Introduction

Across the world, there is an increasing growth in the number of patients with end-stage kidney disease, with over 2 million people receiving renal replacement therapy worldwide [1]. Peritoneal dialysis (PD) has several advantages over hemodialysis (HD), including preservation of vasculature for future dialysis access [2], an initial survival advantage [3, 4], cost effectiveness [5], and preservation of residual renal function [6, 7]. From a patient's perspective, there is also a greater level of satisfaction and quality of life, as well as an enhanced flexibility to travel [8–10]. Moreover, initiating patients on PD is associated with a significantly lowered risk of death compared to hemodialysis with a central venous catheter (CVC) in the first year after dialysis initiation [11].

Despite several clinically important and patient-centered advantages of PD, its uptake has been static or declining in some parts of the world [8, 12, 13]. One of the main barriers to broader utilization of PD has been reluctance to initiate PD in settings where dialysis access has not been established [14]. About 80% of patients commence dialysis using a CVC due to a lack of established dialysis access [15–18], despite well-known complications associated with use, including association with all-cause mortality, hospitalization, fatal infections, and cardiovascular events [19–21]. The prevalence of CVC usage has remained relatively unchanged over the last decade in countries such as the United States, with frequencies exceeding 80% of all hemodialysis access types in 2006 according to the US Renal Data System (USRDS) report, with similar usage reported in 2015 [22, 23]. These trends have not been effectively mitigated by implementation of targeted strategies, including an incentivized government-funded scheme to reward units achieving reductions in CVC-utilized dialysis [24].

Once established on center or satellite hemodialysis via CVC, patients are also less likely to undergo modality transfer to PD [25, 26]. Reluctance to utilize PD under these clinical contexts stems from a recommendation from the International Society for Peritoneal Dialysis (ISPD) to avoid initiation of PD for at least 2 weeks after insertion of a PD catheter to reduce the risk of catheter-related complications [27]. This practice is supported by results from several studies [27, 28], including a recently completed randomized controlled trial involving 122 PD patients [29], which showed an increased risk of catheter-related complications, such as leaks, when PD was initiated earlier than 2 weeks after catheter insertion. There is increasing evidence that the long-term outcomes of PD patients managed with early catheter access are comparable to those who received conventional-start PD [30–32].

Consequently, in patients who require urgent initiation of dialysis without established dialysis access, there has been emerging support for expedited initiation of PD prior to reaching the 2-week break-in period milestone [30, 33–35], referred to as *urgent-start PD*. This initiative has been introduced as an effective alternative for patients commencing unplanned dialysis with several aims, including reduced patient harm through avoidance of CVC insertion, increased utilization of home-based dialysis, and

enhanced cost-effectiveness. In this chapter, we will summarize the evidence to date regarding the definition, prevalence, and outcomes of urgent-start PD.

Definition

A universal definition of urgent-start PD does not currently exist in the literature (Table 49.1). Urgent-start PD is most commonly defined as the initiation of PD within 2 weeks of PD catheter insertion in a patient who is not yet established on any form of renal replacement therapy and does not have established dialysis access available for use [30, 31, 39–42]. However, the time period criterion used to define urgent-start PD has been variably reported in the literature, ranging from immediately after PD catheter insertion to up to 14 days [28, 34, 35, 39, 41, 43].

Alkatheeri et al., from Ontario, Canada, have reported their experience in initiating an urgent-start PD program involving 30 PD patients in their unit, whereby urgent-start PD was defined as commencement of PD within 2 weeks of insertion depending on the patient's condition or indication for dialysis [42]. The median time interval between PD catheter insertion and initiation was 6 days [42], and 20% of these patients required immediate-start PD following catheter insertion due to uremic symptoms and/or severe volume overload [42]. Dias et al. from Brazil conducted a single-center observational study reporting outcomes in 35 patients with end-stage kidney disease who required PD initiation within 72 hours after PD catheter insertion [43]. The indications for urgent dialysis included uremia, fluid overload, hyperkalemia ($K > 6.5$ mmol/l), and metabolic acidosis ($HCO_3 < 10$ mmol/l) that were refractory to clinical measures. Other investigators incorporated these clinical criteria and defined a subgroup within the urgent-start PD cohort, referred to as immediate-start [42] or emergent-start PD [30, 41, 42, 44], whereby dialysis was required within 24–48 hours after initial clinical assessment. Patients categorized into these groups were treated with either PD [42] or temporary hemodialysis via a CVC line to achieve clinical stabilization prior to being reactivated in the urgent-start PD pathway [30]. Other groups have variably treated patients with an unplanned dialysis requirement using hemodialysis prior to progressing into the PD pathway and without adopting a clear definition of timeline or clinical indication [35]. As the time interval between PD catheter insertion and initiation can impact on the risk of early complications, it is important to be aware of how urgent-start PD was defined in these studies until a universally agreed definition can be determined.

Table 49.1 Urgent-start peritoneal dialysis.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Urgent-start PD compared with conventional-start PD	We suggest that for patients with end-stage kidney disease who require urgent dialysis and are suitable for PD, urgent-start PD can be considered to avoid HD via a central venous catheter. Although urgent-start PD may increase the likelihood of dialysate leak, it has uncertain effects on catheter malfunction, exit-site infection, peritonitis, technique, and patient survival compared with conventional-start PD.	Low (dialysate leak) Very low (catheter blockage, catheter malposition, catheter readjustment, exit-site infection, peritonitis, technique survival, and mortality)	Weak [36]
Urgent-start PD compared with urgent-start HD	We suggest that urgent-start PD can be considered for patients with end-stage kidney disease who require urgent dialysis and are suitable for PD because urgent-start PD may reduce the risk of bacteremia compared with urgent-start HD. Urgent-start PD has uncertain effects on catheter malfunction, catheter readjustment, exit-site infection, peritonitis, technique, and patient survival compared with urgent-start HD.	Low (bacteremia) Very low (catheter malfunction, catheter readjustment, exit-site infection, peritonitis, technique survival, and mortality)	Weak [37]

GRADE assessment of the certainty of the evidence [38]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. *Substantially different = a large enough difference that it might affect decision-making.
HD, hemodialysis; PD, peritoneal dialysis.

In summary, urgent-start PD is most commonly defined as the requirement to initiate PD within 2 weeks of PD catheter insertion in patients who require unplanned dialysis. Depending on urgency or clinical stability, investigators have variably further distinguished patients requiring immediate- or emergent-start dialysis who received PD or temporary hemodialysis depending on their local protocol or practice pattern.

Epidemiology

Povlsen and Ivarsen were two of the earliest researchers to describe a dedicated urgent-start PD program in Denmark [28]. Between 2000 and 2002, 52 patients commenced PD within 24 hours of catheter insertion [28]. Since then, there has been growing evidence and literature on the topic, with most outcomes reported from single-center studies [30, 33–35, 42, 45, 46], publishing their clinical experience without a standardized approach in the delivery of therapy or even an agreed definition of urgent-start PD. There are currently no reported data to ascertain the global uptake of urgent-start PD programs.

To our knowledge, the largest observational cohort study conducted to date was in China, with 922 patients who initiated urgent-start PD from January 2003 to May 2013, defined as commencing PD within 1 week after PD catheter insertion [47]. PD catheters were inserted under local anesthesia using an open surgical approach by a nephrologist. Almost half of the patients initiated PD within 24 hours of catheter insertion due to the presence of indications for acute dialysis [47].

Whilst delivery of urgent-start PD has been described in both higher income [31, 33, 48] and lower income [43] countries, the majority of the literature originates from countries in North America, Asia, Europe, and Australia (Table 49.1) [30, 31, 34, 35, 39, 41, 42]. Most studies have reported their experience in commencing PD prior to reaching the 2-week milestone after PD catheter insertion without an increase in infrastructural support to formally implement urgent-start PD program in their institutions [31, 34, 45, 46].

A barrier to broader uptake of urgent-start PD may be attributable to physician practice patterns, which may be largely contributed to by a lack of adequate resources necessary to execute urgent-start PD [12, 49]. While most medical centers are well equipped for providing emergent or urgent hemodialysis for patients by using interventional radiology for CVC insertion with available nursing staff, it is less common to have a dedicated team to deliver urgent-start PD. Pioneers of urgent-start PD programs have previously emphasized the need for novel infrastructure to establish urgent-start PD programs [33, 50]. For example, Alkatheeri et al. reported their experience in initiating an urgent-start PD program in July 2010, which involved an international nephrologist, a surgeon, a dedicated urgent-start PD case manager, and a dialysis access coordinator [42]. Patients who were identified as being suitable for urgent-start PD were assessed by a dedicated team within 24 hours of referral and, if eligible, were offered urgent-start PD whereby a PD catheter was inserted either percutaneously by an interventional nephrologist or laparoscopically by a general surgeon. All patients initiated PD within 2 weeks of insertion, depending on their condition or indication for dialysis [42], either as an inpatient or outpatient. Successful implementation of the program led to a significant increase in the size of their PD patient population from 90 to 133 patients in 3 years [42].

Patient Selection

Patients who have received urgent-start PD have largely been those who were referred late to the nephrology service [30, 31, 47] without adequate predialysis education and preparation. Under such circumstances, the decision to undertake PD has often needed to be made quickly as a result of symptomatic uremia or fluid overload [30] without sufficient opportunity to receive education or a home visit to verify the appropriateness of PD. To ensure suitable patient selection, Ghaffari et al. have developed and successfully applied a "Predialysis patient questionnaire: modality selection" in their program in the United States [30]. The 15 questions cover areas including status of dialysis education, work/home situation, and medical/surgical history. Based on the answers, the physician in charge of the urgent-start PD program determines the appropriateness of PD in patients in need of urgent-start dialysis. From embedding a formally protocol-based pathway, there was 100% retention of urgent-start PD patients on PD during follow-up with growth in their PD program by 37.5% in 12 months after commencement of the urgent-start PD initiative [30].

Catheter Insertion

There have been varying approaches to catheter insertion among the different urgent-start PD programs reported. Two Chinese studies involving 657 and 178 patients adopted insertion of a PD catheter by nephrologists via a laparotomy approach [46, 51], similar to that of other reported studies [28, 47]. To minimize the risk of leaks from early access of the PD catheter, some groups have

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

inserted PD catheters via a surgical technique using purse-string sutures to fixate the peritoneum to the catheter [52]. Other groups from the United States [30], Canada [42], and Singapore [53] had PD catheters inserted by interventional radiologists. Where catheters could not be inserted fluoroscopically, laparoscopic insertion by surgeons took place [42]. Varying insertion approaches were adopted largely due to local expertise availability, resources, and beliefs regarding the association between catheter insertion techniques and risks of early complications [30, 42, 46]. A recent randomized controlled trial comparing open and laparoscopic insertion of PD catheters observed similar outcomes in patients with regards to the risk of complications [54]. However, this study was in patients initiating PD 2–4 weeks after catheter insertion, and therefore may not be applicable to urgent-start PD patients [54].

Urgent-start PD Prescription

The reported approaches to delivering urgent-start PD have been variable with regards to PD modality (continuous ambulatory PD [CAPD] vs. automated PD [APD]), fill volume, and treatment delivery frequency. Most commonly, studies have adopted a protocol utilizing intermittent PD in the supine position with low initial intraperitoneal fill volumes [30, 31, 34, 46, 48] to reduce the risks of PD catheter leaks and infections through lowered intra-abdominal pressure [55]. Ghaffari et al. reported a detailed prescription using intermittent peritoneal dialysis, administered three times a week, and calculated the volume and number of exchanges based of the modification of diet in renal disease estimated glomerular filtration rate (MDRD eGFR) and body surface area (BSA). Fill volumes ranged from 500 to 1000 ml, four to six cycles were utilized, and various combinations of 1.5%, 2.5%, and 4.25% dextrose exchanges were used, depending on the patient's volume status [30]. For example, an initial fill volume of 500 ml/exchange was used for patients with BSA $< 1.65/m^2$ compared to 1000 ml for those with BSA $> 1.8/m^2$ [30]. The duration of total cycler time and number of cycles varied depending on the baseline MDRD eGFR and BSA, and the frequency of therapy was generally thrice weekly unless more frequent treatment was indicated [30].

A smaller number of studies have reported using CAPD in their delivery of urgent-start PD [47, 51]. Liu and colleagues from China have recently published their experience with urgent-start PD delivered using three different treatment approaches, including traditional incremental CAPD ($n = 26$), APD ($n = 42$), and combined APD-CAPD ($n = 28$) in patients who commenced PD within 1–3 days after open surgical PD catheter insertion. PD prescription varied in the three groups, but fill volume was not determined by body size. For example, the initial regimen in the APD group included nine cycles of 650 ml fill volume during the day with an overnight dwell for the first 3 days, eight cycles of 1000 ml with an overnight dwell on days 4–6, then finally six cycles of 1500 ml with an overnight dwell on days 7–9. In contrast, the CAPD group received four cycles of 500–800 ml fill volumes, which gradually increased to 1000 and 1500 ml fill volumes within the first 9 days. The APD-CAPD group were initiated with the regimen described for the APD group for the first 6 days followed by CAPD during the subsequent 3 days (four cycles of 1.5 l over 4 hours with an overnight dwell) [56]. Although the investigators reported better small solute clearance in APD initiated patients ($P < 0.05$) with a comparable risk of complications ($P > 0.05$), the findings were potentially limited by indication bias with residual confounding given the retrospective observational design of the study.

The majority of studies have reported initiating urgent-start PD with fill volumes less than 1.2 l [31, 42, 45]. However, some studies have utilized an initial fill volume of up to 2 l, commencing within the first 24 hours after PD catheter insertion by nephrologists, as reported in a randomized controlled trial [57]. The use of full volume dialysate (2 l) at day 1 was compared to incremental dialysate volumes with CAPD exchanges starting at 500 ml for the first 6 days then gradually increasing to the full volume exchanges at 2 weeks. It was shown that dialysate leaks occurred at a similar rate in both groups with 10.5% of patients in the full volume group developing leaks compared to 9.5% in the incremental group. Overall, the short- and long-term outcomes from patients who received initial fill volumes of 2 l were comparable with those of the stepwise incremental protocol [57].

In summary, the studies to date have reported varying approaches to the prescription of urgent-start PD. While there are some studies comparing PD modalities and different fill volumes, urgent-start PD is still lacking an overall evidence-based guideline for optimal prescription and initiation of the treatment.

Outcomes

The outcomes of patients undergoing urgent-start PD program can be broadly compared to those of patients receiving conventional-start PD or urgent-start hemodialysis via a CVC, and further classified according to early- and late-outcomes in each of these groups (see Table 49.2).

Urgent-start PD vs. Conventional-start PD

Unlike conventional-start PD when initiation of therapy is delayed until at least 2 weeks after catheter insertion to promote wound healing, earlier treatment initiation has raised concerns about an increase in the risk of mechanical complications, such as peri-catheter leaks (Tables 49.3, 49.4a, and 49.4b). The likelihood of developing these complications may also be influenced by insertion technique, duration between catheter insertion, and PD commencement (e.g. immediate vs. 7 days), fill volume or modality of dialysis delivery (CAPD vs. APD) [59, 60]. Moreover, the characteristics of patients undergoing urgent-start PD program may be inherently different from those receiving planned conventional PD treatment. See et al. have previously conducted a 1 : 3 matched case-control study involving 26 urgent-start and 78 conventional-start PD patients [31]. The patients were well-matched on age (50.6 ± 13 years vs. 51 ± 14.5 years, $P = 0.9$) and diabetic status (35% vs. 35%, $P = 1.0$) at the time of PD initiation. Compared to conventional-start PD patients, those who

Table 49.3 Urgent-start PD versus conventional-start PD.

Study	Design	Study population	Outcomes	Results
Povlsen and Ivarsen [28]	Retrospective, observational with unmatched controls	Group 1: urgent-start PD ($n = 52$) Group 2: conventional-start PD ($n = 52$)	Catheter-related complications (short term): Technique survival, mechanical complications, infectious complications	Technique survival: • G1 86.7% vs. G2 90% Catheter replacement: • G1 19.2% vs. G2 3.9% Total mechanical complications: • G1 28.9% vs. G2 7.7% Infections: no difference
Yang et al. [32]	Retrospective with unmatched controls	Urgent-start PD ($n = 226$) vs. conventional-start PD ($n = 84$)	Catheter-related complications within 6 months of catheter insertion	Urgent-start PD vs. conventional-start PD: • Complications: 14.6% vs.13.1% (NS) • Bridge hemodialysis 31.4% vs. 57.1% • Peritonitis 4% vs. 2.4%
Ghaffari [30]	Prospective, observational	Urgent-start ($n = 18$) vs. planned-start PD ($n = 9$)	Complications (peritonitis, catheter leaks, and malfunction, exit site infection) Clinical outcomes (PTH, albumin, Kt/V, hemoglobin, iron studies, phosphate, and calcium)	Urgent-start vs. planned-start PD • Minor catheter leaks: 4% vs. 1% • Peritonitis: 1% vs. 1% • Malfunction 2% vs. 2% Short-term clinical outcomes similar between the two groups
Liu et al. [46]	Retrospective observational	Group 1: PD start <7 days ($n = 344$) Group 2: 8–14 days ($n = 176$) Group 3: 14 days ($n = 176$)	Catheter dysfunction Peritonitis Technique survival Patient outcomes (death, transfer to HD)	Mechanical complications higher in G1 (8.4%) vs. G3 (1.7%) No difference in prevalence of catheter dysfunction, technique failure or peritonitis between the three groups
See et al. [31]	Matched case control study	Urgent-start PD ($n = 26$) vs. conventional-start PD ($n = 78$)	Early complications Peritonitis rates Long-term technique survival	Urgent-start PD had increased leaks post catheter insertion (12% vs. 1%) and more frequent catheter migration post commencement of PD (12% vs. 1%) No differences in infections Long-term technique and peritonitis-free survival was the same
Ranganathan et al. [29]	Randomized control trial	Group 1: PD start at 1 week post catheter insertion ($n = 39$) Group 2: at 2 weeks ($n = 42$) Group 3: at 4 weeks ($n = 41$)	Catheter leaks	Catheter leaks: • Group 1: 28.2% vs. Group 2: 9.5%, Group 3 2.4%

Peritonitis	–	–	–	No studies	Absent	
Catheter readjustment	–	–	–	No studies	Absent	
Technique survival	892 per 1000	**972 per 1000** (892–1000)	**RR 1.09** (1.00–1.20)	122 (1 study)	⊕⊖⊖⊖ VERY LOW	It is uncertain whether urgent start PD increases technique survival

CI, confidence interval; PD, peritoneal dialysis; RR, risk ratio.
GRADE Working Group grades of evidence: High: Further research is very unlikely to change our confidence in the estimate of effect. Moderate: Further research is likely to have an important impact on our confidence in the estimate of effect and may change the estimate. Low: Further research is very likely to have an important impact on our confidence in the estimate of effect and is likely to change the estimate. Very low: We are very uncertain about the estimate.
[a] **The risk in the urgent-start PD group** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).

received urgent-start PD were significantly more likely to be referred late to the nephrology service, defined as requiring to commence dialysis within 3 months of first nephrology review (73% vs. 1%, $P < 0.001$). The two groups were otherwise well matched for their demographic and clinical characteristics. The risk of complications within the first 4 weeks after catheter insertion was generally comparable between groups (e.g. catheter blockage, migration, exit-site infection, or peritonitis), other than a statistically significant increase in the risk of peri-catheter leak in the urgent-start PD group (12% vs. 1%, $P = 0.047$). Similarly, the risk of catheter migration was significantly higher in the urgent-start PD patients (12% vs. 1%, $P = 0.047$) within the first 4 weeks after PD commencement [31]. The peritonitis-free and technique survivals were comparable between the two groups in multivariable analyses adjusted for obesity and late referral status (peritonitis-free survival: adjusted hazard ratio [HR] 1.05, 95% confidence interval [CI] 0.25–4.37, $P = 0.95$; technique survival: adjusted HR 0.78, 95% CI 0.18–3.32, $P = 0.74$) [31]. Similar results, with an increase in the risk of early mechanical complications without impact on infection or technique survival, have been reported in other groups, including by Povlsen and Ivarsen, who were the early pioneers of urgent-start PD (28.9% vs. 7.7% in the first 3 months after PD commencement) [28]. A Canadian group also reported a higher incidence of catheter leaks (10%) in urgent-start PD patients, although all of the cases were successfully managed conservatively with lower dwell volumes [42]. Furthermore, at 24 months, 80% of patients were still performing PD, with only two patients switching to HD and the other 13.3% receiving transplantation [42]. Although there have been concerns about an increase in the risk of complications with higher initial fill volumes, studies have not been able to demonstrate this to date [57] and direct comparisons across literature have not been possible due to differences in the timing of PD initiation, approaches to PD catheter insertion, and PD modality [28, 30, 46, 51].

