR 0.82; 95% CI 0.68–0.99, $P = 0.03$).

The Study of Heart and Renal Protection (SHARP) trial examined the role of lipid lowering with a statin and ezetimibe regimen in patients with CKD. One-third of the patients with CKD enrolled in the SHARP trial were on dialysis at the outset of the trial [86]. The SHARP trial demonstrated a significant benefit of simvastatin plus ezetimibe in patients with CKD on the outcome of first major atherosclerotic event. This benefit was consistent with the previous trials of statins in patients with normal renal function when adjusted for LDL lowering achieved. Within the subgroup of patients on dialysis in the SHARP trial there was no statistically significant benefit of LDL lowering therapy. SHARP was not powered to assess the subgroup of patients on dialysis. There was no statistical evidence that the effects in patients on dialysis differed significantly from the beneficial effect seen in patients with CKD not on dialysis but, as in most trials, there was limited power to detect such difference in effect.

The Cholesterol Treatment Trialists (CTT) conducted a meta-analysis on the topic of the effect of CKD on LDL lowering with statin-based regimens using individual participant level data [87]. There was evidence that statin therapy lowered the risk of vascular events in patients with CKD not on dialysis. Even when accounting for the smaller decreases in LDL seen in CKD this relative benefit declined proportionately with estimated glomerular filtration rate (eGFR). There was little evidence of any benefit in patients on dialysis [87]. A Cochrane Review on the topic of statins in patients on dialysis found similar results showing no significant benefit of statin therapy on mortality or cardiovascular events [88].

On the basis of these studies, there is no compelling evidence that initiation of hemodialysis is an indication for statin therapy to prevent cardiovascular events (Table 42.1). By the same token, there is no compelling evidence that patients already receiving a statin at the time of hemodialysis initiation should have the statin discontinued since patients with a historical indication for statin therapy were not studied.

Nutrition

Introduction

Malnutrition is reported in up to 72% of adult patients receiving hemodialysis. Chronic inflammation and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cardiovascular disease are commonly associated with the development of malnutrition, leading to the concept of the malnutrition–inflammation–atherosclerosis syndrome. The International Society of Renal Nutrition recommends the term protein-energy wasting syndrome, rather than malnutrition, to better characterize the loss of body protein and fuel reserves in patients receiving hemodialysis, which may be independent of nutritional intake. While some studies demonstrated declining nutritional status was associated with adverse outcomes in hemodialysis patients, this finding was not universal. Whether discrepancies between results reflect the use of different nutritional markers, measurement error inherent in assessing nutritional status, or whether poor nutrition is not truly causative of poor outcome but rather reflects declining health for other reasons, remains uncertain. However, since poor nutrition is reasonably likely to be at least partially causative of malnutrition/protein-energy wasting and its associated poor outcomes, it is commonly perceived as a therapeutic target.

Assessment of Nutritional Status

Clinical practice guidelines developed in Australasia, Canada, Europe, the UK, and the USA made specific recommendations to assess nutritional status in hemodialysis patients. Although these guidelines differed in terms of the method of assessing nutritional status, they all suggest a combination of measures should be used (Table 42.1). The most commonly recommended assessment methods follow.

Subjective Global Assessment

The Subjective Global Assessment (SGA) is the most commonly recommended method and includes an evaluation of gastrointestinal symptoms (appetite, anorexia, nausea, vomiting, diarrhea), weight change over time, functional impairment, and a visual examination of subcutaneous tissue and muscle mass. While the SGA is inexpensive and easy to perform, it has not been rigorously validated as a measure of malnutrition and may be insensitive to nonsevere forms of malnutrition.

Markers of Visceral Protein Stores

Like SGA, markers of visceral protein stores, for example serum albumin, are commonly recommended to assess malnutrition. However, serum albumin decreases with systemic inflammation and other factors not associated with nutrition. Other potentially useful markers of nutrition include serum creatinine and thyroid binding protein (prealbumin or more correctly transthyretin). Plasma creatinine concentrations reflect muscle mass, dietary protein, residual kidney function, and dialysis clearance, in addition to nutritional status. Blood transthyretin concentrations change rapidly in response to changes in hepatic protein production and may add prognostic information independent of albumin concentrations. Overall, the degree to which these are markers of malnutrition or are prognostic markers independent of nutrition is unclear.

Dietary Protein Intake

A measure of dietary protein intake is commonly recommended and may best reflect the role of nutritional intervention. Food diaries, including mobile applications or food intake recall instruments, are the most common way to measure dietary protein intake. A simple method free of recall bias is to measure protein nitrogen appearance (PNA), a proxy for protein catabolic rate and roughly equivalent to protein intake. PNA can be calculated from total nitrogen appearance (the sum of dialysis, urine, and fecal nitrogen losses) and should be normalized to fat-free, edema-free standardized body weight. Since measuring nitrogen in stool is difficult, equations estimate PNA from nitrogen in serum, urine, and dialysate. These equations are more accurate in peritoneal dialysis patients, in whom dialysate urea concentrations can be measured directly rather than estimated.

Assessment of Changes in Lean Body Mass

Lean body mass may be estimated using anthropometrics, multifrequency bioimpedance assay (BIA), and dual-energy X-ray absorptiometry (DEXA). BIA parameters indicative of poor nutritional status predicts mortality in dialysis patients. DEXA measurements are reproducible but the degree to which they associate with mortality in dialysis patients is uncertain. Hand grip strength is a simple marker of muscle mass and predicted clinical events in men but not women in one study of patients receiving hemodialysis.

Management of Malnutrition

The general principles of treating a patient receiving hemodialysis who is malnourished are (i) to treat any underlying cause (e.g. infection, heart failure, depression etc.), (ii) to ensure the patient is receiving adequate dialysis, and (iii) to increase nutritional intake. While the first of these principles does not have any evidence to guide it, it seems logical and at low risk of causing harm. The second principle is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

guided by the observations that some individuals with lower small solute clearance are more likely to have protein-energy wasting. However, in the HEMO trial that compared a higher dialysis dose (average delivered *Kt*/*V* of 1.53) to a lower dose (average delivered *Kt*/*V* 1.10) there was no evidence that a higher dose improved markers of nutritional status [89] (HEMO). Similarly, in the Frequent Hemodialysis Network trial, daily dialysis did not improve markers of nutrition [90].

Although intensive nutritional support may improve markers of poor nutritional status, it is uncertain whether this translates to improved survival, function or quality of life for patients receiving dialysis. Having said that, increasing nutritional intake may start with dietary advice/counseling and encouraging intake of food with or without supplements (Table 42.1). RCTs of nutritional supplements compared to standard diets appear to increase markers of nutrition (e.g. serum albumin and lean body mass) but it is uncertain if they improve quality of life, physical or mental function, or survival. These trials tend to be at high risk of bias (unblinded, unclear allocation methods) and have small sample sizes.

If oral nutrition is not feasible, tolerated or does not improve markers of nutrition, enteral feeding is an option for some. Similar to supplements, enteral feeding appears to improve markers of nutritional status but its effect on patient-important outcomes is unclear.

Finally, one may consider parenteral nutrition, either intradialytic or total parenteral nutrition. While these may also improve markers of nutritional status in small, randomized trials at high risk of bias, they have also not demonstrated benefits in patient important outcomes. For both enteral and parenteral feeding, understanding the risk of harm is less well delineated than estimating benefits. Risks are often extrapolated from other populations which may or may not be broadly similar to hemodialysis patients.

Infections in Hemodialysis Patients

Bourne L. Auguste[1] *and Christopher T. Chan*[2]

[1] *Division of Nephrology, Sunnybrook Health Sciences Centre, Toronto, Canada*
[2] *Division of Nephrology, Toronto General Hospital, Toronto, Canada*

Introduction

As the global rates of hypertension and diabetes continue to rise, the burden on end-stage kidney disease (ESKD) progression is steadily increasing [1–3] such that the prevalence of patients on hemodialysis (HD) has nearly doubled since 1990 [2]. However, the long-term survival of patients on HD can be compromised by cardiovascular events and infections [4–9].

Infections are the second leading cause of death after cardiovascular disease among HD patients and are on the rise [6, 10]. This rise in infection-related hospitalizations over the last decade has driven healthcare providers and policymakers from the Center for Disease Control (CDC) and American Society of Nephrology to embark on an initiative aimed at reducing infectious complications among in-center hemodialysis patients. This initiative, called Nephrologist Transforming Dialysis Safety, focuses on infection prevention to reduce mortality and morbidity among HD patients [11, 12].

Additionally, vascular access related infections among HD patients were historically felt to be one of the most important vascular access outcomes [13, 14]. Vascular access related infections are more prevalent in patients with central venous catheters (CVCs) than those with arteriovenous grafts (AVGs) and arteriovenous fistulas (AVFs) [13]. The 2012 United States Renal Data System (USRDS) annual data report revealed a fourfold increase in risk of infectious complications in patients initiating dialysis with a CVC compared to either a fistula or graft [15, 16]. In North America, 20–30% of patients have a catheter as their prevalent form of access [17]. The increase in prevalence of CVC use is likely due to the changing demographics of HD patients, older age and a greater burden of comorbidities, including diabetes and cardiovascular disease [18].

Higher prevalence of multidrug-resistant organisms poses additional challenges. Antibiotic overuse with an increase in patient-to-patient transmission of resistant organisms are leading factors accounting for this increase [19, 20]. Infections caused by resistant microorganisms are associated with a two to five times higher morbidity and mortality rate compared to antimicrobial susceptible microorganisms [21] and account for 23 000 deaths annually in the United States with an associated cost of more than US$20 billion [22].

Bloodborne viral infections including hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV) also poses risk among HD patients. The extracorporeal nature of HD along with occasional transfusion requirements increases the risk of bloodborne viral infections [7]. This is further amplified if there is a breakdown in infection-control practices.

In this chapter, we will describe in further detail risk factors for vascular and nonvascular infections in HD patients. We will also discuss the current evidence for prevention and management of various infections. Additionally, given the increasing resistance patterns of pathogenic microorganisms, we will highlight the risks of common nosocomial and bloodborne viral infections among HD patients.

Definition

Infections among HD patients can be classified into two main groups: vascular access and nonvascular access related infections. Vascular access infections among HD patients are usually defined as localized or systemic and simple or complicated. Localized infections are confined to

the access site and may be associated with overlying cellulitis or purulent drainage. In patients with catheter-related bloodstream infections (CRBSIs) (see Table 43.2 for definitions), the most sensitive clinical symptom is fever or chills, which is seen in about 60–80% of patients with positive blood cultures [23–26]. Patients can also present with nausea, vomiting, altered mental status, hypotension, and other clinical features of sepsis [26]. Vascular access sites, AVFs, AVGs, and CVCs are the most common site of infection among HD patients [27, 28]. Patients on HD are also at an increased risk for nonvascular access related infections such as bacterial and viral pneumonia, *Clostridium diffiicile* associated diarrheal illness, and many other nosocomial infections.

Epidemiology

At baseline, HD patients have a mortality rate that is 100–300 times greater than that of the general population [29]. The Hemodialysis (HEMO) study showed that overall probability of death due to an infection-related hospitalization was about 15% among HD patients [30]. This increased morbidity and mortality risk from infections is multifactorial, with the main influencing risks being pathogenicity, transmissibility, frequency of infections, and host-specific factors. Host-specific factors include impairments in immune system function and the management of these patients can be challenging given the inherent susceptibility to infections [31]. From a health systems perspective, infections and related complications in HD patients account for significant costs. CRBSIs account for the majority of costs related to CVCs [32] and include indirect and direct costs associated with hospitalization, treatment and CVC management, which have been estimated to range from US$17 000 to US$32 000 annually in North America [32–35].

Pneumonia is the second most common infection among HD patients with a prevalence in HD patients of about 15 times that of the general population [6]. One in five patients with ESRD develops at least one episode of pneumonia within their first year on dialysis [36]. While the most common causative organism is *Streptococcus pneumoniae*, many other infectious bacterial organisms, seasonal influenza, or a superimposed bacterial infection after viral infection are seen in this vulnerable population.

Nosocomial infections pose additional challenges in the management of HD patients as they tend to be more resistant to usual antimicrobial treatment. Prospective results have shown that hospital length of stay is doubled in HD patients when compared to the general population with nosocomial infections [37]. The increase in morbidity stems from the alteration of naturally occurring flora with recurrent use of antibiotics [38]. Consequently, these practices confer resistance and give rise to methicillin-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant enterococcus (VRE), and extended-spectrum beta lactamase (EBSL) organisms [39–41]. Beyond the risk of resistant organisms from antibiotic overuse, HD patients are more susceptible to an increase in *Clostridium difficile* infections [42].

Pathophysiology

CRBSIs are believed to occur via extraluminal or intraluminal routes by microbes originating from the skin or via contaminated fluids [43]. Catheters can also become innoculated by hematogenous spread of microorganisms (Figure 43.1). Observational data demonstrates that extraluminal spread is more common in catheters with a shorter duration of time (<10–14 days), whereas intraluminal spread predominates in prolonged catheterization [44, 45]. Intraluminal colonization is also likely to occur with prolonged catheterization, with one study showing 40–50% of catheters were covered with biofilms with catheters in place for >30 days [46].

Biofilms are an aggregation of bacterial organisms that form extracellular polysaccharides (EPSs) and produce adhesins, adhering to prosthetic material (CVC or AVG), accounting for persistence in infections [47]. Figure 43.2 outlines the phases of biofilm production: planktonic, adhesion, maturation, and detachment. Studies have demonstrated that antibiotic concentrations must be 100–1000 times greater than usual to kill stagnant bacteria (biofilm) versus planktonic bacteria in the bloodstream [48–51].

In HD patients, biofilms can also lead to sporadic dissemination of bacteria into the bloodstream, leading to complications [47] including metastatic deposits in the form of infective endocarditis, discitis, epidural abscess, osteomyelitis, septic arthritis, septic emboli or other complications leading to death [5, 24, 52–58]. Vascular access may also be compromised by thrombosis or deep-seated infections requiring surgical extraction to achieve source control [59, 60]. Metastatic infections complicate about 5–10% of CRBSIs with the most common being infective endocarditis, and the most common pathogens are *S. aureus* and coagulase-negative staphylococcal (CNST) organisms. *S. aureus* has an increased propensity to cause disseminated infections, with metastatic complications seen in about 30% of HD patients [61].

Diagnosis

HD patients can have a variety of presentations related to the underlying cause of infection. Clinical manifestations

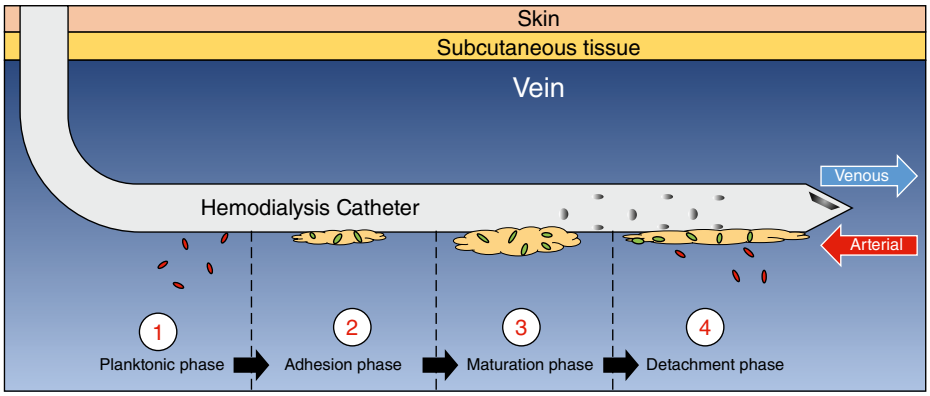

Figure 43.1 Microbial sources of catheter-related blood stream infections (CRBSIs). Microorganisms can be spread via three routes in CRBSIs: extraluminal, intraluminal, and hematogenous. Extraluminal spread is associated with colonization of the exit site by skin flora and can also be related to contamination of the exit site due to the lack of aseptic techniques. Microorganisms can be spread through the intraluminal route due to infusion of contaminated fluid or medication. Whereas, deep-seated infections entering the bloodstream give rise to CRBSIs via hematogenous spread.

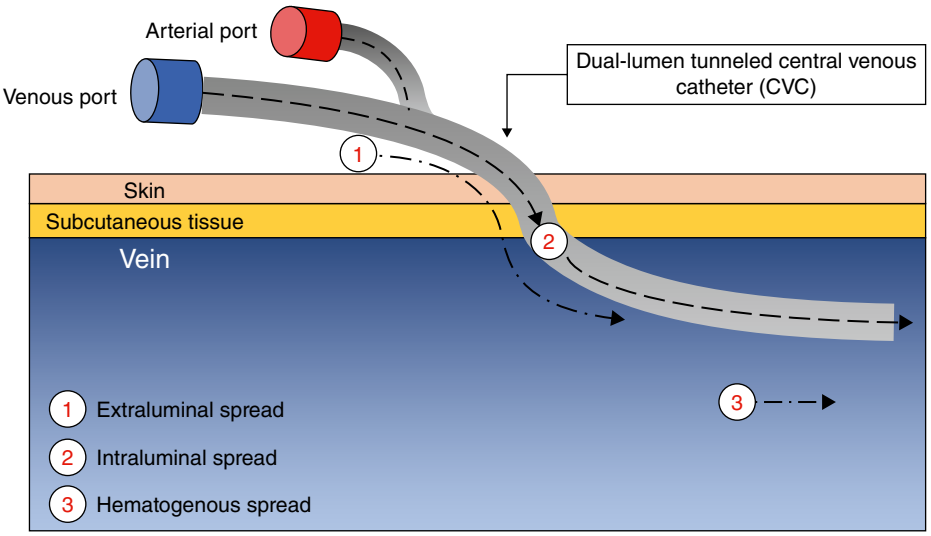

Figure 43.2 Schematic illustration of biofilm formation on central venous catheters (CVCs). (1) Planktonic phase: the bacteria are mobile in the bloodstream and may originate from intraluminal, extraluminal, or hematogenous sources. (2) Adhesion phase: bacteria attach to prosthetic material by production of adhesins to become sessile. (3) Maturation phase: bacterial organisms multiply and produce extracellular polysaccharide (EPS), leading to biofilm development. (4) Detachment phase: planktonic bacteria are released from biofilm which has matured.

may include fever, chills, nausea, vomiting, cough, hemodynamic instability, and altered mental status for both vascular and nonvascular related infections. Vascular access related infections, particularly CRBSIs, have a variety of clinical definitions with no consensus on a common definition. For example, despite the lack of consensus on a definition between the CDC, the Infectious Disease Society of America (IDSA), and the Kidney Disease Outcomes Quality Initiative (KDOQI) groups, there is some overlap in making the diagnosis of CRBSIs. Table 43.2 summarizes the differences in CBSI definitions. Regardless, patients must have positive blood cultures drawn peripherally with no other apparent source for infection along with the same organism being cultured from the catheter to make a diagnosis of CRBSI.

Although AVG infections are a less common cause for vascular access related infection, prompt recognition and diagnosis can reduce significant complications [62]. HD patients presenting with any of the following clinical features are suggestive of an infection of the AVG: overlying erythema, fluctuance, new mass or rapid development of an aneurysm, pus or prosthetic material exposure [63]. Alternatively, early graft infection can also present as thrombosis or bleeding at the cannulation site and may

Table 43.1 Treatment and prevention of infections in hemodialysis (HD) patients.

Strategy	Recommendation	Certainty of evidence	Strength of recommendation
Catheter-based treatment and prevention strategies			
Antimicrobial locks	We suggest antibacterial lumen locks be considered in HD patients with a very low degree of certainty that there is reduction in central venous CRBSI Patients receiving this therapy with systemic antibiotics for infection have better response rates and lower recurrences of infection based on a moderate degree of certainty	*Very low* (prevention of CRBSI) *Moderate* (adjuvant treatment of CRBSI)	Weak [1–3]
Impregnated catheters	We suggest the use of impregnated central venous catheters with minocycline/rifampin or chlorhexidine/silver sulfadiazine to reduce the risk of CRBSI with a high degree of certainty	*Low*	*Weak* [4–6]
Vascular access removal	We suggest that removal of central venous catheters be done in cases with metastatic complications, persistent bacteremia or infection with *Staphylococcus aureus*, *Pseudomonas* spp. and fungal organisms with a high degree of certainty in treating CRBSI	*High*	Weak [3]
Cannulation and topical prevention strategies			
Cannulation technique	We suggest that cannulation of AVF with the rope ladder technique be utilized over buttonhole based on a high degree of certainty that it reduces vascular access related infection	*High*	Strong [7, 8]
Exit site care	We suggest topical antibiotics or povidone-iodine ointment be applied to exit sites of central venous catheters after every dressing change with a high certainty that it reduces likelihood of infection	*High*	Weak [9, 10]
Vaccination			
Pneumonia vaccines	We recommend that all HD patients barring any specific contraindications receive 23-valent polysaccharide pneumococcal vaccine every 5 years with a moderate degree of certainty that it reduces risk of contracting pneumonia	*Moderate*	Strong [11, 12]
Influenza vaccines	We recommend that all HD patients barring any specific contraindications receive annual influenza vaccines that it reduces risk of contracting pneumonia with a moderate degree of certainty	*Moderate*	Strong [11, 12]
HBV vaccine	We recommend that all HD patients barring any specific contraindications who are nonimmune to HBV receive vaccination to prevent HBV infection with a high degree of certainty	*High*	Strong [13, 14]
Bloodborne viral infections			
HCV treatment	We suggest patients with HCV infection be evaluated for treatment with an interferon-free regimen based on genotype, residual renal function, comorbities, life expectancy, and renal transplant candidacy on a moderate degree of certainty	*Moderate*	Weak [15]
HBV treatment	We suggest patients with HBV infection with active viral replication, and transaminase levels >2000 IU/ml be treated with a nucleotide or nucleoside analog on a moderate degree of certainty	*Moderate*	Weak [14]
HIV treatment	We suggest that all patients with HIV infection regardless of CD4 count be treated with antiretroviral therapy with a moderate degree of certainty	*Moderate*	Weak [16]

GRADE assessment of the certainty of the evidence: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

Table 43.2 Variations in clinical definitions of CRBSIs.

	Clinical definitions
CDC	Clinical manifestations and at least one positive peripheral blood culture and no other apparent source, with either positive semiquantitative (>15 CFU/catheter segment) or quantitative (>10 CFU/catheter segment) culture, whereby the same organism is isolated from the catheter segment and a peripheral blood sample. Simultaneous quantitative cultures of blood samples with a ratio of ≥3 : 1 (catheter vs. peripheral). A differential period of catheter culture vs. peripheral blood culture positivity of at least 2 hours. **OR** The isolation of the same organism from semiquantitative or quantitative culture segment and from blood with accompanying symptoms of bacteremia and no other apparent source of infection.
IDSA	Bacteremia or fungemia in a patient with an intravascular catheter with at least one positive blood culture and with clinical manifestations of infections and no apparent source for the bacteremia except the catheter. **AND** One of the following must be present: i) A positive semiquantitative (>15 CFU/catheter segment) or quantitative (>10^3 CFU/catheter segment) culture whereby the same organism is isolated from the catheter segment and peripheral blood. ii) Simultaneous quantitative blood culture with a >5 : 1 ratio catheter versus peripheral. iii) Differential time period of catheter culture versus peripheral blood culture.
KDOQI	**Definite:** Same organism from a semiquantitative culture of the catheter tip (>15 CFU/catheter segment) and from a blood culture in a symptomatic patient with no other apparent source of infection. **Probable:** Defervescence of symptoms after antibiotic treatment with or without removal of the catheter in the setting where blood culture confirms an infection, but the catheter tip does not or vice versa in a symptomatic patient with no other apparent source of infection. **Possible:** Defervescence of symptoms after antibiotic treatment or after removal of catheter in the absence of laboratory confirmation of bloodstream infection in a symptomatic patient with no other apparent source of infection.

mimic flow obstruction as the underlying cause of thrombosis and bleeding. Systemic symptoms with fever, chills, and other signs of sepsis along with any of the aforementioned clinical findings over the AVG should raise suspicion for infection [63]. Blood cultures should be drawn when AVG infection is suspected. It is also important to first identify the age of the AVG such as to determine whether it may be related to recent surgical graft implantation (<30 days) or due to a breakdown in sterility from recurrent cannulations required for HD [64]. Duplex ultrasonography can be used serially as an adjunct to make the diagnosis of AVG infection by evaluating graft flow and fluid collections [60, 65]. However, evaluating fluid collections with ultrasonography is limited by its lack of specificity in differentiating hematomas, seromas, and abscesses; in such cases the utilization of nuclear scans using radiolabeled techniques with technetium-99 m tagged white blood cells has been proposed [63].

Blood cultures are not always positive in patients and frequent cannulation of peripheral veins may also hinder the future creation of fistulas or grafts. A recent single-center Canadian prospective study demonstrated that blood cultures drawn from the HD circuit were most sensitive and specific in diagnosing CRBSI [66]. This practice in turn could not only reduce peripheral vein cannulation but also improve diagnostic yield of blood cultures in diagnosing CRBSIs. Therefore, if there is a high suspicion for vascular access related infection, clinicians should get two sets of blood cultures (at least one preferably from the HD circuit) and start broad-spectrum antibiotics.

Prognosis

Other prognostic factors beyond immune system dysregulation in HD patients include the type and location of access site along with cannulation methods utilized. For example, CRBSIs account for a two- to threefold increase in infection risk, hospitalization, and death compared to an AVF or AVG [67]. Observational studies have also reported an incidence of five infection episodes/1000 catheter days but there is significant variation across different types of vascular access [23, 53, 68]. Among hemodialysis catheters, tunneled cuffed lines carry a lower risk of infection compared to lines that are not tunneled [23, 68–70].

However, disagreement exists among practitioners as to whether the site of CVC is a major risk factor for developing catheter-related infections. A recent observational study from China suggested that the femoral vein site carries the highest risk for all types of catheter-related infections regardless of whether it is tunneled or not

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(Table 43.3) [71]. However, data on this point are inconsistent. In the ICU literature some studies show the femoral vein position to be worse than other sites while others don't show this consistent relationship [72, 73]. Importantly, it is unclear if these results translate to noncritically ill HD patients, but the data do suggest that a certain subset of patients with higher body mass index may be at increased risk for infection with femoral catheters. Despite the conflicting data, the CDC still recommends that catheters be placed at other sites over the femoral site to reduce risk of infection [74]. Most importantly, catheter insertion site must be prioritized according to the care plan and patient specific needs until more data becomes available.

The lowest risk of infection has been identified in patients with primary AVF [75]. A small Canadian study revealed that bacteremia rates were about 10 times greater in AVGs compared to AVFs with 2.5 and 0.2 episodes per 1000 dialysis sessions, respectively [76]. AVG infection has been identified as one of the leading causes of graft loss among HD patients, accounting for about 35% of cases [77].

Although buttonhole techniques cannot be utilized in patients with AVGs, there are still variations in cannulation methods used for AVFs which may present differing risks for developing local and systemic infections. Recent randomized controlled trials and a systematic review have revealed that patients who use buttonhole compared to rope-ladder cannulation techniques for AVF have an increased risk of infection and a slight increase in risk of metastatic complications arising from *S. aureus* bacteremia [78, 93]. Additionally, the most recent and largest randomized trial yet has shown that buttonhole cannulations were associated with increased rates of localized and systemic infections [82]. Patients who perform buttonhole cannulation tend to be home HD patients and thus perform dialysis more frequently [83, 84]. Several other factors, including more frequent cannulation and deviations from routine sterile techniques, may also account for increases in risk of infection. Wong et al. [79] reported in their systematic review that buttonhole cannulation was consistently associated with higher rates of systemic and local AVF related infections.

Other confounding factors are important. Patients who have to start dialysis urgently are more likely to have a CVC access site given the time limitations required for maturation for an AVF or AVG and are more likely to be late referrals or have ESKD as a result of catastrophic acute kidney injury. Consequently, these patients may have a greater burden of disease accounting for their increased morbidity and mortality rather than factors related to their type of access [85, 86]. Furthermore, higher blood flow rates in AVF compared to CVC may account for improved dialysis adequacy and in turn better outcomes [87].

According to the 2017 USRDS data, hospitalization rates related to sepsis among hemodialysis patients has steadily increased over the last 15 years [88]. In 2012, the 3-month mortality from sepsis was about four times greater in patients who started hemodialysis with a CVC compared to those who started with an AVF [89]. Regardless, all vascular access infections pose significant risks for developing sepsis and there is general agreement among clinicians

Table 43.3 Infection rate comparison between types of catheters and location in HD patients.

	Infection rate (infections/1000 catheter days)		
Vascular access type	**CRBSI**	**Tunnel infection**	**Exit site infection**
Tunneled central venous catheter			
Right internal jugular	6.69	2.76	4.93
Left internal jugular	6.49	2.68	5.06
External jugular	6.62	2.72	5.26
Femoral vein	10.08	3.56	10.68
Subclavian vein	6.42	2.75	5.16
Nontunneled central venous catheter			
Right internal jugular	3.57	–	8.79
Left internal jugular	3.61	–	8.54
Femoral vein	9.93	–	19.66
Subclavian vein	3.75	–	8.85

that the primary goals must focus on prevention. Unfortunately, large randomized controlled studies to provide robust evidence are lacking. Most guidelines are formulated based on a combination of expert opinion and observational data.

Treatment

Management of Vascular Access Infections in Hemodialysis

All HD patients with vascular access infections require early treatment and close observation to reduce risk of significant complications. Patients must have their dialysis access site evaluated regularly to determine if combined surgical and medical treatment strategies are warranted. The IDSA guidelines recommend that broad-spectrum antibiotics should include vancomycin plus gram-negative rod coverage based on local microbiological patterns for treatment of CRBSIs [3, 40]. Cefazolin can be used as an alternative to vancomycin if local methicillin-resistant staphylococcal rates are low [90, 91] (Table 43.4).

Table 43.4 Recommended dosing for broad-spectrum antibiotics while awaiting blood culture results.