There are limited studies comparing the outcomes among different PD modalities within an urgent-start PD program. Liu et al. compared the early complications and overall efficacy among three different PD modalities: incremental CAPD, APD, and APD followed by CAPD. All

patients were started on PD 1–3 days post-catheterization, but each group received different fill volumes without specific reference to their body size (650–1500 ml in the APD/APD-CAPD group and 500–1500 ml in the CAPD group). There was no difference amongst the groups in the risk of mechanical or infective complications within 1 month after PD commencement [56].

Urgent-start PD vs. Urgent-start HD

There have been studies that have evaluated outcomes in urgent-start PD versus unplanned HD which have shown that urgent-start PD was comparable to HD with respect to safety outcomes (Tables 49.5 and 49.6) [34, 35, 45, 51]. Jin et al. published a study in 2016 comparing the short-term

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 49.5 Urgent-start PD versus urgent-start HD.

Study	Design	Study population	Endpoint	Outcome (HD vs. PD)
Lobbedez et al. [35]	Prospective, observational	Unplanned HD ($n=26$) vs. urgent-start PD ($n=34$)	Hospitalizations and patient survival at 1 year Survival at 1 year	Mortality: 21.2% vs. 17.1% Hospitalizations: 24 ± 28 vs. 30 ± 33
Koch et al. [34]	Observational, cohort study	Unplanned HD ($n=57$) vs. urgent-start PD ($n=66$)	Mortality rates Risk of bacteremia Hospitalizations	Bacteremia within first month of dialysis: 21.1% vs. 3% Mortality: 42.1% vs. 30.3%
Ghaffari et al. [61]	Prospective cohort study	Unplanned HD ($n=78$) vs. urgent-start PD ($n=46$)	Hospitalizations, technique survival, catheter-related bacteremia	Catheter-related bacteremia: 4.3-fold higher adjusted rate in HD group Hospitalization: 1.43-fold higher adjusted rate in HD group Technique survival (6 month): 90% vs. 98%
Jin et al. [51]	Nonmatched, retrospective observational study	Unplanned HD ($n=82$) vs. urgent-start PD ($n=96$)	Dialysis-related complications, bacteremia, and patient survival at 30 days	Dialysis-related complications: 24.4% vs. 5.2% All HD patients with complications required catheter reinsertion Bacteremia: 13.4% vs. 3.1% Mortality: 1.6% vs. 2.3%
Jin et al. [45]	Retrospective, observational	Urgent-start HD ($n=41$) vs. urgent-start PD ($n=53$)	Dialysis-related complications Survival rates at 6, 12, 24, and 36 months	Dialysis-related complications: 30 days; 24.4% vs. 5.7% Survival rates: 6 months 94.6% vs. 92.3%, 12 months 81.3% vs. 82.4%, 36 months 60.6% vs. 69.5%

complications and survival rates between HD and PD patients requiring dialysis urgently. It was a retrospective, observational study involving 96 PD patients and 82 unmatched HD patients. Patients in the PD group had more cardiovascular disease (21.9% vs. 9.8%) and were less likely to suffer from heart failure (30.2% vs. 48.8%). However, there were no significant differences in age (PD group 55.2 ± 17.9 vs. HD group 51.2 ± 20.0), gender (males PD 58.3% vs. HD 53.7%) or prevalence of diabetes mellitus (32.3% vs. 24.4%) or hypertension (72.9% vs. 73.2%) between the groups. This study observed that, at 30 days, the rate of dialysis-related complications was much higher among HD patients than PD patients (24.4% vs. 5.2%, $P < 0.001$) [51]. For example, all of the 20 HD patients with dialysis-related complications required re-insertion of a CVC in contrast to only one PD patient who required PD catheter re-insertion. Furthermore, there was a higher incidence of bacteremia within the urgent-start HD group (13.4% vs. 3.1%). The survival rates were comparable in the two groups with actuarial patient survival at 12 months being 93% for HD and 92.1% for PD patients after 1 month of follow up [51]. Two single-center studies in France [35] and Germany [34] comparing unplanned PD and unplanned HD also showed similar mortality rates between the two groups. Koch et al. reported similar results to Jin et al., showing that patients started on unplanned HD had higher rates of bacteremia during the first 6 months of initiation dialysis (2.1% vs. 3%, $P < 0.01$) in the setting of using CVCs as initial vascular access [34]. These results were echoed in a prospective cohort study, which reported urgent dialysis through a CVC was associated with a 43% increase in hospitalizations compared with urgent-start PD, and the rate of catheter related bacteremia was 4.3-fold higher [61]. Overall, all of the studies comparing urgent-start PD and HD have observed increased rates of bacteremia in the setting of CVC use, with a higher burden of hospitalizations and need for catheter re-insertion.

Health Economics

There are also significant cost savings that can be seen in an urgent-start PD program in comparison to urgent-start HD. In 2014, Liu et al. performed an economic evaluation and found that the cost per patient over the first 3 months of urgent-start PD was $16 398. Comparatively, the estimated cost of urgent-start HD was $19 352 per patient for the first 90 days, showing that urgent-start PD may be a more cost-effective program [26].

Conclusion

There is a growing burden of patients with end-stage kidney disease worldwide, with increasing numbers of patients commencing on renal replacement therapy [62]. A significant factor contributing to this burden is the number of patients initiating renal replacement therapy with a lack of established dialysis access. Urgent-start PD is emerging as a potentially safe and feasible solution to mitigate the need for CVC-facilitated HD in this population [62, 63]. There have been reports of an increase in the burden of early mechanical complications, particularly peri-catheter leaks, but these have often been managed successfully using conservative measures. However, it should be noted that the quality of reported evidence is restricted to often single-center, retrospective observational studies at risk of indication bias and residual confounding.

Introduction

Responsive and high-quality peritoneal dialysis (PD) access is an essential requirement for successful PD. For a PD catheter to work it requires the delivery of flow rates of up to 300 ml/min with the higher requirements being when automated PD is performed using a machine than for manual continuous ambulatory peritoneal dialysis (CAPD) using gravity to facilitate the drain [1]. If the flow rate cannot be delivered the consequences vary from troublesome machine alarms to extended treatment times and the inability to deliver the therapy. PD catheter insertion has a major impact on the uptake of the therapy for two important reasons. Poorly responsive access pathways delay and therefore inhibit access to PD, and poor catheter function increases early technique failure [2]. Mechanical causes of technique failure are a particular problem early in the course of PD, and poor catheter function can prevent patients from getting their chosen dialysis modality. Catheter dysfunction may be difficult to identify and can be misdiagnosed as impaired ultrafiltration.

Epidemiology

The evidence to support one insertion technique over another is not robust and the characteristics of the local kidney failure service and healthcare system are key factors in determining the approaches that are used. Although inserting PD catheters is a simple concept the reality is that there is considerable variation in primary catheter function and complication rates between centers within and between countries. For example, 1-year catheter survival in from the UK Renal Registry varies widely, with some centers reporting no catheter failures compared with others where the rate was greater than 40%; the median rate was 13% having fallen from 20% in previous reports [3]. The Brazilian Peritoneal Dialysis multicenter study identified comparable outcomes between surgical PD catheter insertions and those placed by interventional nephrologists. They reported mechanical complication rates of 10.5% and peritonitis rates of 10.2% by 3 months post insertion but were higher in those centers where the number of catheter insertions was low (<5), suggesting that operator experience may be more important than the actual insertion technique [4, 5].

Systematic reviews have not identified better outcomes of PD catheters placed using the percutaneous method compared with surgical insertion [6, 7] and gave inconsistent conclusions comparing open surgical to laparoscopic surgical insertion [8, 9]. A potential advantage of laparoscopy is that advanced techniques can be employed at the time of insertion to optimize catheter function, including omentopexy and adhesiolysis. There are no randomized controlled trials that examine this approach, but a systematic review of cohort studies reported an advantage for advanced laparoscopic interventions consisting of rectus sheath tunneling and adjunctive procedures compared with basic laparoscopy, which is used only to verify the catheter position [10]. This may have particular value in the evaluation or replacement of catheters that did not work well at the first insertion. Of course, one of the difficulties in evaluating advanced technique evidence is that studies may use some, but not all, of the techniques and this generates considerable heterogeneity.

International variation in PD access will be reported from the Peritoneal Dialysis Outcomes and Practice

Patterns Study (PDOPPS) [11]. Early data indicates that the open surgical approach is favored in Japan, laparoscopy in the United State, with percutaneous techniques being available in about 50% of Australian, UK, and Canadian centers (Wilkie M et al., [51]. Abstract to European Renal Association – European Dialysis and Transplant Association meeting June 2017). Local factors influence the catheter insertion process, such as the availability of surgical staff and the responsiveness of the service, which impacts on whether PD can be used to treat late-presenting patients. Many centers rely on a single surgical approach for all patients, whereas others practice a combination of medical or percutaneous and surgical insertion techniques stratified according to individual requirements [3].

The Catheter Insertion Pathway

The decision regarding the most appropriate PD catheter insertion technique is influenced by a range of factors. For example, those who present unexpectedly to the renal service, or have a rapid decline in renal function, require a responsive PD catheter insertion pathway if they are to be able to successfully commence PD. There is some evidence to suggest that percutaneous insertion may potentially result in a more responsive service [12], with particular advantages for patients presenting late with advanced chronic kidney disease and in need of urgent start PD [13]. This may be because it is logistically easier to organize a percutaneous compared to a surgical insertion that may be at more risk of delay due to such factors as availability of operating theater space and the requirement for preoperative anesthetic assessment. Percutaneous insertion by nephrologists was associated with increased uptake of PD in a population-based retrospective cohort study using administrative health data from Ontario, Canada [14]. In the 2016 UK Renal Registry reported incident use of PD was 25.9% at centers that placed nonsurgical PD catheters compared with 21% in centers that used only used surgical placement [3].

Success of PD catheter insertion is impacted by a multiplicity of factors, including patient comorbidities, aspects of patient preparation including education, logistics of catheter insertion (e.g. access to theater space, bed availability, and responsiveness of the pathway), post-catheter care, the approaches to catheter use, and patient training. These practices vary considerably between patients and centers, and although there are recommendations with respect to components of the pathway, robust evidence is lacking [15]. Certain characteristics define those who are suitable for percutaneous insertion, including the absence of significant central obesity and of major abdominal scars. Significant lower abdominal surgery will affect the catheter insertion approach since the likelihood of success may be affected by the presence of residual adhesions. Upper abdominal surgery is generally not likely to interfere with the placement or function of the PD catheter. With the surgical insertion technique the majority of patients will receive a general or spinal anesthetic and although this may be performed as a day-case procedure, patients receiving general anesthesia may well require a short inpatient hospital stay and commonly a preoperative assessment.

An important aspect of catheter insertion is that the care pathway extends beyond the actual catheter insertion and includes appropriate patient preparation, with many centers employing the practices of decolonization of *Staphylococcus aureus*, antiseptic skin washes, bowel preparation, appropriate catheter selection, and exit site planning. The location for the catheter exit site should be determined in discussion with the patient, giving consideration to body shape and size, as well as clothing and sleeping habits. If the exit site is placed below the abdominal fold then it is more difficult for the patient to care for the site themselves, and if it is placed at the belt line abrasion will prevent healing and rapidly precipitate infection, risking catheter survival. Appropriate catheter length can be determined using an approach that considers patient size carefully to ensure that the catheter tip is placed in the pelvis, but not so long that it causes contact pain or kinks. There are approaches that can be used here, including the use of a template to guide catheter size or adjustments to the exit site position so that it is optimally placed [16]. There is no evidence for the routine use of plain abdominal X-rays to locate the catheter position post insertion or at intervals as part of follow-up.

Insertion Techniques

The techniques that are commonly used for PD catheter insertion include surgical placement by dissection [17], blind percutaneous placement using a guidewire (Seldinger technique) [18], percutaneous insertion guided by ultrasound [19] and fluoroscopy [20], as well as peritoneoscopic [21] and laparoscopic insertion techniques [22, 23]. Modifications of PD catheter insertion include embedding the external end of the catheter in a subcutaneous pouch until required [24] and the use of extended (upper abdominal and presternal) catheters [25, 26]. It is beyond the scope of this chapter to describe the techniques in detail. However, it is important to note that many studies include variations of described techniques that can significantly impact on outcome. For example, suture of the catheter tip to the bladder or uterus is commonly used to reduce tip migration [27] but may be associated with rare complications [28]. The laparoscopic technique commonly includes the addition of one or several additional procedures (as described below).

Interventions

The literature is full of single-center cohort studies, commonly retrospective, that claim advantage for one insertion technique over another or a "new" variant of a technique or catheter. Blinding of the operator to the insertion technique is not possible and where cohort studies compare catheter insertion techniques it is difficult to be clear on the decision making that led to the selection of a particular technique for a particular patient. For this chapter we present evidence from randomized controlled trials involving adults and children, and have referred to cohort studies for descriptive purposes only. Data extraction was carried out independently by two authors (VB/MEW) using standard data extraction forms. The same authors assessed risk of bias using the appropriate assessment tool [29] and the quality of the evidence using the GRADE system [30]. JF and BMS reviewed evidence independently and adjudicated in the ensuing discussions. Outcomes include catheter survival, technique failure, surgical complications (hernias, leaks, and hemorrhage), infection (including peritonitis, exit site, and tunnel infections), patient-reported outcomes if reported (e.g. catheter related pain), catheter obstruction, and tip migration. The data we present will have similarities to a Cochrane review that is in preparation [31].

Laparoscopic Versus Open Surgical PD Catheter Insertion

Four studies randomized a total of 272 patients to receive either laparoscopic or open surgical PD catheter insertion (Table 50.1) [32–35]. Outcomes reported included peritonitis rates, exit site infection, post-operative dialysate leak, all-cause catheter removal, and operative time. Catheter tip migration, mechanical catheter failure, mean catheter survival, post-operative bleeding, and exit site infection were reported by some but not all studies. One- and 2-year catheter survival was only available as raw data for one of the four studies examined [35] since although survival analysis was undertaken in two of the studies [33, 34], the data were not available in a form to accurately determine 1- and 2-year catheter survival.

Insertion technique had no evidence of impact on catheter removal, peritonitis, or exit site infection rates following PD catheter insertion. All four studies collected data on the number of dialysate leaks post-operatively. The resulting meta-analysis showed a high level of heterogeneity.

Key differences existed between these studies, since the Tsimoyiannis study compared basic laparoscopy (plus suture fixation of catheter to the bladder or uterus) with open insertion [33] and the Van Lannen (CAPD 1 trial) included adhesiolysis where necessary and pre-peritoneal tunneling for all cases [35]. These two studies included adhesiolysis, whereas the Wright study did not include additional techniques [34]. The catheter fixation approach used in the Tsimoyiannis study clearly represented a major technique variation and we therefore conducted a sensitivity analysis and excluded that study [33]. Repeat meta-analysis improved heterogeneity significantly but still did not show any evidence for different outcomes related to open surgical PD catheter insertion over laparoscopic insertion (relative risk [RR] 2.31, 95% confidence interval [CI] 0.31– 17.32, I^2 0%). Three studies reported catheter tip migration [32, 33, 35] including 212 patients with meta-analysis showing no difference between the techniques (RR 0.31, 95% CI 0.07–1.48, $P = 0.114$, I^2 40%). The risk of bias was moderate in all studies (mainly due to inability to blind the operator/assessors). The CAPD 1 trial [35] used different terminology ("malposition within the bowels") and there was no difference in this parameter between the groups.

We present a summary of findings table (Table 50.1) for the following outcomes: all-cause PD catheter removal, peritonitis, exit site infection, post-operative dialysate leak, and catheter tip migration. These outcomes were reported with either three or four studies.

Peritoneoscopic Versus Open Surgical PD Catheter

The peritoneoscope allows visualization of the peritoneal cavity, but does not permit manipulation of peritoneal cavity contents and cannot be classed as a variation of laparoscopy. It is, however, distinct from percutaneous technique, which is a blind technique.

A single study examined peritoneoscopic insertion versus open surgical insertion reporting superior catheter survival for the former [36]. PD catheter survival was 77.5% vs. 62.5% ($P = 0.02$) at 12 months, 63% vs. 41.4% ($P = 0.01$) at 24 months, and 51.3% vs. 36% ($P = 0.04$) at 36 months in the peritoneoscopic and the open surgical PD catheter groups, respectively. Leaks and peritonitis were more common in the open surgical group, indeed early peritonitis (less than 2 weeks following surgery) occurred in 12.5% of the open surgical group and 2.6% of the peritoneoscopic insertion group. The level of early peritonitis reported in the open surgical group was much higher than that described as acceptable in international guidelines [15]. Equally, the 1-year catheter survival in the open surgical group was lower than that in most centers reporting to the UK Renal Registry [3]. We downgraded the evidence from this study for catheter survival on the basis of inconsistency

Table 50.1 Summary of findings.

Laparoscopic compared to open surgical PD catheter insertion for improving catheter function and clinical outcomes in peritoneal dialysis patients

Patient or population: Improving catheter function and clinical outcomes in peritoneal dialysis patients
Setting:
Intervention: Laparoscopic
Comparison: Open surgical PD catheter insertion

	Anticipated absolute effects[a] (95% CI)					
Outcomes	**Risk with open surgical PD catheter insertion**	**Risk with laparoscopic**	**Relative effect (95% CI)**	**No. of participants (studies)**	**Certainty of the evidence (GRADE)**	**Comments**
Peritonitis	250 per 1000	**280 per 1000** (173–455)	**RR 1.12** (0.69–1.82)	167 (three RCTs (randomized controlled trial))	⊕⊕⊕◯ MODERATE[b]	Evidence downgraded due to risk of bias consequent on absence of blinding.
All cause PD catheter removal	297 per 1000	**341 per 1000** (238–487)	**RR 1.15** (0.80–1.64)	257 (four RCTs)	⊕⊕⊕◯ MODERATE[b]	Evidence downgraded due to risk of bias consequent on absence of blinding.
Exit site infection	139 per 1000	**153 per 1000** (82–286)	**RR 1.10** (0.59–2.06)	212 (three RCTs)	⊕⊕⊕◯ MODERATE[b]	Evidence downgraded due to risk of bias consequent on absence of blinding.
Dialysate leak	70 per 1000	**63 per 1000** (7–568)	**RR 0.90** (0.10–8.08)	257 (four RCTs)	⊕⊕⊕◯ MODERATE[b]	No significant difference in the rate of dialysate leak was demonstrated.
Dialysate leak, excluding Tsimoyiannis	10 per 1000	**22 per 1000** (4–123)	**RR 2.36** (0.43–12.92)	209(three RCTs)	⊕⊕⊕◯ MODERATE[b]	Due to high heterogeneity (56%), Tsimoyannis study excluded. There was a significant variation in the type of laparoscopic procedure performed in this study. On exclusion, heterogeneity reduced to 0%. No significant difference was demonstrated.
Catheter tip migration	135 per 1000	**42 per 1000** (9–199)	**RR 0.31** (0.07–1.48)	212 (three RCTs)	⊕⊕⊕◯ MODERATE[b]	Evidence downgraded due to risk of bias consequent on absence of blinding.

CI, confidence interval; RR, risk ratio.
GRADE Working Group grades of evidence. High certainty: We are very confident that the true effect lies close to that of the estimate of the effect. Moderate certainty: We are moderately confident in the effect estimate: The true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. Low certainty: Our confidence in the effect estimate is limited: The true effect may be substantially different from the estimate of the effect. Very low certainty: We have very little confidence in the effect estimate: The true effect is likely to be substantially different from the estimate of effect.
[a] **The risk in the intervention group** (and its 95% confidence interval) is based on the assumed risk in the comparison group and the **relative effect** of the intervention (and its 95% CI).
[b] High risk of bias due to inability to blind either operators or assessors.

to moderate, i.e. the infection rate in the control group was higher than expected and this was likely to impact on the catheter survival rate. The results of this study should be evaluated in a further randomized controlled trial.

A second study used a cystoscope (usually used for examining the bladder) to visualize the peritoneal cavity [37]. This study randomized 29 patients to either open surgical PD catheter insertion or insertion assisted with direct vision using the cystoscope. The study was too small to be able to draw robust conclusions and did not add materially to the evidence base. The complication rate in the cystoscope group was very low at 1 out of 14 and in the open surgical group was 12 of 15 cases. Here we felt there was inconsistency of results and therefore lacked the confidence to perform a meta-analysis of these two trials.