Broad-spectrum antibiotics and dosing*a* for patients on hemodialysis
• Vancomycin or cefazolin plus empirical gram-negative rod coverage based on local microbiological patterns
– Vancomycin*b* plus gentamicin
○ Vancomycin: 20 mg/kg loading dose infused during the last hour of hemodialysis, followed by 500 mg during the last 30 min of each subsequent hemodialysis session
○ Gentamicin (or tobramycin:) 1 mg/kg, not to exceed 100 mg after each dialysis session
– Cefazolin*b*
○ 1 g intravenously postdialysis on dialysis days
○ If patient <50 kg, 750 mg intravenously postdialysis on dialysis days
• For Candidemia
– An echinocandin
○ Caspofungin 70 mg intravenous loading dose followed by 50 mg intravenously daily
○ Micafungin 100 mg intravenously daily
○ Anidulafungin 200 mg intravenously daily loading dose, followed by 100 mg intravenously daily
– Fluconazole 200 mg orally daily
– Amphotericin-B intravenously (usually given thrice weekly; refer to other sources for specific details)

Sources: Mermel et al. [3], Fogel et al. [100] and Barth et al. [104].
[a] Broad -pectrum dosing until the blood culture results become available.
[b] Cefazolin can be used instead of vancomycin in areas where there is a low prevalence of methicillin-resistant staphylococci.

Beyond local microbiological patterns, antibiotics should also be chosen with two things in mind: (i) the feasibility of administering around or with dialysis sessions and (ii) the side effect profile (e.g. ototoxicty, reducing residual renal function). Cephalosporins can usually be given after dialysis and do not cause ototoxicity nor lead to further reductions in residual renal function as compared to their counterparts, aminoglycosides [23, 72, 73]. It is for this reason that third- or fourth-generation cephalosporins are preferred over aminoglycosides in treating gram-negative organisms.

In all HD patients with CRBSI, early source control with catheter removal is an important consideration. Catheters should be removed in a variety of clinical situations (e.g. metastatic complications, persistent bacteremia or infection with *S. aureus*, *Pseudomonas* spp. and fungal organisms) (Table 43.1) but if alternative access cannot be established then catheter salvage procedure or changes over a guidewire should be considered [26, 90]. Catheter salvage has been defined as the continued use of a catheter throughout a CRBSI and concurrent treatment occurring with a combination of systemic antibiotics and antibiotic lock therapy [26]. However, this technique should not be utilized in cases of persistent bacteremia for more than 72 hours after initial treatment, metastatic complications, concomitant exit or tunnel site infection, or infection with pseudomonal, *S. aureus*, and fungal mircoorganisms [26, 90].

In terms of definitive treatment, management must be individualized according to specific patient needs, microorganisms isolated, and the type of vascular access. Miller and colleagues [90] highlighted that treatment of a CRBSI should focus on systemic antibiotics, antimicrobial lock solutions, and catheter management. Alternatively, for AVFs or AVGs management should focus on systemic antibiotics and managing any access site complications. The surgical management of an AVG infection may require total graft excision or subtotal or partial excision to achieve source control [77, 92]. Therefore, prompt consultation with vascular surgeons is required to definitively manage and reduce morbidity when AVG infection is suspected.

Infection Prevention Strategies

i) *Antimicrobial central catheter lock techniques*

The use of catheter lock techniques with antibiotics has become a more prevalent practice in the prevention and treatment of CRBSIs. In this practice, antimicrobial solu-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tions of varying concentrations are placed within the catheter lumen and then allowed to dwell for a period of time when the catheter is not being used for dialysis treatment [74]. Given the significant differences in patient populations, local resistance patterns, and relatively small studies, there are currently no FDA approved formulations of antimicrobial solutions for large-scale distribution [74]. The composition of solutions has been largely done with the assistance of pharmacists at local healthcare institutions. Additionally, antimicrobial solutions have also been used as flushes rather than being locked in catheters for prevention of CRBSI.

Although many randomized controlled studies and meta-analytic data have shown reductions in the rates of CRBSI, the results may have been confounded by factors such as concomitant topical antimicrobial treatment [23, 25, 73, 93–98]. Additionally, these studies have been further limited by short duration and thus the long-term sequelae of lock therapy have not been vigorously scrutinized, particularly rates of antimicrobial resistance.

It is important to note that despite the limitation of these studies, the additional benefit of antimicrobial lock solution has been identified when used in conjunction with systemic antibiotics. A systematic review of observational data involving over 1500 hemodialysis patients showed that combination antibiotic lock therapy and systemic antibiotics resulted in better outcomes than systemic antibiotics alone in treating CRBSI [78], including a lower rate of recurrent infection. This added benefit of antibiotic lock treatment hearkens back to the earlier discussion of biofilms and the need for much higher concentrations than usual doses required to eradicate sessile bacteria [47, 51, 101, 102]. However, one major potential drawback has been that antimicrobial solutions can lead to changes in local resistance patterns. This concern has been supported by recent observational studies showing an increase in gentamicin resistance when gentamicin-heparin locks were utilized as a prevention strategy for CRBSIs [101, 102].

A recent Cochrane review of over 27 studies with nearly 3000 patients suggested that antimicrobial lock solutions may be superior to heparin lock solutions in preventing CRBSIs with a low degree of certainty based on the current evidence (Table 43.5) [103]. In clinical situations where recurrent and difficult to eradicate infections persist, combination therapy with targeted antibiotic lock solutions and systemic antibiotics may be beneficial (Table 43.1). Therefore, clinical strategies should consider targeted and short duration antibiotic lock therapy to avoid conferring resistance among organisms until more data becomes available.

ii) *Other intracatheter lock techniques*

Other intracatheter lock techniques that been have shown to reduce infections include the use of recombinant tissue plasminogen activator (rt-PA) based on the results from one randomized trial. The Prevention of Dialysis Catheter Lumen Occlusion with rt-PA versus Heparin (PreCLOT study was a multicenter randomized controlled trial [104]. PreCLOT enrolled 225 HD patients and showed that patients receiving rt-PA (1 mg in each lumen) once per week had lower rates of catheter-associated bacteremia. The heparin-only group had 1.37 episodes/1000 patient days compared to 0.40 episodes/1000 patient days in the rt-PA group [104]. Despite the promising results from this study, the use and benefits of rt-PA in preventing infections may be limited to HD patients with newly inserted catheters. Therefore, additional studies are warranted before a broad recommendation on rt-PA use for infection prevention purposes can be made for all HD patients. Additionally, no meta-analytic data involving HD patients examining the use of rt-PA in reducing CRBSIs have been found from which we can propose evidence-based recommendations.

iii) *Coating or impregnation of central catheters for dialysis*

In terms of CVCs, several strategies, including impregnated lines with chlorhexidine, silver sulfadiazine, platinum/silver (e.g. silver iontophoretic), and antibiotics (minocycline, rifampin), have been developed to reduce vascular access-related infections [35, 74, 105–112]. Although impregnated catheters may cost more than standard catheters, they may reduce the risk of CRBSI and hospital-related costs of treating CRBSI [113, 114]. A majority of the studies examining impregnated catheters were conducted using triple-lumen, uncuffed catheters that were put in place for less than 30 days [74]. Although there may be some benefit in reducing infection risk in the short term, there may be an overestimation of benefit bias given the type of catheter and duration in these studies.

Catheters coated with chlorhexidine/silver sulfadiazine have evolved over the last several years. The first generation of chlorhexidine/silver sulfadiazine impregnated catheters were coated only externally whereas the second generation of catheters have evolved to include coating both inside and outside the catheter lumen [74]. There is also an increase in the external concentration of chlorhexidine that is three times greater in the second generation of catheters compared to the first [74]. Meta-analytic studies showed a significant reduction in CRBSI rates with chlorhexidine/silver sulfadiazine coated catheters when compared to standard catheters [114, 115]. Subsequent prospective studies examining second-generation catheters showed lower rates of colonization but lacked statistical power to demonstrate meaningful differences in CBRSI rates between standard and coated catheters [116–118]. Despite the aforementioned benefits of chlorhexidine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

catheters in reducing the rates of CBRSI, there have been rare reports of anaphylactic reactions [119–122]. Therefore, clinicians should be aware of this potentially life-threatening hypersensitivity reaction in patients with chlorhexidine-impregnated catheters.

Minocycline and rifampin have demonstrated short-term benefit, primarily against *Staphylococcus epidermidis* organisms [113, 114, 123]. A multicenter randomized controlled trial showed that CVCs impregnated on both the external and internal surfaces with minocycline and rifampin were associated with lower rates of infection [109]. On the other hand, there has been a theoretical risk of conferring increased antimicrobial resistance among organisms exposed to impregnated catheters. However, the reports of minocycline/rifampin-resistant organisms have been extremely low in in vitro prospective studies [124, 125]. Furthermore, there have been no previous reports in the clinical setting of resistant organisms arising from antibiotic impregnated catheters.

Although many of these studies highlighting impregnated catheters are underpowered, observational data suggests that these interventions may reduce risk of CRBSIs among hemodialysis patients (Table 43.1). Until larger trials are published that go against current practices, the benefits of impregnated catheters outweigh potential risks.

iv) *Noncatheter-based general strategies*

Other noncatheter-based infection prevention strategies should also focus on cannulation methods. Cannulation methods, particularly buttonhole cannulations, is another factor to consider that increases risk of vascular access related infection in hemodiaysis patients. At least two systematic reviews have shown good evidence that rope ladder cannulation should be utilized over buttonhole cannulation to reduce infection risk [79, 80]. Based on those reviews, we recommend that rope ladder cannulation be chosen over buttonhole technique to reduce the risk of vascular access related infections (Table 43.5).

Table 43.5 Summary of findings: catheter and cannulation-based infection prevention strategies.

Outcomes	No. of participants (no. of studies)	Events per 1000 catheter/AVF[a] days (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Antimicrobial lock solutions versus heparin lock solutions					
CRBSI	2994 (27)	161 fewer (190–122 fewer)	0.38 (0.27–0.53)	Low ●●○○	Antibiotic locks may be superior to heparin compared to lock solution with low degree of certainty
Thrombosis	2080 (14)	69 fewer (158–73 fewer)	0.15 (0.03–0.81)	Very low ●○○○	It is uncertain whether there are any differences in antibiotic and heparin lock solutions in preventing catheter-related thrombosis
Antibiotic impregnated catheters versus standard catheters					
All-cause mortality	2643 (10)	50 fewer (105 fewer to 21 more)	0.92 (0.80–1.07)	High ●●●●	Antibiotic impregnated catheters do not reduce all-cause mortality compared to nonimpregnated catheters with a high degree of certainty
CRBSI	10 405 (42)	112 fewer (140–77 fewer)	0.62 (0.52–0.74)	High ●●●●	Antibiotic impregnated catheters reduce CRBSI with a high degree of certainty, particularly in the ICU setting
Buttonhole versus rope-ladder cannulation					
Infection	90 (15)	Not estimable	3.18 (2.12–4.77)	High ●●●●	Buttonhole cannulation is associated with higher rates infection (local and systemic) compared to rope ladder cannulation

CI, confidence interval; CRBSI, catheter-related bloodstream infection.
Estimates are drawn from two Cochrane reviews and one systematic review [6, 91, 114]. GRADE assessment of the certainty of the evidence: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. v) *Topical ointments*

The colonization of the exit site by organisms from skin flora poses a significant risk for patients to develop exit site infections and bacteremia. The application of topical antiseptic agents including chlorhexidine, povidone-iodine and antimicrobial ointments has been shown to reduce the risks of infection [74, 107, 126, 127]. In 2010, a Cochrane Review of preventative strategies against infections related to hemodialysis catheters found that there were significant reductions in CRBSIs and exit site infections with mupirocin and polysporin based-antibiotic ointments along with povidone-iodine ointment (Table 43.6) [94]. Recent observational and meta-analytic data have also suggested that chlorhexidine is superior to povidone-iodine ointments in preventing infections [35, 94, 106]. Although there are some potential drawbacks with topical solutions, including damage to silicone-based catheters, bacterial resistance, and fungal colonization, the preventative

Table 43.6 Summary of findings: topical antibiotic ointments for preventing vascular access related infections.

Outcomes	No. of participants (no. of studies)	Events per 100 000 catheter days (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Topical antibiotic ointment versus no ointment					
CVC infection	193 (2)	Not estimable	0.33 (0.18–0.61)	Moderate ●●●○	Topical antibiotic ointments likely reduce CVC infections
Exit site infection	346 (4)	Not estimable	0.20 (0.09–0.45)	Moderate ●●●○	Topical antibiotic ointments likely reduce exit site infections
CRBSI	212 (2)	1051 fewer (1142–880 fewer)	0.19 (0.12–0.32)	Moderate ●●●○	Topical antibiotic ointments, particularly with mupirocin compared to no agents reduce CRBSIs
Mortality (all-cause)	332 (3)	Not estimable	0.36 (0.12–1.07)	Low ●●○○	It is uncertain whether topical antibiotics improve all-cause mortality
Mortality (infection-related)	332 (3)	Not estimable	0.15 (0.03–0.81)	Low ●●○○	It is uncertain whether topical antibiotics improve mortality related to infections
Topical honey versus antibiotic ointment					
CVC infection	– (—)	Not estimable	No studies	Absent	No studies to evaluate impact of topical honey compared to topical antibiotics on CVC infection alone
Exit site infection	150 (2)	Not estimable	0.45 (0.10–2.11)	Very low ●○○○	It is uncertain if topical honey reduces exit site infection compared to topical antibiotic ointment
CRBSI	150 (2)	337 fewer (1052 fewer–973 more)	0.83 (0.47– 1.49)	Very low ●○○○	It is uncertain if topical honey reduces CRBSIs compared to topical antibiotic ointment
Mortality (all-cause)	– (—)	Not estimable	No studies	Absent	No studies to evaluate impact of topical honey compared to topical antibiotics on all-cause mortality
Mortality (infection-related)	– (—)	Not estimable	No studies	Absent	No studies to evaluate impact of topical honey compared to topical antibiotics on infection-related mortality

CI, confidence interval; CRBSI, catheter-related bloodstream infection; CVC, central venous catheter.
Estimates are drawn from one Cochrane review [9]. GRADE assessment of the certainty of the evidence: High: This research provides a very good indication of the likely effect. benefits outweigh risks such that the CDC recommends antibiotic or povidone-iodine ointment to exit sites after every dressing change [74] (Table 43.1). Alternatively, topical agents such as honey to exit sites have shown promising results in reducing catheter-associated infections in a small randomized control study [130]. However, the small sample size in this study limits the wider adoption of honey as a topical agent on exit sites among hemodialysis patients.

As mentioned earlier, the colonization of exit sites by skin flora poses significant risk for infection among hemodialysis patients [55, 129]. Colonization of other areas beyond the exit site can also pose risks for infection. *S. aureus* is the most common nosocomial pathogen worldwide [130], associated with high morbidity and mortality rate, attributable to its widespread colonization. The nasal passage of about 25% of chronic HD patients is colonized by *S. aureus* [131]. Furthermore, given the morbidity and mortality associated with *S. aureus* infections and that a majority of infections originate from the nasal cavity, its eradication reduces risks to patients. A success rate for *S. aureus* eradication of >90% occurs with mupirocin 2% when used for 30–90 days [131, 132]. However, the success rate of eradication dramatically decreases when used beyond 90 days, possibly due to emergence of *S. aureus* resistance. Therefore, given the prevalence of *S. aureus* colonoziation among HD patients, eradication with mupirocin and wearing surgical masks at times when vascular sites are being accessed reduces risk of contamination [133, 133–135]. Additionally, the use of aseptic techniques and barriers helps further reduce infection risk with needle insertion and CVC manipulation for the initiation of dialysis [24, 26, 115]. The importance of proper aseptic practices cannot be understated as rates of infection increase when nursing staff are inadequately trained [136, 137].

Nosocomial Infections

As mentioned earlier, HD patients are at increased risk for all types of infection, including *C. difficile* associated diarrheal illness and pneumonia. The treatment of *C. difficile* in HD patients is similar to that used in the general population with some minor adjustments in the dosing for metronidazole [138, 139]. Similarly, the treatment of pneumonia is quite similar to that for the general population with alterations in dosing for renally cleared medications being the only significant difference. Furthermore, current guidelines recommend that all patients on hemodialysis should receive the annual influenza vaccine and 23-valent pneumococcal polysaccharide vaccine every 5 years provided that there are no contraindications [140–142] (Table 43.1).

Bloodborne Viral Infections

Apart from bacterial infections, HD patients are at increased risk for bloodborne viral infections, including HBV, HCV, and HIV [7]. The new 2017 Kidney Disease International Global Outcomes (KDIGO) clinical practice guidelines recommend that all HD in-center patients should be screened initially for HCV and then once every 6–12 months afterwards [143]. Additionally, all HD patients should be evaluated for treatment with an interferon-free based regimen and the choice of direct acting antiviral agent should be based on HCV genotype, viral load, drug interactions, degree of hepatic fibrosis, eGFR, and other medical comorbidities [143] (Table 43.1). In order to limit the intra-unit spread of these bloodborne viruses, hemodialysis units must ensure that there is implementation of and adherence to infection control practices. These practices will prevent the transfer of infections through contaminated fluids, equipment, and/or surfaces. Strict infection control procedures [143] are the mainstay of preventing the spread of viral infections. For patients infected with HCV and HIV, patient isolation and the use of dedicated machines is not required.

However, the practices for HBV are different and patients with positive hepatitis B surface antigen (HBsAg) should be isolated in separate rooms with dedicated machines and equipment (Table 43.7) [144, 145]. Despite the increased risk of transmission among HD patients, the prevalence of HBV infection has remained stable over the last decade owing to infection control measures, screening for infection, and vaccination [146]. The prevalence of HBsAg positivity among HD patients is also

Table 43.7 Recommended HBV precaution and isolation practices.

- Patients should be placed in a private room or segregated area
- Healthcare workers caring for patients with HBV cannot care for HBV-susceptible patients concomitantly
- Healthcare workers caring for patients with HBV should be HBV immune
- Contact precautions should be undertaken by wearing gloves and gowns
- Facial mask with eye protection with every cannulation and decannulation
- Dialyzers should not be reprocessed/reused

HBV, hepatitis B virus.

dependent on the endemic state within the general population. In 2002, the prevalence of HBsAg positivity among HD patient was about 1% in the United States [146], whereas the prevalence of HBV infection among HD patients from most Pacific Asian countries ranges from 5% to 15% [147].

HBV maintains environmental stability by persisting on surfaces and equipment at ambient room temperatures, where it can remain infectious for up to 7 days after contamination [152]. Additionally, patients with HBV infection also tend to have high viral titers; coupled with environmental stability, this makes the risk of HBV transmission much higher than that seen with other bloodborne viruses. Additionally, HD patients with active HBV infection that are treated with a nucleotide or nucleoside analog, which reduces the overall risk of infection to other patients within a dialysis unit [148]. Treatment for acute and chronic infections are dependent on patient viral load (HBV DNA >2000 international units [IU]/ml), abnormal liver enzymes and evidence of active replication with a positive hepatitis B e antigen (HBeAg) [148].

All HD patients who are nonimmune to HBV should receive HBV vaccine in an attempt to reach the desired antibody titer of ≥10 mIU/ml. Patients receive three doses of 40 μg at three intervals (months 0, 1, and 6) and if the patient does not achieve the desired antibody titer then a repeat course of vaccination is recommended [144, 145]. If a patient still does not respond after the second course of vaccination, no further doses of intramuscularly administered vaccine are recommended [144]. However, patients who are nonresponders can be given intradermal HBV vaccine [149]. Observational studies have shown significant improvement in the rates of vaccine-induced seroconversion after intradermal administration in HD patients who did not respond initially to intramuscularly administer vaccines [150–153]. Patients who remain nonimmune to HBV despite the abovementioned strategies must be followed with monthly HBsAg as they remain susceptible for future infection.

Conclusion

Patients on hemodialysis continue to be at an extremely high risk of contracting infections. Given the degree of immune dysregulation along with increases in CVC use seen in HD patients, infection risk is further potentiated, particularly for CRBSIs. There is data showing that various prevention strategies can reduce vascular access related infections among patients. However, an approach that extends beyond aseptic technique practices, impregnated catheters, and antibiotic locks is demanded. Given the significantly higher risk of infection with CVCs compared to an AVF, tireless strategies prioritizing fistula creation are warranted. Development of infectious surveillance programs has seen tremendous success across various centers in tracking local infection rates and reducing recurrences of CRBSI, therefore all dialysis programs must consider the creation of an infection surveillance team consisting of dedicated clinical staff and resources, ensuring that timely treatment occurs. This team should also perform ongoing catheter audits and rationale for catheters in an attempt to promote a "fistula first" and "lines last" strategy to further improve clinical outcomes. Adjunctive approaches with impregnated catheters and antibiotic locks as a prevention strategy can be considered on an individual basis. However, antibiotic locks should strongly be considered in conjunction with systemic antibiotics for the treatment of CRBSIs in an attempt to eradicate biofilms on the catheter. Although some of these preventative and treatment strategies appear promising, there continues to be a lack of high-quality data to support their efficacy in HD patients. Future priorities must focus on generating data from larger and more robust studies to improve current evidence-based guidelines and in turn clinical outcomes for all HD patients.

Furthermore, HD patients are at risk for all types of infection therefore appropriate vaccinations for respiratory infections are recommended and the risk of bloodborne viral infections particularly HBV demands consistent vigilence and strict infection control procedures.

Vascular Access for Hemodialysis

Kevan R. Polkinghorne[1] *and Andrea K. Viecelli*[2]

[1] *Department of Nephrology, Monash Medical Centre, Melbourne, Victoria, Australia*
[2] *Department of Nephrology, Princess Alexandra Hospital, Brisbane, Queensland, Australia*

Introduction

Hemodialysis is the dominant form of therapy for patients with end-stage kidney disease (ESKD) and requires repetitive, complication-free access to the peripheral blood circulation. Hence the establishment and maintenance of vascular access is pivotal and has long been labeled the Achilles heel of hemodialysis due to its vital role in the delivery of hemodialysis [28]. The provision of vascular access for hemodialysis patients therefore represents a major management focus for all nephrologists.

Definition

Vascular access for hemodialysis can be achieved in three ways: by a native arteriovenous fistula (AVF), an arteriovenous graft (AVG) (usually polytetrafluoroethylene or PTFE), or a cuffed (or uncuffed) central venous catheter (CVC) (Figure 44.1). The native AVF, first described by Brescia, Cimino, and colleagues in 1966 [29], is a surgically constructed connection between a peripheral artery and vein. The most common configurations are either at the wrist (radiocephalic AVF) or at the elbow (brachiocephalic AVF), although several other surgical configurations are used. All AVFs require time to mature before they can be used for dialysis, with time durations that can range from as low as 1 month up to 6 months.

The AVG is constructed by implanting a synthetic tube (most commonly PTFE) between an artery and a vein in the arm, usually as a loop between the cephalic artery and vein at the elbow. The major advantage of AVGs is the shorter maturation period – usually 1–2 weeks – but this is at the expense of the need for more interventions to maintain patency. Successful use of the PTFE AVG was first reported in 1976 and by the late 1980s it was the predominant vascular access used in the United States [30]. Following the preference of AVFs over AVGs by clinical guideline groups [31–34], use in the United States and other countries has declined [35].

Cuffed CVCs are tunneled subcutaneously, ideally into the right internal jugular vein but can be placed in other central veins depending on clinical circumstances. The main role of the cuffed CVC is as a bridge until either an AVF or an AVG can be constructed or kidney transplantation occurs or as permanent access in the patient who has exhausted all other vascular access possibilities.

Epidemiology

Clinical practice guidelines recommend the native AVF as the vascular access of first choice for patients treated with hemodialysis [31–34]. These recommendations derive from an assessment of vascular patency rates, infection risk, lower mortality, and lower costs. Here we discuss these recommendations and provide interpretation in relation to more recent data published since the guidelines were written.

Prior to the mid 2000s, it was clear that, compared to AVGs, AVFs had superior long-term patency rates as well as lower intervention rates to maintain patency [33]. However, with the changing demographic of the dialysis population, principally due to increasing age and comorbidity (especially diabetes mellitus and cardiovascular disease), the superiority of AVFs over AVGs in terms of patency has become less clear, specifically when AVF primary failure is considered [36]. Rates of primary failure of AVFs increased from 15–20% in 1980s and 1990s [37] to 40–50% in study cohorts assessed after 2005 [38]. Rates as high as 60% have been seen in trials addressing antiplatelet

agents and their effect on primary AVF failure [39, 40]. However, it is clear that once an AVF has been established, the long-term intervention-free patency remains superior compared to that of an AVG [36]. Data from the Dialysis Outcomes and Practice Patterns study (DOPPS), assessing noninfectious vascular access-related complications, show that after commencement all access types experience high compilation rates in the first 6 months of dialysis, with steep declines thereafter [41]. The overall risk of complications is lowest for AVFs, highest for CVCs, and AVGs have an intermediate risk [41]. Subsequent work suggests that CVCs have a 40% lower risk of noninfectious patency complications compared to AVFs in the first 90 days after dialysis commencement, which then reverses to a 22% increase risk in the subsequent 90 days [42].

Infectious complications of vascular access are also lowest for AVFs, highest for CVCs, and intermediate for AVGs [41–43]. Infection rates for CVCs are about twice the rate for AVFs in the first 6 and 12 months following dialysis commencement [41, 42]. Catheter-related bacteremia is responsible for 70% of vascular access-related bacteremia in the United States [44] and can result in prolonged hospitalization with major compilations such as endocarditis and metastatic infections. While AVFs have the lowest rate of infection, bacteremia as a result of an infected AVF is an important complication. In particular, rates of infection are consistently higher with the use of buttonhole needling such that it should only be used in situations where rope ladder cannulation is not possible or easy [45, 46].

Mortality according to access type has been assessed in a number of different populations [47–50], with all the observational studies summarized in a recent systematic review [43]. CVC use is consistently associated with higher risk of all-cause and infectious death compared to AVF use. However, while results are consistent across multiple studies and different populations, patients who commence with a CVC are different to those using an AVF, and therefore results remain susceptible to residual confounding and indication bias. Recent data suggest that mortality rate by access type may not be directly attributable to the actual access in use [42, 51]. However, only adequately powered randomized trials can address such a question, with attempts underway to ascertain initial feasibility of such a study [52, 53].

The maintenance of vascular access in hemodialysis patients is estimated to account for at least 25% of all dialysis patient hospital admissions in the United States [54, 55]. Two early studies specifically performed a cost analysis by vascular access type [56, 57], both from Canada. The first study [57] considered the costs of maintaining a functioning access in prevalent patients, demonstrating significantly lower access-related costs per patient per year for patients who were using an AVF compared to those with an AVG and catheter. Total costs, including access-related interventions and hospital stays, were lowest for AVFs, highest for AVGs and intermediate for CVCs. The same

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. group then prospectively studied the costs for the establishment and maintenance of vascular access in an incident cohort of subjects [56]. In that time, 18.4% of all hospital admissions were vascular access related. Again, the mean cost of access care per patient-year at risk was lowest for AVFs compared to catheters and AVGs: CAN$9180 for maintaining a catheter exclusively, CAN$11685 for attempting an AVG, and CAN$7989 for attempting an AVF. More recent estimates suggest that AVF costs are lowest over 2 years in those in whom primary patency of the AVF is maintained but highest in subjects who commence dialysis with a CVC and a maturing AVF in situ [58]. Patients who dialyze solely with a CVC and did not have an AVF created had higher healthcare delivery costs compared to those with a patent AVF, but significantly lower than those with a CVC and maturing AVF. Similar to the mortality question, an unbiased cost-effective analysis would require an adequately powered and designed randomized trial.

Both incidence and prevalence rates for the three vascular access types vary considerably across different countries and indeed across different jurisdictions and hospitals [59]. In the majority of countries, new ESKD patients commencing hemodialysis for the first time do so via a CVC [59]. However incident CVC rates vary from as low as 10% in Japan to 50% in the UK, Australia, and New Zealand, and 70% in the United States and Canada. Likewise, AVF/AVG prevalence rates vary significantly across countries. Canada, for example, has one of the lowest AVF/AVG prevalence rates in the developed world at approximately 55%. In contrast, the United States, which implemented the "fistula first" program, have increased the AVF prevalence rate from 30% in the early 2000s to 65% in 2016 [60]. The Australia and New Zealand AVF/AVG prevalence rates sit at 75–80% and have remained stable over the last 15 years [61], with rates in Japan consistently at 97% [60]. In addition to the prevalence rates, there is marked variation across countries in relation to anatomical location and successful usage of AVF. In Japan, more than 90% of AVFs are placed in the lower arm whereas in the United States upper arm AVFs are the most prevalent [62]. In Europe, Australia, and New Zealand lower arm AVFs make up approximately 65% of all AVFs used [62]. While differences in permanent access rates can be attributed in part to differences in patient case mix, differences in physician and healthcare practice patterns will also play an important role.

Pathophysiology

A large number of interventions aimed to prevention of vascular access dysfunction have been tested and are summarized in table 44.1. Before presenting the evidence for each treatment in detail we first discuss the pathophysiology of vascular access dysfunction.

Pathophysiology of Arteriovenous Access Dysfunction

Delivery of effective hemodialysis via an AVF or AVG requires sufficient access blood flow and an accessible conduit that can resist repeated cannulation. Failure to attain these properties is usually the result of a vascular stenosis due to neointimal hyperplasia, access thrombosis, inadequate vasodilatation and vascular remodeling or any combination of these [63]. An AVF usually takes between 1 and 9 months to be usable for dialysis and around 20% and 60% of AVFs fail to mature adequately [39, 40, 64]. AVGs can be used within days [65], but require more interventions to maintain long-term patency compared to AVFs [36].

The complex pathophysiology of neointimal hyperplasia and maladaptive vascular remodeling causing access dysfunction or failure can be conceptualized as a cascade of "upstream" and "downstream" events [66]. "Upstream" events describe factors that cause endothelial and smooth muscle cell injury, including hemodynamic shear stress due to the altered hemodynamics following creation of an arteriovenous anastomosis, surgical manipulation, repeated cannulation, angioplasties, and the use of bioincompatible graft material. These events lead to a complex "downstream" response characterized by the interplay of pro-inflammatory cytokines, chemokines, metalloproteinases, and adhesion molecules that promote cell activation, proliferation, and migration with neointimal hyperplasia formation (a fibromuscular thickening of the vascular wall composed of extracellular matrix, myofibroblasts, and differentiated contractile smooth muscle cells) and unfavorable vascular remodeling (Figure 44.2). Other modulators include the uremic milieu characterized by inflammation, oxidative stress, and endothelial dysfunction [67–69], and genetic predispositions to neointimal hyperplasia formation, vasoconstriction, inflammation, and thrombosis [63, 70–73].

Pathophysiology of CVC Dysfunction

CVCs are the least preferred hemodialysis access due to the high risk of malfunction and infection that compromises the efficacy of hemodialysis and may increase patient morbidity, mortality, and healthcare costs [41, 48, 56]. In an attempt to standardize the definition of CVC dysfunction, the Kidney Health Initiative Vascular Access Working Group of the American Society of Nephrology has proposed the following criteria: "the inability of a CVC to (i) complete a single dialysis session without triggering recurrent pressure alarms or (ii) reproducibly deliver a

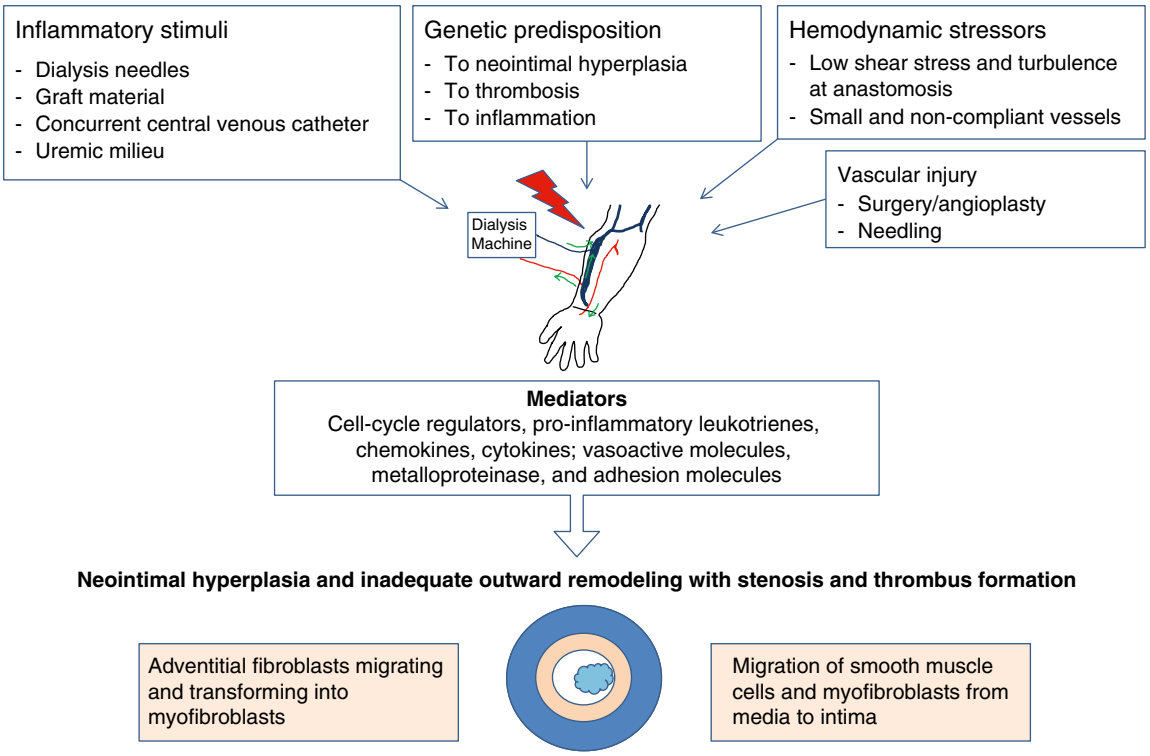

Figure 44.2 Pathogenesis of arteriovenous access failure. This figure summarizes the pathogenetic cascade of events that result in arteriovenous access failure: Hemodynamic and surgical stressors, inflammatory stimuli such as bioincompatible graft material, uremia and recurrent needling as well as genetic predisposition lead to activation of pro-inflammatory mediators that promote inadequate outward remodeling, migration and transformation of smooth muscle cells and fibroblasts with resulting neointimal hyperplasia, luminal narrowing and thrombus formation. *Source:* Viecelli et al. [98]. © 2018 John Wiley & Sons.

mean dialysis blood flow ≥300 ml/min (with arterial and venous pressures being within the hemodialysis unit parameters) or provide a Kt/V of 1.2 in 4 hours or less [74]."

Primary (early) dysfunction is typically caused by a mechanical problem including catheter malpositioning, tip malorientation, catheter kinking or constrictive sutures, and manifests during the first few catheter uses. Secondary (late) dysfunction may be the result of an intrinsic thrombosis within the catheter lumen, extrinsic thrombosis encasing the catheter and/or formation of a fibrin sheath [74] (Box 44.1). Exposure of the artificial catheter material to blood leads to protein adsorption and activation of the complement and coagulation pathways [75]. Fibrin deposition typically occurs at the site of intimal injury and can wrap the entire catheter within a few days [76]. In addition to fibrin, these sheaths contain laminin, fibronectin, collagen, and smooth muscle cells and overlying endothelial cells. Fibrin sheath formation is closely linked to biofilm formation. Biofilms are characterized by a sessile community of microorganisms that produce and embed themselves in an exopolysaccharide matrix [77, 78]. Biofilms facilitate sustained infection and subsequent hematogenous seeding of infective microorganisms, exemplifying the close interplay between catheter malfunction and catheter-related infections.

Table 44.1 Prevention of vascular access dysfunction.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Arteriovenous access			
Pre-operative ultrasound imaging	We suggest pre-operative ultrasound imaging be considered to increase the likelihood that an AVF will be created, mature and be used for dialysis.	*Low*	Very weak [1]
Preemptive correction of stenosis	We suggest that AVF surveillance coupled with pre-emptive correction can be used to reduce AVF thrombosis and potentially reduce AVF loss. AVG surveillance coupled with pre-emptive correction should not be used to prevent AVG thrombosis or loss.	*Low* (AVF) *Moderate* (AVG)	Weak [2]
Antiplatelet agents	We suggest antiplatelet agents can be used in AVF to reduce early thrombosis and failure (thrombosis or loss of patency). Patients with an AVF or AVG may reasonably choose not to receive antiplatelet therapies based on the low certainty that treatment makes any difference to attain arteriovenous access suitability for hemodialysis or reduce access interventions and may cause bleeding.	*Moderate*[a] (early thrombosis and access failure) *Low*[a] (failure to attain suitability for dialysis, need for arteriovenous access interventions, major or minor bleeding)	Weak [3, 4]
Fish oil	We suggest fish oil supplementation can be used in AVF and AVG to reduce primary patency loss. Patients with newly created arteriovenous access may reasonably choose not to receive fish oil based on the low to very low certainty that it makes a difference to the need for interventions to maintain patency or assist maturation, dialysis suitability (AVF), arteriovenous access abandonment, hospitalizations, all-cause or cardiovascular mortality, and uncertain adverse effects including bleeding and gastrointestinal adverse effects related to treatment.	*Moderate* (primary patency loss) Low (AVF dialysis suitability, interventions to maintain patency or assist maturation [AVF/AVG], arteriovenous access abandonment, gastrointestinal adverse effects, hospitalization) Very low (bleeding, all-cause mortality, cardiovascular mortality)	Weak [5]
Statins	Patients may reasonably choose not to take statins to improve arteriovenous access patency based on very low certainty that treatment makes little or no difference to AVF failure, primary or secondary arteriovenous access patency.	*Very low*	Weak [6]
ACEI/ARB	Patients with an arteriovenous access may reasonably choose not to take an ACEI or ARB based on the absence of randomized controlled trial evidence to support their potential benefits in improving primary or secondary arteriovenous patency.	*Not graded*	Very weak [7–11]
Calcium channel blockers	Patients with an arteriovenous access may reasonably choose not to take a CCB based on the absence of randomized controlled trial evidence to support their potential benefits in improving primary or secondary arteriovenous patency.	*Not graded*	Very weak [12, 13]
Infrared therapy	We suggest far infrared therapy can be used in AVF to improve primary patency and assisted patency, and reduce surgical interventions for AVF dysfunction.	*Not graded*	Weak [14]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 44.1 (Continued)

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
PRT-201 elastase	Patients undergoing arteriovenous access creation may reasonably choose not to have local application of PRT-201 elastase based on the absence of randomized controlled trial evidence to support their potential benefits in improving access patency.	*Not graded*	Very weak [15–17]
Endothelial loaded gel foam wrap (Vascugel)	Patients with an arteriovenous access may reasonably choose not to have Vascugel applied at time of AVF creation based on the absence of randomized controlled trial evidence to support their potential benefits in improving access patency.	*Not graded*	Very weak [18]
Paclitaxel-coated balloons	Patients with AVF stenosis may choose not to undergo revascularization with paclitaxel-coated balloon angioplasty based on the absence of high-quality, large-scale randomized controlled trial evidence.	*Not graded*	Weak [19]
Local application of sirolimus (COLL-R)	Patients undergoing arteriovenous access creation may reasonably choose not to have periadventitial application of R-COLL (a combination product of sirolimus and a collagen membrane) to improve arteriovenous access outcomes based on the absence of high-quality, large-scale randomized controlled trial evidence.	*Not graded*	Very weak [20]
Novel surgical techniques	Patients undergoing AVF creation may reasonably choose not to have novel surgical techniques including the use of an Optiflow anastomotic device or a piggybacking straight-line onlay technique based on the absence of randomized controlled trial evidence to support their efficacy.	*Not graded*	Very weak [21–23]
Endovascular arteriovenous fistula creation	Patients may reasonably choose not to undergo endovascular arteriovenous fistula creation based on the absence of randomized controlled trial evidence to support the superiority of this technique over open surgical access creation.	*Not graded*	Weak [24]
Central venous catheters			
Alterative anticoagulant locking solutions	Patients may reasonably choose not to use alterative anticoagulant locking solutions to prevent CVC thrombosis. We suggest that alternative anticoagulant locking solutions should be used to prevent CVC bacteremia. Antibiotic-based solution may be superior to nonantibiotic solutions.	*Low* (CVC thrombosis) *Moderate* (CVC bacteremia)	Weak [25]
Topical interventions to exit site	We suggest that topical interventions to the exit site should be used to prevent CVC bacteremia.	*Low*	Very weak [26]

ACEI, angiotensin converting enzyme inhibitor; ARB, angiotensin II type I receptor blocker; AVF, arteriovenous fistula; AVG, arteriovenous graft; CCB, calcium channel blocker.
GRADE assessment of the certainty of the evidence [27]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. affect successful AVF/AVG placement such as a history of peripheral and/or central venous cannulation and pacemaker insertion. Likewise a detailed clinical examination is extremely important, including evaluation of the arterial and venous system in both upper limbs, neck, and chest [79].

In addition to a clinical evaluation, preoperative assessment of the venous and arterial system in the arms has been recommended as an adjunct to assist the surgeon in selecting the best site for access formation and therefore improve AVF/AVG suitability [31]. Table 44.2 summarizes findings from randomized trials comparing ultrasound preoperative assessment to a standard clinical assessment on AVF creation, maturation and usability for hemodialysis [1]. Despite the widespread practice of ultrsound preoperative vein mapping, the evidence that this practice improves AVF outcomes is uncertain largely due to the small sample sizes and the number of trials. Current trial data suggest that the use of ultrasound at best modestly improves AVF maturation and usability by about 12% over a standard clinical assessment.

Vascular Access Surveillance

Once permanent vascular access has been established, the major clinical goal is to prevent complications, principally vascular stenosis resulting in failure (thrombosis) of the AVF or AVG. The ability to prevent AVF and AVG failure is an important clinical goal as early elective repair can avoid interruption to dialysis. The distinction between monitoring and surveillance of the vascular access is important. Vascular access monitoring refers to regular physical examination of the AVF or AVG by inspection, palpation and auscultation to detect physical signs of access dysfunction. Vascular access surveillance refers to the periodic evaluation of the vascular access by means of specialized tests that involve special instrumentation which includes the assessment of dynamic venous pressure (DVP) and static venous pressure (SVP), vascular access recirculation, doppler ultrasound (DU) screening, and vascular access blood flow (Qa) measurement. Vascular access monitoring and surveillance are complementary techniques.

Regular physical examination plays an important role in the management of the hemodialysis patient and is the most important first step in the assessment of the AVF/AVG [79]. Assessment of the pulse, thrill/bruit, and clinical features together with the arm elevation test and pulse augmentation demonstrate reasonable sensitivity and specificity for the detection of inflow and outflow AVF stenosis [80, 81]. Physical findings suggesting a significant venous stenosis include edema of the access extremity, prolonged bleeding post venipuncture, and changes in the physical characteristics of the pulse or thrill. Physical examination has excellent specificity to detect central venous stenosis but sensitivity is poor [80]. Coexistent inflow and outflow stenosis are also poorly detected by physical examination [80].

Vascular Access Surveillance: Access Blood Flow Monitoring

The most commonly used surveillance technique is the measurement of access blood flow. Vascular access blood

Table 44.2 Summary of findings: use of pre-operative imaging prior to AVF formation.

Outcomes	No. of participants (no. of studies)	Absolute effect per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Pre-operative Ultrasound imaging vs. standard assessment					
AVF created	433 (4)	51 more (43 fewer to 154 more)	1.06 (0.95–1.18)	Very low ●○○○	It is uncertain whether pre-operative ultrasound imaging increases AVF creation
Mature AVF	356 (3)	78 more (14 fewer to 176 more)	1.11 (0.98–1.25)	Low ●●○○	It is uncertain whether pre-operative ultrasound imaging increases AVF maturation
AVF used for dialysis	286 (2)	86 more (7 fewer to 200 more)	1.12 (0.99–1.28)	Low ●●○○	It is uncertain whether pre-operative ultrasound imaging increases AVF usability

flow can be measured by indicator dilution techniques or by estimating Qa most commonly using Doppler ultrasound [31]. Prospective studies, including one randomized trial [82], have sought an association between Qa and the risk of thrombosis and/or the presence of stenosis [82–87]. AVGs are at risk of thrombosis at higher flows (cut off 500–750 ml/min) [84, 85] and AVFs at lower flows (300–500 ml/min), which makes comparisons difficult [87]. However, for vascular access surveillance to be successful the individual screening tests must be efficient at detecting the presence of an underlying significant stenosis, and any pre-emptive correction of a stenosis thus detected should result in a reduction in access thrombosis rates and prolong access survival.

Trials assessing vascular access surveillance with pre-emptive correction of the vascular access stenosis have recently been summarized [2]. This Cochrane review included all trials assessing active surveillance, irrespective of the technique, with comparison to usual clinical monitoring. Results are summarized in Table 44.3. Overall there were 14 studies, including a total of 1212 participants. The most commonly used surveillance technique was the measurement of Qa by either ultrasound dilution or Doppler ultrasound. Study sample size was small and in general the risk of bias was high or unclear in the majority of included studies. Flow thresholds used for the triggering of investigation also varied between the studies. When assessing the effect of surveillance on access thrombosis for both AVG and AVF there is a suggestion for a modest 19% reduction in the risk of thrombosis (relative risk [RR] 0.79, 95% confidence interval [CI] 0.65, 0.97). When AVF and AVG were assessed separately the reduction in thrombosis rate was

Table 44.3 Summary of findings: access surveillance.

Outcomes	No. of participants (no. of studies)	Absolute effect per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Access surveillance with pre-emptive correction (comparator clinical dysfunction)					
Access loss (assisted patency): AVF and AVG combined	972 (11)	54 fewer (98 to 3 fewer)	0.80 (0.64–0.99)	Low ●●○○	It is uncertain if surveillance of AVF/AVG with pre-emptive correction reduces AVF/AVG loss
Access loss (assisted patency): AVG only	662 (7)	91 fewer (218 fewer to 77 more)	0.87 (0.69–1.11)	Moderate ●●●○	It is probable that surveillance of AVG with pre-emptive correction does not reduce AVG loss
Access loss (assisted patency): AVF only	310 (4)	110 fewer (157 to 31 fewer)	0.50 (0.29–0.86)	Low ●●○○	It is possible that surveillance of AVF with pre-emptive correction reduces AVF loss
Access thrombosis (unassisted patency): AVF and AVG combined	1212 (18)[a]	74 fewer (123 to 11 fewer)	0.79 (0.65–0.97)	Low ●●○○	It is possible that surveillance of AVF/AVG with pre-emptive correction reduces AVF/AVG thrombosis
Access thrombosis (unassisted patency): AVG only	697 (11)	20 fewer (82 fewer to 49 more)	0.95 (0.80–1.12)	Moderate ●●●○	It is probable that surveillance of AVG with pre-emptive correction does not reduce AVG thrombosis
Access thrombosis (unassisted patency): AVF only	515 (7)	139 fewer (181 to 81 fewer)	0.50 (0.35–0.71)	Low ●●○○	It is possible that surveillance of AVF with pre-emptive correction reduces AVF thrombosis
Catheter use	394 (6)	NA	0.58 (0.35–0.98)	Low ●●○○	It is possible that access surveillance reduces CVC use
Mortality	386 (5)	59 more (14 fewer to 173 more)	1.38 (0.91–2.11)	Low ●●○○	It is uncertain if access surveillance reduces mortality

confined to studies assessing AVF (RR 0.50, 95% CI 0.50, 0.71) while no effect was seen in those assessing AVG (RR 0.95, 95% CI 0.80, 1.12). Similarly, when the more important endpoint of access loss was examined, there was again a suggestion of a modest reduction in access loss with surveillance for AVF/AVG combined which was driven by a beneficial effect seen in AVF than was not evident in AVG. While the data suggest a potential benefit for access surveillance in relation to AVF loss, the results should be tempered by the fact that conclusions are based on only four studies with a small overall sample size, translating into a low certainty in the evidence. Finally, six studies also assessed the effect of surveillance on subsequent catheter use and suggested a reduction in catheter use in patients randomized to the surveillance arm.

Vascular Access Surveillance: Other Screening Techniques

Numerous other techniques have been advocated, including the measurement of access recirculation (AR), and dynamic and/or SVPs. AR reduces dialysis efficiency and occurs when the dialyzed blood, returning via the venous needle of the extracorporeal circuit, is taken up again through the arterial needle. This leads to bypassing of the systemic circulation and occurs within the AVG or AVF, when Qa is less than the dialyser blood flow (Qb) [88]. Thus, the presence of AR signifies reduced Qa resulting from the presence of a hemodynamically significant stenosis. The clinical usefulness of AR measurements in AVG surveillance is limited as the risk of thrombosis in AVG is high once Qa is reduced to 500–800 ml/min, a range of blood flow which is too high to cause AR [33]. Unlike AVG, AVF blood flow can decrease to lower than prescribed dialyzer blood flow while still maintaining patency. Thus, the measurement of AR can be a useful tool to detect AVF stenosis although there have been no randomized trials performed to date. However, measurement of AR using saline dilution failed to detect a significant number of patients with documented low AVF blood flow and thus does not add any extra benefit to Qa monitoring [86, 89, 90].

Pressure within AVGs and AVFs can be considered as a surrogate of blood flow but the relationship between pressure and flow differs between them (reviewed in [91]). Pressure is measured either at the venous drip chamber during dialysis (DVP) or with the blood pump stopped (SVP) using standardized methods [33, 92]. Schwab et al. [93] first described an association between raised DVP and the presence of AVG stenosis at the venous anastomosis and subsequently developed a screening/monitoring protocol [94]. Serial measurements should be performed, with the trend being more important than single values, remembering that any lesions within the body of an AVG will not be detected if proximal to the venous needle [95]. Given the problems associated with measuring venous drip chamber pressure, Besarab et al. suggested the measurement of intra-access pressure [95, 96]. While demonstrating a reduction in the thrombosis rate using historical controls [96], at present no randomized controlled trial (RCT) of either dynamic or intra-access pressure measurements in AVG or AVF has been performed [92]. An RCT of SVP monitoring versus clinical evidence of access dysfunction in AVG did not demonstrate a benefit of screening using SVP with angioplasty on AVG survival [97]. While venous pressure monitoring is widely practiced, the evidence that the detection and treatment of a significant stenosis in AVG prolongs graft survival is of poor quality [92]. Since the presence of collaterals prevents the rise in venous pressure consequent on a reduction in Qa due to a stenosis, DVP is not recommended as a surveillance technique to detect significant stenosis in AVF although for upper arm AVF this may not be the case where there is predominantly one draining vein.

Treatment

Prevention of Arteriovenous Access Failure

The main goal of treating arteriovenous access failure is to maintain access patency by preventing stenosis and thrombosis formation. In newly formed AVF and to a lesser extent AVG, an additional treatment target is the successful maturation of the access characterized by achievement of an adequate caliber, wall strength, and blood flow to resist repeated cannulation and achieve prescribed hemodialysis.

Recent advantages in the understanding of the biology of access maturation and the pathophysiology of vascular access dysfunction/failure (Figure 44.2) have helped to develop novel treatment targets and interventions to establish and maintain a functional arteriovenous access. These interventions can be classified into (i) systemic medical therapies including antiplatelet agents, omega-3 polyunsaturated fatty acid (fish oils), statins, inhibitors of the renin-angiotensin-aldosterone system (RAAS), and calcium channel blockers (CCB) and (ii) local treatment approaches such as novel surgical techniques, minimally invasive AVF creation, far infrared therapy, perivascular application of recombinant elastase, endothelial loaded gel foam wrap (Vascugel), and antiproliferative agents such as sirolimus (Coll-R) and paclitaxel-coated balloon angioplasty. Most of these interventions are multitargeted with pleotropic effects on flow dynamics and the vascular biology (Box 44.2) [98]. Despite multiple treatment strategies, most of the benefits are limited to the reduction of early thrombosis and patency loss, while high-quality evidence

Box 44.2 Treatment Strategies to Improve Arteriovenous Access Function

Systemic medical interventions	Effects on vascular biology/hemodynamics
Antiplatelet agents – Aspirin – Thienopyridines (e.g. clopidogrel, ticlopidine) – Dipyridamole – Sulfinpyrazone – Picotamide	Antiaggregatory Anti-inflammatory Antiproliferative
Omega-3 polyunsaturated fatty acids (fish oils)	Antiaggregatory Vasodilatory Inhibition of smooth muscle cell proliferation Reduction in blood viscosity Anti-inflammatory, resolution of inflammation Improved cardiovascular health
Statins	Anti-inflammatory Antiaggregatory Vasodilation Inhibition of smooth muscle cell proliferation Improved cardiovascular health
RAAS inhibitors – Angiotensin converting enzyme inhibitors – Angiotensin II type I receptor blockers	Inhibition of smooth muscle cell proliferation Antiaggregatory Vasodilation
Calcium channel blockers	Vasodilation Inhibition of neointimal hyperplasia
Local interventions	
Novel surgical techniques – Piggybacking straight-line onlay technique (pSLOT)	Optimizing flow and shear stress
– Optiflow device	Optimizing flow and shear stress by fixation of anastomotic angle of AVF at 60° Shielding of peri-anastomotic region
Endovascular AVF creation using radiofrequency magnetic catheter-based system	Reduction in vessel trauma and resulting triggers for neointimal hyperplasia formation
Far infrared therapy	Inhibition of vascular smooth muscle cell proliferation Inhibition of platelet aggregation Vasodilation Reduction in oxidative stress
Perivascular application of recombinant elastase Human type 1 pancreatic elastase (PRT-201)	Vasodilation by fragmentation of elastin in blood vessel wall Inhibition of adventitial myofibroblast migration to the intima
Endothelial loaded gel foam wrap (Vascugel)	Inhibition of thrombus formation Reduction in negative remodeling (inward) following vascular injury by reducing matrix metalloproteinase-2 expression, neovascularization, and adventitial fibrosis)
Antiproliferative agents – COLL-R (drug-eluted combination product of collagen membrane and sirolimus) – Paclitaxel-coated balloon angioplasty	Inhibition of vascular smooth muscle cell proliferation

to demonstrate long-term benefits for clinically meaningful outcomes such as the usability of an AVF or AVG are largely absent.

Systemic Medical Interventions

Antiplatelet Agents

Antiplatelet agents are expected to reduce patency loss of AVF and AVG predominantly via an antithrombotic effect. Individual agents may have additional inhibitory actions on smooth muscle cell proliferation (e.g. dipyridamole) and inflammation (e.g. aspirin), with the potential to reduce neointimal hyperplasia, stenosis, and thrombosis formation [98, 99]. Based on a meta-analysis of 21 RCTs of any type of antiplatelet agent (summarized in Table 44.4) [3], the benefits of antiplatelet therapies are restricted to reducing the risk of early thrombosis and patency loss of AVFs, while their benefit remains uncertain for AVGs. There is insufficient evidence to determine the longer-term benefits of antiplatelet agents on arteriovenous access suitability for hemodialysis, the need for access interventions or their safety, particularly the risk of bleeding. Treatment benefits of individual anti-

Table 44.4 Summary of findings: antiplatelet therapies[a].

Outcomes	No. of participants (no. of studies)	Absolute effect per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion

platelet agents has been assessed in a Cochrane review published in 2015 [4]. With the exception of low-quality evidence to support the use of ticlopidine to reduce early AVF thrombosis (three trials, 239 participants, odds ratio [OR] 0.45, 95% CI 0.25–0.82), there was insufficient evidence to determine whether other antiplatelet agents were effective in preventing arteriovenous access failure [4]. A recently published RCT of fish oil supplementation and aspirin use in patients undergoing AVF creation showed that 100 mg of aspirin given to a subgroup of 388 participants for 3 months did not reduce the composite primary outcome of AVF failure at 12 months (RR 1.05, 95% CI 0.84–1.31) [40]. Similarly, no treatment benefit was seen for the individual outcome components in the composite AVF failure outcome, including AVF thrombosis (RR 1.09, 95% CI 0.72–1.64), AVF abandonment (RR 1.31, 95% CI 0.89–1.95), and cannulation failure (RR 0.99, 95% CI 0.76–1.27) [40]. In summary, these data suggest that antiplatelet agents may be used to prevent early thrombosis and patency loss but longer-term benefits on access patency and usability remain uncertain.

Omega-3 Polyunsaturated Fatty Acids (Fish Oils)

Omega-3 polyunsaturated fatty acids inhibit platelet aggregation [100] and exert anti-inflammatory [101, 102], antiproliferative [103, 104], and vasodilatory effects [105] on vascular structures. The evidence for fish oil supplementation to reduce arteriovenous access failure has been summarized in a recent systematic review and meta-analysis (Table 44.5) [5]. Moderate certainty evidence suggests that fish oil supplementation prevents primary arteriovenous patency loss, but fish oil has little or no effect on dialysis suitability failure, arteriovenous access abandonment or need for interventions, based on low-level evidence. The risks of treatment-related bleeding or gastrointestinal side effects are uncertain.

Statins

The pleiotropic effects of statins on the vasculature outlined in Box 44.2 may reduce arteriovenous access stenosis and thrombosis [106, 107]. The clinical evidence for statin effects on arteriovenous access failure is restricted to observational trial data and post hoc analyses of RCTs. A post hoc analysis of 2352 participants from the Study of Heart and Renal Protection (SHARP) trial suggested a 13% reduction in vascular access occlusive events in participants treated with simvastatin plus ezetimibe compared to placebo while this benefit was not found in a second post hoc analysis of a RCT of similar size using rosuvastatin [108]. Several other retrospective analyses did not support the use of statins to improve primary or secondary arteriovenous access patency [109], access maturation [110], stenosis formation [111], time to recurrent angioplasties [111], or cumulative access survival (after excluding primary failure) [109, 110]. A recently published meta-analysis of six retrospective cohort studies and one small RCT of 90 participants demonstrated uncertain effects of statin use on AVF failure (seven studies, 20 126 participants, pooled RR 0.89, 95% CI 0.70–1.12) based on low-level evidence [6]. In summary, there is insufficient evidence to support the use of statin therapy for preventing arteriovenous access failure and larger, international RCTs to further explore this treatment option are needed.

Renin-Angiotensin-Aldosterone System Blockers (Angiotensin Converting Enzyme Inhibitors and Angiotensin II Type I Receptor Blockers)

Preclinical data suggests a vascular benefit of angiotensin converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) via inhibition of intimal hyperplasia formation, platelet activation, and adhesion as well as promoting vasodilation [112–116]. Clinical evidence for ACEI/ARB use is confined to cohort studies and large registry analyses with conflicting results regarding benefits on primary and secondary arteriovenous access patency. Data interpretation is limited by the large variations in treatment agents, dose and duration, outcome definitions, study populations, and unadjusted confounding inherent to observational studies [7–11]. Additional evidence from RCTs will be required to ascertain potential benefits of using ACEIs/ARBs to improve arteriovenous access outcomes.

Calcium Channel Blockers

Calcium channel blockers (CCBs) may promote arteriovenous access maturation and reduce (re-)stenosis via vasodilation and inhibition of neointimal hyperplasia [12, 13, 117, 118]. No RCT has been performed to assess the effect of CCB on arteriovenous access outcomes. A large retrospective analysis of 42 244 participants (13 121 on CCB) suggests an association between CCB use and prolonged primary patency of AVFs (hazard ratio [HR] 0.485, 95% CI 0.44–0.50) and AVGs (HR 0.48, 95% CI 0.44–0.53) [11]. This association was only evident in AVG but not in AVFs in another smaller retrospective study of 2312 participants of whom 970 were on CCBs [109].