Percutaneous Versus Open Surgical PD Catheter Insertion

Two studies looked at the use of a percutaneous method to insert PD catheters and compared this to standard open surgical insertion. One study looked at a pediatric population below the age of 15 years [38] and the other included adult patients only [39]. Both studies followed patients up for 2 months only.

The adult study was conducted in Iran, recruiting 64 patients, although three were excluded by the authors because of cardiac death [39]. One catheter in the percutaneous group and four catheters in the open surgical group developed outflow failure within 2 months. Two patients in each group developed catheter tip migration. Five patients developed catheter malfunction due to omental wrapping (four in the surgical group and one in the percutaneous group) and omentectomy was carried out for these five patients. Hemoperitoneum was not clearly defined in the paper, but was reported in four patients in the surgical group but only one in the percutaneous group. Exclusion criteria with respect to previous surgery were not reported. The study concluded that percutaneous insertion has fewer complications and is quicker than the open surgical approach.

The second was a pediatric study of 35 patients (mean age 6.7 years) from the same Iranian hospital and recruited patients for 1 year [38]. Reported early complications were two exit site infections, post-operative bleeding, and dialysate leak. Omentectomy was performed in patients with catheter dysfunction but the study did not report any other survival data. Catheter malposition was seen in 17.6% of the surgical group and 5.5% of the percutaneous group, but the study sample was small and no *P* value was reported.

Both studies reported duration of hospital stay and operative time. There were no differences in these times between the two studies although it is not clear whether the operators were the same in the two studies. The operative time in the percutaneous insertion group was significantly lower than in the open surgical group in both studies (approximately 10 minutes). We do not present a meta-analysis of these two studies because of the age group difference, but there are no obvious differences in mechanical catheter failure. We have downgraded the evidence from these studies on the basis of the short follow-up period, but they provide moderate evidence of similar outcomes between percutaneous and open surgical techniques.

Radiological Versus Laparoscopic Catheter Insertion

A single noninferiority randomized controlled trial compared radiologically guided fluoroscopic with laparoscopic PD catheter insertion, excluding patients who were obese or who had previous abdominal surgery [40]. This study also examined the economic impact of each type of PD catheter insertion, particularly as the type of anesthetic can impact on the length of hospital stay for each procedure and laparoscopy requires a general anesthetic whilst percutaneous procedures that are guided fluoroscopically can be done with local anesthesia. Although there was no difference in catheter survival between the groups, complication-free catheter survival was significantly higher at 42.5% (95% CI 29.3–55) in the radiological group compared with 18.1% (95% CI 8.9–29.8) in the laparoscopic group. Complications in the laparoscopic group included infection (peritonitis and exit site), peritoneal dialysate leaks, and umbilical hernia. The radiological percutaneous approach was associated with benefits with respect to pain scores, procedure time, and direct hospital costs. This study was well conducted and provides evidence that the fluoroscopic method of PD catheter insertion was not inferior to laparoscopic insertion.

Laparoscopy with Adjunctive Techniques

The advanced laparoscopic insertion technique, introduced by Crabtree et al., involves placement of the PD catheter under laparoscopic visualization, with additional components such as rectus sheath tunneling, omentopexy, adhesiolysis, excision of appendix epiploica (epiploectomy), salpingectomy, and colopexy [23, 41]. This approach has only been examined in cohort studies, both retrospective and prospective. A meta-analysis of six observational studies [23, 42–46] compared the outcome of advanced laparoscopy with open insertion and reported reduced risk of catheter obstruction (odds ratio [OR] 0.14, CI 0.03–0.63), migration (OR 0.12, 95% CI 0.6–0.26), peri-catheter leak

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. (OR 0.27, 95% CI 0.11–0.64), and hernia (OR 0.29, 95% CI 0.09–0.94), as well as improved 1-year (OR 0.52, 95% CI 0.08–0.97) and 2-year catheter survivals (OR 0.50, 95% CI 0.28–0.92). There was no difference in infectious complications between the two groups [10]. Three studies compared the outcome of basic and advanced laparoscopy [23, 43, 47]. In meta-analysis, catheter obstruction (OR 0.11, 95% CI 0.05–0.21) and migration (OR 0.07, 95% CI 0.01–0.51) were significantly lower in the advanced laparoscopic group, whereas peri-catheter leak, infectious complications, and catheter survival were similar in both groups [10]. The quality of this evidence is low on the basis of the lack of randomization and blinding. The single randomized controlled trial that compared laparoscopy involving preperitoneal tunneling compared with open surgical insertion did not demonstrate a difference in catheter survival and we have included that study in the meta-analysis of laparoscopic versus surgical insertion (Table 50.1) [35].

Other Approaches

A prospective randomized study of standard open surgical PD catheter insertion compared buried (embedded) to nonburied catheters in 60 participants in whom PD start was planned for at least 6 weeks after PD catheter insertion [48]. Catheter failure due to mechanical reasons was very low, with only one patient in the buried catheter group terminating PD for this reason. There was a nonsignificant trend to lower peritonitis rates in the buried group. The Kaplan–Meier curves produced were not sufficiently detailed to be able to extract numerical information. A limitation of this study was that the insertion technique differed slightly between the two centers that participated.

Omental wrapping is a cause of PD catheter dysfunction and can require catheter removal or replacement. Whilst not a direct comparison of insertion techniques, a prospective randomized study examined the role of intra-operative greater omental folding during PD catheter placement to determine impact on PD catheter function [49]. One difficulty of this study was that the decision regarding whether the greater omentum was of sufficient size to merit inclusion into the study had to be made by the surgeon intraoperatively. Omental folding had no impact on technique failure ($P = 0.32$), infection rates ($P = 0.74$) or other postoperative complications such as bleeding ($P = 0.35$) and dialysate leak ($P = 0.57$). However, there were significantly lower levels of PD catheter tip migration and irreversible PD catheter dysfunction ($P = 0.03$) in patients with omental folding ($P = 0.04$).

PD catheter fixation within the pelvis at the time of PD catheter insertion was examined in a single randomized controlled trial [27]. In this study 152 patients were randomized to a traditional open surgery group, a modified open surgery group or a modified open surgery with catheter fixation group. The surgical modification was to use a lower than usual implantation position 7 cm above the pubic symphysis and the catheter fixation was by means of a suture around the catheter 3 cm below the inner cuff. Complication rates were comparable between the two techniques, but catheter tip migration (with catheter malfunction) was lower in the group with catheter fixation ($P < 0.05$). Catheter survival at 1 year following catheter insertion was 84% in the traditional open surgical group, 96% in the modified open surgical group, and 100% in the catheter fixation group.

Quality Assurance of Catheter Insertion Pathways

The objective of access pathways is to provide safe and responsive PD access that works. Audit standards have been suggested in guidelines with little evidence to demonstrate their utility. Currently recommended outcome measures focus around 1-year catheter survival censored for death and transplantation. However, much more proximate measures of success would be beneficial. The key question for patients is whether the catheter worked at the time it was needed for the therapy that was preferred.

Complications that should be monitored include infection (exit site and peritonitis), catheter flow problems, leaks, catheter tip pain, hemorrhage (defined as sufficiently extensive to lead to blood transfusion), and perforation of a viscus. The last two from that list are extremely rare and although guidelines recommend that they are included in the post-insertion audit, the numbers are not sufficient to permit comparative audit. PD catheter dysfunction has been variously defined, perhaps a functional definition is most useful such as catheter function being sufficient to permit treatment with the patient's chosen modality (be that automated peritoneal dialysis [APD] or CAPD).

Guidelines have recommended delaying the use of the PD catheter for 2 weeks post catheter insertion to permit healing and reduce the likelihood of leaks, but this recommendation may have inhibited the use of urgent start PD [15]. PD catheters can be used immediately as long as appropriate measures are taken to reduce the risk of leaks, such as ensuring that the patient is supine while there is fluid in the peritoneal cavity during the first few days of use. A randomized controlled trial of early versus later start demonstrated increased complications in the early start group, but complication rates were higher than those reported from other centers where early start PD is used [50].

Table 50.2 Treatment recommendations.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Method of peritoneal dialysis catheter insertion	We do not suggest any specific PD catheter insertion technique for improving PD patient outcomes based on low to very low certainty of the evidence that choice of catheter insertion technique makes any difference to the outcomes of peritonitis, all-cause PD catheter removal, exit site infection, post-operative dialysate leak, incisional hernias catheter obstruction or catheter tip migration	Low to very low evidence	Weak

Conclusion and Recommendation

Evidence is not sufficient to recommend one PD catheter insertion technique over another therefore operators should continue to use techniques with which they are familiar (Table 50.2). We performed meta-analysis for four randomized controlled trials comparing laparoscopic versus open surgical insertion and did not find any significant advantages for one technique over another for the outcomes we considered. A weakness of our analysis is that the technique is defined only by the use of the laparoscope or not techniques that it is used for. There is the potential that combining laparoscopy with adjunctive techniques that can be performed during the procedure could reduce the risk of catheter migration or obstruction. This insertion technique may have particular value when individuals have had previous lower abdominal surgery or a first catheter that did not work. This has not been tested in randomized controlled trials (table 50.2).

A recommendation for a particular PD catheter insertion technique should take into consideration the characteristics of the patient, locally available expertise, and resources. For example, the use of local anesthesia for percutaneous insertion has the advantage that it can provide definitive access in individuals with significant comorbidities and for whom a general anesthetic may be contraindicated. We would therefore recommend that where possible centers aim to provide a combination of approaches that are stratified according to the needs of the individual. It is important that regular local audit is conducted of PD catheter outcomes and complication rates.

Overview of Kidney Supportive Care

Kelly Li and Mark Brown

St. George Hospital, University of New South Wales, Sydney, New South Wales, Australia

Defining Kidney Supportive Care

Kidney supportive care (KSC) is the integration of palliative care principles in the holistic, patient-centered management of chronic kidney disease (CKD). It has evolved out of the recognition that patients with CKD, particularly those with advanced CKD with or without dialysis, have high symptom burden and poor quality of life. Furthermore, there are increasing numbers of patients with end-stage kidney disease (ESKD) who are older, frail, and have multimorbidity and poor functional status, where treatment with dialysis may be of little or no benefit and potentially harmful (Table 51.1). While this is the group for whom KSC most often applies, patients with all stages of CKD require active and holistic management of their evolving care needs (see Table 51.2) and as such patients may benefit from KSC at any stage in their CKD trajectory.

The key elements of KSC include:

1) Active care aligning nephrology and palliative care, best provided by a multidisciplinary team that includes kidney and palliative care expertise from physicians, nurses, and allied health staff such as dieticians and social workers, underpinned by education, research, and quality assurance.
2) Meticulous and evidence-based symptom management in CKD.
3) Shared decision-making, with an emphasis on skilled communication, provision of information including prognosis, and informed decision-making regarding the initiation and withdrawal of dialysis or opting for conservative (nondialysis) kidney management (CKM).
4) Provision of active patient-centered care for patients with advanced CKD or ESKD, particularly those who are planning CKM, addressing physical, psychosocial, and spiritual needs.
5) Advance care planning.
6) Terminal/end-of-life care.

Rationale for the Development of a Kidney Supportive Care Model

Several key observations underpin the need for a KSC model. First, the mortality for ESKD remains high despite the availability of renal replacement therapy (RRT), particularly for those on dialysis. Second, CKD patients are increasingly older, with multimorbidity and the difficult decision of determining which patients may benefit from dialysis and actively supporting those who may not benefit becomes a core skill and imperative for nephrologists. Third, symptom burden is high for patients with CKD, especially for those with advanced CKD and ESKD, whether treated with dialysis or CKM. These symptoms are often under-recognized and untreated in routine nephrology practice.

Mortality in End-stage Kidney Disease

ESKD is associated with high mortality and although dialysis may prolong survival in selected patients, it does not restore normal life expectancy [15]. Mortality is particularly high among older patients commencing dialysis. Table 51.3 shows life-expectancy of ESKD patients in several Western countries with widespread availability of

Table 51.1 Summary of the key components of kidney supportive care.

Component	Recommendation	Certainty of evidence	Strength of recommendation
Symptom management	We suggest regular symptom assessment using validated tools such as iPOS renal and ESAS-r : Renal	Low	Weak [1–4]
Shared decision-making	We encourage shared decision-making at key time points, including dialysis initiation and withdrawal, advance care planning, and pursuing CKM	Absent	Weak [5]
Prognostic information	We suggest clinician-led discussions of prognosis, as the majority of patients on dialysis would like this information	Low	Weak [6, 7]
	Furthermore, dialysis may not offer survival advantage to older patients with comorbidities and poor functional status	Low	Weak [8–11]
Advance care planning	We suggest advance care planning for patients with advanced CKD	Very low	Weak [5, 12]
Communication	We suggest nephrologists have proficiency in communication skills to lead serious illness conversations using communication tools	Absent	Weak [13, 14]

CKD, chronic kidney disease; CKM, conservative kidney management; ESAS-r:R, Edmonton Symptom Assessment System-Revised: Renal; iPOS, Integrated Palliative Care Outcome Scale.

RRT [15, 16, 18]. Table 51.4 shows survival on dialysis in Australia, New Zealand, and Canada, with comparisons to common cancers in Australia [16, 20, 21].

Age and Comorbidities

Patients with ESKD are increasingly older with multimorbidity. In the United States, patients aged 75+ make up the largest group of incident dialysis patients, followed by those aged 65–74. Patients aged 65–74 remain the most prevalent group, likely due to higher mortality in the 75+ group, although data from the United States Renal Data System (USRDS) shows that those aged 75+ have formed the fastest growing group of prevalent dialysis patients in recent years. [22] Similarly, in Australia, between 2012 and 2016, the largest group of new dialysis patients were aged 75–84, followed by those aged 65–74 [23], although similar to the United States, patients aged 65–74 remained the most prevalent group [24].

In addition, comorbidities are common among ESKD patients, indicating that these patients are living with multiple serious chronic diseases. Australia and New Zealand Dialysis and Transplant Registry (ANZDATA) shows that between 2006 and 2016, the prevalence of type 2 diabetes is rising, both in Australia and New Zealand, approaching 40% by 2016 [24]. In Canada, Canadian Organ Replacement Register (CORR) shows that over 50% of incident dialysis patients in 2016 were diabetic [20].

Cardiovascular disease has remained more stable in Australia and New Zealand, with prevalence of coronary artery disease around 35% in Australia, lower in New Zealand [24]. USRDS data shows prevalence of any cardiovascular disease at over 70% for prevalent hemodialysis patients. The most common cardiovascular diseases include atherosclerotic heart disease, congestive heart failure, and peripheral vascular disease. In those aged 65 years or older, prevalence of atherosclerotic heart disease alone exceeds 50% [22].

Table 51.3 Life expectancy on renal replacement therapy for older patients.

United States
Expected survival (years) of prevalent dialysis patients having attained a certain age, compared to general US population
Based on 2013 data [15]

Survival in years	Prevalent dialysis patients		General age-matched population	
Age group	Male	Female	Male	Female
40–44	11.0	10.4	36.4	40.3
45–49	9.2	8.9	31.9	35.6
50–54	7.9	7.8	27.7	31.1
55–59	6.6	6.6	23.7	26.8
60–64	5.5	5.7	19.8	22.6
65–69	4.5	4.8	16.2	18.5
70–74	3.8	4.0	12.8	14.7
75–79	3.2	3.5	9.8	11.3
80–84	2.6	2.9	7.1	8.4
85+	2.2	2.4	3.7	4.4

Australia and New Zealand
Median survival of incident dialysis patients by age, compared to general Australian population having attained a certain age
Based on 2017 ANZDATA [16]
Comparison with general population in Australia having attained a certain age

Survival in years	Incident dialysis patients		General population (2014–2016 in Australia) [17]		
Age group	Australia	New Zealand	Age	Male	Female
45–64	6.5	5.4	45	37.1	40.6
65–74	4.6	3.7	65	19.6	22.3
75–84	3.5	2.9			
85+	2.3	1.9	85	6.2	7.3

Median survival on dialysis is lower if patients have vascular disease and/or diabetes

United Kingdom
Median survival of incident RRT patients by age[a] compared to general population in UK at age 65
Based on 2015 data from UK Renal Registry [18]

Survival in years	Incident RRT patients	General population (2015–2017) [19]		
Age group		Age	Male	Female
55–64	6			
65–74	3.5	65	18.6	20.9
75+	2–2.5			

[a] Renal replacement therapy (RRT) includes both dialysis and transplantation.

Symptoms in End-stage Kidney Disease

Symptoms are prevalent in CKD, particularly across stages 3–5. Table 51.5 shows the most commonly reported symptoms in patients with CKD. More recent research has highlighted fatigue as the most common and distressing symptom, experienced in approximately 80% of patients with CKD or ESKD, regardless of whether they are treated with dialysis or CKM [4, 25]. Symptom assessment needs to be performed regularly and using validated tools.

Table 51.4 Survival on dialysis compared with common cancers.

Age group	1 year	5 years
Australia: Incident dialysis patients 2007–2016 [16] % survival (95% CI)		
65–74	88 (87–89)	50 (48–51)
75–84	83 (82–84)	33 (32–35)
85+	72 (69–76)	20 (16–24)
New Zealand: Incident dialysis patients 2007–2016 [16] % survival (95% CI)		
65–74	87 (85–89)	38 (34–41)
75–84	81 (77–84)	20 (16–25)
85+	85 (65–94)	19 (6–39)
Canada: Incident dialysis patients 2007–2016 [20] % survival		
65–74	81.7	39.0
75+	73.4	25.7
Australia: Cancer patients 2009–2013 [21] 5-year survival		
Breast cancer (all)		90%
Breast cancer (aged 75+ at diagnosis)		79%
Colorectal cancer (all)		69%
Colorectal cancer (aged 75+ at diagnosis)		61%
Lung cancer (all)		16%
Lung cancer (aged 75+ at diagnosis)		10%

The Integrated Palliative Care Outcomes Scale (iPOS renal) [26] and Edmonton Symptom Assessment System-revised: Renal (ESAS-r:R) [27, 28] are such tools developed and used in research and in clinical practice [29–31]. Without the use of symptom tools, patients may be reluctant to disclose their symptoms to treating physicians. Studies have found that systematic questioning of symptoms yields many more symptoms than patients' self-reporting [5, 6]. Furthermore, this helps to direct the consultation toward more patient-centered goals and concerns that matter the most to patients.

Integration of Palliative Care

Palliative care is a discipline that focuses on improving the quality of life of patients and their families living with life-limiting illnesses through impeccable assessment and management of physical, psychosocial, and spiritual needs [7]. This can occur at any stage in the disease trajectory, alongside therapies that prolong life. The philosophy of palliative care can be applied to the management of patients with CKD to improve symptom burden, facilitate discussions regarding goals of care, offer better psychosocial and spiritual support, and prepare those patients and their families facing end-of-life issues. (Refer to Chapter 52 for a detailed discussion on the epidemiology and approach to symptoms in patients with CKD.)

Table 51.5 Prevalence of symptoms in chronic kidney disease.

Symptom	Prevalence	Evidence
Sleep disorders	60%	40 studies of 7391 patients
Pain	58%	>50 publications of 7500 CKD patients
Anorexia	56% (range 9–82%)	18 studies of 3122 patients
Nausea	46% (range 9–90%)	14 studies of 1774 patients
Uremic pruritus	41% (reported as severe in 24.5%)	24 studies of 19 226 dialysis patients
Constipation	40% (range 8–65%)	17 studies of 2001 patients
Vomiting	23% (range 11–68%)	12 studies of 1511 patients
Depression	22% in CKD stage 1–4 23% in dialysis patients	Palmer et al. [1]
Diarrhea	21% (8–33%)	10 studies of 921 patients
Restless legs syndrome	10–20% of long-term dialysis patients	Novak et al. [2]

Source: Adapted from Davison et al. [3].

Nonabandonment

The principle of nonabandonment can be defined as a longitudinal commitment from the physician both to care about patients and to jointly seek solutions to problems with patients throughout their illness, as an open-minded, caring, and knowledgeable partner [32]. It is a central principle in KSC in providing an engaged long-term relationship with patients and ensuring continuity of care regardless of their decision to commence or forego dialysis and other life-prolonging treatments. Several aspects of nonabandonment are particularly important for the physician to adopt in the KSC setting:

- Commitment to working with the patient through an unknown future without shying away from difficult decisions such as the appropriateness of dialysis and to continue to respond together to changing clinical situations.
- Willingness to be opened-minded about patients' values and goals and to share in patients' vulnerability and suffering in the context of a chronic and incurable illness.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

- Obligation to continue to care and advocate for patients through progressive disease to the end of life, accepting the limitations of medical therapies to prolong life or relieve suffering, and not deserting patients.