Local Treatment Strategies

Far Infrared Therapy

Far infrared radiation (FIR), an invisible electromagnetic wave applied locally over the skin, has been shown to inhibit vascular smooth muscle cell proliferation and platelet aggregation, promote vasodilation, improve endothelial function, and reduce oxidative stress [119–121]. A meta-analysis of four RCTs in FIR to improve AVF outcomes is summarized

in Table 44.6 [14]. Applying FIR for 40 minutes during each hemodialysis session had a beneficial effect on unassisted and assisted patency as well as intervention. A second meta-analysis published in 2017 [122] reported additional benefits on surrogate markers including mean blood flow (10 studies, 864 participants, mean change 82 ml/min, 95% CI 46–117), AVF diameter (five studies, 381 participants, 0.36 mm, 95% CI 0.22–0.51), and reduction in needling pain (three studies, RR 0.08, 95% CI 0.06–0.10). The quality of evidence is limited by small-scale studies (32–280 patients) of relatively short duration (maximum 12 months) with limited external validity, largely unknown or high risk of study bias and significant heterogeneity [14, 122]. Given the convenience of FIR application during dialysis sessions and its non-invasive nature, well-designed, international, multicenter RCTs of longer follow-up duration are warranted.

Novel Surgical Techniques

Surgical techniques have been developed to optimize flow dynamics at the site of the anastomosis with the intension of reducing endothelial dysfunction and the downstream vasoconstrictive, prothrombotic, and inflammatory cascade that follows [66, 123]. A sutureless vascular anastomotic device called Optiflow has been developed to maintain an optimal angle of 60° between artery and vein to optimize flow patterns and shear stress as well as shielding the perianastomotic region to prevent stenosis formation. Feasibility and safety were demonstrated in a small pilot study [23]. A prospective study of 41 patients undergoing AVF creation demonstrated promising 42- and 90-day maturation (72% and 68%) as well as primary unassisted patency rates (88% and 78%) [22]. Similarly, the use of the piggybacking straight-line onlay technique may reduce AVF failure compared to the traditional end-to-side and side-to-side straight-line onlay techniques [21]. However, there are currently no RCTs to confirm potential treatment benefits of these novel surgical techniques.

Endovascular Arteriovenous Fistula Creation

The endovascular creation of an AVF using a radiofrequency magnetic catheter-based system may cause less vessel trauma compared to open surgical creation, thereby reducing downstream stimuli for neointimal hyperplasia and stenosis formation [124]. Using this minimally invasive technique in a prospective, single-arm, multicenter study of 80 participants resulted in 98% successful AVF creation and 87% (95% CI 75–94%) physiological maturation within 3 months (brachial artery flow ≥500 ml/min and vein diameter ≥4 mm) [24]. Sixty-four percent (95% CI 48–78%) of participants were able to receive prescribed hemodialysis through the AVF using two-needle cannulation with an intervention rate of 0.46/patient-year. Primary patency at 12 months was 69% (95% CI 54–79%) and cumulative patency 84% (95% CI 71–91) [24]. Comparing this technique to surgical AVF creation in an RCT may be difficult due to the unique location and type of vessels used for endovascular AVF creation and the inability to blind the treatments.

Local Application of Antiproliferative Agents

Antiproliferative agents including sirolimus (rapamycin) and paclitaxel applied locally either around the adventitial surface (e.g. COLL-R, a combination product of siroli-

Table 44.6 Summary of findings: far infrared therapy.

Outcomes	No. of participants (no. of studies)	Absolute effect per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Primary AVF patency	610 (4)	137 more (60 to 221 more)	1.23 (1.12–1.35)	Very low ●○○○	Infrared therapy may increase primary patency of AVF
Assisted AVF patency (following salvage procedure for dysfunctional AVF)	300 (2)	94 more (34 more to 163 more)	1.11 (1.04–1.19)	Very low ●○○○	Infrared therapy may increase assisted primary patency of AVF
Surgical interventions for AVF dysfunction	249 (2)	93 less (137 to 9 less)	0.49 (0.25–0.95)	Very low ●○○○	Infrared therapy may reduce surgical interventions for AVF

mus and a collagen membrane) or endoluminal during balloon-angioplasty (e.g. paclitaxel-coated balloon) can reduce vascular smooth muscle cell proliferation and neointimal hyperplasia formation, thereby preventing (re-)stenosis [125]. Following promising results on AVG patency from a single-arm phase II study using COLL-R in 12 hemodialysis patients [20], the results from a phase III RCT using COLL-R to improve AVF hemodialysis suitability is currently awaited (NCT02513303). Similarly, the use of paclitaxel-coated balloon angioplasty to treat AVF stenosis has shown beneficial effects on revascularization-free survival compared to high pressure balloon angioplasty in a small single-center RCT [19], but multicenter, large-scale RCTs are currently lacking to provide certainty on the treatment benefits of these treatment approaches.

Perivascular Application of Recombinant Elastase

Recombinant human type-1 pancreatic elastase (PRT-201) applied locally during arteriovenous access creation is used to fragment elastin with the premise to promote vasodilation and inhibit migration of adventitial myofibroblasts into the intimal layer [15, 98]. An immediate effect of high-dose PRT-201 on intraoperative vein outflow diameter and blood flow has been shown in an RCT of 89 patients undergoing AVG creation [17], yet clinically meaningful long-term effects on unassisted primary patency within the first year of access creation have not been found in an RCT of 151 patients undergoing AVF creation [16].

Endothelial-loaded Gel Foam Wrap (Vascugel)

Vascugel is an endothelial-cell-loaded wrap containing allogeneic aortic endothelial cells to promote outward vascular remodeling and prevent neointimal hyperplasia [18, 125]. Despite promising preclinical studies to support endothelial-mediated beneficial effects [126, 127] and a phase I/II trial to confirm the safety of this procedure [18], there is currently no phase III RCTs available to further explore this local treatment approach.

In summary, there is moderate certainty evidence to suggest a short-term benefit of anti-platelet therapies to improve AVF patency and of fish oil supplementation to improve arteriovenous patency within the first 12 months of access creation. Low to very low certainty evidence supports to use of FIR therapy applied during dialysis to improve AVF maturation, patency, and reduce needling pain. Novel local treatment approaches, including novel surgical techniques, minimally invasive endovascular AVF creation, and local application of antiproliferative agents, will require further study in well-designed, international RCTs to increase the certainty of the evidence.

Prevention of Arteriovenous Access Failure

Prevention and Treatment of CVC Malfunction

With the widespread use of cuffed CVCs in hemodialysis patients, the prevention of complications related to their use has become a major focus. The two principle CVC complications are CVC malfunction, which is principally due to catheter-related thrombosis, and CVC-related bacteremia, which is discussed in the next section. Catheter-related thrombosis is a common problem and is classified as either extrinsic where thrombus forms outside the catheter or intrinsic with thrombus forming inside the catheter [128]. Causes of extrinsic thrombi include central vein thrombosis, intra-atrial thrombus, and cardiac mural thrombus. Intrinsic thrombus may be intraluminal, attached to the catheter tip or surround the catheter – formation of a fibrin sheath [128].

Strategies tested to prevent CVC thrombosis have generally assessed newer novel anticoagulant agents, thrombotic agents or a systematically administered agent. Results of the two Cochrane reviews are summarized in Table 44.7 [25, 129]. Currently the newer novel anticoagulant agents do not offer any advantage over conventional heparin locks regarding CVC thrombosis, although they may offer advantages for other outcomes such as bacteremia, as discussed below. Likewise, systemic agents such as warfarin are also no more effective than standard heparin lock.

Interventions aimed at treating CVC thrombosis and malfunction include Instillation of thrombolytic agents, systemic administration of thrombolytic agent, radiologic fibrin sheath stripping +/- means with or without CVC guidewire exchange. Few randomized trials have been performed to guide specific recommendations. Instillation of a thrombolytic catheter lock likely are to be more effective than placebo [130] while fibrin sheath stripping may be as effective as thrombolytic therapy.

Prevention of Catheter-related Bacteremia

Catheter-related bacteremia is a major complication associated with CVC use, responsible for 70% of vascular access-related bacteremia in the United States [44], causing significant morbidity and mortality [43] as well as increased healthcare costs. Therefore, prevention of catheter-related bacteremia is an important treatment goal in the management of hemodialysis patients.

Trials addressing interventions aimed at reducing CVC-related bacteremia can be divided into three broad groups: those where the intervention is administered at the CVC exit site, those where antibiotic or antimicrobial is used as a catheter lock solution, and finally structural or

[b] Some studies included citrate combined with antibiotic.

mechanical devices related or attached to the catheter to prevent infection.

Topical Interventions to the CVC Exit Site

Interventions applied to the cuffed CVC exit site aim to reduce CVC-related bacteremia by preventing bacterial skin growth and subsequent catheter colonization. Agents assessed in trials include mupirocin and polysorin antibiotic ointment, chlorhexidine impregnated dressings, and topical medi-honey. The most recent systematic review is now relatively out of date (published in 2010) and includes only studies assessing mupirocin, polysorin, and medi-honey (summarized in Table 44.8). The review suggests positive effects for the use of topical agents in reducing

rates of CVC bacteremia, exit site infection, and removal, but firm conclusions are difficult due to small sample size, the low quality of the included trials, and an unusually high rate of bacteremia in the some of the control groups. Since 2010, three trials assessing the use of chlorhexidine-impregnated dressings in hemodialysis have been reported. Rosenblum et al. in a large cluster RCT of 211 dialysis facilities assessed chlorhexidine application to the CVC exit site at each dialysis and dressing change showing a 41% reduction in CVC bacteremia [132]. Two small studies demonstrate conflicting results, with one showing no difference in bacteremia rates [133] while the other found significantly lower rates in the chlorhexidine-impregnated dressing group [134]. Finally, a recent systematic review assessing all CVCs (predominantly those in the intensive care unit setting but including three studies in hemodialysis patients) suggests there is moderate quality evidence that chlorhexidine-impregnated dressings reduce the frequency of catheter-related BSI per 1000 patient-days compared with standard polyurethane dressings (RR 0.51, 95% CI 0.33–0.78) [135].

Antimicrobial/Antibiotic Locking Solutions

Antimicrobial and antibiotic locking solutions are the best-studied interventions. These solutions are instilled into the catheter after every dialysis and aim to limit the formation of a biofilm which acts as a nidus for CVC-related bacteremia. Four systematic reviews have been published, two focusing on citrate-based locking solutions [129, 136] and one assessing antibiotic-based solutions with and without citrate [137]. The most recent (updated to include all studies to December 2017) included all antimicrobial solutions whether antibiotic or nonantibiotic based [25]. Table 44.8 summarizes the most recent review. Overall 39 individual trials (4216 subjects) were included, although only 30 trials (3392 subjects) could be incorporated into the meta-analysis. Overall study size was small and risk of bias in the majority uncertain or high for all domains except reporting bias. In all trials the comparator arm used a standard heparin catheter lock. Overall there is moderate certainty that the use of antimicrobial lock solutions results in a 55% reduction in the incidence of CVC-related bacteremia (Table 44.8). The beneficial effect remained consistent when assessed according to CVC type: tunneled or nontunneled. When assessed according to antibiotic and nonantibiotic antimicrobial solutions, the treatment effect strengthened in the case of antibiotic locks whereas for the nonantibiotic-based locks treatment estimates weakened and were not consistent. Mortality was not assessed in the majority of studies, making many any conclusions uncertain. Taurolidine has been assessed in two additional trials not included in the recent systematic review [138, 139]. Like the majority of previous studies both trials are limited by the small sample size (106 and 177 patients, respectively) while one reported catheter bacteremia in combination with catheter thrombosis, making any interpretation difficult [138], and the other compared taurolidine to a citrate-based solution [139].

Potential safety concerns in the use of antibiotic locks include concerns regarding drug-specific toxicity (e.g. gentamicin-induced ototoxicity [140]) and the emergence of antibiotic resistance [141, 142], while the use of high-dose citrate can potentially cause pulmonary embolism and fatal arrhythmias [143]. While it is clear that the use of an antimicrobial or antibiotic lock reduces CVC bacteremia, the optimal lock solution has yet to be determined. Only one trial [139] has compared the different locks against each other so whether or not an antimicrobial lock has advantages over an antibiotic-based lock is unknown and requires further study. Whether antimicrobial or antibiotic lock solutions are more effective than topical interventions to CVC exit site is also currently unknown; the rates of CRB are similar across the studies but no trials have compared them directly. Larger studies are also required to ascertain whether such interventions reduce mortality.

Structural or Mechanical Devices

Like the antimicrobial or antibiotic lock solutions, structural or mechanical devices related or attached to the catheter prevent infection by limiting the formation of a biofilm. The ClearGuard HD Antimicrobial Barrier Cap (Pursuit Vascular Inc.) is a chlorhexidine-coated catheter cap which dissolves into the lock solution proximal to the clamp. Two cluster randomized trials, both performed in 40 dialysis facilities with 2470 [144] and 627 [145] patients respectively, showed that compared to conventional dialysis caps, the bacteremia rates were lower in the intervention arms by 56% and 63%. Results were consistent across a number of subgroups, using stricter definitions of bacteremia, as well as reducing hospital admissions. Mortality was not reported in one of the studies [144] and was not different in the other although absolute numbers were very low (three total deaths only) [145]. Finally, one trial has compared a silver-coated to standard dialysis CVC and did not demonstrate any benefit [146]. Data for antibiotic-impregnated versus standard uncuffed general nondialysis catheters is summarized in Chapter 43.

Patient and Caregiver Treatment Preferences

Advances in hemodialysis vascular access care have been hindered by the significant heterogeneity of outcomes reported across trials that may be of limited relevance to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. end-users including patients and their caregivers. Standardized definitions for vascular access outcomes have been proposed by multiple working groups and initiatives [74, 147–151], yet the uptake in clinical trials has been minimal to date [152]. This issue is being addressed by the international Standardized Outcomes in Nephrology (SONG) initiative [153]. This initiative aims to establish and implement critically important outcomes (i.e. core outcomes sets) [154] across the spectrum of kidney disease that are based on the shared priorities of patients, caregivers, and health professionals. These core outcome sets are expected to be reported consistently in all trials of a specific area of research (e.g. hemodialysis, peritoneal dialysis, transplantation) to inform clinical practice in a reliable, consistent, and meaningful manner. For hemodialysis, the core outcomes identified include vascular access function, fatigue, cardiovascular disease, and all-cause mortality [155–157]. Based on the global input of patients, caregivers, health professionals, researchers, policy makers, and industry representatives, an outcome measure for vascular access function has been established and will be validated prior to its global implementation in hemodialysis research [156]. Consistent reporting of standardized outcome measures that are considered important not only by researchers but also by patients, caregivers, and clinicians is expected to advance future vascular access research to inform clinical practice in a meaningful way and improve patient-important outcomes.

Conclusion

Hemodialysis remains the dominant form of dialysis therapy for patients with ESKD and hence the provision and maintenance of vascular access for hemodialysis patients represents a management goal. Currently, the AVF remains the optimal vascular access for a majority of patients but not necessarily all patients. Of the strategies aimed at reducing primary AVF failure, antiplatelet agents and fish oils may be beneficial whereas statin and ACE/ARB therapy cannot currently be recommended. More recent novel therapies, such as infrared therapy and novel surgical techniques among others, require further investigation. Once established, AVF blood flow surveillance with pre-emptive stenosis correction reduces AVF thrombosis and may improve AVF loss. AVG blood flow surveillance with pre-emptive correction cannot be recommended. In patients dialyzing with a CVC, the alterative anticoagulant locking solutions (especially antibiotic-based solutions) reduce the incidence of CVC-related bacteremia and should be used. Alternatively, topical antimicrobial dressing applied the CVC exit site can also be considered to reduce the incidence of CVC-related bacteremia.

Small Solute Clearance in Peritoneal Dialysis

Kannaiyan S. Rabindranath[1], Sharon J. Nessim[2], and Joanne M. Bargman[3]

[1] *Renal Unit, Waikato Hospital, Hamilton, New Zealand*
[2] *Division of Nephrology, Jewish General Hospital, McGill University, Montreal, Canada*
[3] *Department of Medicine, Division of Nephrology, University of Toronto, Toronto, Canada*

Introduction

The ideal method of assessing the adequacy of peritoneal dialysis (PD) has yet to be determined. Early studies attempting to quantify dialysis dose in hemodialysis (HD) patients used urea as a low molecular weight putative uremic toxin, eventually leading to the establishment of Kt/V_{urea} as a useful surrogate for small solute clearance [16, 17]. This term, Kt/V_{urea}, factors in several important parameters: clearance of urea (K), time on dialysis (t), and the urea distribution volume, or total body water (V). At the same time as the studies on Kt/V_{urea} were emerging in the HD literature, there was a relative paucity of data on quantification of the dose of PD, with only one group addressing kinetic modeling of peritoneal transport [18]. The data on Kt/V_{urea} in HD were therefore extrapolated to PD, with the addition of creatinine clearance (CrCl) as a complementary surrogate. While measures of solute clearance have traditionally focused on small solutes such as urea and creatinine, little attention has been paid to clearance of larger molecular weight uremic toxins, the so-called "middle molecules" and protein-bound uremic toxins which may have important pathophysiological impacts on mortality and morbidity. It is important to note the current PD prescription approach is moving away from just delivering "adequate dialysis" to a more "goal-directed" approach where the PD regimen is tailored to the individual patient's lifestyle and health goals [19]. In this approach, small solute clearance target values only form a part of the assessment of the quality of dialysis delivered, and the emphasis is on the assessment and management of more meaningful measures such as patient-reported outcomes, blood pressure control, quality of life, nutrition, and cardiovascular risk factors.

Investigations of the impact of PD dose have largely focused on patient survival, but have also looked at several other outcomes, including technique survival, hospitalization, nutritional status, and quality of life. In this chapter, we will focus on the existing evidence with respect to the impact of peritoneal solute clearance and residual kidney function (RKF) on patient survival, as well as evidence for the targets that are currently in use. We will also discuss strategies to optimize peritoneal solute clearance and preserve RKF, providing evidence when available. (Refer to Table 45.1).

Definitions

It has been conventional for PD adequacy to be measured in terms of small solute clearance. The solutes usually measured for theses indices are urea and creatinine. To compare clearance values among patients, these values are normalized to a function of patient size. For urea, the metric is typically the volume of urea distribution (V), which equates to total body water, and creatinine is typically is normalized to 1.73 m^2 body surface area (BSA). V is usually estimated from published formulas such as the Watson formula and BSA estimated using the Dubois formula [20, 21]. The fractional clearance of urea is expressed as Kt/V_{urea}, which is the clearance of urea (K) per time unit (t) in relation to its volume of distribution or total body water (V), and the fractional clearance of creatinine is known as creatinine clearance (CrCl). In both cases, the clearance includes both peritoneal and kidney clearances of these solutes. The dialytic component is calculated by measuring the urea and creatinine content of a 24-hour collection of dialysate effluent. These values are then divided by the serum urea and creatinine levels, respectively, to give the

Table 45.1 Dialysis adequacy targets and preservation of RKF in PD patients.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Total (peritoneal + kidney) Kt/V_{urea}	We suggest that achieving a total weekly Kt/V_{urea} in the range between 1.7–2.0 and >2.0 probably makes little or no difference to patient survival (moderate certainty evidence) A Kt/V_{urea} of <1.7 may lead to an increased risk of patient death (low certainty evidence)	Moderate (Kt/V 1.7–2.13) Low ($Kt/V < 1.7$)	Weak [1–5]
RAS inhibitors	We suggest that RAS blockers can be used to reduce RKF decline in PD patients	Moderate	Weak [6]
PD modality	We suggest that PD modality may make little or no difference to RKF decline	Low	Weak [7]
Use of diuretics	We suggest that diuretics may make little or no difference to RKF in PD patients, but may increase urine output	Low	Weak [8]
Use of aminoglycosides	We suggest that it is uncertain whether or not aminoglycosides hasten RKF decline in PD patients	Very low	Weak [9–13]
Dietary protein restriction	We suggest that dietary protein restriction coupled with keto-acid supplementation may help reduce RKF decline in PD patients	Low	Weak [14]
Neutral pH low GDP solution	Refer to Chapter 47, the certainty of evidence is high and the strength of recommendation is strong.	Refer to Chapter 47	Refer to Chapter 47

GRADE assessment of the certainty of the evidence [15]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.
PD, peritoneal dialysis; RAS, renin-angiotensin system; RKF, residual kidney function.

daily urea and creatinine clearance. The kidney component of urea and creatinine clearance is calculated in the same manner with a 24-hour urine collection, except that, in the case of creatinine clearance, an average of residual kidney urea and creatinine clearance is typically used. This is because creatinine clearance substantially overestimates the true glomerular filtration rate as creatinine is not only filtered but also secreted into the tubules. Both the Kt/V and CCr are expressed as weekly values and therefore the total daily values are multiplied by 7.

Epidemiology

According to the International Society of Nephrology Global Kidney Health Atlas 2019, only 58% of countries where PD is available measure small solute clearance (Kt/V_{urea}, CCr) [22]. Measurement and reporting of small solute clearance are closely correlated with national incomes. Nearly all high-income countries (85%) measure and report small solute clearance, compared to 45% of upper-middle, 17% of lower-middle, and none of the low-income countries. Importantly, countries in which there is no or limited ability to provide an adequate PD dose (defined as three to four exchanges per day or equivalent cycles on automated PD) were least likely to monitor and report small solute clearance.

The average total weekly urea Kt/V achieved in most countries was >2, except in Canada and Japan [23]. Average peritoneal Kt/V was highest in Thailand (1.73 in continuous ambulatory peritoneal dialysis [CAPD] patients) and lowest in Japan (1.09 and 1.16 on automated PD [APD] and CAPD patients, respectively). The correlation between achieved total Kt/V and daily number of PD exchanges and volume of dialysate is unclear. There is a large variation among countries in the number of exchanges used. No patients in Thailand compared to 40% of patients in Japan on APD use fewer than three exchanges. In the United States, clinics may be financially impacted by a failure of a proportion of PD patients at a clinic to achieve a total $Kt/V > 1.7$. It is tempting to surmise that the concern about reaching a Kt/V target may explain our observation that the

United States has the lowest percentage of patients with $Kt/V < 1.7$ and the highest percentage with $Kt/V > 2$ among countries participating in the Peritoneal Dialysis Outcomes and Practice Patterns Study (PDOPPS) [23].

Pathophysiology of Solute Transport in Peritoneal Dialysis

The peritoneum is a serous semipermeable membrane composed of a thin layer of connective tissue covered by a mesothelial cell monolayer. It covers most of the abdominal wall and intraabdominal organs. The mesothelial cells at the peritoneal cavity side have abundant cytoplasmic extensions (microvilli), which have anionic fixed charges and play a role in the transmembrane transfer of small charged molecules as well as plasma proteins [24]. The mesothelial microvilli increase the effective peritoneal surface up to 40 m^2 although the surface area of the human adult peritoneum is only about 1.6–2.0 m^2 [25].

Solute transport occurs through both diffusion and convection. Diffusion involves solute movement across a semipermeable membrane due to the presence of a concentration gradient. Convection occurs when solutes move along with water during ultrafiltration by the process of solute drag. The two-pore theory proposed the presence of abundant small pores, 40–50 Å, and few larger pores, up to 150 Å, in the peritoneal membrane capillary endothelial wall through which solute and fluid transfer occur [26]. Subsequently the finding of transcellular (endothelial cells) ultra-small pores (aquaporin-1 channels, 3–5 Å) led to the proposal of a three-pore model, in which around 50% of the transcapillary ultrafiltration occurs through aquaporin-1 channels and the remainder mostly through small pores [27, 28].

The different factors influencing solute transport include solute concentration gradient across the peritoneal membrane, peritoneal membrane characteristics such as surface area available for transport (determined by the number of capillaries available and the area of peritoneal membrane in contact with the dialysate), water flux, solute reflection coefficient of the membrane and importantly the intrinsic permeability of the peritoneal membrane. Transport of low-molecular-weight (LMW) and medium-molecular-weight (MMW) solutes depends mostly on their size and the surface area available for transport and to a lesser degree on changes in the permeability of the peritoneum [29]. Transport of larger molecules is size-selective, therefore it depends on several variables, including effective membrane surface area, permeability of the membrane itself, and, importantly, the molecular size of the solute.

Assessing Peritoneal Transfer Rate

The peritoneal equilibration test (PET) is the most widely used test to characterize the rate of solute and water transfer in patients undergoing PD. Briefly, the overnight dialysate is drained and 2 l of 2.27% glucose (2.5% dextrose) dialysis fluid is infused and dialysate samples are taken after infusion and then after 2 and 4 hours, at which time the dialysate is drained and the volume recorded. A blood sample is drawn at 2 hours dwell time. Usually, the dialysate drainage volume (used as a measure of ultrafiltration capacity [UFC]) and D/P (dialysate/plasma ratio) for creatinine are compared with standard values [30].

Large population-based studies suggest that, on average, the concentration of creatinine in the dialysate at 4 hours is about two-thirds that in the blood (or 4-hour D/P creatinine is 0.67). It is conventional to assign patients a "transport" type based on the results of the PET as being low, low-average, high-average, or high transporters [30]. Individuals assigned as having an average transport are the ones that are within one standard deviation of the mean, and the ones with low or high transport are more than one standard deviation below or above the mean, respectively. The 4-hour D/P creatinine ratios for low, low-average, high-average, or high transporters are <0.5, 0.50–0.65, 0.65–0.81, and >0.81, respectively.

Assessment of Impact of Small Solute Clearance on Patient Survival

Understanding of the impact of small solute clearance on patient survival in PD has evolved over time. Early studies suggested a beneficial effect of small solute clearance, as assessed by Kt/V_{urea} and CrCl, on survival. The largest of these early studies was the Canada-USA (CANUSA) study, which evaluated the association between adequacy of PD and patient survival among 680 incident CAPD patients over 2 years [31]. In this study, total (kidney and peritoneal) small solute clearance was found to be an independent predictor of patient survival. Based on a fitted model, there was a 5% decrement in expected patient survival for every 0.1 decrease in total weekly Kt/V_{urea} for values between 1.5 and 2.3, and a 7% decrement in expected survival for every 5 l/week/1.73 m^2 decrease in CrCl. The assumption was that peritoneal and kidney contributions to small solute clearance were equivalent, and therefore additive. However, a subsequent re-analysis of the CANUSA data, focusing on the relative contributions of kidney and peritoneal clearances, provided new important insights into the impact of RKF on survival [32]. For each

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

5 l/week/1.73 m^2 increase in kidney CrCl, there was a 12% decrease in the relative risk (RR) of death. Furthermore, each 250 ml increment in urine volume was associated with a 36% decrease in the RR of death. Neither peritoneal CrCl nor peritoneal ultrafiltration was associated with patient survival.

In 2002, the ADEMEX trial which was done to assess the effect of small solute clearance on survival was published. It remains the largest randomized controlled study published in the PD literature [1]. In this study, 965 incident and prevalent PD patients were randomized to a standard CAPD regimen of 2 l exchanges four times daily or a modified dialysis prescription to achieve a peritoneal CrCl of >60 l/week/1.73 m^2. To achieve this, individual dwell volumes were increased, followed by the addition of a fifth dwell if the target was not reached by 2 months. Patients were followed for a minimum of 2 years, with a primary endpoint of death. The mean age of patients enrolled was approximately 47 years, with an incidence of pre-existing ischemic heart disease that was low in both groups (<5%) and not different between the two. While the intervention group had significantly higher peritoneal Kt/V_{urea} than the control group (2.13 vs. 1.62) and peritoneal CrCl (57 vs. 46 l/week/1.73 m^2) than the control group, there was no difference in patient survival (69.3% vs. 68.3% at 2 years, RR 1.00 95% confidence interval [CI] 0.80–1.24). The major cause of death in both groups was ischemic heart disease. In the control group, a higher death rate due to congestive heart failure and a combination of uremia/hyperkalemia/acidosis was reported. It is worth pointing out that hyperkalemia and acidosis are complications that rarely occur in PD patients, and it is especially rare to be severe enough to cause death. Since a composite endpoint of death due to uremia/hyperkalemia/acidosis was used, it is possible that uremia accounted for the majority of the difference between the groups. It is also reported that more patients in the control group withdrew from the study because of uremia. Unfortunately, uremia was not specifically defined, and since the study was not blinded, this may have introduced a significant bias. Knowing which patients were receiving a lower dialysis dose may have led physicians to attribute nonspecific symptoms or death in the control group to uremia. With regard to the higher mortality related to congestive heart failure in the control group, this is not necessarily attributable to underdialysis. Rather, it can instead be plausibly explained by a difference in ultrafiltration attributable to the use of an additional exchange in 22% of patients in the intervention group. In fact, the intervention group had approximately 100 cc/day more ultrafiltration on average than the control group. In contrast to peritoneal clearance in this study, kidney Kt/V_{urea} and kidney CrCl did emerge as predictors of improved outcome, with a RR of 0.89 per 10 l/week/1.73 m^2 increase in CrCl and 0.94 per 0.1 increase in Kt/V_{urea}.

Another randomized controlled trial by Lo et al. confirmed the lack of survival benefit with increased peritoneal clearance [2]. In this study, 320 incident CAPD patients were randomly assigned to one of three groups, Kt/V_{urea} 1.5–1.7, 1.7–2.0 or >2.0, and followed over 2 years. Patients with an initial kidney Kt/V_{urea} of greater than 1.0 were excluded. Kidney Kt/V_{urea} in the study patients was not significantly different between the groups, so that the difference in Kt/V_{urea} was accounted for by differences in peritoneal clearance. Overall, 2-year patient survival was 84.9%. After adjustment for age and diabetes, total Kt/V_{urea} did not affect survival in patients with $Kt/V_{urea} > 2.0$ vs. 1.7–2.0, although there was a trend toward better survival in patients with Kt/V_{urea} 1.7–2.0 vs. 1.5–1.7 ($P = 0.054$).

Given the overarching effect of RKF on survival, dose of PD may be more important in those who have lost their RKF. Two prospective studies in anuric PD patients using Kt/V_{urea} and CrCl have shown a statistically significant association between peritoneal clearance and better survival [33, 34]. The first study to show a positive association between peritoneal clearance and survival was performed by Szeto et al. and involved 140 anuric CAPD patients followed for 22 months [33]. In this group, it was estimated that there was a 6% decrease in the RR of death with an increase in Kt/V_{urea} of 0.1/week and a 12% decrease in the RR of death for each 5 l/week/1.73 m^2 increase in peritoneal CrCl. Jansen et al. followed a cohort of 130 anuric CAPD patients over 2 years [34]. While peritoneal Kt/V_{urea} and CrCl were not associated with survival when analyzed as continuous variables, when the results were analyzed dichotomously, a weekly Kt/V_{urea} of <1.5 compared to >1.5 (RR 3.28, 95% CI 1.25 to 8.60, $P = 0.02$) and a weekly CrCl <40 l/1.73 m^2 compared to >40 l/1.73 m^2 (RR 3.26, 95% CI 1.24 to 8.55, $P = 0.02$) were associated with an increased RR of death. Fried et al., in a retrospective study of 1432 anuric PD patients, found that when adjusted for age, sex, race, diabetes, and serum albumin level Kt/V_{urea} of <1.7 was associated with significantly higher risk of mortality and hospitalization [4]. Adjusted CrCl on the other hand did not predict mortality.

The findings from various studies on the effect of small solute clearances in all PD patients and in anuric PD patients are summarized in Tables 45.2 and 45.3, respectively.

Overall, there is now evidence from two randomized trials and several supporting observational studies to suggest that while the total clearance is important, improved patient survival appears to be more strongly associated with kidney clearance and not peritoneal clearance.

The basis for the survival advantage associated with RKF is unclear, with several possible contributors. First, the presence of residual urine output facilitates volume management, which may have a favorable effect on blood pressure control and subsequent left ventricular geometry [53, 54]. Both hypertension and left ventricular hypertrophy are associated with loss of RKF and are known to be independent predictors of mortality in PD patients [55]. Second, RKF allows for clearance not only of small solutes but also middle molecules [56–58]. The latter are not as easily removed across the peritoneal membrane due to the time dependence of their diffusion and the limited permeability of the peritoneal membrane. Finally, patients with preserved RKF may represent a population who are intrinsically healthier and thus more likely to survive.

Summaries of findings with regards to the effect of targeting weekly CrCl of >60 l/week and different Kt/V targets are given in Tables 45.4–45.6.

Recommended Targets and Monitoring of PD Adequacy

Based on moderate certainty evidence, increasing Kt/V beyond 1.7 does not appear to have an impact on patient survival. Weekly Kt/V levels below 1.7 may be associated with an increased risk of death (low certainty evidence), although a minimum total weekly Kt/V target has not been definitively established.

Adequacy targets and frequency of monitoring as recommended by the various kidney societies are summarized in Table 45.7. The current International Society for Peritoneal Dialysis (ISPD) guidelines for PD prescription recommend measurement of Kt/V_{urea} or CrCl to provide a quantitative measure of amount of dialysis delivered, but do not recommend achieving a minimum target of Kt/V_{urea} given the poor quality of evidence linking achieving a Kt/V_{urea} of >1.7 to survival. According to this guideline, PD prescription should be tailored to the individual patient's lifestyle and healthcare goals based on multidimensional assessment of several factors, such as quality of life, patient-reported outcomes, nutrition, etc., to maintain quality of life, minimize symptoms and treatment burden, and ensure high-quality care [59]. Given the inaccuracies in the measurement of Kt/V_{urea}, the guideline recommends using a range of acceptable Kt/V_{urea} for the individual patient rather than a single cut-off value. All of the other renal society guidelines in general recommend a total (kidney + peritoneal) weekly Kt/V_{urea} of 1.7 [60–63]. The European Best Practice Guideline (EBPG) states a weekly Kt/V_{urea} target of 1.7 only for anuric PD patients and does not make any specific recommendations for those with RKF [63]. The Renal Association (UK) recommends a total (kidney + peritoneal) weekly Kt/V_{urea} of 1.7 or CrCl of 50 l/week/1.73 m [61]. The ISPD recommends an additional target of 45 l/week/1.73 m^2 CrCl for APD patients [59]. The EBPG recommends the same CrCl target (45 l/week/1.73 m^2) for APD patients who are on short frequent exchanges with slow transport status [63]. It is important to point out that while these minimum targets do not differentiate between kidney and peritoneal contributions, it is clear that kidney and peritoneal clearance are not simply

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 45.4 Summary of findings: PD prescription adjusted to achieve peritoneal CrCl of 60 l/week (actual achieved total Kt/V_{urea} 2.27) versus standardized PD prescription of four 2 l exchanges/day (actual achieved total Kt/V_{urea} 1.8).

	PD prescription adjusted to achieve peritoneal CrCl of 60 l/week (actual achieved total Kt/V_{urea} 2.27) versus standardized PD prescription of four 2 l exchanges/day (actual achieved total Kt/V_{urea} 1.8)				
Outcomes	**No of participants (studies)**	**Absolute effect (95% CI)**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
All-cause mortality	965 (one RCT)	Seven more per 1000 (from 48 fewer to 72 more)	RR 1.02 (0.85 to 1.22)	⊕⊕⊕⊕ High	Target CrCl of 60 l/week in PD patients will have little or no effect on all-cause mortality

CI, confidence interval; CrCl, creatine clearance; PD, peritoneal dialysis; RCT, randomized controlled trial; RR, relative risk.

Table 45.5 Summary of findings: total Kt/V_{urea} 1.7 to 2.0 versus total Kt/V_{urea} 1.5–1.7.

	Total Kt/V_{urea} 1.7 to 2.0 versus total Kt/V_{urea} 1.5 to 1.7				
Outcomes	**No of participants (studies)**	**Absolute effect (95% CI)**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
All-cause mortality	208 (one RCT)	39 more per 1000 (from 55 fewer to 198 more)	RR 1.20 (0.71–2.03)	⊕⊕⊖⊖ Low	Achieving a total Kt/V_{urea} of 1.7 to 2.0 in PD patients may make little or no difference to all-cause mortality

CI, confidence interval; PD, peritoneal dialysis; RCT, randomized controlled trial; RR, relative risk.

Table 45.6 Summary of findings: total $Kt/V_{urea} > 2.0$ versus total Kt/V_{urea} 1.7–2.0.

	Total $Kt/V_{urea} > 2.0$ versus total Kt/V_{urea} 1.7 to 2.0				
Outcomes	**No of Participants (studies)**	**Absolute effect (95% CI)**	**Relative effect (95% CI)**	**Quality of the evidence (GRADE)**	**Conclusion**
All-cause mortality	216 (one RCT)	Two more per 1000 (from 88 fewer to 147 more)	RR 1.01 (0.62–1.64)	⊕⊕⊖⊖ Low	Achieving a total $Kt/V_{urea} > 2.0$ in PD patients may make little or no difference to all-cause mortality

CI, confidence interval; PD, peritoneal dialysis; RCT, randomized controlled trial; RR, relative risk.

additive, in that any small solute clearance provided by RKF is accompanied by improved clearance of middle molecules and better salt and water control.

In keeping with the current ISPD guideline on PD prescription and the limitations of current techniques to assess clearance, a patient's clinical status must always be considered when trying to determine the adequacy of dialysis. The outcome of interest in the studies discussed has principally been survival. There are no rigorous studies prospectively examining dose of PD and health outcomes other than death. Therefore, the guidelines all suggest that the dose be increased as a trial in the patient not doing well for reasons not explained by comorbidity, regardless of their current prescription.

To ensure a total delivered Kt/V_{urea} that is commensurate with optimal clinical wellbeing of the patient using a multidimensional assessment, solute clearances can be followed with the use of 24-hour collections of dialysate and urine. While data on frequency of measurements are sparse, we would recommend the following schedule. If small solute clearance is going to be monitored, the first measurement of peritoneal and kidney Kt/V_{urea} should be

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 45.7 Summary of guidelines on small solute clearance targets and frequency of PD adequacy testing.

Renal society	Small solute clearance targets	Frequency of measurement
International Society of Peritoneal Dialysis (ISPD) [59]	Small solute clearance should be routinely measured using Kt/V_{urea} or creatinine clearance to provide a quantitative measure of the amount of dialysis delivered It does not recommend achieving a minimum target of Kt/V_{urea} given the poor quality of evidence linking achieving a Kt/V_{urea} of >1.7 to survival In setting a Kt/V_{urea} target for the individual patient, defining an acceptable range that recognizes the uncertainty of the measurement, rather than applying a single cut-off value is more appropriate	Not stated explicitly in the guideline other than it should be routinely measured
Kidney Diseases Outcomes Quality Initiative (KDOQI) [60]	For patients with RKF (urine volume > 100 ml/day), total weekly (renal + peritoneal) Kt/V_{urea} should be at least 1.7/week For patients without RKF (urine volume < 100 ml/day) peritoneal Kt/V should be at least 1.7	If patients have RKF, total clearance should be measured within 4 months and at least once every 4 months thereafter If patients do not have RKF, peritoneal Kt/V should be measured within the first month and at least every 4 months thereafter
Renal Association (UK) [61]	Total weekly (renal + peritoneal) Kt/V_{urea} should be 1.7/week or a creatinine clearance of 50 l/week/1.73 m^2	Both residual urine and peritoneal dialysis components of small solute clearance should be measured at least 6-monthly or more frequently if dependent on residual kidney function
Canadian Society of Nephrology [62]	PD prescription to achieve a total weekly Kt/V_{urea} of at least 1.7	Residual renal urine volume and residual renal Kt/V (rKt/V) should be measured every 3–6 months in patients with a peritoneal Kt/V (pKt/V) of less than 1.7 weekly, especially if RKF is rapidly declining In all other PD patients, rKt/V and urinary volume should be measured together with pKt/V when clinically indicated A measurement of total Kt/V should be carried out 4–6 weeks after initiation of PD The measurement of total Kt/V should be repeated if there is an unexplained or unexpected change in the patient's clinical status or a problem with ultrafiltration
European Best Practice Guidelines [63]	Minimal weekly peritoneal Kt/V_{urea} of 1.7 for anuric patients In APD patients using short frequent exchanges and slow transporter status, an additional target of 45 l/week/1.73 m^2 for peritoneal creatinine clearance is recommended	None recommended

APD automated peritoneal dialysis, PD, peritoneal dialysis; RKF, residual kidney function.

performed approximately 1 month after initiation of PD. Subsequent monitoring of peritoneal clearance is controversial. While the K/DOQI guidelines recommend checking peritoneal clearance at least once every 4 months, the peritoneal Kt/V_{urea} is unlikely to change in patients with a stable PD prescription [60]. Therefore, an alternative approach would be to re-measure peritoneal clearance only if changes are made to the PD prescription or if there is deterioration in the patient's clinical status. In the event of an episode of peritonitis, peritoneal clearance measurements should not be made until at least 1 month after resolution of the peritonitis because the inflammation can affect the trans-peritoneal transport of solutes. If a patient has >100 cc/day of residual urine output and achieving a total weekly Kt/V_{urea} of at least 1.7 is dependent on the kidney contribution, a 24-hour urine collection to assess kidney Kt/V_{urea} and urine volume should be performed regularly to avoid missing a decline in RKF.

Strategies for Optimizing Peritoneal Solute Clearance

The routine measurement of small solute clearance serves to screen patients for evidence of underdialysis. If a patient is not meeting the minimum recommended PD dose, the basis for this should be determined. Before assuming that a given PD prescription is inadequate, patient-related causes of failure, such as adherence, lack of understanding or sampling and collection errors, should be sought. If none of these potential causes is found, several strategies can be employed to optimize a patient's PD prescription to improve peritoneal solute clearance. Common interventions include increasing the dwell volumes, increasing the frequency of exchanges or increasing peritoneal ultrafiltration [64, 65]. While the focus of these interventions is often to increase peritoneal small solute clearance, the importance of middle molecule clearance must also be considered, especially in patients with little or no RKF.

Increasing dwell volumes is an effective means by which peritoneal small solute clearance can be increased in both CAPD and APD patients [66]. The increase in Kt/V_{urea} and CrCl is due to both an increased plasma-to-dialysate concentration gradient and an increased effective peritoneal surface area [67, 68]. While increasing dwell volumes is often effective, this strategy leads to increased intra-abdominal pressure, which may lead to back pain and a higher risk of abdominal wall leaks and hernias [69], although this has not been borne out in some other studies [70–72]. The lower intra-abdominal pressure in the supine position may make increasing dwell volumes easier during the overnight exchange in CAPD patients or during the night exchanges in APD patients [73]. An additional concern is that increasing exchange volumes may limit peritoneal ultrafiltration by increasing intra-abdominal pressure, but the greater persistence of the osmotic gradient is likely to offset this [74].

Another commonly used strategy is increasing the frequency of exchanges. In patients on CAPD, this may require increasing from three to four or from four to five exchanges daily. Potential disadvantages include the burden an additional manual exchange places on the patient, and a decrease in middle molecule clearance due to a greater proportion of time spent draining and filling with less time for dialysate to dwell in the peritoneal cavity. In patients on cycler-based therapy, we advise against the use of nocturnal intermittent PD (NIPD) unless a significant amount of RKF remains or other special mitigating circumstances exist. An excellent method of increasing clearance in patients on NIPD is to add a day dwell. Maximizing the time spent with dialysate in the peritoneal cavity, especially with the use of a long dwell, is an important strategy because this leads to improvement in clearance of both small and larger solutes. While increasing the frequency of night-time cycles can also augment peritoneal small solute clearance by maximizing the concentration gradient between blood and dialysate, there are some concerns with this strategy [75]. First, if the cycles become too short, especially with larger dwell volumes, clearance of both small and larger solutes will diminish owing to "lost time" draining and filling [76]. In addition, rapid cycling can lead to reduced net sodium removal due to sodium sieving [77]. For these reasons, we do not recommend routinely increasing frequency of cycles on APD to optimize peritoneal clearance.

Increasing peritoneal ultrafiltration is another method of increasing peritoneal clearance. Raising the gradient for diffusion with the use of hypertonic glucose or icodextrin is the primary means by which ultrafiltration can be increased, with the additional fluid removal leading to increased clearance via convective transport [78, 79]. However, use of long-term hypertonic glucose as a method to optimize peritoneal clearance is not generally recommended given the potential deleterious effects on the peritoneal membrane and increased glucose loading [80]. Icodextrin is a viable option for the long dwell in patients in whom poor ultrafiltration is an issue but is not generally recommended for the sole purpose of increasing clearance [81]. A systematic review of biocompatible PD fluids showed that icodextrin did not improve small solute clearance, as determined by peritoneal creatinine clearance (three studies, standard mean deviation 0.36, 95% CI −0.24 to 0.96, $P = 0.020$) [82].

Ultimately, the decision as to which strategy to use to optimize peritoneal solute clearance will depend on the individual patient. Factors to consider include peritoneal membrane characteristics, the potential impact of increasing intra-abdominal pressure, and the patient's abilities and preferences. In general, attention should be focused on maximizing the contact time of dialysate in the peritoneal cavity.

Strategies for Preserving Residual Kidney Function

Because of the impact of RKF on the outcome of patients on PD, its preservation should be considered important. Strategies to preserve RKF include use of medications that might slow the decline in RKF and avoidance of agents known to have deleterious effects. Because of the paucity of data, many of our current practices are extrapolated from patients with chronic kidney disease.

Biocompatible Fluids

The effect of neutral pH, low-glucose degradation product (GDP) solutions on RKF has been looked at in numerous studies, with several showing a protective effect [82]. There is some debate as to whether this benefit is due to a direct protective effect or whether the finding is associative and related to the decrease in peritoneal ultrafiltration (UF) seen in many of the same studies [83]. For an extensive review of the studies on biocompatible solutions and RKF, refer to the chapter 47 on PD solutions.

RAS Blockade

Table 45.8 summarizes studies on the effect of renin angiotensin system (RAS) blockade in PD patients [11, 84–92]. While this strategy is known to be effective in both hypertensive and normotensive patients with many forms of chronic kidney disease, the data in patients on dialysis are not as robust. Overall, in moderate certainty evidence, angiotensin-converting enzyme inhibitor (ACEi) or angiotensin receptor blocker (ARB) therapy administered for 12 months or more probably reduces the rate of RKF decline in patients receiving chronic PD. Summaries of findings with regards to the effect of RAS blockade on RKF are given in Tables 45.9–45.13.

Aminoglycosides

Aminoglycosides are frequently used to treat peritonitis in PD patients because of their effectiveness as bactericidal agents and the ease of intraperitoneal administration. They are, however, also nephrotoxic. Several prospective cohort studies and one randomized controlled trial have assessed the effect of aminoglycosides on RKF. These studies are summarized in Table 45.14.

In a randomized, controlled trial, Lui et al. compared the use of cefazolin and ceftazidime with cefazolin and netilmicin for the empiric treatment of peritonitis in 50 PD patients with RKF [9]. In both groups there was a significant decline in RKF at 2 weeks which returned to near baseline by 6 weeks, but there was no significant difference in RKF between the groups. While this represents the only randomized study of aminoglycosides and RKF, the follow-up period was short, and some of the patients in the aminoglycoside group were exposed to only a few days of netilmicin. The summary of findings from the data in this study is presented in Table 45.14.

Shemin et al. assessed the rate of decline of RKF in 72 PD patients followed for 4 years [10]. Patients who had peritonitis episodes treated with intraperitoneal or intravenous aminoglycosides had more rapid decline in kidney creatinine clearance and residual urine volume than either those who had never had a peritonitis episode or those who had peritonitis treated with other non-nephrotoxic antibiotics. In another study analyzing the risk factors associated with a faster rate of decline, use of aminoglycosides was found to be an independent predictor of a more rapid loss of RKF [11]. In contrast to the findings in the above studies, Baker et al., using a prospective cohort design with a historical control, did not find an accelerated decline in RKF with the use of aminoglycosides to treat peritonitis [12]. One large retrospective study looked at the slope of RKF decline in 2715 Australian patients and compared the slope of RKF decline in the 1075 patients who received at least one course of aminoglycoside for peritonitis compared to those who had not received any aminoglycosides [13]. The slopes of RKF decline were found to be the same in both groups, suggesting that treatment of peritonitis with aminoglycosides was not associated with an adverse impact on RKF in PD patients. In very low certainty evidence, it is uncertain whether aminoglycosides lead to faster RKF decline.

A summary of the findings with regards to the effect of aminoglycosides on RKF is given in Table 45.15.

Iodinated Radiocontrast Media

Two small, prospective studies have addressed this issue [93, 94]. Dittrich et al. assessed RKF (mean of 24-hour urine urea and CrCl) in 10 PD patients who were given iodinated radiocontrast media and compared them with eight control patients who did not receive radiocontrast media [92]. Patients who received radiocontrast media showed an initial decline in RKF reaching its lowest point by 6 days after contrast administration (3.78 ml/min/1.73 m^2, interquartile range [IQR] 2.56–6.77 vs. baseline 5.50 ml/min/1.73 m^2, IQR 2.91–8.10). However, after 30 days, there was no difference in either patient group compared to baseline values. In the study by Moranne et al. RKF (mean of 24-hour urine urea and CrCl) was compared between 36 PD patients who received iodinated radiocontrast media and 36 comparable patients who did not receive radiocontrast media [93]. RKF was measured prior to and 2 weeks after contrast media administration. In those who received contrast media, RKF values were not significantly different prior to and 2 weeks after contrast administration (mean 7.0 vs. 7.2 ml/min/1.73 m^2, $P = 0.12$). When compared to the control group, those who

received contrast media did not have a significant difference in variation in RKF over the 2-week study period (mean 0.1 vs. 0.1 ml/min/1.73 m^2, $P = 0.9$). Nevertheless, given the small numbers of patients in these dialysis studies and the clear data in patients with chronic kidney disease (CKD), it would be prudent to avoid using radiocontrast media if other acceptable alternatives exist. If use of radiocontrast dye is required, volume contraction should be avoided, and the smallest volume of the least toxic dye should be used.

Dietary Intervention

One small Chinese trial randomized 20 stable PD patients each to diets containing 0.6–0.8 g of protein/kg ideal body weight/day supplemented with 0.12 g/kg ideal body weight/day keto acids (group sLP), 0.6–0.8 g of protein/kg ideal body weight/day (group LP), or 1.0–1.2 g of protein/kg ideal body weight/day (group HP) [14]. All patients had >800 ml/day urine output or estimated glomerular filtration rate (eGFR) >2 ml/min/1.73 m^2. Seven patients dropped out during the study. Follow-up period was 12 months. At the end of study period, a significant decline in RKF was noted in the HP (4.25 ± 2.34 to 2.55 ± 2.29 ml/min/1.73 m^2, $P < 0.05$) and LP groups (4.02 ± 2.49 to 2.29 ± 1.72 ml/min/1.73 m^2, $P < 0.05$) but no such decline was noted in the sLP group (3.84 ± 2.17 to 3.39 ± 3.23 ml/min/1.73 m^2, P = ns). The study suggested that RKF was better preserved in PD patients on la ow-protein diet supplemented with keto-acids.

In the prospective cohort study by Johnson et al. each 1 g/kg body weight/day increase in dietary protein consumption was found to be associated with an adjusted hazard ratio of 2.87 (9% CI 1.01 to 2.72, $P < 0.05$) for RKF loss [85].

In low certainty evidence, dietary modification in terms of reduced protein intake with keto-acid supplementation may help preserve RKF in PD patients.

Diuretics

In a small 12-month randomized controlled trail (RCT) of 61 patients, furosemide at a dose of 250 mg per day was found to significantly increase urine volume over 12 months (+48.8 ml/24 hours) compared to a decline (−305 ml/24 hours, $P < 0.05$) in the no furosemide group [8]. However, the decline in creatinine and urea clearance was similar in both groups. Some cohort studies noted diuretic use to be associated with a more rapid decline in RKF [95, 96]. In low certainty evidence, furosemide may make little or no difference to RKF preservation.

Other Factors

Despite the lack of evidence in dialysis patients, avoidance of nonsteroidal anti-inflammatory drugs or any other known nephrotoxins in patients with RKF would seem prudent.

If there is a significant decline in RKF that cannot be explained, consideration should always be given to the possibilities of volume depletion or obstruction, as these are easily correctable causes of loss of RKF.

Conclusions

Our understanding of the effect of PD adequacy on outcomes is subject to the limitations of the existing literature. In the absence of a "gold standard" for assessing clearance, all studies to date have focused on small solute clearance. This has led to a relative neglect of the impact of middle molecule clearance on outcome. The data presented in this chapter highlight the relative contributions of kidney and peritoneal clearance to PD adequacy, demonstrating that maintenance of residual kidney clearance is strongly associated with patient survival. It is not yet clear if this association is related to improved volume

Table 45.15 Summary of findings: effect of netilmicin (aminoglycoside) + cefazolin versus ceftazidime + cefazolin for PD peritonitis on RKF.

Netmicin + cefazolin versus ceftazidime + cefazolin					
Outcomes	**No. of participants (studies)**	**Assumed risk**	**Corresponding risk**	**Quality of the evidence (GRADE)**	**Conclusion**
Residual kidney function ml/min/1.73 m^2	36 (one RCT)	Mean RKF in control (ceftazidime + cefazolin) group was 4.16	Mean RKF in netilmicin + cefazolin group was 0.25 lower (1.65 lower to 2.15 higher)	⊕⊕⊖⊖ Low	There may be little or no difference between aminoglycoside vs. no aminoglycoside containing antibiotic regimens for treatment of PD peritonitis with respect to RKF
Urine volume ml/day	36 (one RCT)	Mean daily urine volume/day in control (ceftazidime + cefazolin) group was 799	Mean daily urine volume in netilmicin + cefazolin group was 29 higher (316 lower to 374 higher)	⊕⊕⊖⊖ Low	There may be little or no difference between aminoglycoside vs. no aminoglycoside containing antibiotic regimens for treatment of PD peritonitis with respect to daily urine volume

PD, peritoneal dialysis; RCT, randomized controlled trial; RKF, residual kidney function.

management and middle molecule clearance, or if it is merely an association, with RKF serving a marker of a healthier population.

Based on moderate certainty evidence, increasing *Kt*/*V* beyond 1.7 does not appear to have an impact on patient survival. Weekly *Kt*/*V* levels below 1.7 may be associated with an increased risk of death (low certainty evidence), although a minimum total weekly *Kt*/*V* target has not been definitively established. Even though there is not yet sufficient evidence regarding the effect of middle molecule clearance on survival in PD patients, it would be prudent for efforts to improve peritoneal clearance to address both small and middle-molecule clearances. Furthermore, the true adequacy of PD as a form of kidney replacement therapy depends not only on successful clearance of uremic toxins, but also on adequate volume management through a combination of peritoneal ultrafiltration and residual urine volume. There is an increasing realization that the assessment of dialysis adequacy should be multidimensional and should include other important parameters such as patient reported outcomes [97]. These concepts underpin the current ISPD guideline on optimal PD prescription which now recommends that clinicians not use small solute clearance measures alone to make important clinical decisions such as PD prescription and modality switches [59].

In low to very low certainty evidence, PD modality, diuretic, and aminoglycoside use may have little or no impact on RKF. However, given the survival advantage that is associated with kidney clearance, every effort should be made to preserve RKF with neutral pH, low GDP solutions, the avoidance of potential nephrotoxins, the use of agents with potentially protective effects, and a search for reversible etiologies when a decline in RKF is noted.

Salt and Water Balance

Mathew Tabinor, Mark Lambie, and Simon J. Davies

Renal Research Group, Faculty of Medicine and Applied Clinical Sciences, Keele University, Newcastle-under-Lyme, UK

Introduction

Achieving salt and water balance is fundamental to optimizing fluid status, one of the key objectives of peritoneal dialysis (PD) treatment. Excess salt and water, accumulating in the intravascular and extravascular extracellular spaces, cause hypertension and target organ damage (e.g. increased left ventricular mass, stroke), pulmonary oedema, and oedema of other tissues (laryngeal, gut, lower limb, anasarca), which can affect organ function and contribute to morbidity and mortality [1–5]. Conversely, negative salt and water balance can be a reflection of reduced nutrition, reflecting poor intake [6, 7], or accelerated losses in residual kidney function if due to excessive salt and water removal [8, 9]. Achieving appropriate salt and water balance is an important balance for clinicians.

The relative importance of salt and water management to patient outcomes was historically underestimated by early treatment guidelines, which tended to focus on small solute clearance as the principal metric of dialysis adequacy. The realization that the survival benefits of small solute clearance mainly reflect the component attributable to residual kidney function, combined with increasing evidence that inherent differences in peritoneal membrane function that potentially affect salt and water removal has led to a paradigm shift, with increasing emphasis on fluid status. However, optimal management of salt and water balance is a complex problem and decisions made by clinicians often represent a compromise between attempts to normalize fluid status while taking additional factors, notably comorbidity and hypoalbuminemia, into account. It is possible to divide the components of this complex process and the limited evidence to support decision-making into two broad components: (i) interventions designed to influence salt and water balance (e.g. dietary salt intake, prescriptions that optimize fluid removal) and (ii) interventions designed to guide clinical decision-making through accurate ascertainment of fluid status (e.g. bioimpedance) (Table 46.1).

Definitions

Optimal salt and water balance might be defined as the input and output which enables an individual to achieve a stable and normal body composition, and includes normal extracellular (intra- and extravascular) fluid volumes (also referred to as the normally hydrated weight), as well as maintaining healthy lean and fat tissue masses. The main problem with this definition is that there are other factors which influence this optimal goal [10]. For example, muscle wasting is very common in dialysis patients and yet in the absence of kidney failure this is often associated with a relative excess in the hydrated weight even though the total water volume of the patient is reduced. Reducing salt and water intake in this context is unlikely to benefit the underlying problem of muscle wasting unless it can be linked to increased calorie intake.

There is, as yet, no evidence-based practice that tells the clinician how to take these additional factors into account, although it can be envisaged in the future it will be possible to take a stratified approach to defining the optimum body composition goal for a given degree of comorbidity, muscle wasting, and hypoalbuminemia. Currently, this is based on best clinical judgment. The potential role of bioimpedance to guide fluid management is discussed below.

Another definition that is required is the conditions in which no amount of clinical intervention will solve the problem of salt and water balance, i.e. ultrafiltration insufficiency. While this occurs in a minority of patients, usually a problem that is either revealed by the loss of residual kidney function or because of acquired peritoneal membrane injury, it is an important cause of technique

Table 46.1 Salt and water balance.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Dietary advice on salt intake	We suggest that salt intake can be reduced to ≤6 g/day to lower blood pressure and improve fluid balance. Patients receiving PD may reasonably choose not to accept this level of salt restriction based on the very low certainty evidence that treatment makes a difference to longer term outcomes, including quality of life and mortality, and very low certainty evidence that very low salt intake (<4 g/day) may lead to malnutrition.	Very low	Weak
Diuretics (high-dose furosemide)	We suggest that furosemide can be prescribed in a dose of 250 mg daily to increase urine output.	Low	Weak
APD	We suggest that APD can be prescribed to increase peritoneal ultrafiltration, particularly in patients with rapid solute transfer in whom APD may also reduce mortality.	Very low	Weak
Glucose polymer (Icodextrin)	We suggest that glucose polymer solution can be used to increase daily ultrafiltration and reduce uncontrolled fluid overload in peritoneal dialysis patients. PD patients may reasonably choose not to use glucose polymer as treatment makes no difference to hard outcomes, including technique survival and mortality.	Moderate: Net daily ultrafiltration, uncontrolled fluid overload and improved extracellular fluid volume Low to very low: Residual renal function, urine volume, rash, peritoneal creatinine clearance, peritonitis, technique survival, and mortality	Weak
Bioimpedance-guided fluid management	We suggest that bioimpedance-guided clinical fluid management can be used to improve fluid status and blood pressure. Patients receiving PD may reasonably choose not to receive bioimpedance-guided clinical fluid management based on very low certainty evidence that such treatment makes any difference to longer term outcomes such as quality of life or mortality.	Low	Weak

APD, automated peritoneal dialysis; PD, peritoneal dialysis.

failure in long-term PD patients [11]. It is also a risk factor for encapsulating peritoneal sclerosis (EPS) [12]. Ultrafiltration insufficiency can be defined strictly from membrane function tests (see section "Diagnostic Tests"), but there are relative definitions applied in clinical practice, for example an inability to maintain optimal salt and water balance without an unacceptable amount of glucose peritoneal exposure.