Models of Care

Based on the considerations relevant to this population, suggested components of a KSC team include some or all of:

- clinical nurse consultant specializing in KSC
- nephrologist
- palliative care physician
- trainee doctors and nurses
- nephrology and/or palliative care trainee
- social worker
- renal dietician
- renal pharmacist
- research assistant and data manager
- occupational therapist
- physiotherapist
- psychologist.

Models of care will depend largely on local needs and resources available, thus not all team members will be incorporated into one KSC service.

Integrated Model

The KSC model established at St. George Hospital in metropolitan Sydney, Australia integrates expertise from nephrology, palliative medicine, and a range of allied health disciplines to provide a service for patients and their families that is embedded within the existing kidney unit. The service is available to all patients with CKD, although the majority utilizing this service are older patients with advanced stages of CKD, about two thirds are pursuing a CKM pathway, and the remainder are undergoing dialysis or have advanced CKD with symptoms. All patients receive ongoing care from their treating nephrologist, including those with ESKD, regardless of their decision to pursue, withhold, or cease dialysis, adopting the principle of nonabandonment. The key elements of this model include:

- A dedicated KSC outpatient clinic, staffed by a palliative care physician, a nephrology advanced trainee, clinical nurse consultants, dietician, and social worker.
- Inpatient consultative service, led by the KSC nurse consultant.
- Regular and ad hoc phone and tele-health consultations for outpatients.
- Data collection for research and quality assurance purposes.
- Close liaison with treating nephrologists, dialysis staff, and local hospice and community palliative care services.
- Training and support for nephrology advanced trainees, and medical, nursing, and allied health staff from other kidney units.
- Regular meetings of the KSC team to ensure the service continues to develop, discuss difficult cases, and enhance research ideas.

Consultative Model

Embedding palliative care within a kidney unit allows for their regular and comprehensive involvement in providing a KSC service. However, this may not be practical or sustainable due to financial, logistic or resource constraints in many units. Furthermore, the care provided by a nephrologist to his or her patients may extend over many years, and it is desirable to maintain and build on this therapeutic relationship at difficult time points in a patient's disease trajectory. As a result, it is important that nephrologists develop core palliative care skills such as basic symptom management, including psychosocial assessment, key communication skills, and a general understanding of end-of-life care and managing dialysis withdrawal. This set of skills will allow a nephrologist to manage most aspects of KSC, along with experienced nursing and allied health staff.

Specialist palliative care advice should be sought when basic management is felt to be inadequate at addressing more complex clinical scenarios. Some of these challenging cases can include difficult and refractory symptoms, both physical and psychological, family conflicts, and ethical issues regarding appropriateness of commencing or continuing with dialysis. In these settings, the palliative care team can assist in a consultative service. Knowledge about and regular liaison with local palliative care services is important to allow their involvement when difficult cases arise. Table 51.6 summarizes some aspects of general and specialist palliative care [13].

Shared Decision-making

The Kidney Disease Improving Global Outcomes (KDIGO) consensus conference in supportive care defined shared decision-making as the following:

> "Shared decision making is a process of communication by which physicians and patients agree on a specific course of action based on a common understanding of the patient's treatment goals, taking into account

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. > the benefits and harms of treatment options, and the likelihood of achieving the outcomes that are most important to individual patients" [3].

Shared decision-making requires the physician to have respect for and curiosity about the patient, to tailor an individualized treatment plan, and to empower patients to be actively involved in their healthcare. In KSC, this is particularly applicable to the decision regarding the initiation of dialysis or to pursue CKM, the withdrawal of dialysis, and advance care planning. Shared decision-making is discussed further in Chapter 71.

Prognosis

Prognosis is an essential part of any shared decision-making process involving a life-limiting illness, as assessing and conveying prognostic information helps patients make informed decisions about their future. Although not all patients wish to know their prognosis, the vast majority of nephrology patients do want life-expectancy information and for the physician to provide this without prompting [33]. Over 90% of patients on dialysis believe it is important to know their prognosis or how their disease will progress [34]. Prognostic information is often the single most important piece of information that patients need to make informed choices [35] and serves as a starting point for patients to consider the risks and benefits of dialysis [8]. Dialysis patients tend to be overly optimistic about their prognosis compared to their nephrologists [9]. Misinformation about prognosis can lead to inappropriately aggressive treatments. Patients with CKD in whom prognosis is particularly poor should be informed that dialysis may not confer a survival advantage, or improve quality of life or functional status over CKM, although cultural and ethnicity factors may influence the willingness to know or participate in such decision-making [3].

Despite observational studies generally showing a survival advantage with dialysis [10, 11, 30, 36], direct comparisons of survival on dialysis and nondialysis pathways are inherently flawed in that dialysis patients are preselected and thus tend to be younger, have fewer extrarenal comorbidities, and have better performance status. In addition, time points from which survival is measured vary significantly between studies, particularly as glomerular filtration rate (GFR) at dialysis initiation is variable. Conservatively managed patients are also a heterogeneous group, consisting of those who are candidates for dialysis but for whom dialysis is not available, those who choose not to have dialysis, and those who are not offered dialysis for various reasons such as comorbidities, advanced age, frailty, lack of capacity or a separate and more advanced life-limiting illness such as cancer, to name a few. Therefore, observations of survival advantage with dialysis over CKM need to be interpreted in such a context.

There is increasing evidence that dialysis does not offer a survival advantage to some patients with ESKD. Observational studies have demonstrated that patients over 75 years of age with a high number of extrarenal comorbidities, particularly diabetes [36] and ischemic heart disease [37], are unlikely to derive any survival advantage with dialysis, compared with those managed on a nondialysis pathway. Similarly, there appears to be no survival advantage for patients aged 80 years old regardless of comorbidities [38, 39], nor for patients with poor functional status (World Health Organization Performance Score 3 or more) [39].

Initiation of Dialysis

It is imperative that nephrologists lead discussions about the appropriateness of dialysis. In addition to prognosis, other aspects that should be incorporated into these discussions include quality of life and anticipated effects of dialysis on physical function, social circumstances, and family and carers. Patients may be willing to trade off significant life expectancy to reduce the lifestyle restrictions imposed by dialysis. In an Australian study, patients were willing to forego 7 months of life expectancy to reduce the number of visits to hospital and 15 months to increase their

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ability to travel [40]. Ethical principles of beneficence and nonmaleficence obligate the nephrologist to weigh potential benefits and harms to the individual patient and plan a course of treatment that is individualized to each patient's unique circumstances. Dialysis should be offered to patients who are expected to benefit, and this includes an expectation of longer survival as well as an acceptable quality of life. Those who would not be appropriate for dialysis or who choose CKM should be offered active alternative care. The epidemiology, content, indications, and decision-making regarding CKM as a treatment option for patients with ESKD are discussed in detail in Chapter 55.

Except in situations of medical emergency, patients commencing dialysis should have informed consent to undergo treatment. The key elements of legally binding consent, in common law jurisdictions, include [41]:

- decision-making capacity
- voluntariness
- provision of adequate information.

Provision of information is vital to allow patients to participate in the decision-making process and make meaningful choices. Adequate information must also include disclosure of any possible alternative treatment, which in the case of dialysis is an explanation of CKM and the material risks associated with dialysis. Material risks include [41]:

- complications of dialysis such as hypotension and sepsis, as well as symptoms such as fatigue
- prognosis (a best estimate by available tools)
- anticipated effect on the life of the patient, family, and carers.

A KSC team can facilitate ongoing discussions and provide support for patients and families. It is essential that patients are aware of an active and viable alternative to dialysis in making their decision to commence dialysis.

Withholding or Withdrawal from Dialysis

Ethical decision-making in the area of RRT has shifted from the early days of "who should be dialysed?" to the more recently pertinent question of "who should *not* be dialysed?" Perhaps the latter question has always been pertinent. Belding Scribner, in his 1964 presidential address to the American Society of Artificial Internal Organs, identified several issues with the introduction of a chronic hemodialysis program. Two of the issues Scribner raised were withdrawal from dialysis – "what criteria to use and to whom to turn to make such a difficult life and death decision" – and dying with dignity and without prolonged suffering [42].

Withdrawal from dialysis is a common cause of death in ESKD patients (Table 51.7). Withholding and withdrawal from dialysis is both legal and ethical if:

- a competent patient has refused to commence or continue dialysis
- the dialysis treatment is of no benefit to the patient.

Withholding and withdrawal of dialysis in these settings do not constitute euthanasia or physician-assisted suicide [43].

If dialysis treatment is of no benefit to the patient, the nephrologist is under no legal or ethical obligation to provide dialysis [43]. The principle of autonomy has been used to justify treatments on the view that doctors ought to provide what the patient requests. However, each of the bioethical principles are important and autonomy does not override the other principles. While patients' wishes and values should be considered, they should not be considered in isolation [44]. Nephrologists should offer treatments that they believe are of benefit to the individual patient but are under no obligation to provide treatment they feel is of no benefit and potentially harmful to the patient. In situations where there is a conflict between the nephrologist and the patient, or the surrogate decision maker, involving the multidisciplinary team and seeking a second opinion regarding diagnosis and prognosis is usually helpful. If the patient is incompetent, the decision should be communicated to the surrogate decision maker, including an assessment of the patient's best interest. Ultimately, disputes can be resolved by appropriate legal channels. The Renal Physician's Association (USA) have formulated a set of recommendations regarding withholding and withdrawing from dialysis, and these serve as a useful starting point to guide physicians. The epidemiology and decision-making regarding dialysis withdrawal as well as the approach to care are discussed in detail in Chapter 55.

Table 51.7 Prevalence of patients who withdraw from dialysis.

United States: Dialysis discontinuation before death [12]		
All ages	23.4%	
Aged 85+	34.2%	
Australia and New Zealand: ANZDATA: % of death listed as due to dialysis withdrawal [16]		
	Australia	New Zealand
Hemodialysis all ages	34.4%	27.6%
Hemodialysis aged 75+	42.1%	52.9%
Peritoneal dialysis all ages	28.8%	27.8%
Peritoneal dialysis 75+	36.2%	39.45

Ultimately, decisions to forego or withdraw from dialysis can be difficult and fraught with emotions. Sensitive communication with care and empathy from healthcare professions are imperative. It is important to remember the principle of nonabandonment, and to support patients and their families through these times. This is where KSC comes to the fore, emphasizing an active treatment to improve the patients' symptoms while supporting them and their families.

Advance Care Planning

Advance care planning is a process that involves understanding, reflection, communication, and discussion, with the aim of clarifying preferences for end-of-life care for a patient [45]. This often occurs over many conversations between the patient, their family or carer, and their healthcare providers. Advance care planning for patients with advanced CKD has been recommended by clinical practice guidelines in many countries [3, 46, 47]. It provides a broad focus on patient values and goals of care and assists patients in understanding their illness, prognosis, and anticipated disease trajectory. It can include, but is not limited to, an advance care directive, a not-for-resuscitation order, and the appointment of surrogate decision makers. Failure to discuss prognosis and end-of-life preferences can lead to unwanted suffering, continuation of aggressive treatments at the end of life, and patient preferences not being respected. For example, in considering preferences for resuscitation, patients need to be aware that outcomes of aggressive treatments such as in-hospital cardiopulmonary resuscitation (CPR) for dialysis patients are poor, with less than one-third surviving in one study and most survivors being discharged to care facilities [48].

In patients planned for CKM, advance care plans can set out their wishes not to be dialysed as well as their preferences for other forms of life support. For patients on dialysis, discussions around resuscitation and withdrawal from dialysis remain important aspects, and structured programs in dialysis units have proven success in increasing the number of patients with plans in place [49]. In addition, discussions need to focus on how illness and interventions affect the individual, his or her life, relationships, and what he or she values most [45]. Open and honest discussions about the future can empower patients, enhance hope, and alleviate fears [50].

Studies show that patients would like their nephrologist to initiate advance care planning conversations [45, 51]. However, barriers to these discussions include system factors such as fragmented medical care across many providers as these patients have complex diseases processes, a lack of communication among the providers, and an unclear locus of responsibility [52]. Clinician factors also hinder effective advance care planning (ACP) such as nephrologists' lack of training in communication, a lack of available time, and the mistaken perception that ACP may cause harm by destroying hope [14, 47]. For further discussion of ACP in CKD please refer to Chapter 54.

Conservative Kidney Management

CKM is an active care pathway for patients with ESKD for whom dialysis was unlikely to be beneficial and who chose not to pursue dialysis. It comprises holistic, patient-centered care that actively manages patients' physical, psychosocial, and spiritual needs. The principle of nonabandonment is fundamental, which means that nephrologists continue to play an important and ongoing part in the patients' care with the added support of palliative care physicians and allied health staff. The key components of CKM are outlined in Table 51.8 and are fully discussed in Chapter 55.

It is difficult to estimate the incidence or prevalence of patients on a conservative nondialysis pathway. An Australian population-based study from 2003 to 2007, linking mortality data for the general population to ANZDATA of patients receiving RRT, suggested that for every new patient in Australia who died receiving RRT (dialysis or transplant), there was one new patient who did not [53]. The majority of those who did not receive RRT were older, with more than 80% over the age of 70 years. Similarly, a Canadian cohort study showed that in adults aged over 75 years, untreated kidney failure was 2–10-fold more common than in those treated with dialysis [54]. There is increasing data around survival for those on a nondialysis pathway. A large Australian prospective study reported that conservatively managed patients ($n = 122$) with an average age of 82 years survived a median of 16 months and about one-third survived 12 months past a time when

Table 51.8 Components of conservative kidney management.

Patient-centered holistic care for patients with ESKD
1) Interventions to delay progression of CKD and minimize risk of adverse events or complications, including nutritional assessment and management
2) Shared decision-making and communication, including advance care planning
3) Active symptom management
4) Psychosocial and family support
5) Cultural and spiritual domains of care
Does not include dialysis

dialysis might otherwise have been indicated (eGFR < 10 ml/min) [30]. For a full discussion on CKM refer to Chapter 55.

Communication

Clinician-led conversations about patient preferences, goals, values, and expectations form an important part of patient-centered care. It is essential that clinicians working within the KSC framework are proficient in engaging in conversations about a range of serious and important topics, including choice to pursue a dialysis or CKM, prognosis, goals of care, CPR, withdrawal from dialysis, adverse health outcomes from nonrenal comorbidities, advance care planning, and transitioning to end-of-life care. Eliciting a patient's big picture goals in these conversations can be accomplished by exploring hopes and expectations, identifying concerns about the future, and determining situations in which the patient would consider forgoing a life-supporting therapy such as dialysis [8]. Having good communication around these issues can enhance goal-consistent care such as dying in a preferred setting, reduced hospitalization, and less aggressive care at the end of life. This may also improve outcomes for families without an increase in patient distress or anxiety [55]. Some specific time points and triggers for these conversations are listed in Table 51.9 [8, 55, 56].

Communication is a two-way process and provision of information, likewise, is not a unidirectional flow of facts from the physician to the patient. The *Ask-Tell-Ask* approach (Table 51.10) can be a useful framework for providing information. It focuses on two-way interactions and ensuring adequate understanding of provided information [57]. These conversations can be emotional and potentially confrontational. It is useful to have a structured approach so that conversations address the critical issues. One way of structuring a serious illness conversation is outlined in Table 51.11 [58].

Goals of care should be reassessed regularly, especially as clinical situations change. It is important to have these conversations in a private setting without time constraints. Busy nephrology clinics or dialysis units surrounded by other patients and staff are not ideal settings. Documentation of the conversation is critical to ensure the content is recorded correctly and will be accessible at a later date. This may include documentation within electronic medical records, dialysis units' records, personal copies given to patients, and forwarded communication to family physicians and other specialists involved in the patient's care.

Table 51.9 Triggers for initiating discussions about dialysis or conservative kidney management.

Triggers [8, 55, 56]
• At time of referral for dialysis (discussion is necessary to ensure informed consent for dialysis)
• Patients considering CKM
• "No" to the Surprise Question (would you be surprised if this patient died in the next 12 months?)
• Worsening or high symptom burden
• Worsening or poor QOL
• Multiple or prolonged hospital admissions
• Functional decline, increased dependence or moving into long-term care facility
• Unintentional weight loss/progressive malnutrition
• Repeated dialysis access complications
• Unable to tolerate dialysis
• Cardiovascular events: myocardial infarction, cerebrovascular events, amputations
• High comorbidity: extensive cardiovascular disease, malignancy, cirrhosis, chronic lung disease
• Patient or surrogate decision-maker request to stop dialysis

CKM, conservative kidney management; QOL, quality of life.

Table 51.10 Ask-Tell-Ask framework.

Ask-Tell-Ask	
Ask	Asking what the patient understands before giving information is useful as patients have different levels of understanding and may desire different levels or amounts of information. In particular, it is useful to ask the patient if and how much prognostic information they desire before providing it.
Tell	In providing serious or confronting information such as poor prognosis, it is helpful to start with a "warning shot" such as "I am worried about how sick you are". This helps patients better prepare cognitively and emotionally for potentially distressing news. Sometimes this is best stated at one consultation before the more detailed information is provided at the next. Information should be given in direct and plain language, appropriate for the patient's educational level and avoiding medical terminology. No more than three pieces of information should be given at any one consultation.
Ask	Asking the patient about the information given can reinforce the information as well as assess understanding and correct misconceptions. It is also an opportunity to invite patients to ask questions.

Source: Adapted from Schell and Arnold [57].

Conclusion

KSC is an active approach to kidney care that integrates palliative care principles with nephrology to provide holistic, patient-centered care to a worldwide growing population of patients with CKD, typically those who are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 51.11 Suggested content for serious illness conversations.

Structure for serious illness conversations with some examples	
Understanding of illness	"What do you understand about your health and what lies ahead?" "What do you think starting dialysis means for your future health and quality of life?" "How has your recent hospitalization changed your understanding about your health in the future?"
Information preferences	**How much information and in what form** "Do you want me to talk about what lies ahead for you and your health?"
Prognosis	**Depending on information preference** "Sometimes patients wonder about how long they might have. Is that something you would like me to share with you?" **Acknowledge uncertainty** "I can't predict exactly what would happen, and based on available information, I would say weeks to a short number of months/a few months to a year/1 or 2 years/a few years." "I wish I could tell you things will get better, but we need to prepare for. . . if your health declines suddenly OR if your time is short OR if how you feel now is as good as you will be."
Goals	"What are your most important goals for your life and your health?" "What do you hope dialysis will accomplish for you?"
Fears/worries	"What worries you the most?" "What worries you the most about. . . starting dialysis OR stopping dialysis OR the future OR your illness?"
Function	**What abilities are critical for reasonable quality of life** "What functions or activities are so important that you can't imagine living without them?"
Trade-offs	**How much are you willing to go through for the possibility of more time** "What are you willing to go through to achieve your goals?" "Is dialysis something you are willing to go through to achieve. . .?"
Family	**How much families know about patient's wishes and preferences** "Have you shared your thoughts/health problems/fears/preferences with your loved ones?" "Would you like your medical team to discuss this with your family?"

Source: Adapted from Bernacki et al. [58].

older, comorbid patients with advanced CKD, a high symptom burden, and poor quality of life. It leads a paradigm shift within nephrology that redirects the focus to shared decision-making, quality of life, and providing an individualized care pathway for vulnerable patients. It is an evolving field arising out of increasingly robust evidence-based practice. Ongoing research will be essential to further explore areas of uncertainty and develop more nuanced approaches to care as well as to improve outcomes.

Nephrologists should receive KSC training and incorporate it into their core skill set, much like hypertension management or dialysis prescription. This will ensure that nephrologists always see CKM as the third potential pathway for management of patients with ESKD, alongside transplantation and dialysis. It is now imperative for kidney units to incorporate KSC into their standard of care with the aim of providing appropriate, individualized, and active management of all CKD patients at all times in their lives.