Epidemiology

Evidence that Salt and Water Balance is Important

Ultrafiltration insufficiency, although relatively uncommon, is strong evidence that a failure of adequate salt and water balance can be a modality-limiting factor for patients on PD. Uncommon in the early stages of treatment (affecting <10%) and potentially masked by persisting residual kidney function, the incidence rises to ~25% after 5 years of treatment [11, 12]. Ultrafiltration insufficiency is, however, one end of the severity spectrum and various degrees of less efficient salt and water removal may be contributing to mortality on PD before it is formally recognized, prior to necessitating dialysis modality switch (see Table 46.2). The European Automated Peritoneal Dialysis Study (EAPOS) suggests this is the case. A nonrandomized cohort study of automated peritoneal dialysis (APD) to treat anuric PD patients, with pre-agreed intervention targets for both solute clearance and fluid removal (>750 ml ultrafiltration per day) found that failure to reach the fluid target was associated with lower survival, partly explained by having less efficient membranes [13, 17]. This is supported by a similar analysis of anuric PD patients from the Netherlands Cooperative Study of Adequate Dialysis (NECOSAD) in

[b] Adjusted for age, comorbidity, subjective global assessment, time on dialysis, albumin, and hemoglobin.
[c] Adjusted for age, comorbidity, albumin, protein nitrogen appearance, inflammation, and pro-brain naturetic peptide.
[d] Adjusted for comorbidity, serum creatinine, and residual kidney clearance.
[e] Adjusted for age, gender, BMI, comorbidity, baseline mean arterial pressure, hemoglobin, albumin, calcium, phosphate, LDL, solute clearances, and C-reactive protein.
[f] Time-dependent sodium removal adjusted for age, comorbidity, and time-dependent solute transfer rate (which was a strong predictor of mortality in the model).

which anuric patients with less than 1 l of ultrafiltration had worse survival [14]. Whether the reduced ultrafiltration is a marker of membrane dysfunction or a reflection of low nutritional intake, this is evidence that salt and water balance may be of greater immediate importance than peritoneal solute clearance in anuric patients.

Peritoneal Solute Transport Rate and Outcomes

There is now a large body of evidence to suggest that peritoneal membrane function, specifically the rate of peritoneal solute transfer, which varies quite considerably between patients, is an important determinant of survival on PD. The rate of small solute transfer diffusion across the membrane is inversely associated with survival, as demonstrated by several single-center studies [7, 11, 18], a systematic review [19], and large multicenter cohorts, such as the Canada-USA (CANUSA) study [20], the Australian and New Zealand Dialysis and Transplant (ANZDATA) Registry [21], the Davita Database [22], and prevalent patients in the Global Fluid Study [23] (summarized in Table 46.3). There is no conclusive evidence that faster solute transfer leads to technique failure, although in the Davita database it was associated with an increase in hospitalization events [22]. It is important to note that the increased risk extends across the range of solute transfer and is not limited to just very fast transfer (i.e. ratio >0.8).

Blood Pressure and Salt and Water Balance

Hypertension is common in PD patients and, given the high cardiovascular morbidity and mortality in dialysis patients, it is a crucial aspect of patient management. Despite this, the evidence linking salt and water balance to blood pressure and blood pressure to survival in PD is of low certainty. Bioimpedance studies would indicate that whereas overhydration in PD patients is common, this is only associated with poor blood pressure control in about half of these patients and conversely hypertension was observed in over one-third of the normo-volaemic patients [24]. Longitudinal studies have suggested that blood pressure is relatively good

in the early years of PD, but once residual kidney function has diminished this becomes more difficult to control, indirectly implicating a role for worse salt and water balance in blood pressure management [2]. However, it should be remembered that blood pressure may also be influenced by increasing arterial stiffness related to increasing vascular calcification over time. It has been demonstrated that blood pressure control can be achieved by reducing salt intake and increasing ultrafiltration after antihypertensive drug withdrawal, confirming a short-term association, but it is not clear that this is the correct treatment strategy and the intervention did result in a significant and relatively rapid decline in residual kidney function [9]. Sodium removal can also be increased by using a low sodium containing dialysate and this has led to modest reductions in blood pressure in two intervention studies, providing further modest evidence that blood pressure can be improved by manipulating salt and water balance [25, 26]. However low sodium solutions are not currently commercially available and cannot be considered as a treatment option.

Studies show that, as for hemodialysis patients, the relationship between blood pressure and survival is complex, exhibiting reverse epidemiology (U-shaped relationship to survival) [27, 28] that likely explains at least in part the poor correlation between fluid status and blood pressure as a consequence of poor cardiac function [29]. Poor control of high blood pressure in patients on the transplant waiting list is associated with worse long-term survival [27].

Compared to hemodialysis, the evidence base for pharmacological interventions to improve blood pressure control is very modest, with studies limited to renin-angiotensin system blockade and in half these studies the primary outcome was preservation of residual kidney function [30–32]. Although these trials overall give a weak signal of benefit, suggesting that decline in kidney function and progression of left ventricular mass are slowed, they have small sample sizes and limited conclusions can be drawn.

Pathophysiology

Peritoneal Membrane Function

Given the importance of the peritoneal membrane in facilitating salt and water balance, the considerable degree of individual variation in membrane function, and the strong association of membrane function with patient survival, it is important that membrane physiology is well understood. The three-pore model developed by Rippe and colleagues remains the best tool for this [33, 34], with its ability to explain free water transport via the aquaporin pathway, predict sodium removal [35], show how polyglucose solutions can work [36], and provide a mechanistic understanding of fluid reabsorption via Starling forces [37], providing an overall theoretical framework.

Physiology of Small Solute Transport

Applying this model to explain why a fast solute transfer rate might lead to worse outcomes shows how this will impair salt and water removal by two mechanisms. First, the more rapid transport of glucose from the peritoneal cavity to the circulation will lead to a faster reduction in the osmotic gradient and thus more rapid reduction in the ultrafiltration rate. Second, once there is osmotic equilibration across the membrane, which happens earlier in individuals with rapid transfer, there will be back flow of salt and water into the circulation driven by Starlings forces that will be more severe because these individuals effectively have larger membranes. The three-pore model shows that the anatomical structure (or pore) responsible for small solute transfer is the intercellular tight junction between endothelial cells, so membrane size here refers to the capillary circulation in contact with dialysate rather than the physical size of the membrane. It is now clear that the most important determinant of individual variation in solute transfer rate is due to local inflammation within the membrane, determined by the local production of inflammatory cytokines, most notably IL-6 [23]. This is independent of systemic inflammation, which is more closely aligned to age and comorbidity. Thus, the possibility that high solute transfer mediates its effects on survival through an association with systemic inflammation, as was once thought, may be incorrect, further emphasizing the importance of salt and water balance.

Physiology of Fluid Transport and Ultrafiltration Failure

Although fast peritoneal solute transfer causes reduced salt and water removal by these mechanisms, patients with ultrafiltration insufficiency usually have the additional problem of reduced membrane efficiency. For the same osmotic gradient across the membrane they ultrafiltrate less, referred to as a reduction in the osmotic conductance of the membrane. Typically, this is a problem that is acquired with time on treatment [38, 39] and the pathophysiology is characterized by progressive fibrosis of the membrane and, in particular, by a vasculopathy [40]. A modification of the three-pore model in which a fiber matrix is placed in series with the capillary endothelium shows how this can impede water flow (and thus convective salt removal) even when the capillary surface area is increased [34]. Drivers of this progressive fibrosis of the membrane include glucose and other non-biocompatible components of dialysis fluid (osmolality, glucose degradation products, pH), local inflammation, and infection [41]. It is theoretically possible that there are other mechanisms responsible for the reduction in osmotic conductance, such as a reduced aquaporin expression. Aquaporins, responsible for about 50% of ultrafiltration (free water transport) [37, 42], are essential for peritoneal dialysis to work. However, in patients with severe acquired membrane failure aquaporin expression is still present whereas the presence of fibrosis is often extreme [40].

There is another important consequence of the presence of the free water aquaporin pathway. While it is essential to ensure that adequate ultrafiltration is achieved, it does mean that the sodium concentration in ultrafiltrate is always less than that of plasma. At the start of a hyperosmolar exchange there is a fall in the sodium concentration of dialysate due to water crossing via the free water pathway, a process often referred to as sodium sieving [33, 35]. This fall or dip in the dialysate sodium, which can typically be 10 mmol/l, takes time to equilibrate but does mean that for a typical continuous ambulatory peritoneal dialysis (CAPD) regimen the sodium removal is 100–110 mmol/l ultrafiltrate and for a typical APD regimen it is 70–80 mmol/l over a 24-hour period. This has implications for balancing salt and water intake with output when designing the optimal dialysis regimen.

Hypoalbuminemia and Fluid Status

PD is associated with hypoalbuminemia for several reasons, including peritoneal protein losses, systemic inflammation, and malnutrition. The most important of these is peritoneal protein loss, which is associated with a faster peritoneal transport rate. While this may not affect salt and water balance directly, every study examining the relationship between bioimpedance-determined fluid status and serum albumin levels so far published has found a negative correlation which likely contributes to salt and water retention occurring as membrane transport rate increases [24, 43, 44]. Isotopic studies have shown that the overhydration associated with hypoalbuminemia is not correlated with plasma volume, which is normal in PD patients, implying that it increases the extravascular extracellular fluid compartment [45]. Increasing salt and water removal may benefit this and should be considered when there is a risk of pulmonary or laryngeal oedema. However, care should be taken not to centrally deplete the patient too rapidly if residual kidney function is present. As in hemodialysis patients, hypoalbuminemia is a predictor of worse survival but there is no compelling evidence to indicate that it is a reason for switching dialysis modality at present [46].

Diagnostic Tests

Evaluation of Peritoneal Membrane Function

The peritoneal equilibration test (PET) was developed to assess two aspects of peritoneal membrane function, the rate of small solute transfer determined from the dialysate: plasma creatinine ratio and the net ultrafiltration capacity [47]. It requires standardized conditions (4 hours duration, glucose concentration, dwell volume) and standardized measurements (calculation of net ultrafiltration volume that accounts for the variable overfill of dialysis bags and use of laboratory assays that either measure creatinine directly or account for the presence of glucose, which can interfere with some methods, e.g. Jaffe method). Even taking these precautions into account, studies that have included data from multiple sites have found a center effect in the measurement of solute transfer which means that direct comparisons of absolute values should be made with care and preferably after establishing the mean value and distribution in the local population (solute transfer rate is normally distributed).

Solute Transfer Rate: Reproducibility and Diagnostic Value

Expressed as the dialysate:plasma ratio of creatinine at 4 hours, the range is 0.3–1.1, with a typical mean value of 0.67. The coefficient of variation is about 10% when measurements are taken close together so a change in >0.1 should be considered clinically meaningful. It is independent of the glucose concentration used (provided assays correct for glucose interference if needed). Over time, there may be fluctuation in the peritoneal transport rate in any one individual, likely reflecting variations in local membrane inflammation. At a population level over several years, the solute transfer rate tends to increase [39, 48]. The primary diagnostic value is in identifying individuals at the high end of the range as this is a predictor of adverse outcomes, worse survival, possibly technique failure, and hospitalization (see Table 46.3). This should prompt the clinician to make prescription changes if needed. The other main clinical use of the solute transfer measure is in designing the optimal dialysis prescription schedule for solute clearance. Slow transfer membranes require longer dwell lengths to optimize larger molecule clearance (e.g. phosphate).

Ultrafiltration Capacity: Reproducibility and Diagnostic Value

The net ultrafiltration capacity at 4 hours using a 2-l exchange (this volume is adjusted in children according to size) represents the composite of a number of processes, including the amount of ultrafiltration that has occurred through the two main pathways less the fluid reabsorption that occurs via Starlings forces and "lymphatics." Despite the number of mechanisms involved, it is the key metric for defining ultrafiltration insufficiency. A strict membrane definition is <400 ml net ultrafiltration using a 3.86% glucose concentration or <100 ml using a 2.27% glucose concentration (values exclude any overfill of the dialysis bag) [49].

It is important, however, that these values are derived and interpreted in context. The reproducibility of the drained dialysate volume is more than for solute transfer, with a coefficient of variation close to 25%, and can be worse in a patient with catheter drainage problems. Indeed, on obtaining a low net ultrafiltration volume while undertaking a peritoneal equilibration test, it is most appropriate to ensure catheter function is adequate.

The main value of this test is in helping to determine whether membrane function is contributing to a failure to maintain salt and water balance. It should be done when there is clinical evidence of problems, including poor overall ultrafiltration, a need for excessive glucose usage to maintain fluid balance, and evidence of excess salt and water retention such as hypertension, oedema, or worsening bioimpedance measurements. Given that ultrafiltration insufficiency is a risk factor for subsequent EPS, it also has a role in deciding whether PD treatment should be continued after a number of years [12].

Adding the Sodium Dip: Additional Value

The standard PET has limitations, especially when it comes to distinguishing *true* poor ultrafiltration from catheter dysfunction or identifying when the cause of ultrafiltration insufficiency is due to reduced membrane efficiency (*osmotic conductance*) as opposed to just rapid solute transfer. The most comprehensive way of doing this is to undertake a double mini-PET which involves doing two back-to-back 1-hour tests using a weak (1.36%) followed by a strong (3.86%) glucose exchange [50, 51]. The value of using two different glucose concentrations is that the difference in ultrafiltration obtained between them is a measure of the osmotic conductance (see Box 46.1). A patient with a low osmotic conductance as a cause for ultrafiltration insufficiency should be transferred to hemodialysis (unless otherwise inappropriate) as it is unlikely to be possible to achieve satisfactory salt and water balance and there is a risk of future EPS. However, the double mini-PET is quite labor intensive and still subject to the error associated with measuring drain (ultrafiltration) volumes, especially when there is a large residual volume within the peritoneum at the end of the dwell [52].

Box 46.1 Advanced Testing of Membrane Function (Osmotic Conductance, Sodium Dip, and Sieving)

	Example value *(normal value)*		Diagnostic value
PET glucose concentration	PET1: 1.36%	PET2: 3.86%	
Net ultrafiltration (UF) at 1 h (ml)	260	615	
Osmotic conductance (μl/min/mmHg)	3.75 *(>1.85)* [51]		Diagnoses ultrafiltration insufficiency that will not be solved by prescription (e.g. APD, icodextrin) in anuric patients
D/P creatinine at 1 h	0.36	0.32	
MTAC creatinine (ml/min)	5.2		
Dialysate sodium (mmol/l) at 1 h	129	122	
Sodium dip, mmol/l (131-[$Na_{3.86\%}$] at 1 h)	9 *(8.4, IQR 6–11)* [53, 54]		Normal values established from 758 incident patients. Low value was the best membrane function discriminator for EPS (added to age, time on treatment, and solute transfer) based on 161 long-term patients of which 13 developed EPS
Sodium sieving ratio (1-([$Na_{3.86\%}$]/131) at 1 h)	0.068 (>0.06) [40]		Based on 35 long-term (matched) patients, seven with EPS <0.03, associated with 50% risk of EPS which equates to a sodium dip <5

Definitions and calculations:

Osmotic conductance (OC) is the fluid removed per minute per osmotic gradient due to glucose, calculated fwrom the difference in ultrafiltration (UF) obtained at two glucose strengths. Values <1.85 indicate severe ultrafiltration insufficiency, >4 well preserved UF.

$$OC = 1700 \times \left(\text{UFv}3.86\% - \text{UFv}1.36\%\right) / \left(1158 \times \left(\frac{3.86}{0.018}\right) - \left(\frac{1.36}{0.018}\right)\right)$$

D/P, dialysate: plasma ratio; MTAC, mass transfer coefficient (for creatinine), the rate of creatinine diffusion across the membrane, calculated as:

$$\text{MTAC} = \left(\text{UFv}3.86\% / 60\right) \times \ln\left(\left(2000 \times \left[\text{plasma creatinine}\right]\right) / \left(\text{UFv} \times \left(\text{plasma} - \text{dialysate creatinine}\right)\right)\right)$$

A simpler solution is just to measure the sodium dip at 1 hour using a single 3.86% exchange. This gives a good estimate of the ultrafiltration due to free water transport at 1 hour that is not dependent on precise measurement of the ultrafiltration volume (see Box 46.1). There is also evidence that this is a better predictor of future EPS than ultrafiltration volume alone [40, 53].

Bioimpedance

Prognostic Value

Bioimpedance is increasingly used to assess body composition in dialysis patients. By passing a weak, unfelt alternating current between the extremities of the upper and lower limbs, it is possible to measure both tissue resistance and reactance. Resistance is inversely proportional to body water whereas reactance is proportional to the impedance of cell membranes and thus an indicator of tissue mass [55]. All bioimpedance devices use this information to model the body composition, typically using population-derived equations that then estimate the volume of tissue compartments with varying degrees of sophistication. Regardless of how sophisticated these methods are, the relationship of reactance to resistance (cell mass to total body water) is key to the prognostic value of this test. A reduction in this ratio will reflect both overhydration and reduced muscle mass to varying degrees and is strongly predictive of worse survival. In a meta-analysis of 38 dialysis cohort studies that undertook multivariate analyses adjusting for confounders, such as age and comorbidity (including 10 in PD patients), all but one estimated that bioimpedance measurements of overhydration was an independent predictor of worse survival [44]. In a subgroup meta-analysis, overhydration >15% (hazard ratio [HR] 2.28, 95% confidence interval [CI] 1.56–3.34) or a 1° decrease in the phase angle (HR 1.74, 95% CI 1.37–2.21) was associated with increased mortality. In two very large hemodialysis cohorts the increase in mortality was additive to inflammatory status and blood pressure at whatever level of the U-shaped survival relationship [56, 57].

Although these data demonstrate the prognostic value of bioimpedance, it is important to recognize that the mortality association with excess salt and water may not be amenable to changes in salt and water balance in all situations. Illness of whatever cause, especially when there is muscle wasting and poor nutrition or frailty [58], is associated with a relative

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

increase in tissue hydration for a given muscle mass, which may account for a substantial part of this association but is hard to change through clinical interventions.

Guidance of Salt and Water Balance

Given the predictive value of bioimpedance, it is natural to ask if it can be used to guide and thus improve fluid management in dialysis patients. Two recent meta-analyses have assessed the limited trial literature [59, 60], in both cases including both hemodialysis (HD) and PD studies. The first of these limited its scope to trials using multifrequency bioimpedance and was undertaken for the National Institute for Health and Care Excellence (NICE) and is published alongside their guidance [61]. Since publication of these meta-analyses, one further trial in PD has been published [62]. Overall, the conclusions were limited to beneficial effects on maintaining or improving fluid status absolute reduction in overhydration (mean difference −0.39 l [−0.62, −0.15] [59] or −0.43 l [−0.71, −0.15] [63]) and lower systolic blood pressure (mean difference −2.73 mmHg [−5.00, −0.46] [63]). So far, trials have not been powered to determine the effects of bioimpedance-guidance of salt and water balance management on mortality or cardiovascular events. To date, only three trials [62, 64, 65] have been undertaken in PD patients (although one had four nested subgroups) [65] and these are summarized in Table 46.4. They were heterogeneous in their approach but there were some common features. Fluid status was stable over 12 months in the control groups of nonanuric patients (both countries in the UK–Shanghai trial, [65] COMPASS trial [62]). In the active limb for nonanuric patients, clinicians were either reluctant to intervene to target or, when they did by setting a lower target weight without changing the dialysis prescription, there was no change in fluid status. In the Shanghai anuric subtrial, body composition did deteriorate in the control group, mainly as a function of losing muscle mass, and this was prevented in the active limb. At present, there is insufficient evidence to guide the use of bioimpedance-guided fluid management as part of routine clinical practice [66].

Treatment

Dietetic Advice on Salt Intake

In advising an appropriate salt intake for subjects on PD, three things need to be taken into account: (i) given the high prevalence of hypertension and its complications, there should be a modest restriction applied as recommended for all such individuals (given there is no specific evidence for this patent group) [67], (ii) salt intake should match achievable removal so as to make balance possible, and (iii) salt restriction should not compromise good nutrition.

If salt and water balance is to be achieved, then salt intake must be matched to an achievable output but at the same time not prohibit adequate nutritional input. For example, in an anuric patient on PD, it is reasonable to aim for a daily ultrafiltration of around 1 l. This would equate typically to 100 mmol of sodium per day (or 6 g of salt) for a CAPD patient and 80 mmol (5 g of salt) for an APD patient, but this should be measured in individuals if in doubt. This is close to the current recommendations for people with hypertension [67] and should be achievable while maintaining adequate nutrition. There are no trials of different levels of salt intake in PD on which to base a tested recommendation but cohort studies which measured sodium intake, or inferred this from sodium removal, are summarized in Table 46.2. These generally show that survival is associated with higher sodium removal and in particular a low sodium removal is associated with poor survival. Regardless of the direction of causality, or the role of membrane function, restricting salt intake to less than 5 g per day does not appear to be justified and may be problematic in terms of maintaining adequate nutrition. Patients on PD may infrequently have very high ultrafiltration volumes and can lose excessive amounts of salt. This may be exacerbated if they also have a salt-losing nephropathy as the cause of their renal failure. Limiting the number of dialysis exchanges or using very long dwells with a low glucose concentration can encourage net salt and water reabsorption as well as encouraging salt intake.

Use of Diuretics

A number of studies have been undertaken with diuretics in PD patients, summarized in Table 46.5. Taken together, there is modest evidence that furosemide can maintain urine volume and possibly delay time to anuria [68, 69]. In one of these studies, this was associated with a higher sodium excretion than controls [68]. Whether this translates into a patient-level benefit is uncertain, although in principle it should mean that there is less need to achieve higher peritoneal ultrafiltration, thereby sparing intraperitoneal glucose administration. There is no evidence that it benefits blood pressure or fluid status, although total body water was a lower proportion of body weight in patients randomized to furosemide. It should be noted that the typical amount of sodium removed per liter of urine is usually significantly less than per liter of ultrafiltrate. Studies of aldosterone antagonists (e.g. spironolactone) are more numerous but have mainly focused on outcomes other than salt and water balance [70–72]. None that measured urine volume or sodium excretion reported any effect (Table 46.5).

Mitigation of Poor Ultrafiltration Associated with Fast Solute Transport

As outlined above, the problems of poor salt and water balance in the context of fast small solute transfer are twofold: early loss of ultrafiltration in the dwell followed by more rapid reabsorption of salt and water. This problem may be underestimated in CAPD patients if the overfill of dialysis bags is not accounted for in the calculation of daily ultrafiltration (an overestimate of 100–200 ml ultrafiltration per exchange) [73]. There are two tools available to clinicians to solve this problem. One is the use of APD, which allows the dwells to be shortened thereby ensuring net ultrafiltration (and in fast transport patients there will be more rapid diffusion of sodium, so the negative effects of sodium sieving are less of a concern). The other tool is icodextrin, which prevents fluid reabsorption during the long exchange. If APD and polyglucose (icodextrin) are not available, it is still usually possible to construct regimens that obviate excess fluid absorption, even if this requires more dialysate glucose. The evidence supporting these interventions is summarized in Table 46.6, although the chapter on dialysis solutions covers the evidence for polyglucose solutions in more detail, including the benefits not directly related to salt and water balance. Broadly, in observational studies APD is associated with reduced mortality and hospitalization in fast transporters but does not fully abrogate the risk (Table 46.6a) [19, 22, 74]. There are no trials published that address this issue directly (i.e. salt and water removal in APD versus CAPD according to membrane transport characteristics). A Cochrane systematic review found no differences by modality in survival or residual kidney function, but the number and sample sizes of trials were extremely small [78]. Polyglucose does improve salt and water removal [75, 79], in particular by preventing excessive reabsorption [80], which translates into improved fluid status [76, 77] and can reduce the risk of acute episodes of fluid overload (Table 46.6b) [75, 79]. There are no randomized studies powered to interrogate cardiovascular or mortality outcomes. A more detailed discussion and summary of potential adverse effects can be found in Chapter 3.

Conclusion

Achieving salt and water balance to obtain optimal fluid status in PD requires knowledge and integration of a number of components, e.g. clinical and nutritional assessment, blood pressure, membrane function, and body composition. The evidence to support clinical decision-making is limited. Nevertheless, cohort studies have identified key factors, such as fast peritoneal solute transfer, ultrafiltration insufficiency, and worse outcomes associated with low salt and water removal, that must be taken into account. Our improved understanding of membrane (patho-)physiology provides a strong rationale for our recommended treatment interventions, although the evidence certainty remains low due to the lack of hard outcomes reported. This mechanistic understanding does inform clinical practice and should be considered an important evidence source on which to make clinical judgments. There are still considerable evidence gaps to be filled. These include the role for volume assessment technologies in guiding fluid management and the balance between normalizing fluid status, maintaining residual kidney function, and the role of pharmacological agents in achieving optimal clinical outcomes.

Introduction

Peritoneal dialysis (PD) is a well-established form of kidney replacement therapy (KRT) [1, 2], with possible early survival advantage as compared to hemodialysis [3–5]. Preservation of residual renal function (RRF) is of paramount importance in PD given that RRF contributes significantly to survival advantage in PD patients [6]. Conventional PD solutions are considered bio-incompatible in light of their low pH, high lactate concentrations, and high glucose concentrations with high glucose degradation product (GDP) content, which are generated during the heat sterilization process [7–14]. GDPs cause renal tubular apoptosis [15], which can potentially result in decline of RRF. Studies have reported that low pH in conventional solutions is a culprit for inflow pain in PD patients [16, 17]. More importantly, the bio-incompatible nature of conventional solutions has been reported to have a negative impact on the growth of mesothelial cells [7, 10–14] and the function of phagocytic cells [8]. Chronic exposure to conventional solutions has been implicated in the pathogenesis of peritoneal membrane fibrosis, which stems from loss of mesothelial cells, epithelial-to-mesenchymal transition of mesothelial cells, thickening of the submesothelial compact zone, and development of vasculopathy [18–20].

In this chapter, we summarize the published studies available for neutral pH, low GDP solution, icodextrin, or amino acid-based solutions in the treatment of peritoneal dialysis and provide recommendations for the nephrologist treating patients on peritoneal dialysis (Table 47.1).

Epidemiology

The recent Global Kidney Health Atlas (GKHA) survey reported that chronic PD service was available in only 76% of the countries worldwide, with particularly reduced accessibility in low-income countries (23%) [23]. The majority of PD patients are on conventional PD solutions, although some countries, including India, China, and Latin American countries, practice domestic manufacture of PD solution in order to reduce the cost by avoiding transport fees and import taxes [24]. Neutral pH, low GDP biocompatible solutions are less widely available than conventional solutions, and are primarily restricted to high-income and upper-middle-income countries. Similarly, glucose polymer-icodextrin is also not universally available. The limited access of lower-middle and low-income countries to biocompatible solutions is probably related to funding and healthcare policies given that these solutions are generally more expensive than conventional solutions. The recent GKHA survey reported that PD patients from low-income countries pay a large proportion of dialysis treatment costs using out-of-pocket money [23].

Pathophysiology

In an attempt to overcome the unphysiological nature of conventional solutions, biocompatible solutions were introduced and have been available for almost two decades. Neutral pH and low GDP solutions have been achieved using dual or triple chamber bag designs in which glucose is kept at a lower pH (2.5–3) in a separate chamber away from

Table 47.1 Peritoneal dialysis solution.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Neutral pH low GDP solution	We suggest that neutral pH, low GDP solution can be used to preserve residual renal function and urine volume in peritoneal dialysis patients. These may be used to reduce inflow pain in peritoneal dialysis patients. Peritoneal dialysis patients may reasonably choose not to use neutral pH, low GDP solutions based on low to very low certainty evidence that treatment makes no difference to peritonitis, technique failure, and mortality.	High (residual renal function, urine volume) Low to very low (peritoneal ultrafiltration, small solute transport, inflow pain, peritonitis, technique failure, and mortality)	Weak [21]
Glucose polymer	We suggest that glucose polymer solution can be used to increase daily ultrafiltration and reduce uncontrolled fluid overload in peritoneal dialysis patients. Peritoneal dialysis patients may reasonably choose not to use glucose polymer as treatment makes no difference to hard outcomes, including technique survival and mortality.	Moderate (daily ultrafiltration, uncontrolled fluid overload) Low to very low (residual renal function, urine volume, rash, peritoneal creatinine clearance, peritonitis, technique survival, and mortality)	Weak [21]

GRADE assessment of the certainty of the evidence [22]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

electrolytes and buffer to prevent or minimize GDP formation during heat sterilization and storage [25].The seal between chambers is broken prior to use, which enables the final product of a neutral pH, low GDP solution [25]. There have been several different types of low GDP solutions, which differ according to the type of buffer employed (lactate and/or bicarbonate). However, the majority of studies of biocompatible solutions have evaluated lactate-buffered solutions [26–32]. A number of studies have been published regarding the role and potential benefit of neutral pH, low GDP solutions on clinical outcomes, including RRF, urine volume, peritoneal membrane function, ultrafiltration, peritonitis risk, inflow pain, technique survival, and patient survival [26–34].

Glucose has been employed as the principal osmotic agent to promote peritoneal ultrafiltration in PD, but may be harmful to the peritoneal membrane [7, 11, 13, 35, 36]. It is also a source of GDPs [37, 38], which in turn promote advanced glycation end-product (AGE) formation in the peritoneal membrane and correlate with membrane fibrosis [37]. To overcome the disadvantage of glucose in conventional solutions, nonglucose agents have been used as an alternative to glucose. One such example is icodextrin, which not only provides the benefit of avoiding peritoneal glucose exposure but also has the advantage of enhancing ultrafiltration through colloidal pressure, which is especially beneficial for patients with high membrane transport characteristics [39], prolonging an osmotic gradient for fluid removal during the entire dwell. There have been a number of studies comparing the clinical outcomes of icodextrin with conventional solutions [39–43]. Amino acids are another nonglucose osmotic agent that have been examined in the peritoneal dialysis setting as a means of sparing glucose, whilst possibly providing nutritional supplementation [44, 45]. However, very few studies have compared the effects of amino-acid-based solutions with conventional solutions on nutritional indices and other clinical outcomes [45–48].

Treatment

Neutral pH, Low GDP Solutions

Residual Renal Function

The potential benefit of biocompatible solutions on RRF has been examined in multiple RCTs since the early 2000s with conflicting results. Some showed improved RRF [27, 29, 30, 32] while others did not show any benefit [31, 33, 34]. These disparities may have at least been partly due to small trial sample sizes, single center designs, short follow-up durations, and suboptimal methodologic quality. One of the large well-conducted studies of biocompatible solutions on RRF reported that biocompatible solutions were associated with better preservation of urine volume and showed a trend toward preserving the RRF, although the result did not reach

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the statistical significance [27]. However, re-analysis of the effect of biocompatible solution on RRF after adjusting for other potential confounders, including baseline renal function, longitudinal trend of blood pressure, longitudinal trend of peritoneal ultrafiltration, and glucose exposure over time, demonstrated that the use of biocompatible solution was significantly associated with better preservation of RRF compared with conventional dialysis solutions [49]. Meta-analysis of studies evaluating biocompatible solutions published in 2014 reported that the benefit of biocompatible solutions on preservation of RRF was apparent with long-term (>1 year) exposure to biocompatible solutions [50]. However, moderate to severe heterogeneity was observed [50]. Subsequent meta-analysis in 2015 with additional two studies identified reported better preservation of RRF with biocompatible fluids that was observed as early as 6 months follow-up duration. This effect extended beyond 1 year follow-up duration [51]. An updated systematic review of biocompatible solutions reported with high certainty of evidence that use of biocompatible solutions was associated with better preservation of RRF (15 randomized controlled trials [RCTs]: 835 participants, relative risk [RR] 0.19, 95% confidence interval [CI] 0.05 to 0.33) at all the time points examined (12 months, 12–24 months, and beyond 24 months) [21] (Table 47.2).

Urine Volume

The association of urine volume and patient survival was first demonstrated by Bargman et al. in a re-analysis of the CANUSA study, in which a 250 ml increase in urine vol-

Table 47.2 Summary of findings: neutral pH, low GDP peritoneal dialysis solutions.

Neutral pH, low GDP PD solutions versus standard glucose PD solutions						
	Anticipated absolute effects (95% CI)					
Outcomes	**Risk with standard glucose dialysate**	**Risk with low GDP dialysate (all buffer types)**	**Relative effect (95% CI)**	**No. of participants (studies)**	**Certainty of the evidence (GRADE)**	**Conclusions**
Residual renal function	The mean residual renal function (GFR) in low GDP group was 0.54 ml/min/1.73 m^2 (0.14–0.93) higher		–	835 (15)	⊕⊕⊕⊕ High	Neutral pH, low GDP solution improves residual renal function
Urine volume	The mean urine volume in low GDP group was 114.37 ml/day (47.09–81.65) higher		–	791 (11)	⊕⊕⊕⊕ High	Neutral pH, low GDP solution improves urine volume
Peritoneal ultrafiltration: 4 h	The estimated mean peritoneal ultrafiltration in low GDP group was 69.72 ml/4 h (16.60–122.84) lower		–	414 (9)	⊕⊕⊖⊖ Low	Neutral pH, low GDP solution may slightly reduce peritoneal ultrafiltration during 4-h peritoneal equilibration test
Peritoneal solute transport rate (4-h dialysate: plasma creatinine)	The mean peritoneal solute transport rate in low GDP group was 0.01 (0–0.03) higher		–	746 (10)	⊕⊕⊖⊖ Low	Neutral pH, low GDP solution may slightly increase peritoneal solute transport
Peritonitis rate (episodes/total patient-months)	31 per 1000	36 per 1000 (26 to 51)	RR 1.18 (0.84–1.64)	18 184 (10)	⊕⊕⊖⊖ LOW	Neutral pH, low GDP solution may make little or no difference to peritonitis rate
Technique failure (death-censored)	74 per 1000	81 per 1000 (55 to 120)	RR 1.10 (0.75–1.63)	1275 (15)	⊕⊕⊖⊖ LOW	It is uncertain whether neutral pH, low GDP solution reduces technique failure
Death (all causes)	77 per 1000	21 per 1000 (41 fewer to 11 more)	RR 0.73 (0.47–1.14)	1229 (15)	⊕⊕⊖⊖ LOW	It is uncertain whether neutral pH, low GDP solution reduces death (all-cause)

ume was associated with 36% reduction in risk of mortality [6]. One of the largest multicenter trials examining the effects of biocompatible solutions on RRF reported longer time to anuria and better preservation of residual urine volume with biocompatible solutions than conventional PD solutions [27]. This finding was supported by subsequent meta-analysis of RCTs (seven studies, 520 participants), who reported larger urine volume with the use of biocompatible solutions than conventional solutions [50]. In the latest update review of biocompatible solutions by Htay et al. it was reported with a high certainty of evidence that use of biocompatible solutions improved urine volume, (11 RCTs, 791 participants, RR 0.21, 95% CI 0.05–0.37), which was observed beyond 12 months of follow-up duration (Table 47.2) [21].

Peritoneal Membrane Function

Previous meta-analysis reported no difference in peritoneal ultrafiltration between neutral pH, low GDP, and conventional solutions [50]. A recently updated Cochrane review reported with low certainty evidence that neutral pH, low GDP solutions may slightly reduce peritoneal ultrafiltration during the 4-hour peritoneal equilibration test. It is uncertain whether neutral pH, low GDP solutions reduce 24-hour peritoneal ultrafiltration compared with conventional PD solutions given that considerable statistical heterogeneity was observed [21].

Biocompatible solutions may slightly increase 4-hour dialysate:plasma creatinine ratio in low certainty evidence [21] (Table 47.2). However, a previous study examining the longitudinal trend of membrane solute transport reported lower 4-hour dialysate:plasma creatinine ratio with biocompatible solution [52]. Most studies included in the meta-analysis did not examine the longitudinal changes in peritoneal solute transport but rather reported the solute transport at a single time point at the end of the study [50, 51]. More studies are needed to examine the effect of biocompatible solution on peritoneal membrane transport status.

Peritonitis

Peritonitis is one of the most common reasons for patients discontinuing PD therapy [53, 54]. The first RCT to show the potential effects of biocompatible solutions on the risk and severity of peritonitis was reported in the BalANZ trial, in which patients receiving biocompatible solutions experienced fewer peritonitis episodes than those on conventional solutions, and peritonitis episodes were rated as being milder in severity [27]. It was postulated that bioincompatibility of conventional PD solutions, due to acidic pH and high GDP content, would have adversely impacted on local host defense mechanisms, including impaired phagocytic function of macrophages and polymorphonuclear leukocytes, thereby rendering patients more susceptible to infection [8, 27].

Despite the promising results from the previous large RCT, the findings of benefit of biocompatible solutions on the risk and severity of peritonitis were unable to be replicated in subsequent RCTs [28–30, 32, 33]. Similarly, the benefit of biocompatible solutions on the risk and rate of peritonitis was unable to be demonstrated in a systematic review and meta-analysis [50], although subgroup analysis of studies with a low risk of attrition bias did find an appreciably lower risk of peritonitis with biocompatible solutions compared to conventional PD solutions [21]. Given that a considerable number of studies in the meta-analysis had a high risk of attrition bias (median drop-out 51%), it was concluded from low certainty evidence that neutral pH, low GDP solution may make little or no difference to the risks of peritonitis or peritonitis rates compared with conventional PD solutions (Table 47.2).

Technique Failure and Mortality

Most available studies on biocompatible solutions have been too small with too short a follow-up duration to have adequate statistical power to examine hard clinical outcomes, including technique failure and mortality. It is therefore uncertain whether neutral pH, low GDP solutions reduce technique failure or mortality [21, 50].

Inflow Pain

Inflow pain can significantly affect the quality of life of patients on peritoneal dialysis. Inflow pain has been mainly attributed to the low pH of conventional solution and improvement in the acidity of the solution with neutral pH, low GPD solution has shown decreased the burden of inflow pain [55]. In low certainty evidence, neutral pH, low GDP solutions may slightly improve inflow pain [50].

Adverse Effects

The available data have not demonstrated any harms resulting from the use of neutral pH, low GDP solution compared with conventional PD solution [50].

Bicarbonate ± Lactate Buffered Solution

The majority of studies comparing the clinical outcomes of neutral pH, low GDP solutions versus conventional solutions used neutral pH, low GDP, lactate buffered solutions rather than pure bicarbonate buffered or bicarbonate/lactate buffered solutions. The results of meta-analyses of neutral pH, low GDP solutions have therefore been heavily based

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

on the findings of RCTs with low GDP, lactate buffered solutions. For example, in a meta-analysis of neutral pH, low GDP solutions evaluating RRF, 10 out of 15 RCTs used lactate buffered solution, only three RCTs used pure bicarbonate buffered solutions, and two RCTs used a mixture of lactate buffered and bicarbonate/lactate buffered solutions [21].

There were few studies comparing the effects of bicarbonate/lactate buffered or pure bicarbonate buffered solutions with lactate buffered solutions [55–59]. Mactier et al. conducted a double-blind, cross-over RCT comparing the effects of different PD solutions, including bicarbonate buffered, bicarbonate/lactate buffered, and conventional solutions, on inflow pain using a verbal rating scale and the validated McGill Pain Questionnaire in 18 patients. They reported that inflow pain was significantly reduced with both bicarbonate or bicarbonate/lactate buffered solutions compared to conventional solution, and bicarbonate/lactate buffered solution was the most effective in alleviating pain [58].

Another area of interest with respect to the comparative effects of bicarbonate or bicarbonate/lactate buffered solutions and conventional solutions is correction of metabolic acidosis. A previous cross-over RCT including 28 patients (children, age 6 months to 15 years) reported that neutral pH, low GDP, bicarbonate buffered solution achieved more effective correction of metabolic acidosis than conventional lactate buffered solution [56]. A multicenter RCT comparing the effect of bicarbonate/lactate buffered versus conventional lactate buffered solution on correction of acidosis reported that venous plasma bicarbonate level increased by 3.1 mmol/l from a baseline level of 23 mmol/l in patients treated with bicarbonate/lactate buffered solution during the study period, and that the number of patients with acidosis (defined as plasma bicarbonate <24 mmol/l) was significantly reduced in the bicarbonate/lactate group [60]. However, a multicenter RCT comparing bicarbonate/lactate versus lactate buffered solution in 123 patients (only 69 patients completed the 6-month study) was unable to demonstrate any significant difference in acid-base status between the two groups [61]. This finding, however, has to be interpreted with caution given the suboptimal quality of the study and associated high risk of attrition bias.

Glucose Polymer Dialysate (Icodextrin)

Ultrafiltration

Icodextrin is a high molecular weight, iso-osmolar, glucose polymer that was first used in a clinical study in the 1980s [62]. Since then, several studies have been published on the effect of icodextrin on peritoneal ultrafiltration as compared with that of different strengths of conventional solutions, including 1.36%, 2.27%, or 3.86% dextrose solution during the long dwell (over 8–16 hours) either as a day- or night-dwell [39–41, 63, 64]. The updated meta-analysis, including four RCTs (102 participants), reported that icodextrin probably improves peritoneal ultrafiltration in moderate certainty evidence [21, 50] (Table 47.3).

Icodextrin has been demonstrated to generate better ultrafiltration compared with conventional dextrose solutions (1.36% or 2.27%). Patients with high peritoneal membrane solute transport characteristics have been known to experience poor peritoneal ultrafiltration with conventional solutions, especially during the long dwell [65], which is considerably augmented with the use of icodextrin [65, 66]. A meta-analysis of two RCTs (100 participants) reported that icodextrin probably reduces uncontrolled fluid overload (371 fewer per 1000); moderate certainty evidence [21, 50] (Table 47.3).

Technique Survival

A previous RCT conducted by Takatori et al. in 41 patients with diabetes and end-stage kidney disease reported better technique survival with icodextrin (71.4% vs. 45%) [67]. Although there has been evidence that icodextrin improves ultrafiltration and reduces uncontrolled fluid overload, available data from meta-analysis suggests that icodextrin may make little or no difference to technique survival; very low certainty evidence [50] (Table 47.3).

Residual Renal Function

There have been conflicting results regarding the effects of icodextrin on RRF and urine volume. A previous RCT by Konings et al., including 40 patients of whom only 33 (19 on icodextrin and 13 controls) completed the trial, reported a significant decline in RRF (glomerular filtration rate [GFR] 4.8–3.2 ml/min) and urine volume (1131–913 ml) over a 4-month follow-up period in the icodextrin group, which the authors postulated was due to a reduction in overhydration-stimulated pressure diuresis [68]. However, a multicenter RCT conducted by Davies et al. including 50 patients with urine output <750 ml reported that there was no significant reduction in urine volume in the icodextrin group [69]. Meta-analysis, to date, reported that icodextrin may make little or no difference to RRF (four RCTs, 114 participants, RR 0.12, 95% CI −0.26–0.49) and residual urine volume (three RCTs, 69 participants, RR −0.10, 95% CI −0.58–0.38); low certainty evidence [21, 50] (Table 47.3).

Solute Clearance

Apart from improving daily ultrafiltration, icodextrin may make little or no difference to peritoneal creatinine clearance (three RCTs, 237 participants).

Peritonitis

Similarly, with moderate certainty evidence, icodextrin probably makes little or no difference to the risk of developing peritonitis. Most of the available RCTs on icodextrin had short follow-up periods, which might not have allowed sufficient time to confidently detect an impact on mortality. It is therefore uncertain whether icodextrin reduces all-cause mortality in PD patients; low certainty evidence [21, 50] (Table 47.3).

Metabolic Parameters

Icodextrin has also been demonstrated in RCTs to improve patients' metabolic profiles. A multicenter RCT conducted by Paniagua et al. including 59 patients followed up for 1-year duration reported that icodextrin use was associated with a better metabolic profile including less glucose absorption, reduced insulin requirement, improved fasting glucose level, reduced HbA1c level, and also lower triglyceride level in diabetic PD patients compared with use of conventional PD solution [66].

Adverse Events

There were few reports about icodextrin use and the development of skin rash [70–72]. In a meta-analysis including three RCTs and 755 participants, icodextrin may have slightly increased the risk of developing rash (66 more per 1000) as compared with conventional solutions; low certainty evidence [21]. In addition, caution should be exercised when monitoring blood glucose levels in diabetes patients who use icodextrin in light of the fact that maltose, which is a metabolite of icodextrin, can be interpreted falsely as glucose, leading to overestimation of blood glucose level by glucose dehydrogenase-based methods using pyrroloquinoline quinone (GDH-PQQ) as a cofactor [73, 74].

Amino Acid Dialysate

Malnutrition is common in PD patients [75] and is a known risk factor for mortality [76]. Peritoneal dialysis itself has been a known cause for loss of amino acids (3–4 g/day) and protein (8–15 g/day) during dialysis exchanges [76]. Supplementing these losses by the use of amino acids as an alternative osmotic agent to dextrose in PD solutions was started in the late 1960s [44] (Table 47.4).

The potential benefit of amino-acid-based solution has been examined in a few studies, but most available studies have been non-RCTs with small sample sizes and/or insufficient follow-up duration to detect hard clinical outcomes, including technique failure and mortality [45, 47, 48]. The largest RCT of amino acid PD solution with the longest follow-up to date was that by Li et al., which included 60 Chinese malnourished patients who were randomized to receive once-daily amino acid solution (nutrineal) or conventional solution and followed up for 3 years [46]. The investigators reported that there were no significant differences observed in composite nutritional indices, technique failure, hospitalization or mortality between the two groups [46]. Based on the available data, it is uncertain whether once-daily amino acid solution improves nutritional parameters in malnourished PD patients.

Conclusions

To date, the available evidence suggests that neutral pH, low GDP PD solutions improve RRF and urine volume and may slightly improve infusion pain compared with conventional PD solutions. However, neutral pH, low GDP solutions may slightly increase peritoneal solute transport and slightly reduce peritoneal ultrafiltration, as measured during a 4-hour peritoneal equilibration test, and may make little or no difference to peritonitis rate. It is uncertain whether neutral pH, low GDP PD solutions improve technique or patient survival. Use of icodextrin probably improves daily ultrafiltration and reduces uncontrolled fluid overload but may make little or no difference to RRF, urine volume, peritoneal creatinine clearance, and technique or patient survival. Icodextrin may slightly increase the risk of rash. It is uncertain whether once-daily amino acid solution improves nutritional indices in malnourished patients. Future large well-conducted studies with sufficient follow-up duration examining the effects of long-term use of neutral pH, low GDP PD solutions on hard clinical outcomes, including technique and patient survival, are needed.

Introduction

Peritoneal dialysis (PD) is a well-established form of renal replacement therapy for patients with end-stage kidney disease (ESKD), which accounts for 11% of dialysis therapy for patients with ESKD worldwide [1].

One of the known complications of PD is infection, in particular PD-related peritonitis, which increases patient morbidity, including hospitalization, loss of catheter, and change of dialysis modality and death. Exit site or tunnel infection can progress to peritonitis. Most PD peritonitis episodes resolve with antimicrobial therapy, although this increases risks of further peritonitis, ultrafiltration failure (UFF) [2], and encapsulating sclerosing peritonitis [2, 3].

PD catheter-related infections are a major predisposing factor to PD-related peritonitis [4]. Implementation of effective prevention measures is the ultimate goal. However, peritonitis continues to represent a significant complication of PD despite the introduction of effective prevention strategies, such as modifications of the PD catheter and connection systems [5]. The primary objective of preventing and treating catheter-related infections is to prevent peritonitis. Treatment is aimed at reducing morbidity and recurrence of peritonitis.

Antimicrobial prophylaxis includes oral and topical antibiotics [6], topical disinfectants, co-prescribed antifungal therapy, and prophylactic treatment of *Staphylococcus aureus* nasal carriage. All of these strategies, particularly cleansing and disinfection of the exit site, are widely accepted, but practice patterns are variable and trial results are conflicting [7–9]. Catheter-related intervention strategies which have been studied include modifications of catheter design, implantation technique, connection methodology, and PD modality [10].

When infection does occur, early and effective management is important to reduce complications, such as progression from exit site infection (ESI) to peritonitis, relapse of peritonitis, hospitalization, catheter removal, hemodialysis transfer, and death. The mainstay of management of peritonitis is antimicrobial therapy, although adjunctive treatments such as use of fibrinolytic agents [11–13], peritoneal lavage, and intraperitoneal immunoglobulin administration [14] have been used. Peritonitis treatment regimens vary with regards to antimicrobial agent(s), route of administration, dosing frequency, and total duration of therapy. Center-specific factors such as patterns of antimicrobial resistance and regional isolation also play a role in making treatment decisions [15]. Each PD unit should examine its own pattern of infection, causative organisms, and sensitivities and adapt the protocols according to local conditions as necessary [16].

This chapter reviews and discusses the evidence for supporting practices in the prevention and treatment of PD-related infections, particularly focusing on peritonitis.

Definition

Standardization definitions for exit site/tunnel infections and peritonitis enables comparison of epidemiology, risks factors, and outcomes of PD-related infections. The International

Evidence-Based Nephrology, Second Edition. Edited by Jonathan C. Craig, Donald A. Molony, and Giovanni F.M. Strippoli.

Society for Peritoneal Dialysis (ISPD) has published definitions for PD-related infection in its guidelines/recommendation [4, 16]. Rates of infection should preferentially be reported as episodes per patient-year [4, 16].

Exit Site and Tunnel Infections

An ESI is defined as the presence of purulent drainage from the exit site. This may or may not be accompanied by peri-catheter swelling or erythema of the skin at the catheter-epidermal interface [4, 16]. Erythema or serous discharge alone may or may not represent infection. A positive culture from a swab in the absence of clinical signs may represent bacterial colonization not infection.

Tunnel infection in the absence of concomitant ESI is rare. Tunnel infection is defined as the presence of signs of inflammation (erythema, edema, and/or tenderness) or ultrasonographic evidence of collection along the subcutaneous catheter tunnel [4, 16].

Peritonitis

Peritonitis can be directly related to the PD procedure (PD-associated peritonitis) or can be surgical peritonitis related to intra-abdominal events, such as perforated viscera. This chapter will focus on the prevention and treatment of PD-associated peritonitis.

General definitions of different types of peritonitis are listed here – diagnosis of peritonitis will be discussed further later in the chapter:

Refractory peritonitis – failure of the PD effluent to clear after 5 days of appropriate antibiotics [16].

Relapsing peritonitis – an episode that occurs within 4 weeks of completion of therapy for a prior episode with the same organism or one sterile episode [16].

Repeat peritonitis – an episode that occurs more than 4 weeks after completion of therapy for a prior episode with the same organism [16].

Recurrent peritonitis – an episode that occurs within 4 weeks of completion of therapy for a prior episode but with a different organism [16].

Epidemiology

The incidence of ESI has reduced since the use of prophylactic topical antimicrobial agents as standard of care [6, 17–20]. Similarly, the incidence of peritonitis has improved with the introduction of disconnect systems [21, 22]. The peritonitis rate has been reported to have reduced from 1.1 to 0.46 episodes per patient year from 1994 to 2003 in a single center study from Hong Kong [21]. This improvement was in parallel with replacement of spike PD sets with a disconnect system which resulted in reduction of peritonitis due to Gram-positive organisms [21].

Risk factors for developing peritonitis include advancing age, some ethnicities (particularly Indigenous and First Nations peoples), comorbidities such as diabetes mellitus and obesity, tropical/temperate climates, depression, nasal carriage of *S. aureus*, and the presence of an ESI [23]. Catheter design and implantation technique and connection methodology also modulate the risk of peritonitis. In addition, some studies have shown that PD modality (continuous ambulatory peritoneal dialysis [CAPD] or automated peritoneal dialysis [APD]) affects peritonitis rates [24–26], although other studies have not confirmed this [27, 28].

PD-associated peritonitis results in significant morbidity and mortality. Catheter removal becomes necessary in cases not responding to antibiotic therapy. This may be temporary and followed by a return to PD, or permanent, resulting in technique failure. UFF can occur both acutely due to increases in capillary permeability and in the longer term resulting in technique failure.

In many countries, peritonitis is a leading cause of permanent transfer to hemodialysis. Peritonitis is prevalent among patients with encapsulating sclerosing peritonitis and may be a causal factor [29]. It is estimated that PD-associated peritonitis results in death in approximately 6–10% of affected patients [30, 31].

Pathophysiology

Catheter exit sites can be colonized with bacteria shortly after catheter placement. Biofilm formation following colonization of bacteria can promote bacterial growth and protect them from topical antimicrobial agents [32, 33]. Colonization can lead to ESI, especially following exit site trauma. Infection can either be localized to the exit site only or can extend to involve the tunnel tract leading to a tunnel infection or even further leading to peritonitis [34, 35]. Severity of infection usually depends on the virulence of the causative organisms. Common causative organisms for ESI are Gram-positive organisms, including Staphylococcus species especially coagulase negative *Staphylococcus*. Common Gram-negative organisms causing ESI include *Escherichia coli* and *Pseudomonas aeruginosa* [36].

The most common serious complication of PD is infection of the peritoneal lining – peritonitis. PD patients can acquire peritonitis through different mechanisms, in which microorganisms can gain access to the peritoneum through

touch contamination during the dialysis exchange, translocation from the bowel, hematogenous dissemination, or from exit site/tunnel infection.

Diagnosis

Diagnosis of Exit Site and Tunnel Infections

ESI is diagnosed by the presence of purulent drainage from the exit site, with or without erythema of the skin at the catheter-epidermal interface or peri-catheter swelling [4, 16].

Peri-catheter erythema without purulent drainage is sometimes an early indication of infection but can also be a simple skin reaction, particularly in a recently placed catheter or after trauma to the catheter. A positive culture from a swab in the absence of clinical signs may represent bacterial colonization not infection.

Tunnel infection may present as erythema, edema, or tenderness over the subcutaneous pathway but is often clinically occult. A tunnel infection usually occurs in the presence of an ESI but rarely occurs alone. Ultrasound assists in establishing the presence of fluid collection along the subcutaneous catheter tunnel.

Diagnosis of Peritonitis

Diagnosis of peritonitis must be confirmed by the presence of two out of three of the following findings [16]:

1) abdominal pain or cloudy effluent
2) effluent fluid with leukocyte count over 100 cells per microliter (after a dwell time of at least 2 hours), with more than 50% neutrophils
3) positive culture of peritoneal effluent.

The patient experiencing infectious peritonitis often satisfies all the above criteria. However, not all centers can perform a Gram stain, and the culture becomes positive many hours and sometimes days after admission. Decision on treatment is therefore often based on the first two findings. The diagnostic workup is contributed to by the clinical history, fever occurrence, increased peripheral blood leukocyte count, and other typical symptoms of infectious diseases.

1) Cloudy effluent
   This sign must be confirmed by differential count of white blood cells in the peritoneal effluent; a percentage of neutrophils greater than 50% are as important as a total white cell count of 100 cells per microliter. The increase in white cell count can be delayed in some cases; therefore, a white blood cell count lower than 100 per microliter does not rule out the diagnosis of peritonitis, such that accompanying signs and symptoms should be considered. A repeat count on the effluent following an exchange often shows a cell count increase. Leukocyte esterase reagent strips are used in many centers to enable the patient to check the effluent at home thereby reducing the time to diagnosis and avoiding underestimation of the significance of mild changes in effluent clearness. The sensitivity and specificity of the leukocyte esterase test is comparable to that of visual assessment and light microscopy.
   A cloudy peritoneal effluent can also appear in other conditions besides infectious peritonitis such as mild hemoperitoneum, peritoneal eosinophilia, chylous effluent, chemical peritonitis, and peritoneal-based malignancy.
   A cloudy fluid can often appear in the first bag exchange after a period of empty abdomen ("dry abdomen") and is due to the accumulation of cells in the peritoneal cavity. This may lead to the misdiagnosis of peritonitis in patients undergoing intermittent PD or APD with a dry day, as the first exchange is often cloudy in these patients. This can be avoided by infusing 1 l of PD fluid and allowing it to dwell for a minimum of 1–2 hours before draining and examining for turbidity and for cell count; otherwise, a rapid flushing of the peritoneal cavity with 1–2 l of dialysis fluid can precede that maneuver. Clear effluent is typically observed when dialysis fluid is constantly present and regularly exchanged in the peritoneal cavity.
2) Abdominal pain
   In peritonitis, abdominal pain is typically generalized and is often associated with rebound tenderness. Pain in PD-related infectious peritonitis is often first located in the epigastric region; pain then spreads to the entire abdomen. The intensity of pain is variable; some patients have a frank cloudy effluent with little pain, others complain of severe pain which is not necessarily correlated with changes in the cloudiness of the effluent. The causative microorganism could play a role in the severity of pain, for example streptococcal peritonitis is generally associated with severe pain.
   Peritonitis in PD patients may be secondary to disease of abdominal organs. The differential diagnosis between PD-related peritonitis and peritonitis secondary to other diseases is critical for both diagnostic workup and treatment. Pain localized to the left iliac fossa should be suspicious for diverticulitis; first localized pain in the right iliac fossa necessitates evaluation for appendicitis. Consider cholecystitis when pain is in the right hypochondrium.

3) Positive culture of peritoneal effluent

Gram stain is only positive in a minority of cases, but it is recommended as it may provide a rapid indication of fungal peritonitis.

A positive culture typically occurs in 80–90% of peritonitis episodes. Causative microorganisms include Gram negative and Gram positive bacteria, fungi, yeasts, typical, and atypical mycobacteria. The possibility of a viral peritonitis cannot be excluded, but the literature on this topic is only anecdotal.

PD effluents cultures are negative in 10–20% of cases of clinically diagnosed infectious peritonitis. The low concentration of microorganisms in the effluent accounts for negative culture results but other causes have been reported, above all insufficient volume of the effluent sample, concurrent use of antibiotics, inadequate culture technique or lack of concentration by centrifugation. Other causes are endotoxins or either contaminants of the dialysis fluid or medications introduced in the peritoneal cavity. The ISPD Guidelines suggest that suggest that sampling and culture methods be reviewed and improved if more than 15% of peritonitis episodes are culture-negative [16].

Other signs/symptoms or significant investigation results may also be present in peritonitis, including pneumoperitoneum, elevate amylase concentration in peritoneal fluid, exit site or tunnel infection, leukocytosis, fever, and anorexia. Other important clinical signs and symptoms, including chills, vomiting, lack of bowel sounds, tachycardia, hypotension, and polypnoea, occur in the most severe cases. In some patients (e.g. elderly or on immunosuppressive therapy), these signs can be less severe.

Prognosis

The prognosis of PD-related infection depends on patient and treating center characteristics [37]. One of the patient-level characteristics reported to be responsible for outcomes of peritonitis is causative microorganisms [37]. A previous study including 3305 episodes of peritonitis by Cho et al. reported that some micro-organisms (*Coagulase-negative Staphylococci*, *Streptococci*, and culture negative) were associated with a low risk (<20%) of catheter removal, other microorganisms (including *Corynebacteria*, *Enterococci*, *S. aureus*, and nonpseudomonas Gram-negative organisms) were associated with a moderate risk (20–40%) of catheter removal, and polymicrobial, fungal, and *Pseudomonas* organisms were associated with a high risk (>40%) of catheter removal [38].

Center-level characteristics that have been reported to be associated with more favorable peritonitis outcomes include maintaining a higher proportion of dialysis patients on PD and having a higher percentage of peritonitis episodes treated with empiric antibiotics covering both Gram-positive and Gram-negative organisms at initial presentation [37].