Symptoms

Sara N. Davison

Division of Nephrology and Immunology, Department of Medicine, University of Alberta, Edmonton, Alberta, Canada

Introduction

Kidney supportive care is care aimed at improving the quality of life (QOL) for patients with chronic kidney disease (CKD) throughout the continuum of their illness. A key component of this is meticulous physical and emotional symptom assessment and management [1]. The high symptom burden experienced by patients with CKD throughout their illness trajectory can be extremely debilitating and negatively impacts their QOL and functional capacity. Recent patient engagement has highlighted symptom management as a top research priority for people with advanced CKD [2]. Symptom assessment and management need to be integrated into routine kidney care early and readdressed throughout the patient's illness.

This chapter summarizes the evidence surrounding the epidemiology and impact of symptoms in patients with CKD, and outlines general approaches and tools to assess and manage the symptom burden.

Epidemiology

Prevalence of Symptoms in Advanced CKD and ESKD

People with CKD tend to experience many symptoms such as fatigue, pain, pruritus, restless legs, anorexia, nausea, insomnia, anxiety, and depression [3–8]. While there is tremendous variability in patients' symptom burden, taken as a whole the number and severity of symptoms have been described as being similar to those of cancer patients hospitalized in palliative care settings [9]. The symptom burden is high across age, gender, race, and geographic location. Syndromes such as malnutrition, protein energy wasting, and frailty are also common, leading to muscle and fat loss and cachexia [10]. These factors exacerbate symptom burden and together they profoundly compromise patients' functional capacity and QOL. While dialysis may address some symptoms such as fatigue, anorexia, nausea, and vomiting, especially for more robust individuals with limited comorbidity, it appears to do little to address symptoms in older more frail patients or those with multimorbidity. For some patients, dialysis may add to overall symptom burden. In the meantime, chronic inflammation, malnutrition, and frailty continue to progress regardless of whether dialysis is started or not.

A comprehensive review of the literature identified that the average number of symptoms per patient ranges between six and 20 depending upon the screening tool used [11]. These data came predominantly from hemodialysis patients, with only very small numbers of patients with stages 4 and 5 CKD not on dialysis. There was a high prevalence for almost all symptoms. The five most prevalent symptoms regardless of CKD stage were fatigue or lack of energy 81% (49–100%), feeling drowsy 75% (49–82%), pain 65% (38–90%), pruritus 61% (33–84%), and decreased appetite 57% (9–83%) [11].

More recent studies have begun to explore further the symptom burden in patients with stages 4 and 5 CKD who have yet to start dialysis. Using a cross-sectional design, 436 people with CKD were recruited: 75.5% were receiving dialysis (hemodialysis = 287, peritoneal dialysis = 42) and 24.5% were not undergoing dialysis (stage 4 = 69, stage 5 = 38) [12]. Of the 32 possible symptoms assessed, participants reported an average of 13.01 ± 7.67 symptoms. Consistent with the prior comprehensive review the most prevalent symptoms across all CKD groups were fatigue

(77.0%), bone or joint pain (60.3%), pruritus (59.6%), and decreased appetite (50.5%). However, the five symptoms found to be most distressing across all CKD groups were fatigue, bone or joint pain, feeling irritable, restless legs, and decreased interest in sex. Fatigue and bone or joint pain were the most prevalent and distressing symptoms in CKD stages 4 and 5 CKD regardless of whether they are receiving dialysis or not. Figure 52.1 outlines the overlap in the most common and distressing symptoms reported by patients with CKD.

Overall Symptom Burden Does Not Necessarily Improve after Dialysis Initiation

It is generally assumed that patients with end-stage kidney disease (ESKD) who start dialysis will experience a substantial improvement in physical and psychological well-being. However, when studied at a population level, overall symptom burden does not improve for patients on dialysis. The mean number of symptoms reported by patients on dialysis was more than double the number of symptoms reported by patients with stages 4 and 5 yet to start dialysis (14.7 ± 7.5 vs. 7.5 ± 5.3, $P < 0.001$). [12] Perhaps more importantly, overall symptom distress was higher in the dialysis group ($P < 0.001$). Mean overall symptom severity was highest in patients on hemodialysis followed by patients on peritoneal dialysis, then stage 5 (22.09) with the lowest severity scores in stage 4 ($P < 0.001$) [12]. There may be some slight differences in the distribution of symptoms experienced by CKD stage. While earlier reports, based on very limited data, suggested that people with stages 4 or 5 CKD not on dialysis may experience more psychological problems such as worrying, nervousness, irritability or sadness than those who are receiving dialysis [11], more recent work does not support this. The increased symptom burden in dialysis patients appears to be driven primarily by physical symptoms, as there were no significant differences in the distress levels of psychological symptoms such as feeling sad, worried, anxious, nervous, or depressed among CKD stages [12].

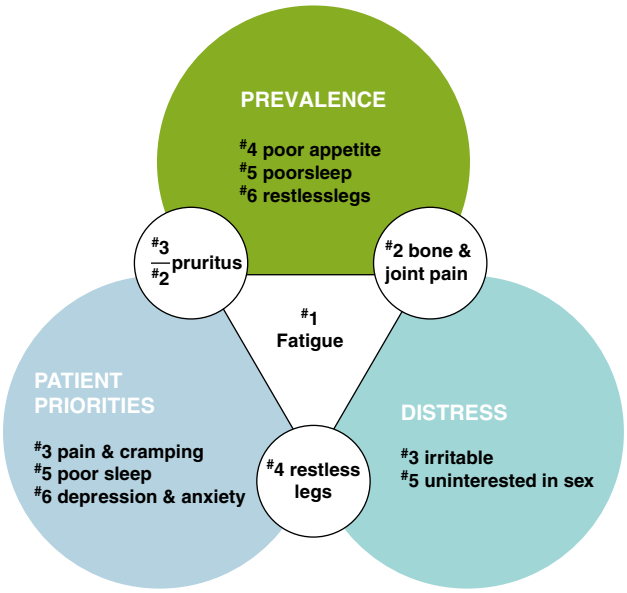

Figure 52.1 The most prevalent, distressing, and highly prioritized symptoms reported by patients with advanced CKD.

Symptom Prevalence in Patients Who Have Chosen CKM

Symptom burden is high but similar for patients who have chosen conservative kidney management (CKM) compared to those on dialysis. The most common symptom reported continues to be fatigue ($n = 191$, 77%) followed by itch (67%), pain (62%), shortness of breath (61%), and edema (54%) [13–17]. The prevalence of other symptoms continues to be high, such as loss of appetite (51%), problems sleeping (51%), and restless legs (33%). Although the prevalence of symptoms may be high, they are not necessarily severe and can be treated. For example, although pain was experienced by 69% of CKM patients, only 26.1% reported their pain as moderate or severe [13, 16, 17]. A qualitative study of patients managed conservatively emphasized the burden of edema, pain, fatigue, and shortness of breath for these patients [18]. Symptom burden appears to be relatively stable until the last month before death but as the disease progresses difficulty concentrating, shortness of breath, and swelling of the legs and arms become more prevalent and may be indicators of near death [11, 16].

Symptom Prevalence in Earlier Stages of CKD

More recently, a few studies have examined symptom burden in earlier stages of CKD. Twenty-five symptoms were assessed in a cohort of 1118 patients with stages 1–5 CKD [15]. CKD stages were categorized as "Early stage" and included CKD stages 1, 2, and 3, "Stage 4", "Stage 5 – Non Dialysis", and "Stage 5 – Dialysis". Overall the prevalence of symptoms was similar and high, irrespective of the stage of the CKD. The most prevalent symptoms in early stages of CKD were bone and joint pain (86%), feeling irritable (77%), and muscle cramps (71%) [15]. In keeping with prior studies, the most prevalent symptoms among those in stage 5 and on dialysis were restless legs, bone and joint pain, and feeling irritable [15]. While bone and joint pain was the most prevalent symptom for the entire cohort (88%), decreased sexual interest was the most severe. Joint

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pain and impaired sexual desire/ability were also the most prevalent symptoms among 35 CKD patients who were in stages 2 and 3 of the disease [19]. Similarly, symptoms were common in a cohort of 283 CKD stage 1–5 patients with a mean eGFR of 38 ml/min/1.73 m^2. The median number of symptoms reported was six out of 11 assessed symptoms (interquartile range 3–8) [20]. Consistent with dialysis patients, the most prevalent symptoms were excessive tiredness (81%) followed by sleep disturbance (70%) and pain in the bones or joints (69%). Clearly, patients in all stages of CKD experience high symptom burden.

Symptom Prioritization

Given the high prevalence of bothersome symptoms, surprisingly little work has been done to understand how patients prioritize symptoms. The international Standardized Outcomes in Nephrology – Hemodialysis (SONG-HD) initiative generated a consensus-based prioritized list of core outcomes for trials in hemodialysis. Symptoms were ranked extremely highly by patients. Fatigue was one of the highest prioritized outcomes and has subsequently been identified as one of five core outcome domains [21]. Pain, sleep, depression, and anxiety were also ranked highly. A Canadian study of key stakeholders, including patients and caregivers, sought to determine research priorities for patients on or nearing dialysis. Symptoms ranked highly and were the focus of three of the top 10 priorities [2]. These involved determining the causes and effective treatment(s) of, and ways to prevent, itching in dialysis patients, the best ways to manage symptoms in people receiving or nearing dialysis, including poor energy, nausea, cramping, and restless legs, and the causes and effective treatment(s) of depression in dialysis patients.

Finally, a small sequential exploratory mixed methods study undertook to identify hemodialysis patient-prioritized symptoms. They found that the top prioritized physical symptoms were insomnia, fatigue, and muscle cramping and the top prioritized mood symptoms were anxiety, depression, and frustration [22]. Participants indicated that symptom frequency, duration, unpredictability, and social and financial effects factored the most into symptom prioritization. To summarize, the most prevalent, distressing, and highly prioritized symptom reported by patients with CKD id fatigue (Figure 52.1). This is followed by pain across all three domains, and then pruritus. Several other symptoms are highly ranked, but vary in importance depending on the domain assessed.

Predictors of Symptom Burden

Overall, few significant associations have been found between biochemical markers of disease severity and symptom burden [8, 11, 23]. Although several studies have not identified an association with gender, the larger more recent studies have showed that being female was independently associated with greater symptom burden [11, 12].

Although there is no consistent relationship between symptoms and CKD stage there does appear to be a moderate trend in the number of symptoms by worsening CKD stage [15, 20] and that being dialyzed or being a CKD stage 5 patient are independently associated with greater symptom burden when compared to predialysis stage 5 CKD patients and patients with less advanced CKD, respectively [12].

Symptom Clusters

Patients with CKD and ESKD often experience symptoms in clusters. Symptom clusters refer to concurrent symptoms related to each other. Theoretically, symptoms within a cluster could have a synergistic relationship. Identification of related clusters of symptoms could provide insight into underlying determinants of the symptom experience that help guide clinical management.

Research into symptom clusters for patients with CKD is extremely limited. Three clusters were identified using principal component analysis based on the 12 symptoms within the symptom problem list of the KDQOL-SF in a study of 1553 incident hemodialysis and peritoneal dialysis patients [24]. These clusters are described in Table 52.1. All clusters showed strong negative associations with QOL dimensions and functional status. Only serum albumin and hemoglobin were significantly correlated with all three clusters, which may hint at underlying pathophysiology such as systemic inflammation (discussed further below). The patient-reported "uremic symptoms" were not related to objective clinical indicators of uremia as we currently understand them and there were no significant associations with other clinical variables.

Table 52.1 Symptom clusters in CKD.

Cluster[a]	Symptoms
General symptoms of uremia	Shortness of breath Feeling faint/dizzy Poor appetite Feeling "squeezed out" Feeling nauseous
Neuromuscular problems	Sore muscles Chest pain Numbness in the hands/feet
Skin problems	Itch Dry skin

[a] Cluster names are not accurate reflections of the underlying pathophysiology.

Pathophysiology

The underlying pathophysiology of symptoms in CKD is poorly understood. Little has been done to determine the role of potential uremic toxins and other biomarkers. Biochemical abnormalities do not appear to be the major drivers. There are likely multiple coexisting mechanisms involved. For example, while anemia may exacerbate fatigue, exertional dyspnea, weakness, and weight loss, there is no specific hemoglobin level at which patients start to experience symptoms. In the current era of high flux dialyzers and phosphate binders, serum phosphorous is not predictive of the presence or severity of pruritus [25]. However, high serum calcium and phosphorous may lead to periarticular calcification, pseudo-gout or gout, and ruptured tendons, all of which can result in pain. Although iron deficiency, anemia, and high serum phosphorus levels may contribute to restless legs syndrome, these associations are inconsistent and it is unclear for whom biochemical abnormalities exacerbate symptoms [26–28].

Systemic inflammation is felt to contribute to many of the symptoms experienced by patients with CKD. It is also likely a major driver behind protein energy wasting, malnutrition, and overall functional decline [29]. Inflammation also contributes to low serum albumin and anemia, the biochemical abnormalities that appear associated with symptoms. Skin and peripheral nerve abnormalities have been implicated for both uremic pruritus [30, 31] and restless legs syndrome [32]. These are also suspected to be due to or exacerbated by chronic inflammation. Other abnormalities, such as an increase in activity of μ-opioid receptors, have been implicated as a possible mechanism for uremic pruritus [33, 34]. The mechanisms underlying these symptoms are likely complex, multifactorial, and inter-related. The relative contribution that each has in symptom experience likely varies enormously between patients. This may explain the tremendous interpatient variability in symptom burden and overall functional trajectory.

Psychological factors are likely extremely important determinants of symptom prevalence and severity given that symptoms are defined as the subjective perceptions of physical, emotional, or cognitive changes as experienced by the patient. Therefore, perceptions of symptom burden may be influenced to a greater degree by psychological factors such as personality or cognitions than physiologic abnormalities [24]. Further details on pathophysiology are described for individual symptoms in Chapters 72–77.

Given our poor understanding of the etiology of symptoms, we have limited means to prevent them. We lack biomarkers to predict onset and progression and we lack effective treatments that target the underlying causes. The necessary psychological supports are not fully understood, tend to be resource intensive, and are typically absent in the routine care of patients with CKD.

The Negative Impacts of Symptoms

Symptom burden is correlated highly with impaired physical and mental QOL in patients with CKD and appears much more important than objective clinical and dialysis characteristics [8, 24, 35–37]. Symptom burden was shown to account for 29–39% of the impairment in dialysis patients' physical QOL scores and 39–43% of their impairment in mental QOL scores in 1098 dialysis patients [3, 35]. Moreover, changes in symptom burden were shown to account for 34–45% of the change in physical QOL and 46–49% of the change in mental QOL in 852 dialysis patients [8, 35]. Similarly, the three previously described symptom clusters accounted for 49% of the variance in QOL scores [24]. The effect of a cluster of symptoms on QOL may be more significant than the effect of an individual symptom [24], a concept widely reported in other chronic health conditions [38]. In addition, symptom burden correlates with depression [11, 37]. Symptoms and QOL of dialysis patients have also been associated with, albeit inconsistently, worsened hospitalization and mortality rates [39]. Given that QOL remains poor, especially for patients on dialysis, and that patients give high priority to symptom management and QOL, symptom reduction is of critical importance in the care of patients with CKD.

Healthcare Provider Education and Attitudes toward Symptom Management in CKD

There are gaps in the skill sets taught in nephrology training that will need to be addressed if we are to provide high-quality kidney care. Most nephrologists have limited expertise in symptom management and feel unprepared to pursue effective treatment options. Some feel that it is not their responsibility to treat symptoms that are not directly related to the CKD or dialysis [40]. Two recent surveys of renal fellows reported that they received little education in the principles of kidney supportive care; only 44% of fellows reported being taught explicitly how to treat dialysis patients' pain [41] (although this had increased from 30% in 2003 [42]) and only 9.4% felt very comfortable treating pain in patients with advanced CKD [43]. However, nearly all thought it was important to provide this care. Clearly, enhanced education in symptom management will be

required to address the symptom burden and suffering experienced by patients with CKD. As a community, we will also have to take responsibility for overseeing symptom management, whether we take primary responsibility or coordinate and share care with other multidisciplinary care providers.

Symptom Screening

Symptom recognition by health professionals caring for patients with CKD is inadequate [40]. When healthcare providers rely on standard consultations, they demonstrate poor sensitivity to patients' symptoms and only weak agreement with their ratings of severity [44, 45]. To address this, Kidney Disease: Improving Global Outcomes (KDIGO) recommends incorporating regular global symptom screening using validated tools into routine clinical practice [1]. Given the high prevalence of symptoms among patients with stages 3–5 CKD and ESKD, whether they are treated with dialysis or CKM, screening for symptoms is appropriate throughout the illness trajectory, starting in the earlier stages of the disease.

There are several aspects of symptom screening and assessment worth consideration. Symptoms are subjective; they are what the patient states them to be. Conceptually, symptoms are a multidimensional construct characterized by prevalence, distress, severity, and frequency. The symptom experience is better understood when considering the multidimensional nature of physical and psychological symptoms. The symptom burden therefore reflects the magnitude of the individual's perceptions of frequency, intensity, and distress of the symptom, totaled for all reported symptoms.

Symptom burden, however, is not necessarily synonymous with symptom suffering. The more encompassing symptom experience and the related suffering is unique for each individual and is modulated by contextual, cognitive, and emotional factors [46]. People develop cognitive models to explain their symptoms, how and why they occur, and what measures can prevent or control them. These cognitive models reflect their knowledge and personal experiences and influence directly the individual's response to physical and psychological symptoms. Exploring patients' (mis)perceptions of symptoms can assist patients in selecting appropriate self-management strategies. Emotional responses, especially fear and uncertainty, also impact suffering. Some patients may be predisposed to respond fearfully to a troublesome situation rather than to the experience of the symptom itself. This is particularly relevant for pain. Emotional distress when combined with negative cognitive evaluations like anticipation of upcoming severe pain or reflections on how harmful or difficult it may be to endure the pain over time may induce considerable suffering even with low pain severity.

Culture factors into the symptom experience. All cultures generate explanatory models that attempt to account for the phenomenon of illness and influence patients' beliefs around illness and suffering [47]. Culture also plays a role in the expression of suffering, with many cultures being reluctant to complain of symptoms such as pain or depression as they may be seen as signs of weakness [47]. South Asian patients often described experiencing symptoms with a greater severity than other cultures [20]. Some cultures are not comfortable with frank, direct styles of communication and therefore may not express suffering overtly as this may be seen as inappropriate. In these cases, emotional containment does not mean a lack of suffering.

Routine screening for symptoms helps to refocus care to a more patient-centered model. These assessments not only identify the presence of symptoms but also provide the opportunity for difficult discussions about appropriate supportive care options. Listening to the patient validates the significance of their symptoms and their suffering, and is an important part of the therapeutic intervention. Patients with CKD have voiced a desire for greater dialogue with their providers around symptoms, noting that such acknowledgement and engagement might improve the symptom experience [22]. The potential benefits to integrating routine symptom management are outlined further in Table 52.2.

Table 52.2 Potential benefits of integrating routine symptom screening.

Identifies and reduces symptoms, minimizes disability, and improves QOL
Encourages patient and caregiver engagement
Acknowledging symptoms and their impact on the patient's life is an important part of the therapeutic intervention and may have health benefits in itself
Increased patient satisfaction by acknowledging and validating their suffering
A "communication" tool that assists clinicians in providing individualized, patient-centered care by aligning care with what matters most to a patient
Provides data to evaluate clinical practices and policies
Allows for assessing and comparing the quality of care providers and clinics
Considers and evaluates patient-reported outcomes such as symptoms increases public accountability of health services and healthcare professionals

Symptom Screening and Assessment Tools

Many global symptom screening and assessment tools of varying length and utility have been used in CKD. Most experience with tools comes from research studies rather than clinical implementation. For clinical utility it is important that tools be short and simple to minimize patient and staff burden. They must also be appropriate for use in high-risk patients such as those who are frail and those with cognitive impairment. Lastly, the tool should be relevant to patients with CKD, reliable, valid, and sensitive to change.

Broadly, symptom assessments can be characterized as either one-dimensional vs. multidimensional or disease specific vs. generic. One-dimensional tools such as rating symptom severity are useful for symptom screening given their simplicity. This allows for routine and regular use. A good example would be the Edmonton Symptom Assessment System – revised: Renal (ESAS-r:R) as seen in Figure 52.2. However, once a symptom is recognized, several core domains should be assessed: intensity, impact on function, and impact on QOL. This may mean better understanding the frequency and level of distress or intrusiveness of the symptom. This requires careful communication with the patient that can be facilitated by a multidimensional symptom assessment tool. Disease-specific tools are tailored to the symptoms and concerns of a specific condition. Generic tools consider general symptoms or concerns that are common to many conditions. Often both types are used, the former having greater face validity and credibility, the latter allowing comparisons across conditions.