The majority of patients who develop peritonitis achieve cure with antibiotic therapy [37]. The other possible outcomes of peritonitis include catheter removal, transfer to hemodialysis, relapsing or recurrent peritonitis, or death. In a study of a registry data including 9100 episodes of peritonitis, Htay et al. reported that 69% of peritonitis episodes achieved cure with antibiotics therapy [37]. Episodes of peritonitis which did not response to medical therapy developed one or more of the following: catheter removal (19%), transfer to hemodialysis (18%), relapsing or recurrent peritonitis (12%), and mortality (9%) [37].

Prevention

Prevention of PD-related infection plays a critical role in PD as most PD-related infections are preventable. Moreover, peritonitis was reported to be independently associated with an increased risk of all-cause mortality, cardiovascular mortality, and infection-related mortality (Table 48.1) [46].

Topical Antimicrobial Agents

In a meta-analysis of mupirocin, including 14 studies examining nasal or topical at catheter exit site versus no treatment, it was reported that mupirocin was effective in prevention of ESI and peritonitis due to *S. aureus* and other organisms [42]. The meta-analysis only included three randomized controlled trials (RCTs) and these three trials examined nasal mupirocin versus no treatment. In the latest Cochrane meta-analysis, which included only three RCTs, it was reported that, in low certainty evidence, nasal antibiotic prophylaxis had uncertain effects on the prevention of peritonitis or exit site/tunnel infection compared with placebo or no treatment [43] (Table 48.2). There was one trial reporting that nasal mupirocin compared with placebo significantly reduced *S. aureus* ESI rate in CAPD patients who were identified as *S. aureus* nasal carriers, but had no significant effect on peritonitis rates [36].

There are very few RCTs examining the effectiveness of topical mupirocin at the catheter exit site in PD patients [47] and most published studies examined those with nasal colonization by *S. aureus*. The greatest concern regarding routine use of topical mupirocin is the risk of emergence of mupirocin-resistant bacteria, which should be monitored closely. The alternative topical antibacterial agents, including gentamicin [48] and medical honey [49], have been examined in RCTs.

Table 48.1 Prevention and treatment of PD-related infection.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Prevention of PD-related infection			
Technique of catheter insertion	We do not suggest any specific method of catheter insertion	*Low or moderate* (peritonitis) *Very low or low* (exit site infection, technique failure and all-cause mortality)	Weak [39, 40]
Type of catheter	We do not suggest any specific type of catheter be used to prevent PD-related infections	*Low or moderate* (peritonitis and exit site infection) *Very low or low* (technique failure and all-cause mortality)	Weak [39, 40]
PD sets and connection methods	We recommend that Y-set or double bag systems be used to reduce the risk of PD-related peritonitis compared with spike systems	*Moderate or high* (risk of peritonitis and peritonitis rate)	Strong [41]
Prophylactic topical antibiotics at exit site	We suggest that topical antibiotics at exit site may be used to reduce exit site/tunnel infection and peritonitis	*Low* (peritonitis and exit site/tunnel infection)	Weak [42]
Prophylactic IV antibiotics prior to catheter insertion	We suggest that prophylactic IV antibiotics prior to catheter insertion may be used to reduce the risk of early PD peritonitis	*Low* (early peritonitis) *Very low* (exit site/tunnel infection)	Weak [43]
Topical disinfectants	We do not suggest any specific type of topical disinfectant be applied to the exit site to prevent peritonitis, exit site/tunnel infection, or catheter removal/replacement	*Low* (peritonitis, exit site/tunnel infection and catheter removal/replacement)	Weak [43]
Nasal antibiotics	We suggest that PD patients may reasonably choose not to use nasal antibiotics to prevent peritonitis, exit site/tunnel infection, or catheter removal/replacement	*Low* (peritonitis, exit site/tunnel infection and catheter removal/replacement)	Weak [43]
Antifungal prophylaxis	We suggest that antifungal prophylaxis may be used to prevent fungal peritonitis during any course of antibiotics prescribed in PD patients	*Low* (fungal peritonitis)	Weak [43]
Treatment of PD-related infection			
Glycopeptides-based regimen for peritonitis	We suggest that a glycopeptide-based regimen may be used to treat peritonitis in PD patients. PD patients with peritonitis may reasonably choose to receive an alternative nonglycopeptide-based antibiotic regimen to prevent primary treatment failure, relapse, and catheter removal	*Low* (complete cure) *Very low* (primary treatment failure, relapse peritonitis, and catheter removal)	Weak [44]
IP route of administration of antibiotics during peritonitis	We suggest that IP antibiotics may be used to treat peritonitis in PD to increase complete cure and reduce primary treatment failure	*Low to very low* (primary treatment failure, complete cure, and relapse peritonitis)	Weak [44]
Intermittent dosing regimen	We suggest that either an intermittent or continuous dosing IP antibiotic regimen may be used to treat peritonitis in PD patients	*Low to very low* (complete cure and primary treatment failure)	Weak [44]
Peritoneal lavage	We suggest that PD patients who developed peritonitis may reasonably choose not to receive peritoneal lavage to reduce the likelihood of complete cure, relapse or technique failure	*Very low* (complete cure, relapse peritonitis, and technique failure)	Weak [44]
Urokinase	We suggest that simultaneous catheter removal and replacement be considered to reduce recurrent peritonitis compared with urokinase therapy in patients with recurrent peritonitis	*Low* (recurrent peritonitis)	Weak [44]

IP, intraperitoneal; IV, intravenous; PD, peritoneal dialysis.
GRADE assessment of the certainty of the evidence [45]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low:; This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Table 48.2 Nasal antibiotics versus no treatment for preventing peritonitis in PD patients.

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)	Conclusions
Peritonitis	RR 0.94 (0.67–1.31)	18 fewer per 1000 (from 91 more to 97 fewer)	338 (three studies)	⊕⊕⊖⊖ Low	Nasal antibiotics make little or no difference to peritonitis
Exit site/tunnel infection	RR 1.34 (0.62–2.87)	56 more per 1000 (from 63 fewer to 308 more)	338 (three studies)	⊕⊕⊖⊖ Low	Nasal antibiotics make little or no difference to exit site/tunnel infection
Catheter removal or replacement	RR 0.92 (0.48–1.78)	Eight fewer per 1000 (from 53 fewer to 80 more)	289 (two studies)	⊕⊕⊖⊖ Low	Nasal antibiotics make little or no difference to catheter removal or replacement

CI, confidence interval; PD, peritoneal dialysis; RR, risk ratio.
Source: Campbell et al. [43].

In a randomized controlled double blinded trial, topical gentamicin reduced catheter infections, time to first catheter infection, and catheter infections due to *P. aeruginosa* compared to mupirocin. Peritonitis rates were not statistically significant on intention to treat analysis (0.56/year compared to 0.30/year for mupirocin and gentamicin groups, respectively,P=0.08) [48]. There were no reports of gentamicin ototoxicity. In a meta-analysis including two trials and 214 participants, topical gentamicin compared to mupirocin had uncertain effects on the prevention of peritonitis (relative risk [RR] 1.39, 95% confidence interval [CI] 0.93–2.07) or exit site/tunnel infection (RR 1.19, 95% CI 0.41–3.46) in PD patients [43].

Another RCT examined topical honey at the catheter exit site versus intranasal mupirocin prophylaxis (only in *S. aureus* carriers) in 371 PD patients [49]. PD-related infection-free survival was not significantly different between the two groups. However, in subgroup analysis, topical medical honey was associated with higher risk of PD-related infection in diabetes patients [49].

Similarly, in a multicenter, double-blind RCT there was no difference for topical mupirocin compared to polysporin triple ointments in the time to first episode of PD-related infection, defined as composite of exit site/tunnel or peritonitis [50].

In a Cochrane meta-analysis comparing topical antimicrobial agents versus placebo or no treatment in PD patients, there was very low certainty evidence for prophylactic oral antibiotics (including ofloxacin, cefalexin, rifampin, or cotrimoxazole) and topical antibiotics (including nasal or exit site mupirocin ointment) on peritonitis, peritonitis rate, exit site/tunnel infection, and exit site/tunnel infection rates compared with placebo or no treatment [43] (Table 48.3). Similarly, in very low certainty evidence, topical antibiotic prophylaxis with either sodium fusidate at the exit site and nasal region or mupirocin at the exit site had uncertain effects on the risks of peritonitis and exit site/tunnel infection compared with oral antibiotics (including ofloxacin or rifampicin) or topical gentamicin cream at the exit site [43].

Topical Disinfectants/Antiseptic Agents

Topical disinfectants have been routinely used to clean the catheter exit site to reduce colonization around the catheter exit site in PD patients. The most commonly used disinfectant examined in the studies was povidone-iodine. In a Cochrane meta-analysis, topical disinfectant at the exit site had uncertain effects on the risks of peritonitis and exit site/tunnel infection compared with standard care or other active treatment, including antibiotics or other disinfectants such as hydrogen peroxide, sodium hypochlorite or chlorhexidine [43] (Table 48.4).

Intravenous Antibiotic Prophylaxis Prior to Catheter Insertion

The latest Cochrane meta-analysis reported in low certainty evidence that prophylactic antibiotics administered prior to PD catheter insertion may reduce the risk of early peritonitis, defined as development of peritonitis within 1 month of catheter insertion, but has uncertain effects on risk of exit site/tunnel infection as compared with no treatment [43]. However, there was no difference in the risk of peritonitis or exit site/tunnel infection more than 1 month after catheter insertion between the interventions [43].

The ISPD guidelines recommend systemic prophylactic antibiotics be administered immediately prior to catheter insertion [4, 16]. The KHA-CARI guidelines recommend use of a first-generation cephalosporin for this purpose based on extrapolations from the results of pre-operative antibiotic trials in patients without ESKD. However, the evidence supporting the use of a first-generation cephalosporin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 48.4 Topical disinfectants versus standard care or other treatment (disinfectant or antibiotic) for preventing peritonitis in PD patients.

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)	Conclusions
Peritonitis	RR 0.83 (0.65–1.06)	40 fewer per 1000 (from 14 more to 82 fewer)	853 (six studies)	⊕⊕⊖⊖ Low	Topical disinfectants make little or no difference to peritonitis compared with standard care or other treatment
Exit site/tunnel infection	RR 1.00 (0.75–1.33)	Zero fewer per 1000 (from 57 fewer to 75 more)	973 (eight studies)	⊕⊕⊖⊖ Low	Topical disinfectants make little or no difference to exit site/tunnel infection compared with standard care or other treatment
Catheter removal or replacement	RR 0.89 (0.57–1.38)	10 fewer per 1000 (from 34 more to 39 fewer)	792 (six studies)	⊕⊕⊖⊖ Low	Topical disinfectants make little or no difference to catheter removal or replacement compared with standard care or other treatment

CI, confidence interval; PD, peritoneal dialysis; RR, risk ratio.
Source: Campbell et al. [43].

in PD patients undergoing PD catheter insertion is scant. Recommendation of a first-generation cephalosporin in preference to vancomycin may be a reasonable compromise because of the risk of vancomycin-resistant enterococcus (VRE) and *S. aureus*. The ISPD guidelines address this issue by recommending that each program weigh up the benefits of vancomycin with the risk of emergence of resistant microorganisms.

Prophylactic Antibiotics Prior to Other Procedures

Invasive procedures pose a risk for developing peritonitis. Therefore, a role for antibiotic prophylaxis prior to invasive procedures appears plausible. To date, there has been no randomized trial to support this practice. However, it is recommended by the ISPD to consider prophylactic antibiotics prior to procedures, including dental procedures, cholecystectomy, colonoscopy, polypectomy, and hysteroscopy, based on the findings of observational studies [16].

Prophylactic Antifungal Therapy

Fungal peritonitis has high morbidity (including technique failure) and mortality. Fungal peritonitis is usually preceded by bacterial peritonitis [51]. Prolonged exposure to antibiotics can predispose to secondary fungal peritonitis in PD patients [52]. Few studies examined the effect of prophylactic antifungal therapy, either nystatin or fluconazole, which was given along with antibiotics therapy for peritonitis or other sources of infection [53–59]. The meta-analysis, including two studies and 817 participants, reported in low certainty evidence that antifungal therapy

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

may reduce fungal peritonitis [60, 61] (Table 48.5). ISPD and KHA-CARI recommend prophylactic use of nystatin during the course of antibiotic therapy to reduce the incidence of fungal peritonitis [16].

Other Interventions

Trials of UV germicidal chambers around the connection device and antistaphylococcal vaccine also showed no effect of these interventions [43]. There are no controlled trials evaluating the effects of antibacterial soap.

Catheter-related Interventions

There were several RCTs that examined the effects of various catheter-related interventions to reduce the risks of PD-associated infection in PD patients [62–68]. Catheter-related interventions included in systematic reviews are surgical approaches (laparoscopy versus laparotomy, standard insertion and resting versus implantation and subcutaneous burying, midline compared to lateral insertion, etc.), type of PD catheter (straight versus coiled, single versus double cuffed, double versus triple cuffed, antibiotic impregnated versus standard catheters), use of silver rings, and immobilization devices. None of these have been shown to significantly affect the rates of exit site/tunnel infections or peritonitis (Tables 48.6–48.9) [40].

The only catheter-related measure that has been shown to influence infection rate in a systematic review is the use of disconnect systems rather than conventional spike systems [41]. Y-set compared to standard spike systems reduce risk of peritonitis and peritonitis rates, but not rates of exit-site/tunnel infection, catheter removal/replacement, and all-cause mortality [41].

Table 48.5 Antifungal agents versus placebo or no treatment for preventing fungal peritonitis in PD patients.

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)	Conclusions
Fungal peritonitis	RR 0.28 (0.12–0.63)	18 per 1000 (8–40)	817 (two studies)	⊕⊕⊖⊖ Low	Antifungal agents may reduce fungal peritonitis compared with placebo or no treatment

CI, confidence interval; PD, peritoneal dialysis; RR, risk ratio.

CAPD Versus APD

APD is associated with a reduced risk of peritonitis compared with CAPD [24, 69] and may reflect the reduced number of connections (and therefore opportunities for intraluminal contamination). In a meta-analysis including two small, relatively short duration RCTs of APD versus CAPD, Rabindranath et al. reported that APD appeared to be superior to CAPD in reducing peritonitis rate but not risk of peritonitis or exit site/tunnel infection [70]. The results should be interpreted with caution as both studies were conducted in the 1990s, one study indicated using a Y-connector [71, 72] but the others did not specify which type of PD set was used for CAPD [71]. There is no recent RCT comparing the effects of CAPD and APD on the outcomes of peritonitis.

PD Training

It is generally accepted that PD training and education play a critical role in prevention of PD-related infection given that proper PD training and education about safe aseptic technique during PD exchanges is considered one of the most important factors to minimize touch contamination, which is the commonest cause of PD-related infection. There are several observational studies on the PD training-related activities, focusing on the number of training hours, trainer experience, ratio of trainers to patients, method/ principle of teaching used for training, and role of retraining on the outcomes of PD patients, including infection-related outcomes (such as peritonitis or exit site/tunnel infection) and noninfection outcomes [73–78]. However, there are no well-conducted RCTs examining the effects of PD training-related activities on infection related outcomes in PD patients. Future RCTs examining the PD training related activities on infection and noninfection related outcomes are needed.

Summary

Interventions that have been shown to be of benefit in prevention of PD-related infection include intravenous prophylactic antibiotics prior to catheter insertion, use of prophylactic topical antimicrobial agents, Y-set or double bag system, and antifungal prophylaxis during antibiotic therapy.

Treatment

Peritonitis causes high morbidity, technique failure, and mortality [46]. Early and prompt treatment of peritonitis is crucial to reduce these complications and improve technique and patient survival. Exit site/tunnel infection can progress to peritonitis [79, 80]. Early and effective treatment of exit site/tunnel infection is important to prevent infection-related technique failure in PD patients.

The mainstay of treatment in PD-related infection is medical therapy (intraperitoneal antimicrobial agents), with surgical intervention reserved for failure to respond to medical therapy (Table 48.1).

Exit Site and Tunnel Infections

Management of exit site/tunnel infection is important as it has been shown to lead to peritonitis and technique failure [80]. ISPD recommends prompt treatment of exit site/tunnel infection to reduce subsequent peritonitis [4]. In addition, ISPD recommends daily cleaning of the exit site during ESI [4]. The role of topical antimicrobial agents in the treatment of exit site/tunnel infection is uncertain given that there has been no RCT conducted on this subject.

There is paucity of study on the treatment of catheter exit-site/tunnel tract infection in PD patients, as most studies emphasize the prevention of exit site/tunnel tract infection. To date, there are two RCTs comparing the different types of antibiotics or route of administration on the treatment of exit site/tunnel infection and both studies were published in the 1990s [81, 82]. Plum et al. conducted a randomized study of oral versus intraperitoneal (IP) administration of clindamycin on 16 CAPD patients with clinically and ultrasound proven tunnel infections and reported that the IP route was superior to the oral route based on resolution of peri-catheter abscess by ultrasound criteria [82]. However, Flanigan et al. conducted a randomized study comparing the effect of a combination of IP vancomycin and oral rifampin versus oral trimethoprim/sulfamethoxazole for treatment of exit site/tunnel infection and reported that the percentage of cure for *Staphylococcal* infections was comparable between the two groups [81]. It is difficult to draw conclusions from these two studies given the small sample size and different antibiotics used between studies.

ISPD recommends empiric oral antibiotics covering *S. aureus,* such as penicillinase-resistant penicillin or first-generation cephalosporin, to be used to treat exit site/tunnel infection unless patients have a prior history of methicillin-resistant *S. aureus* (MRSA) or Pseudomonas species, in which case appropriate antibiotics, such as glycopeptide or clindamycin for MRSA carriers and anti--*pseudomonal* antibiotics for patients with prior history of Pseudomonas infection, should be prescribed [4, 16].

There is no RCT to date examining the effect of antibiotic duration on the outcomes of exit site/tunnel tract infection in PD patients. ISPD recommends 2 weeks of antibiotics for non-*Pseudomonal* exit site/tunnel infection and 3 weeks for infection with *Pseudomonal* species [4, 16].

ISPD recommends catheter removal in refractory exit site/tunnel infection, defined as failure to response to medical therapy despite appropriate antibiotics for 3 weeks, catheter infection that leads to peritonitis or catheter infection that occurs simultaneously with peritonitis [4].

Peritonitis

Early and effective management of peritonitis is important to reduce the risk of adverse outcomes, such as catheter removal. The mainstay of treatment is antimicrobial therapy, although adjunctive therapies have been employed, including the use of fibrinolytic agents [13, 83, 84], peritoneallavage [85], and routine early catheter removal [86].

Empirical Antibiotic Therapy

Once peritonitis has occurred, the ISPD and KHA-CARI guidelines both state that empirical therapy with antibiotics that will cover both Gram-negative and Gram-positive organisms should be initiated at the time a diagnosis of peritonitis is suspected [4, 16, 87].

Specific antibiotic agents are not recommended, although the ISPD guidelines suggest that local patterns of causative organisms and bacterial resistance should be taken into consideration by each center. Following identification of a specific organism, targeted therapy should be initiated [16].

Antibiotic Regimens

The Cochrane review group did not identify any optimal antibiotic agent or combination of agents [44]. IP glycopeptides (vancomycin or teicoplanin) had uncertain effects on primary treatment response, relapse rates, and need for catheter removal compared to first-generation cephalosporin (Table 48.10), although glycopeptide regimens were more likely to achieve a complete cure [44].

A large number of antibiotic regimens used in the treatment of peritonitis have been evaluated in RCTs [88–90]. Only two antibiotic regimens were found to be superior in a systematic review [44]. However, in both cases the applicability to current practice is low. Meta-analysis of two trials comparing cefazolin and vancomycin found vancomycin to be superior at achieving complete cure [44]. This finding was strongly influenced by a large number of patients in one trial in which a low dose of cefazolin (50 mg/l) was used [88]. The other trial included in the meta-analysis used a cefazolin dose of 125 mg/l [90], as is recommended in the ISPD guidelines, and found the two agents to be equivalent. IP ciprofloxacin/rifampicin was

found to be superior to IP cephradine in one trial [91]. The usefulness of this finding is limited by the use of monotherapy with a first-generation cephalosporin in one treatment arm, without any broad Gram-negative cover, a practice which is now uncommon. Similarly, first-line use of ciprofloxacin and rifampicin is restricted in many centers due to concerns regarding the risk of emergence of multiresistant organisms. In summary, there is limited evidence that any specific antibiotic regimen is superior to others in reducing primary treatment failure or relapsing peritonitis in PD patients.

No currently available guidelines recommend specific antibiotic regimens, reflecting the paucity of available evidence, although information regarding factors requiring consideration when selecting antibiotics is provided. ISPD Guidelines recommend that there should be center-specific selection of agents according to local causative microorganism and resistance patterns [16]. The impact of local microbial resistance on peritonitis outcomes was apparent in two trials comparing oral and intraperitoneal quinolone use. In both studies, response rates were low for both treatment arms (41.7% and 55.6% in the oral group and 66.7% and 70.6% in the intraperitoneal group, respectively) [92]. Microorganism resistance to quinolones was the major cause of treatment failure, and previous exposure to quinolones was a risk factor for infection with resistant microorganisms. Similarly, the emergence of VRE is associated with use of broad-spectrum antibiotics [93, 94].

Duration of Antibiotics

Longer duration treatment (21 days of IV vancomycin and IP gentamicin) had uncertain effects on risk of treatment relapse compared with 10 days of treatment (one study, 49 patients, RR 1.56, 95% CI 0.60–3.95) [44].

Route of Antibiotic Administration

The optimal route of antibiotic administration was addressed in trials comparing oral and intraperitoneal administration [92, 95], and IV and IP dosing [96]. IP antibiotics were superior to IV antibiotics in reducing treatment failure in one small study (RR 3.52, 95% CI 1.26–9.81) where the initial antibiotics were given intravenously, followed by oral antibiotics at day 4 if considered appropriate [44]. This finding may relate to achievement of higher intraperitoneal antibiotic concentrations with intraperitoneal administration compared to systemic dosing and early use of oral therapy, however a meta-analysis of 10 trials found that oral dosing was equivalent to intraperitoneal dosing [44]. This was demonstrated when the same drug was administered intraperitoneally and per oral, and when oral quinolone monotherapy was compared to IP combination therapy [92].

Intermittent Versus Continuous Antibiotic Administration

An intermittent dosing regimen has uncertain effects on complete cure (four studies, 338 participants, RR 0.92, 95% CI 0.64–1.33), primary treatment failure (five studies, 522 participants, RR 1.11, 95% CI 0.77–1.62) and risk of relapse (four studies, 338 participants, RR 0.76, 95% CI 0.45–1.28) compared with a continuous dosing regimen [44] (Table 48.11). The applicability of results from trials of intermittent drug therapy in CAPD to APD is unclear. Drug half-lives are greater and clearance more rapid in cycler dwells compared to noncycler dwells [97]. Pharmacokinetic studies of IP antibiotic dosing suggest that therapeutic drug levels are achieved during 6-hour dwells, therefore it is likely that a patient can remain on APD as long as there is at least a 6-hour daytime dwell [97, 98] during which antibiotics can be administered.

Peritoneal Lavage

Peritoneal lavage in conjunction to antibiotic treatment has uncertain effects on improvement in treatment response to antibiotic therapy [44].

Urokinase

Urokinase had no advantages over placebo in improving response rates or reducing relapse and, when compared to early catheter removal, urokinase was clearly inferior in reducing treatment failure for relapsing or persistent peritonitis [44].

Intraperitoneal Immunoglobulin

One study of intraperitoneal immunoglobulin administration in conjunction with antibiotics found that the treatment group achieved biochemical and clinical parameters of improvement sooner and that the duration of antibiotic therapy was shorter [14]. However, the response rate was 100% in both groups with no relapses during a 3-month follow-up period, suggesting that use of immunoglobulin does not change overall patient outcomes. This, together with the expense and limited availability of immunoglobulin therapy, reduces the feasibility of this treatment as part of routine therapy at the present time.

Table 48.11 Intermittent compared to continuous antibiotics for peritoneal dialysis-associated peritonitis.

Outcomes	Relative effect (95% CI)	Absolute effect (95% CI)	No. of participants (studies)	Quality of the evidence (GRADE)	Conclusions
Failure to achieve complete cure	RR 0.92 (0.64–1.33)	21 fewer per 1000 (from 85 more to 93 fewer)	338 (four studies)	⊕⊖⊖⊖ Very low	Intermittent IP dosing has uncertain effects on complete cure compared with continuous IP dosing
Failure to achieve complete cure - gentamicin	RR 0.79 (0.45–1.37)	80 fewer per 1000 (from 141 more to 209 fewer)	100 (one study)		Intermittent IP dosing of gentamicin has uncertain effects on complete cure compared with continuous IP dosing
Failure to achieve complete cure - vancomycin	RR 0.62 (0.18–2.11)	59 fewer per 1000 (from 128 fewer to 173 more)	72 (two studies)	⊕⊖⊖⊖ Very low	Intermittent IP dosing of vancomycin has uncertain effects on complete cure compared with continuous IP dosing
Primary treatment failure	RR 1.11 (0.77–1.62)	17 more per 1000 (from 37 fewer to 99 more)	522 (five studies)	⊕⊖⊖⊖ Very low	Intermittent IP dosing has uncertain effects on primary treatment failure compared with continuous IP dosing
Primary treatment failure - gentamicin	RR 0.67 (0.26–1.73)	59 fewer per 1000 (from 131 more to 133 fewer)	100 (one study)		Intermittent IP dosing of gentamicin has uncertain effects on primary treatment failure compared with continuous IP dosing
Primary treatment failure - vancomycin	RR 1.10 (0.08–15.36)	Three more per 1000 (from 29 fewer to 449 more)	72 (two studies)	⊕⊖⊖⊖ Very low	Intermittent IP dosing of vancomycin has uncertain effects on primary treatment failure compared with continuous IP dosing

Catheter Removal

ISPD recommend catheter removal for refractory and relapsing peritonitis, fungal peritonitis, and some cases where there is no response to therapy [4, 16]. KHA-CARI makes no recommendation about the timing of catheter removal due to lack of evidence but do state that catheter removal is superior to urokinase [87].

For relapsing or persistent peritonitis, simultaneous catheter removal and replacement was better than prolinase at reducing treatment failure rates although evidence was limited to a single small study [86]. There have been no clinical trials evaluating the role of routine early catheter removal in refractory peritonitis, or of temporary transfer of patients from APD to CAPD. In the latter case, the question of when to safely recommence APD has also not been addressed.

Surgical peritonitis refers to cases when peritonitis arises from intraabdominal pathology. This may manifest as polymicrobial peritonitis. Such cases are usually treated by laparotomy and catheter removal at the same time as the underlying pathology is addressed, followed by a course of broad-spectrum intravenous antibiotics. There have been no trials addressing the treatment of this situation, and such trials are unlikely to be performed.

Summary

Even though PD-related infection has a significant impact on patient outcome, trials and reviews examining interventions to prevent infections have been limited by suboptimal methodological quality. There is also a paucity of evidence-based recommendations for treating exit site/tunnel infection in PD patients. For treatment of PD peritonitis, a glycopeptide-based regimen may increase complete cure but exerts uncertain effects on primary treatment failure, relapse, and catheter removal compared with a first-generation cephalosporin. The intraperitoneal route may increase complete cure and reduce primary treatment failure compared with oral or intravenous route of administration of antibiotics during peritonitis. An intermittent dosing regimen has uncertain effects on treatment outcomes compared with a continuous dosing regimen. Peritoneal lavage has uncertain effects on outcomes of peritonitis. Simultaneous catheter removal and replacement may reduce recurrent peritonitis compared with urokinase in patients with recurrent peritonitis. In general, review conclusions were based on a small number of studies with few events in which the risk of bias was generally high, interventions were heterogeneous, and outcome definitions were often inconsistent. There were no RCTs evaluating optimal timing of catheter removal and data for APD were absent.

Definitions of peritonitis, successful treatment and relapse varied between trials thereby reducing their comparability. Similarly, antibiotic doses were not consistent across studies. The follow-up period of most included trials was 28 days or less meaning that several long-term outcomes of peritonitis treatment, such as technique failure and longer-term mortality, were not evaluated. Studies tended to focus on choice and route of antibiotic without consideration of other variables, such as total duration of therapy or drug dose. To date, there have been no RCTs of treatment for fungal peritonitis, a condition that is associated with almost 100% catheter loss and high levels of mortality. Trials often predated the current era of lower peritonitis rates, newer antibiotic therapies, and increased awareness of multiresistant organisms, thereby potentially reducing the applicability of our meta-analyses or the individual trials' results. These aspects all need to be considered when making a decision about recommending or suggesting adoption of these interventions.

Conclusions

In summary, prophylactic intravenous antibiotic prior to PD catheter insertion may prevent early peritonitis, application of topical mupirocin application may reduce exit site/tunnel infection and peritonitis, use of Y-set or double bag systems reduces peritonitis but not ESI, and concomitant use of antifungal prophylaxis with antibiotic therapy may prevent fungal peritonitis. Methods of catheter insertion, types of catheter or immobilization of catheter have uncertain effects on exit site/tunnel infection or peritonitis. With regards to treatment of peritonitis, the available evidence suggests that glycopeptide-based regimens may increase complete cure but have uncertain effects on primary treatment failure, relapse or catheter removal compared with a first-generation cephalosporin regimen. Empirical antibiotic treatment regimens are similar in efficacy to each other, such that no specific regimen can be recommended. The intraperitoneal route may increase complete cure and reduce primary treatment failure compared with oral or intravenous antibiotics. An intermittent dosing regimen has uncertain effects on infection-related outcomes compared with a continuous dosing regimen. Peritoneal lavage or urokinase therapy has uncertain effects on complete cure, relapse or technique failure. When dealing with recurrent peritonitis, simultaneous catheter removal or replacement may reduce recurrent peritonitis compared with urokinase therapy.