Several global symptom screening and assessment tools have been used for patients with CKD. These instruments vary in the types of symptoms assessed: either mental or physical symptoms or both, the number of symptoms included, and the time period over which the symptoms were experienced. These differences make a comparison between studies difficult.

Evidence for validity or reliability is limited for several of them. Table 52.3 outlines recommendations for tools that can be used in routine clinical care and for clinical studies with patients with CKD.

The instruments typically used to screen for symptoms are one-dimensional, focusing on the presence and severity of symptoms. Most are disease-specific. They were originally developed for palliative cancer patients and were subsequently adapted for use with patients with CKD, ensuring the inclusion of relevant symptoms such as problems sleeping, pruritus, and restless legs. Several formats have been used: visual analogue scales (VAS), numerical rating scales (NRS), and Likert scales, often referred to as verbal rating scales (VRS). A VAS consists of a horizontal line, usually 10 cm (or 100 mm) in length, that is anchored with verbal descriptors. A NRS is a segmented version of the VAS in which a respondent selects a whole number that best reflects the intensity of the relevant symptom. Likert scales ask respondents to select the verbal descriptor that best reflects their symptom severity. Patients may interpret different formats differently, which limits the ability to compare findings across populations. Examples of the different severity formats are outlined in Figure 52.3. For some symptoms, such as pain, a 0–100 mm VAS or a 0–10 NRS is advised based on extensive literature around what constitutes clinically important differences in pain intensity. Consensus from the Initiative on Methods, Measurement, and Pain Assessment in Clinical Trials (IMMPACT) was to recommend using a 0–10 NRS in pain studies [58].

Assessment tools specific to individual symptoms have been developed and are discussed in Chapters 72–77. Several self-report QOL measures have been used for patients with CKD and these include multidimensional assessments for physical and emotional symptoms. They also address issues such as burden of disease and effects on daily life, quality of social interactions and social support, and patient satisfaction. Unfortunately, they are more burdensome and are difficult to integrate into routine clinical care in a manner that is responsive to an individual patient at any given clinical encounter. To fully integrate symptom assessments into routine care, simple tools that can be interpreted and completed easily by patients, caregivers, and staff are required [59, 60].

General Approach to the Management of Symptoms

Evidence-based interventions for specific symptoms are discussed in detail in Chapters 72–77. It is important, however, to understand a general approach to symptom management. Key elements to this approach are outlined in Table 52.4. The aim of treatment is to ameliorate symptoms that are burdensome and adversely impact the patient's QOL, as it is not always necessary or possible to resolve them completely. It is important to acknowledge this and negotiate with the patient an acceptable level of symptom control. While there may be variability between patients, there is good evidence in pain research to suggest that targeting a final pain state of less than 33/100 mm on a VAS or 3/10 on a NRS or a change in pain intensity of at least 30% (moderate benefit) or 50% (substantial benefit) will deliver worthwhile QOL benefits [61, 62]. Evidence for

other symptoms is not as robust but may follow a similar pattern.

Given the synergistic and interrelated nature of symptoms experienced in advanced CKD, an approach to care that addresses overall symptom burden is likely to improve QOL even if each individual symptom has not resolved completely. A single symptom may be the root cause for several symptoms and identifying this root cause can help focus therapy. For example, a moderate reduction in pain may be sufficient to improve sleep, improve mood, and increase active coping strategies, resulting in a meaningful improvement in function and QOL. When restless legs or pruritus is recognized and well-managed, other symptoms may improve, such as quality of sleep, depression, and fatigue.

A general stepwise approach to symptom management is strongly advised and involves (i) ruling out contributing

Table 52.3 Global symptom screening and assessment tools for use in patients with CKD.

Symptom assessment tool	Description	Recommended uses
Edmonton Symptom Assessment System – revised: Renal (ESAS-r:R) [3, 8, 48]	• A self-report tool that assesses the prevalence and severity of 13 symptoms using VAS with a superimposed 0–10 NRS for pain, activity, nausea, depression, anxiety, drowsiness, appetite, wellbeing, shortness of breath, pruritus, sleep, and restless legs. The tool provides an opportunity for other symptoms to be added by patients. • The scale for each symptom is anchored by the words "no" and "severe" at 0 and 10, respectively. • The sum of all scores make up the overall symptom distress score ranging from 0 to 130, with higher scores indicating greater symptom severity. • A caregiver can complete several of the items if the patient is too ill to participate in the evaluation. • This instrument is depicted in Figure 52.2	This tool is freely accessible [48]. It has strong evidence for validity. It is short, practical, and can be rapidly and repeatedly completed by patients and therefore incorporated easily into routine clinical care, even for patients who are preterminal. The ESAS-r:R has been translated into several languages. A further advantage is that caregivers can provide validated information in situations where patients become too ill to report their problems.
Palliative Care Outcome Scale – Renal (POS-renal) [49, 50]	• A self-report tool that assesses 17 symptoms: pain, shortness of breath, weakness or lack of energy, nausea, vomiting, poor appetite, constipation, mouth problems, drowsiness, poor mobility, itching, difficulty sleeping, restless legs or difficulty keeping legs still, anxiety, depression, changes in skin, and diarrhea. • Symptoms are rated in terms of their impact on the patient over the last week from 0 (not at all) to 4 (overwhelmingly). • There are also additional questions covering carer anxiety, practical issues, and optional items for any other concerns. These include items such as "family/friends anxious about you," "able to share with family/friends," "as much information as you wanted," "practical problems addressed," and "time wasted on appointments." • There is a patient and staff version. The patient version was recently validated against the ESAS-r:R and the KDQOL-SF v. 1.3 [51].	This symptom screening tool is longer than the ESAS-r:R but is still simple to use and can be incorporated relatively easily into routine clinical care, even for patients who are preterminal. It has been translated into several languages. A further advantage is that the staff version may be helpful in situations where patients become too ill to report their problems.
Dialysis symptom index (DSI) [52]	• A self-report tool that assesses the prevalence and severity of 30 symptoms: constipation, nausea, vomiting, diarrhea, decreased appetite, muscle cramps, leg swelling, shortness of breath, light-headedness, restless legs, numbness, feeling tired, cough, dry mouth, bone or joint pain, chest pain, headache, muscle soreness, difficulty concentrating, dry skin, itching, worrying, nervousness, trouble falling asleep or staying asleep, feeling irritable, sad or anxious, decreased interest in sex, and difficulty becoming sexually aroused. • Symptoms are rated from 1 (not at all bothered) to 5 (very much bothered). • Total score ranges from 0 to 150, with higher scores indicating greater symptom severity.	The tool is easy to use. Respondent burden is slightly greater than for ESAS-r:R but similar to POS-renal and less than the multidimensional HRQOL tools that incorporate symptom assessments. There is limited experience with it being incorporated into routine clinical care for symptom screening.
Physical symptom distress scale (PSDS) [53]	• A self-report tool that assesses the prevalence and severity of 16 symptoms: numbness or tingling, impaired visual ability, swelling in feet, stiffness of joints, constipation or diarrhea, dizziness, headache, pain, and muscle cramps. • Patients rate severity on a four-point Likert scale: 0 = not bothered at all, 4 = extremely bothered.	There is limited experience with this screening tool or evidence for validity. There is some redundancy with respect to items pertaining to pain. However, it appears practical and simple enough to incorporate into routine clinical care.

Table 52.3 (Continued)

Symptom assessment tool	Description	Recommended uses
The CKD Symptom Burden Index (CKD-SBI) [54] see Supplemental Material 1	• This tool is a modification of the DSI. It is a self-report instrument that assesses the prevalence, distress, severity, and frequency of 32 symptoms and provides an opportunity for other symptoms to be added by participants. • The prevalence scale assesses the presence or absence of symptoms (Yes/No). • The other symptom dimensions are rated on a 0–10 NRS anchored by descriptors. For example, patients rate distress from none to very much; severity from none to very severe and frequency from never to constant. • The total score for each of these domains ranges from 0 to 320. Higher scores indicate greater symptom distress, severity, and frequency. • To calculate the total symptom burden score, all subscale scores (prevalence, distress, severity, and frequency) are summed and then multiplied by 0.1008 to report the total score out of 100.	This tool has the advantage of evaluating several dimensions of symptoms rather than just prevalence and severity. This may make it of interest to researchers looking to further explore symptom experience. However, it was developed and used in a relatively young and educated CKD 4–5 patient population. It has yet to be validated externally. Its relatively complexity makes it less likely to be clinically useful, especially for frail or cognitively compromised patients.
Leicester Uraemic Symptom Score (LUSS) [55]	• A self-report multidimensional tool that assesses the frequency and intrusiveness of 11 symptoms: itching, sleep disturbance, loss of appetite, excessive tiredness, pain in bones/joints, poor concentration/mental alertness, impotence/lack of sex drive, loss of muscle strength/power, shortness of breath, muscle spasm/stiffness, and restless legs. Space is given for patients to write and rate any additional symptoms. • Frequency is assessed using the following response options: "Never," "Less than once a week," "1–2 times a week," "Several times a week," and "Every day," scored from 0 to 4. • Intrusiveness is assessed with options of "Not applicable," "Not at all intrusive," "Slightly intrusive," "Quite intrusive," "Very intrusive," and "Extremely intrusive," scored from 0 to 5.	There is very little experience with the LUSS or evidence for validity. However, it appeared sensitive to change in CKD patients not on RRT during an exercise intervention study [55].
Kidney Dialysis Quality of Life-Short Form/SF-36 (KDQOL-SF) [56]	• A self-reported 36-item HRQL measure developed for CKD patients as a less burdensome version of the longer KDQOL questionnaire. • The tool focuses on three dimensions: (i) symptoms and problems, (ii) burden of kidney disease, and (iii) effects of kidney disease. • It includes two summary QOL scales, the physical (PCS) and mental (MCS) health summary scales, that are derived from the generic QOL tool - the Short-Form-12 (SF-12). • Scores range from 0 to 100 for each dimension with higher scores indicating better QOL.	Takes approximately 30 min to complete in healthier individuals but typically requires interviewer assistance and more time in elderly, frail patients. It provides comprehensive QOL information but is more suited to a research environment where dedicated staff can help with the administration and complex scoring. Not suitable for regular, routine screening and assessment or use in patients who are preterminal.
CHOICE Health Experience Questionnaire (CHEQ) [57]	• Self-reported 83-item QOL tool that was designed to complement the generic SF-36 (in a fashion similar to the KDQOL). • It incorporates an assessment of symptoms as 1 of 13 dimensions: (i) freedom, (ii) travel restrictions, (iii) cognitive functioning, (iv) financial, (v) restrictions on diet and fluids, (vi) recreation, (vii) work, (viii) body image, (ix) symptoms, (x) sleep, (xi) sexual functioning, (xii) access-related problems, and (xiii) QOL. • Scores range from 0 to 100, with higher scores indicating better QOL.	Requires approximately 30 min to complete in healthier individuals but typically requires interviewer assistance and takes longer in elderly, frail patients. It provides comprehensive HRQL information but is more suited to a research environment where dedicated staff can help with the administration and complex scoring. Not suitable for regular, routine screening, and assessment or use in patients who are preterminal.

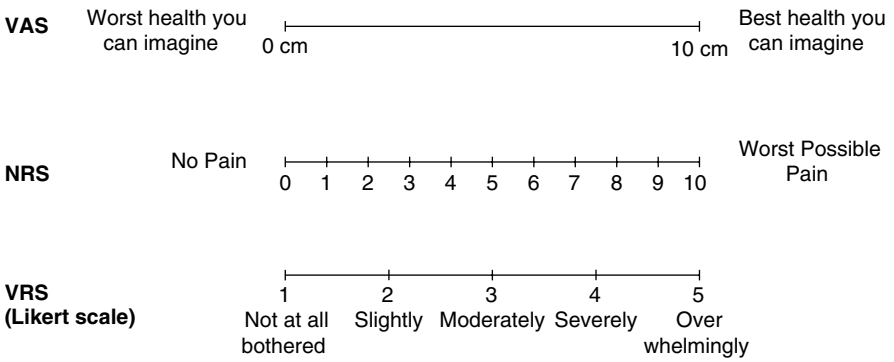

Figure 52.3 Examples of different formats for assessing symptom severity.

Table 52.4 Fundamental aspects of symptom management.

The symptom experience is subjective and multifactorial in nature. Factors including gender, ethnicity, age, and disease severity may contribute to reported symptomatology.
• **Acknowledge the symptom and validate the patient's suffering, as this is an important part of the therapeutic intervention.**
The aim of treatment is to ameliorate symptoms that are burdensome and impact negatively on the patient's QOL. It is not always necessary or possible to resolve them completely.
• **Negotiate with the patient an acceptable level of symptom control.**
Many symptoms are synergistic and interrelated, and not all symptoms will need to be addressed independently.
• **Determine if one symptom is likely the root cause of other symptoms to help focus therapy.**
Use a three-step approach to symptom management.
1) **Rule out and address contributing factors.**
2) **Maximize the use of nonpharmacological interventions.**
3) **Consider pharmacological interventions if symptoms continue to impact adversely on the patient's QOL.**

factors, (ii) maximizing the use of nonpharmacological interventions, and finally (iii) considering pharmacological interventions if symptoms continue to impact adversely the patient's QOL. Nonpharmacologic therapies have become a vital part of symptom management. They may be used successfully as stand-alone therapies but are also often required to augment pharmacologic treatment to achieve adequate relief (i.e. multimodal therapy). This approach not only maximizes health outcomes, including patient safety, but also aligns with most patients' treatment preferences. Some patients express frustration with taking multiple medications and realize that medication is not always the best strategy [22]. Many are interested in nonpharmacological approaches to relieve symptom burden. Optimal patient outcomes often require multiple approaches utilized in concert, coordinated via a multidisciplinary team.

Conclusion

Symptom screening, assessment, and management should be integrated into routine nephrology care for all patients with CKD to improve patient wellbeing and QOL. This is consistent with KDIGO recommendations that state "Symptom assessment and management is an integral component of quality care for patients with advanced CKD. Regular global symptom screening using validated tools such as the ESAS-r:R and POS-renal should be incorporated into routine clinical practice." As the number of patients with CKD rises, it will become increasingly important to direct patient care services and research toward symptom management. There is a critical need for innovation in this area: better insight into the pathophysiological processes is required to inform clinical management and improve patient QOL.

Prognostication in Advanced Chronic Kidney Disease

Katharine L. Cheung[1] *and Cecile Couchoud*[2]

[1] *Division of Nephrology, Department of Medicine, The University of Vermont, Burlington, USA*
[2] *REIN Registry Department, Agence de la biomédecine, Saint Denis – La Plaine, France*

Introduction

Prognostication is a critical component of the care of patients with advanced chronic kidney disease (CKD). Maintenance dialysis in patients with end-stage kidney disease (ESKD) can prolong life and may ameliorate uremic symptoms, and yet annual mortality remains close to 17% [1] and many continue to suffer a high symptom burden even on dialysis [2]. The decision to commence dialysis is complex and relies on patient preferences and past experiences, the nephrologist–patient relationship as well as regional and cultural factors. Ideally, conversations about whether to start dialysis occur in the outpatient setting, with sufficient education and involvement of family. Yet a third of patients begin dialysis with little or no pre-ESKD care, thus without the opportunity for optimal planning [1]. Since dialysis requires frequent procedures that disrupt daily routines, often including travel to appointments, the impact of dialysis extends beyond the patient to the family and caregivers. Discussion of dialysis initiation ought to include a weighing of the burden of dialysis against time gained and other benefits to dialysis. These efforts would be consistent with society guidelines and recommendations to include prognosis sharing in decision-making [3, 4]. Key to this discussion is the prognosis of the patient with and without dialysis. While we lack randomized clinical trials on life expectancy with comprehensive conservative kidney management compared to dialysis with supportive care, observational studies suggest that, in older adults, time gained by choosing dialysis is divided into time spent receiving treatment or in hospital, with a smaller fraction of time at home [5]. Prognosis of patients' quality of life and functional status with and without dialysis would be of value to patients yet even less data is available in this area.

Goals of Prognostication

Prognosis is the likely course of the disease and its impact. In discussing prognosis with patients, the outcome of interest is often survival. This chapter focuses on prognostication with short-term mortality as the goal, given the context of kidney supportive care. Clinicians, patients, and families may also be interested in prognostication of functional status, symptom burden, quality of life, hospitalizations, place of death, and capabilities [6–8].

The immediate goal of prognostication is to share information with the patient and family. Only once the patient is aware of their prognosis can they adequately plan for their future and make decisions. In this way, discussing prognosis may assist the clinician and patient in shared decision-making. In certain circumstances, some patients may defer disclosure of prognosis to family or caregivers, who ultimately will benefit from sharing of prognosis. Prognosis sharing may help patients and families prepare and accept the disease trajectory. This in turn may facilitate planning and empowerment of treatment decisions. Therefore, prognostication has a role in shared decision-making such that it can reduce regret or discordant treatment plans. Prognostication must recur as the status of the patient shifts with accumulation of deficits such as in frailty or following intercurrent illness or hospitalization to provide opportunities for amending the care plan (Figure 53.1).

Prognostication may also improve identification of high-risk patients and thus facilitate access to kidney supportive care and comprehensive conservative care for these patients and, if appropriate, the discussion of withdrawal of dialysis and the organization of a timely transition to hospice [8].

Patients' Preferences on Prognostication

Evidence suggests patients with ESKD wish to receive prognostic information from their nephrologist unprompted [9, 10]. In a Canadian study of 584 CKD and ESKD patients, the vast majority (90.6%) reported it was somewhat or extremely important to be informed about prognosis. Patients in this study overwhelming wanted detailed information about their medical condition and knowledge of treatment options, including withdrawal from dialysis. They also wanted to be prepared and able to plan ahead in the case of death. Yet, in this sample, only 5.6% rated being well informed about their condition [9]. In a qualitative study of US hemodialysis (HD) patients, only 10% reported discussing prognosis and 13% reported discussing end of life with nephrologists, but 80% expressed an interest in having end-of-life discussions [11]. A study of Canadian nephrologists found less than half reported always or often discussing estimated survival in patients who had ESKD [12]. Prognostic information must be presented in the appropriate context. [13] In a qualitative study of US patients, patients reported feeling "shut-down" by nephrologists when they asked about the implications of dialysis for their quality of life and prognosis [11]. In the absence of receiving prognostic information, patients use their own sense of prognosis to inform their decisions. In a US hemodialysis study of 207 patients, none reported receiving prognostic information from their nephrologist. Among these patients, those who felt they had a greater than 90% chance of being alive at 1 year were significantly more likely to prefer life-prolonging measures [11–13]. In summary, patients use prognostic information to make decisions and poor communication about prognosis may lead to difficulty in the patient–physician relationship. Thus, an additional benefit of prognostication may be that truth-telling is an opportunity to build rapport with patients.

Understanding Prognostic Models

Several prognostic models exist to predict short-term mortality in patients receiving dialysis. To identify the most appropriate model to use, it is important to determine the applicability to the desired population. An astute user of prognostic models will want to understand the population from which the model was derived. Did the model include only elderly patients or not? Was the model based on registry data, which might only include patients referred to a nephrologist or a population-based database, which might include all patients in a particular region? Did the model include incident dialysis patients, for whom the decision had already been made that they were appropriate for dialysis, or incident CKD 5 patients regardless of decision to initiate dialysis? Were prevalent patients included in the model? What end-point was chosen (determinants of outcome at 3 months vs. 2 years)? How was the population defined and is this applicable to your patient considering regional differences, recruitment policy, and cultural context?

Prognostic models are evaluated based on discrimination and calibration, and ideally are externally validated in a population different from the one from which it was derived. The Concordance statistic (c-statistic) is a measure of discrimination that summarizes how well a prognostic model differentiates between patients who died and survived at a particular follow-up time. A value of 0.5 for the c-statistic reflects that a model is no better than flipping a coin, while a perfect model would have a c-statistic of 1.0. Calibration reflects how well the predicted probability of survival based on a prognostic model compares to the actual survival outcomes.

There are limits to the use of prognostic models in the context of kidney supportive care. First, prognostic tools should not be used as if they can predict the future course of a given patient with complete certainty, nor as means to withhold treatment. Prognostic tools are best used with an appreciation of the uncertainty of the course of ESKD, in the context of balancing of patient and family preferences with reasonable expectations. Finally, in the application of a prognostic model to a particular patient, the population from which the model was derived and the limitations of that model must be considered. Table 53.1 summarizes suggested uses and contraindicated uses for prognostic models.

Table 53.1 Use of prognostic models in kidney supportive care.

Suggested uses	Contraindicated uses
To aid in shared decision-making with patient and family	To deny a treatment
To respond to patient's request for information on prognosis	To make recommendations in a population that was not tested or validated by the model
To identify high-risk patients who may not benefit from dialysis	To irreversibly categorize a patient without appreciating the possibility of change in status
To identify high-risk patients who may benefit from early supportive care	To make decisions in isolation of clinical context
To organize heath supply by estimating needs	

Availability of the Evidence on Prognostic Models in the Context of Kidney Supportive Care

Current prognostic models for patients with ESKD typically use mortality as the outcome. Predictors of mortality are generally identified from the literature and tested for independent association with the outcome. Most prognostic models in use for ESKD include a combination of age and comorbid conditions, and occasionally information about functional status, laboratory data, clinician assessment or patient trajectory. Earlier research identified the modified Charlson Comorbidity Index was able to predict mortality [14–16], however it did not perform as well in an older cohort [17]. Age is a strong predictor of mortality and is included in several prognostic models. The relationship between age and mortality is influenced by degree of independence (Figure 53.2), such that mortality is greater at a given age if the functional status score is lower [18]. Functional status is an important independent predictor of mortality in ESKD. In the Dialysis Outcomes and Practice Patterns Study of 12 countries and 7226 hemodialysis patients, a low functional status score had more than two-fold the risk of death at 17 months follow-up compared to those with who were functionally independent [18]. Table 53.2 summarizes current prognostic models for ESKD, including scores and multivariable models. Several models are derived from incident dialysis patients in registry data and a few focused specifically on elderly patients. Overall, the discrimination of these models is fair. External validation is limited to a small number of models and generally demonstrates a lower discrimination than the original cohort.

Some prognosis tools were developed in patients with CKD not yet on renal replacement therapy. They often focused on middle-term outcome (2–4 years) or an earlier stage of CKD, which is outside of our scope. One recent tool was developed for a population with severely decreased glomerular filtration rate [29].

Reasons for low or fair discrimination among current prognostic models are multifactorial. External validation performed retrospectively may have relied on operationalized predictors for available data, diminishing the strength of association of those variables [17]. Models derived from one country may not be applicable to another if practice patterns that differ among countries also associate with mortality and are not included in the model. Other tools did not perform well in external cohorts possibly because the external validation included some of the original cohort, which might have falsely elevated the discrimination of the original cohort [25]. The overall low performance of current models may also be due to failure to capture the illness trajectory by using only one time point.

Table 53.2 Comparison of prognostic tools for short-term mortality in ESKD.

Source	Type	Population	Sample	Outcome and follow-up time	Predictors in the score/model (weighted points in score)	Characteristics
Canada [19]	Retrospective	Population based; incident dialysis patients from 2003 to 2012	2199 adults age ≥65 years	17% died at 6 months	6-month score: age ≥80 (2), eGFR (1–3), hospitalization in prior 6 months (2), atrial fibrillation (2), chronic heart failure (2), metastatic cancer (3), lymphoma (5)	Validation cohort c-statistic was 0.72 Good calibration No external validation cohort
France [20]	Retrospective	Registry of all treated ESRD patients; incident dialysis patients from 2002 to 2006	2500 adults age ≥75 years in development cohort; 1642 similar adults in validation cohort	19% died at 6 months	6-month score: low body mass index (BMI) (2), diabetes (1), congestive heart failure stage III–IV (2), peripheral vascular disease (PVD) stage III–IV (2), dysrhythmia (1), active malignancy (1), severe behavioral disorder (2), impaired mobility (3), unplanned dialysis (2)	Validation cohort c-statistic was 0.70 External validation exists on adapted criteria: US <0.70 [17], Spain 0.68 [21]
France [22]	Retrospective	Registry of all treated ESRD patients; incident dialysis patients from 2005 to 2012	12 500 adults ≥75 years in development cohort; 11 848 in validation cohort	10.5% died at 3 months	3-month score: male gender (1); age (0–3); congestive heart failure (2–4); severe PVD (1); dysrhythmia (1); severe behavioral disorders (2); active malignancy (2); serum albumin (2–5); impaired mobility (4–9)	Validation cohort c-statistic was 0.75. Validation in a more recent cohort: c-statistic 0.79. External validation exists: Belgium cohort: c-statistic 0.74 [23]
United States [24]	Retrospective	Registry of treated ESRD; incident dialysis patients from 2009 to 2010	52 796 adults age ≥67 years in development cohort; 16 645 similar adults in validation cohort	12% died at 3 months; 20.3% died at 6 months	6-month score: age (0–3 points), low albumin level (1), assistance with daily living (1), nursing home residence (1), cancer (1), heart failure (1), hospitalization (1)	Validation cohort c-statistic was 0.69–0.72
United States [25]	Prospective	Prevalent dialysis patients from Fresenius dialysis units from 2006 to 2008	512 adults in development cohort; 514 adults in validation cohort	24% died at 6 months	6-month multivariable model: surprise question (not surprised if patient died in 6 months), serum albumin, age, peripheral vascular disease, dementia	Validation cohort (included some derivation cohort participants): c-statistic 0.80 External validation (Canadian cohort c-statistic 0.70 but poor calibration) [26]
Finland [27]	Retrospective	Registry of treated ESRD; incident dialysis patients from 2000 to 2008 for development and 2009–2012 for validation cohort	4 335 adults ≥18 years in development cohort; 1 768 in validation cohort	13.8% died at 1 year and 24.9% died at 2 years in development cohort 11.1% and 21.2% died at 1 and 2 years in validation cohort	1-year multivariable model: phosphorus, C-reactive protein (CRP), heart failure, peripheral vascular disease, age at start of renal replacement therapy (RRT), ESKD diagnosis, serum albumin	Validation cohort (2009–2012 registry data) c-statistic: 0.74 Suboptimal calibration with overestimating death risks in the validation group
Europe [28]	Retrospective	AROii database and DOPPS III were used for development and validation cohorts, respectively	11 508 incident hemodialysis patients in development cohort; 10 615 in validation cohort Mean age 64 years	10.9% and 9.4% died at 1 and 2 years	1-year score: calcium (0–3), creatinine (0–2), serum albumin (0–3), CRP (0–5), ferritin (−1 to 1), hemoglobin (−1 to 2), actual blood flow (−1 to 1), vascular access (0–2), BMI (−1 to 2), CV history (0–2), cancer history (0–4), age (−5 to 6 points)	Validated externally using DOPPS data c-statistic 0.71

Other variables that are not easily identified retrospectively, such as functional status, could improve discrimination [8, 17].

There is a need for prognostic information about the quality of their life and other patient-related outcomes in advanced kidney disease, however little data exists outside of prognostic models for mortality. A Dutch study of 80 dialysis patients created a risk score including a high case complexity score (INTERMED), age, and diabetes [30]. The INTERMED score includes biological, psychological, social, and healthcare domains to produce a score indicating the degree of care needs. Although not yet externally validated, this model was able to detect patients at risk of poor physical and mental quality of life scores, as well as low 1-year survival [30].

Limitations and Future Research Directions

Challenges exist in the current prognostic models. For the clinician seeking prognostic information for patients not yet on dialysis, greater study of population-based cohorts is needed. Many of the available models have not been rigorously tested in external cohorts, and discrimination is generally only fair. Opportunities exist to study novel markers, both at baseline and over time, to determine if this can improve prognostication. Given the mediocre discriminatory power of current models, nephrologists should not use these models to define a patient's treatment options, but rather to inform the discussion of prognosis with patients. Further study is needed to define the patient-reported outcomes most appropriate for future model development, and patients should be involved in future model building to define patient-centered cut-points and to inform the practice of using and integrating these models.

Studies allowing better definition of the spectrum of changes in symptom burden, quality of life, and physical performance are expected. An US study of 32 incident patients starting dialysis found that a composite measure of symptom burden did not change with dialysis initiation [31]. A UK study of conservatively managed patients with stage 5 CKD demonstrated that while average symptom burden increases in the final months of life, individual patterns may vary, making prediction of symptom burden difficult (Figure 53.3) [32]. A Canadian study including 261 HD prevalent patients indicated that change in symptom burden is associated with change in mental and physical health composite [33]. Low functional status is an important outcome in patients receiving maintenance dialysis. For example, two systematic reviews have shown the association of geriatric impairments like frailty, malnutrition, depression or performance status with higher risk of hospitalization in ESKD [34, 35]. Among nursing home residents who initiated dialysis, 58% had died and only 13% maintained their functional status at 1-year follow-up [36]. Among stage 5 CKD patients receiving conservative kidney management in the UK, functional status was fairly stable in the year preceding death but declined in the last month [37] (Figure 53.4). In the US study of 32 incident patients, they found that though patients' self-reported physical functioning may improve following dialysis initiation, objective physical performance does not increase in parallel. In summary, the available data suggests that symptom burden in advanced CKD and ESKD is high, may not improve with dialysis, and increases with time, but interindividual variation is high. Functional status may be more stable until the final month in those receiving

conservative kidney management as opposed to dialysis, but this may depend on the functional status at time of dialysis initiation. Greater study of these patient-centered outcomes is urgently needed.

Excellent communication around prognosis sharing is critical to shared decision-making and nephrologists can enhance their comfort level in communicating prognosis through skill-based training [38, 39]. Further study of how to best disseminate communications skills to nephrologists is needed. Finally, we need greater research on the impact of using prognostic models within a health system, for example whether prognostic models can identify patients who most urgently need advance care planning or supportive care resources.

Advance Care Planning

Frank Brennan[1] and Fahad Saeed[2]

Introduction

A 75-year-old woman has end-stage kidney disease (ESKD) secondary to ischemic nephrosclerosis. She commences hemodialysis. Over time, it becomes apparent that she is developing significant cognitive impairment. The dialysis nurses struggle to deal with her behavioral problems. There is uncertainty within the family and among her clinicians as to whether to continue dialysis. No plan was made or discussed by the nephrologist while the patient was still competent to address her care in anticipation of worsening cognitive impairment. To the best knowledge of the family, the patient never expressed her wishes in the event of incompetence or clinical deterioration.

Advance care planning (ACP) is a message to the future. It is a process of discussion and planning by a competent person, addressed to their future clinicians, expressing their wishes and values in the event of becoming incompetent. Necessarily, it is highly personal. It holds the weight of law and is enforceable, except where it requests an illegal or medically unreasonable act.

The absence of ACP is silence. At the very moment where both clinicians and families struggle with medical decision-making, no one knows the expressed wishes of the patient. Apart from the patient him- or herself, any other decision-maker stands at a metaphorical distance and can, at best, only surmise the wishes of the person, but they cannot truly know. The presence of an advance care plan allows the voice of the person to be heard. That voice is significant and will, ideally, guide both the clinician and the family in acting in the best interests of the patient. Unfortunately, in the context of nephrology the opposite often occurs, where patients have not discussed end-of-life care, have not completed an advance care plan, and die receiving intensive therapies that may be inconsistent with their wishes [1, 2].

The idea of advance directives, the antecedent of ACP, was founded on two principles: the ethical principle of autonomy and the legal principle that patients should not be subject to treatment without their consent. The role of ACP has been acknowledged in nephrology for several decades [3, 4]. Nevertheless, significant deficits in understanding, uptake, and research remain. Many nephrologists do not understand the precise role and process of ACP and many feel unprepared in end-of-life decision making, including undertaking ACP [5]. Globally, the uptake of ACP by nephrologists varies considerably [6, 7]. The level of evidence for the timing, content, comprehension, acceptability, and ultimate effect of ACP on clinical outcomes in nephrology is limited (Table 54.1).

The Nomenclature of Future Care Plans

In any discussion about future care planning, language is a complicating factor. There are multiple forms of future plans for medical care. Table 54.2 summarizes the definitions of commonly used terms. These definitions are important for clear communication. The law views each term discretely in terms of objective, scope, content, and enforceability. Two main types of instruments exist: *instructional*, where the person specifies their preferences in medical care, and *proxy*, where the person nominates a surrogate decision-maker. The person may combine these approaches in one document. There are significant overlaps in these definitions. In nephrology literature, the most commonly used term is ACP.

Table 54.1 ACP for patients with ESKD: a summary of evidence and practice recommendations.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
ACP	We suggest that ACP is an integral part of kidney care	Weak	Low
	We suggest that ACP fosters hope rather than the reverse	Weak	Moderate
	We suggest that ACP of patients with ESKD leads to improved bereavement outcome for caregivers, such as reduced anxiety, depression, and post-traumatic stress disorder	Weak–moderate	Moderate
	We suggest that, as a minimum, ACP should be conducted on patients with chronic kidney disease who have a limited prognosis as evidenced by the surprise question and all patients with ESKD on conservative (nondialysis) kidney management	Weak	Low
	We suggest that nephrologists should initiate and sign off on advance care plans	Weak	Low

ACP, advance care planning; ESKD, end-stage kidney disease.

Table 54.2 The nomenclature of future planning.

Advance care plan

An advance care plan is the end result of a process of advance care planning whereby a competent person plans for future health and personal care when they are incompetent by making their values, beliefs, and preferences known.

Advance directive

An advance directive is a type of advance care plan that is written and signed by a competent adult and recognized by the law. It can record the person's preferences for future care and can appoint a substitute decision-maker to make decisions about healthcare and personal life management. It is activated when the person becomes incompetent. To be valid, an advance directive must meet the local legal requirements of that jurisdiction.

Living will

A living will is another term for an advance directive. Many jurisdictions have living will statutes.

Advance statement

The provision of a UK statute. A statement of wishes and preferences made by a competent person for future medical care in the event the person becomes incompetent.

Advance decision to refuse treatment

The provision of a UK statute. Refers to a specific refusal of treatment in a predefined future medical situation.

Healthcare proxy form

A healthcare proxy form is a legal document that allows a person to choose a surrogate decision-maker, a person to make medical decisions on their behalf when they are incompetent. In some jurisdictions the person who is authorized may be called a "proxy", in others the person may be called an "agent".

Durable power of attorney for healthcare

A competent person may nominate another individual to make healthcare decisions when the principal is incompetent. In the UK, the equivalent is the *lasting power of attorney* and in some Australian jurisdictions, an *enduring guardian*.

Physician orders for life-sustaining treatment

Physician orders for life-sustaining treatment are physician orders for seriously ill patients that guide treatment regarding cardiopulmonary resuscitation, extent of medical treatment and artificial nutrition.

Current Uptake of ACP

> *It is time to stop discussing the need for [Advance Care Planning in nephrology] and to start exploring ways to make it work. . . it is time for nephrologists to assume responsibility for this aspect of dialysis care*
>
> *Source: Holley and Davison [8].*

The uptake of completed advance care plans in patients with CKD is unknown. Studies reveal that the numbers of patients with ESKD who have completed an advance directive (AD) varies considerably, ranging from 6% to 51% [6, 9]. In a nationwide survey of renal clinicians in Australia, 62% of respondents reported that ACP was conducted in their primary workplace "never or hardly ever" or "some of the time" only. Less than one-third reported undertaking

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ACP with a majority of their patients and nearly two-thirds of the respondents felt that ACP was performed "poorly" or "very poorly" [10].

Role of ACP in Nephrology

The role of ACP in nephrology may be illustrated by the following brief case vignettes.

Case 54.1

A 79-year-old man has type II diabetes mellitus and hypertension. Over time he has worsening kidney function. Eventually, he commences dialysis. There are several complications in the first 3 months, including a struggle to come in to the dialysis center on some days, great fatigue, complications of vascular access, sepsis, and herpes zoster. Several months later he collapses at home. Physical examination reveals he has an ischemic right foot. Imaging shows an intracerebral hemorrhage. He is due to have dialysis that day. At a family conference, the nephrologist recommends stopping dialysis and providing end-of-life care. The family is divided as to whether to continue with dialysis or not. During these discussions, the following interchange occurs:

Doctor: "Does your father have an advance care plan?"

Son: "No."

Doctor: "Did he ever talk about what he would want to happen if he became very ill?"

Son: "No…in our family we wouldn't talk about those things. But doctor, did you talk about this with him?"

Doctor: "No, we never got around to it…"

Case 54.2

An 82-year-old man with ESKD is on peritoneal dialysis. He discusses future plans with his nephrologist and an advance care plan is made. Later, he has a major myocardial infarction resulting in cardiogenic shock requiring inotropes. The advance care plan guides the clinicians and family to comply with the wishes of the patient in withdrawing dialysis and inotropes, and providing end-of-life care.

These cases illustrate the utility of ACP when it has occurred and the difficulties that arise when it has not. In the general population, advance care plans have been shown to increase agreement in patient and family members about end-of-life wishes [11], reduce family distress, reduce the use of unwanted life sustaining procedures prior to death, and provide care that is more consistent with the wishes of the patient [12].

The modern epidemiology of ESKD, with its striking combination of advanced age and significant comorbidity, enhances both the relevance and utility of ACP in nephrology. In developed nations, the most prevalent age cohort of dialysis patients is the 65–84-year-old group [13]. In the United States, patients 75 years and over are the fastest growing group of dialysis patients [14]. The prevalence of comorbidities in this cohort, particularly type II diabetes mellitus and cardiovascular disease, reduces overall prognosis. Indeed, the annual mortality of dialysis patients 75 years and older is approximately 25% [13]. It is precisely this cohort that is most likely to experience a sudden, critical deterioration, at which time a completed advance care plan would be extremely useful. Dialysis patients, however, are "typically unprepared for end of life" [15].

The potential utility of advance care plans is highlighted by the common circumstances surrounding dialysis withdrawal. Approximately 15–29% of the deaths of dialysis patients occurs after a decision to withdraw from dialysis [14], yet most dialysis patients report never having had a conversation with their nephrologist about the circumstances under which they would consider withdrawal [4]. An advance care plan prompts such a discussion and gives the patient a voice in what can otherwise be a vexed decision about the scope of care of a patient with ESKD. An advance care plan permits the person to establish limits to their care and guides the clinician and family.

Authoritative Recommendations for ACP in Nephrology

Within the discipline of nephrology, there are several authoritative recommendations and guidelines on advance care plans, which are set out in Table 54.3.

Barriers to Completion of Advance Care Plans

There are many barriers to advance care plan completion. In Table 54.4 these are divided into issues for physicians, patients and families, and medical systems.

One of the enduring myths about advance care plans is that they extinguish hope. Hope is intrinsic to us as human beings. Hope is our imagined future. Davison and Simpson conducted a qualitative study with interviews of dialysis patients who had completed an advance care plan [27]. They found that providing realistic information and a discussion about the future does not destroy hope. Indeed, such discussions enhanced a sense of hope "by providing information early in the illness that focuses on the impact

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 54.3 Guidelines and recommendations for advance care planning in nephrology.

Kidney Disease: Improving Global Outcome (KDIGO) Controversies Conference on Supportive Care in CKD [16]
"The treating nephrology team should engage in advance care planning. These discussions should start early in the disease trajectory and should include discussions about health states in which patients would want to withhold or withdrawal from dialysis."
Renal Physicians Association (USA)
Clinical Practice Guidelines on Shared Decision-Making in the Appropriate Initiation of and Withdrawal from Dialysis [17]
"For dialysis patients, the interdisciplinary renal care team should encourage patient-family discussion and advance care planning and include advance care planning in the overall plan of care for each individual patient." "At a minimum, each dialysis patient should be asked to designate a legal agent. . ." "Patients with decision-making capacity should be strongly encouraged to talk to their legal agents to ensure that the legal agent knows the patient's wishes and agrees to make decisions according to these wishes." "Advance directives should be honored by dialysis centers [and] nephrologists. . . except possibly in situations in which the advance directive requests treatment contrary to the standard of care."
Australian and New Zealand Society of Nephrology (ANZSN**)**
Position Statement on Renal Supportive Care [18]
"Advance care planning should be available to all patients with CKD including ESKD on renal replacement therapy. Advance care planning is a process of patient-centered discussion, ideally involving family/significant others, to assist the patient to understand how their illness might affect them, identify their goals and establish how medical treatment might help them to achieve these."
"An Advance Care Plan is only one useful outcome from the Advance Care Planning process, the education of patient and family around prognosis and treatment options is likely to be beneficial whether or not a plan is written or the individual loses decision-making capacity at the end of life."
"Facilitating Advance Care Planning discussions requires an understanding of their purpose and communication skills that need to be taught. Advance Care Planning needs to be supported by effective systems to enable the discussions and any resulting Plans to be used to aid subsequent decision-making."
The End Stage Renal Disease Workgroup on End-of-Life Care (USA)
Recommendations to the Field [19]
This group recommended dialysis units facilitate advance care planning and that nephrology healthcare professionals "routinely invite patients to express their end-of-life care preferences in the required semi-annual short-term and annual long-term care planning meetings. . .. Encourage patients to communicate their preferences to family and to complete written advance directives."
UK Department of Health
Getting it Right: End of Life Care in Advanced Kidney Disease [20]
This document recommended that all dialysis patients be offered ACP. It stated that "ACP could take more than one discussion with a patient and that for some patients the discussion may take some time and may require revisiting at a future date. If possible involve families and carers in these discussions."

on daily life, empowering patients and enhancing relationships with staff and loved ones" [27]. When the opposite occurred ". . .unaddressed fears about the future and a lack of preparation of what lay up ahead were constant threats to hope" [27].

Threshold Issues

Prior to embarking on ACP in CKD patients, several general points should be considered. The first is that ACP would benefit all patients with complex, chronic diseases. Indeed, most older patients with CKD will die before reaching the need for dialysis or conversations around conservative kidney management (CKM). The second is issue is timing. Most countries emphasize the importance of early discussions which help to normalize the process. Other issues include the following:

Which CKD patients should commence advance care planning?

This is an open question and responses lie on a spectrum. At one end is a recommendation by the US Renal Physicians Association that ACP should be included in the overall plan of care for all chronic dialysis patients [17]. Another response is to concentrate on those patients with a limited prognosis, as evidenced by such factors as advanced age, high comorbidities, poor performance status, frailty, and the use of the surprise question ("Would you be surprised if this patient died in the next year?"). The argument for a focus on this cohort is that they are more likely to present with major sentinel events where an advance care plan would be very useful. The other cohort of patients who will uniformly benefit from an advance care plan are those on a conservative, nondialysis pathway, i.e. CKM [30].

Table 54.4 Barriers to ACP in nephrology.

Physician barriers[a]
• Lack of training in these discussions [5, 21]
• Discomfort in discussing resuscitation [22]
• Time constraints [21]
• Uncertainty as when to raise a discussion about future plans [23]
• Lack of understanding of what palliative care/a palliative or supportive care approach would involve [24]
• Belief that an ACP discussion will destroy hope [21]
• Uncertainty about the law [25, 26]
• Belief that patients/families do not want these discussions [24]
• Thought to be too emotionally draining
Patient and family barriers
• Inadequate understanding of ACP [21]
• Belief that it is the nephrologist's responsibility to raise the subject [27]
• Perception that advance care plans are a mechanism to permit premature medical abandonment or precipitate death [28]
• Reluctance to think about or discuss death
• View that advance care plans are unnecessary because one's family "will know what to do when the time comes"
• Belief that wishes contained in an advance care plan will not be followed
• May not be aware of the serious nature of their illness
System barriers
• Inadequate resources and financial support for training and administration [10]
• Incomplete distribution of advance care plan to all clinicians

[a] This table is based, in part, on similar lists devised by Davison [29] and Brown [30]. Their work is acknowledged.

The culture of the patient is also important to consider. The Western emphasis on individual choice and autonomy may not be appropriate in cultures where decisions, such as future planning, are not made by the individual but by the family as a collective [31]. In some religions it is considered inappropriate for an individual to pre-empt divine will in any future scenario.

When should an advance care plan be raised?

> *It is unacceptable to leave patients and their families dangling in the throes of a progressively debilitating disease wrought with . . . difficult medical decision making that often goes unguided by health care providers* [32].
>
> *Source: Jean Holley and Sara Davison, Nephrologists.*

The timing of an advance care plan is often an unresolved issue that sits between the nephrologist and the patient. The patient tends to wait for the subject of future planning to be raised and the nephrologist is uncertain when to raise it. This paralysis in communication leads to silence and both parties drift into an uncertain clinical future. There is "no universally accepted framework to evaluate either a patient's readiness to engage in ACP or the outcomes of ACP" [32]. Schell and Lam recommended regularly asking patients about their experience of dialysis, which may prompt an open discussion about the goals of care [33]. This basic act of courtesy and curiosity may be all that is needed to open a broader conversation.

Who should participate in these discussions?
Dialysis patients have expressed a preference that their family are present at an ACP discussion [34]. All recommendations advise including the patient, the family, and the surrogate decision-maker. This is logical and prudent. It is considered best practice that the family be aware of the person's decisions, including the detailed wishes of the patient and whom they have nominated as a surrogate decision-maker.

Which clinician(s) should initiate the process of ACP?
Ideally, nephrologists initiate this discussion [35]. Patients with CKD and their families concur [36]. That leaves open the participation of other members of the multidisciplinary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

team, including renal fellows, social workers, and nurses. As Brown stated, whatever the process or professional participation, "at the end of the day, nephrologists need to take final responsibility [for ACP] . . ." [30].

Legal Requirements

A critical issue for the preparation of a valid advance care plan is compliance with the law. There are two sources of law in relation to advance care plans. The first is statutes passed by legislatures. The second is common law (judgments of the courts). The former introduces its own complexity, as each statute may be subtly different. Nevertheless, there are some universal principles uniting both common and statutory law in relation to advance care plans. First, the law requires that the person is competent at the time of completion of an advance care plan. This implies that the nephrologist is satisfied clinically that the person had the requisite elements of competence (capacity), including understanding, retaining the information, and reasoning toward a conclusion. This is a significant point given the increasing evidence that patients with ESKD suffer cognitive impairment prior to and during dialysis [37]. The law assumes that a person was competent when they completed an advance care plan and also states that this presumption can be challenged. The second prerequisite for a valid advance care plan is that the person was not coerced at any stage in the preparation and completion of an advance care plan. Both competency and voluntariness are crucial.

ACP statutes, whether instructional or proxy in nature, vary considerably. If a statute applies in a state, province or nation, it is important that nephrologists understand the relevant local legal requirements as they prepare for and conduct ACP. For instance, some US statutes require a witness or a notary to witness a document and some statues set out precise forms to be completed. Advance care plans have legal force in most western countries. When family members of an incompetent patient have a view conflicting with the advance care plan/AD, ethics and/or legal services should be invited to assist.

When a person lacks capacity and has not nominated a surrogate decision maker, one must be designated. Many countries have laws regarding surrogacy but the rules for nominating this individual differ between countries and states.

What Are the Elements of a Good Advance Care Plan?

ACP is a slow and deliberate process that can constantly evolve with changes in the patient's life situation and preferences (Table 54.5). Important aspects of this process are as follows:

- ACP entails gathering detailed medical and personal information about a patient.
- Ideally, physicians should engage in ACP with each patient who has advanced CKD or is on dialysis. At a minimum, physicians must engage in ACP with patients who have limited life expectancy, such as those with multiple comorbidities, malnutrition, and frailty. A patient requires ACP if a physician responds "no" to the surprise question, which is "Would you be surprised if this patient dies in the next year?" [38].
- ACP can be initiated at the time of diagnosis of advanced CKD or ESKD, at a change in life situation (e.g. moving into a nursing home), at a patients' request, at the time of starting dialysis or during routine nephrology visits.
- Even in the absence of a prior relationship, empathetic communication with the patient helps in initiating ACP conversations. Indeed, embarking on the ACP process actually helps establish a good rapport and trust. Exploring patient values, preferences, fears, hopes, meaning of life, and expressions of empathy help with establishing such rapport, and assists with preparing for the ACP and delivering information according to patient's needs.
- Using emotional ques and direct questions, a physician should assess a patient's readiness to engage in ACP. Barriers to readiness may include personal beliefs, fatalism, and cultural beliefs. For example, in some Asian cultures it is a bad omen to talk about death. In South-East Asian cultures, it is normal to discuss prognostic information with families instead of patients. In Western cultures, it is considered ethical to seek permission from the patient and then discuss prognosis with families, with or without the patient [39].

Table 54.5 Elements of ACP.

1) ACP *can be* initiated at any time in a patient with CKD but *must be* completed in patients with a limited prognosis.
2) A nephrologist should gather medical and personal information (preferences, values, goals, etc.) for each patient undertaking ACP.
3) Use of excellent communication skills with expressions of empathy can help build trust and rapport with the patient.
4) Family members should be involved in the ACP process.
5) An ideal healthcare proxy is a person who can honor the patient's wishes when (s)he is unable to make decisions.
6) A shared decision- making model should be implemented while making end-of-life or dialysis initiation/withdrawal decisions.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

- It is good practice to involve family members, especially the likely healthcare proxy, in ACP decisions. This process can be emotionally meaningful for families [40]. Knowing a patient's wishes may help family members follow the patient's preferences about treatments such as dialysis should the patient not be competent to make decisions for himself or herself. Clinicians should clarify that the healthcare proxy understands and will be able to honor the patient's wishes. If these decisions are too burdensome or confusing for a nominated proxy, patients should be encouraged to designate someone else who is better able to handle decisions.
- Components of ACP that relate to life-sustaining treatments, such as dialysis, cardiopulmonary resuscitation (CPR), use of feeding tubes, and intubation, should include discussions about survival and quality of life. Several tools exist to guide such information: the Charlson comorbidity score [41], the prognostic model developed by Cohen et al. [42], the French Rein registry questionnaire [43], performances status [44], and the surprise question [38]. These prognostic tools are discussed further in Chapter 53.
- Decisions about CPR should be well informed. Large-scale studies have shown that most patients die during the same hospitalization after receiving CPR. Outcomes for older patients with CKD are particularly poor. In a large US-based study, the median survival after CPR was less than 5 months and the majority of the survivors were discharged to nursing homes [45, 46].

In ACP, it is ethically acceptable to make a recommendation based on the patient's life goals and then involve the patient in decision making, using appropriate communication skills. The decision should be documented in medical charts and other forms of documentation, such a living will, Ads, and healthcare proxy forms. A living will offers a detailed documentation of the patient's wishes, while ADs state end-of-life preferences more briefly [47].

What Evidence is there for the Effectiveness of ACP as an Intervention?

In the general population, ACP provides several benefits to patients and families. Completion of an advance care plan can result in improved quality of end-of-life care, fewer hospitalizations, less use of life-sustaining treatments, increased use of palliative care, hospice care, and death at the patient's preferred location [48, 49].

A limited number of ACP interventions have been studied in CKD patients. A pilot study of 27 seriously ill patients, including 10 patients receiving dialysis, showed that an hour-long patient-centered ACP interview reduced decisional conflict and enhanced satisfaction with ACP-related decisions [50]. When the same ACP intervention was studied in a larger number of patients with congestive heart failure and ESKD ($n = 313$ with 134 patients on dialysis), the results were similar between the ACP intervention and control groups for receipt of end-of-life care according to patients' preferences [51]. Another ACP intervention was the Sharing Patient's Illness Representations to Increase Trust (SPIRIT) intervention, a two-visit psychoeducational intervention that taught patients about their prognosis and clarified their wishes. This intervention resulted in enhanced patient-surrogate agreement on decisions and higher confidence of the surrogate decision maker in making decisions [52]. As an alternative to interventions by healthcare personnel, peer mentoring on ACP by other dialysis patients was shown to increase completion of ADs and enhance the wellbeing of dialysis patients, particularly African Americans [53].

ACP strengthens a patient's relationship with his(er) loved ones and helps them prepare for the future. In one study of ESKD patients, ACP also led to improved bereavement outcomes for caregivers, with reduced anxiety, depression, and post-traumatic stress disorder. If performed with sensitivity, ACP conversations can strengthen physicians' relationships with patients and families and improve physicians' wellbeing after a patient's death [54]. For a summary of findings of the current evidence on ACP see Table 54.6.

Importance of Good Communication in ACP

Patients with CKD depend on communication with their physicians to plan for their future. A communication intervention in African American patients was shown to enhance rates of completion of ACP documents [55]. However, physicians often avoid prognostic and ACP discussions because they lack skill in conducting difficult conversations, while patients are afraid that they may disrupt their relationship with their physician by asking probing questions about prognosis and expressing their preferences. Patients typically rate prognostic conversations with clinicians as unsatisfactory [56, 57]. Meaningful conversations earlier in the illness could help avoid such misunderstandings [58].

In the United States most nephrology trainees receive no communication skills training during fellowship, which leaves them uncomfortable in conducting goals of care or end-of-life discussions [59]. Most nephrology trainees have expressed a desire to improve their communication skills [59]. Knowledge of the Renal Physicians Association guidelines for estimating and discussing prognosis is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 54.6 Summary of findings on the evidence base for ACP in nephrology.

Outcomes	Number of participants (no. of studies)	Certainty of evidence	Conclusion
Hope and ACP in CKD patients	19 (1)	Low	Advance care plans do not impair hope. Indeed, they positively enhanced a sense of the future.
ACP interventions in CKD patients	593 patients and 390 relative participants (eight studies: five RCTs, three non-RCT interventions)	Low–moderate	Evidence that ACP interventions improved: • patient's perceived quality of communication • congruence of dyad choices (enhanced patient–surrogate agreement on decisions) • confidence felt by surrogate decision-maker in making decisions • less anxiety, depression, and post-traumatic stress experienced by family in bereavement. There is insufficient evidence that ACP can influence the number of admissions and whether patient choices are ultimately followed in end-of-life care.
Preparedness of nephrologists to commence ACP	360 (1)	Low	Nephrologists were more prepared to embark on ACP if they were aware of the guidelines of the Renal Physicians Association on shared decision-making.
Comfort of nephrologists in end of life conversations	26 (1)	Low	Nephrologists were more comfortable in end-of-life conversations if they had completed workshops on communication skills.

associated with better preparedness to perform ACP [5]. Workshops on communication skills can also enhance physicians' comfort in discussing end-of-life issues [60].

Need for Further Research

We need scalable ACP interventions to enhance advance care plan completion. Targeting all stakeholders, including physicians, patients, and caregivers, may result in better chances of success with an ACP intervention. Future research is needed to study how often patients' ADs are followed near their end of life. In addition, we need research to explore what challenges nephrologists face in their communication with patients. Potentially, this may allow them to benefit from evidence-based identification of the factors associated with effective ACP conversations.

The Challenges for Nephrology in ACP

Currently, we are at an apparent impasse in conducting ACP with patients with ESKD:

- Professional bodies within nephrology have issued clear recommendations for completion of advance care plans with patients with CKD, yet uptake of ACP remains limited.
- Multiple observational studies show that many patients wish to communicate with their nephrologist about their future medical care in the event they lose capacity.
- There are known barriers to the initiation and completion of advance care plans, including absence of professional training and personal discomfort.
- There are few intervention and effectiveness studies.

The pathway through this impasse is indeed challenging. Resolution will involve a combination of three vital developments: (i) the undertaking of large, robust intervention and effect studies, (ii) an attitudinal shift by nephrologists toward a greater openness and confidence in conducting all challenging conversations, including development of ACP, and (iii) formal training of nephrologists and fellows in communication skills, including in conducting ACP. ACP should be understood in the broad context of effective and open communication with patients who have CKD regarding treatment options such as dialysis or CKM, informed consent, advance care plans, dialysis withdrawal, and end-of-life care. Education can foster this openness through formal communication training and role modeling of good communication skills by nephrologists to their trainees.

Conclusion

ACP is an essential component of care of patients with CKD. Nephrologists need to engage patients in ACP conversations and acquire the necessary communication skills to conduct such conversations. For any patient, a diagnosis of advanced CKD and/or any change in social or health conditions should serve as a trigger to initiate ACP. However, only a few randomized controlled trials have tested ACP interventions. We recommend that nephrology fellowship curricula and board certification examinations should emphasize communication skills to help nephrologists undertake a major change in ACP practice.

Introduction

The advent of dialysis transformed end-stage kidney disease (ESKD) from a universally fatal diagnosis to a chronic illness. However, the physical and psychological burdens of maintenance dialysis (e.g. for fatigue, dizziness, dialysis access-related procedures, and travel to and from dialysis) are highly prevalent, are often severe and undertreated, and correlate directly with impaired quality of life (QOL) [1–5].

These issues are disproportionately higher for older patients with ESKD or those with multimorbidity. This is a troubling reality as rates of dialysis initiation among older patients have increased by more than 50% in the United States alone and dialysis may not increase life expectancy for patients over the age of 75 years with significant comorbid conditions, particularly ischemic heart disease and dementia [6–8]. Moreover, initiation of dialysis often means that patients are committing themselves to continued intensive patterns of healthcare utilization and much of their time will be spent going to and from dialysis or in the hospital or nursing facilities [9–11].

Therefore, for a subset of the ESKD population the harms of dialysis may outweigh its benefits or prolong a state of suffering. For this subset, foregoing or stopping dialysis may be appropriate. The purpose of this chapter is to review the definition, epidemiology, content, indications, and decision-making regarding conservative kidney management (CKM) and dialysis withdrawal as treatment options for patients with ESKD.

Definitions

Defining CKM

CKM is a treatment option for patients with ESKD that, through shared decision-making and holistic patient-centered care, emphasizes QOL, active symptom management, and advance care planning but does not include dialysis (Table 55.1) [12]. The guiding principle in CKM is to align all care with the patient's preferences to achieve his or her personal goals, which typically focus on improving symptoms and enhancing QOL. While interventions to delay progression of kidney disease and manage the complications of chronic kidney disease (CKD) may still play an important role in CKM, they drive care only if they also help the patient achieve their specific goals. CKM requires highly integrated communication and care plans with tailor-made processes and interventions to address unique patient needs and unique family/community circumstances. Careful planning is necessary to link and transition patients at various points along the continuum of care such as between primary, secondary, and tertiary care, between community-based and institutional care, and between acute care and long-term care. It may require involvement of mental healthcare, social services, and specialist palliative care and hospice services. Multidisciplinary care teams are required to deliver optimal CKM. Many of these patients will live for several years following the decision for CKM so their care will require the full spectrum of kidney supportive care services, not just terminal, end-of-life care.

Table 55.1 The core components of CKM.

CKM is planned, holistic patient-centered care for patients with ESKD that includes: • shared decision-making • active symptom management • advance care planning • psychosocial and family support • cultural and spiritual domains of care • interventions to delay progression of kidney disease • interventions to minimize the risk of adverse events or complications CKM does not include dialysis.

Source: Davison et al. [12].

Defining Dialysis Withdrawal

It may appear that dialysis withdrawal is simply the stopping of dialysis prior to death. However, dialysis withdrawal has been defined variably in studies examining mortality preceded by withdrawal and none have yet been validated [13]. For example, some have defined dialysis withdrawal based on time without dialysis, such as dialysis stopped longer than 3 days (the usual interdialysis interval) before death while others have defined dialysis withdrawal as death only if signs of uremia were present because dialysis was stopped prior to death [14, 15]. Here, we consider dialysis withdrawal as the conscious decision to discontinue dialysis because its overall burden was considered too high or it was resulting in the prolongation of life with an unacceptably poor quality.

Epidemiology

The Epidemiology of CKM

Establishing the incidence and prevalence of CKM is difficult, in part because patients who do not receive dialysis are not necessarily receiving *comprehensive* CKM, which as described here includes a full range of services. Others may not initiate dialysis because their ESKD has not been diagnosed or they are receiving *choice-restricted conservative care* due to limited access to kidney replacement therapy [12]. None of these scenarios are consistent with the above definition of CKM.

The evidence on the incidence or prevalence of CKM based on national data is limited to Australia and Canada. A population-based study in Australia from 2003 to 2007 found that among patients with incident ESKD for every one that received dialysis or a transplant there was one who did not [16]. A community-based cohort study in Canada found the same [17]. However, CKM in these cohorts was defined by the presence or absence of dialysis and may not actually represent an active choice for CKM. In the United States, the national registry begins collecting information on ESKD patients at the initiation of dialysis so national estimates for CKM are unknown. One study using administrative data and in-depth chart reviews of a national cohort of patients receiving care within the Department of Veteran Affairs (the largest integrated healthcare system in the United States) between 2000 and 2009 found that only about 3% of patients (mean age 75 years) had made a decision to not pursue dialysis [18].

The Epidemiology of Dialysis Withdrawal

Estimates of how often patients opt for dialysis withdrawal are also not well understood, in part due to variable definitions of what constitutes withdrawal as noted earlier. We do know, however, that withdrawal of dialysis has increased as an official cause of death for patients with dialysis-dependent ESKD [19–21] though variation persists with regard to the rates reported worldwide [22]. Withdrawal rates in the United States and Canada may be higher than those of European counties with 8–31% and 2–7%, respectively [19, 21, 23–25].

Patient-level factors associated with higher likelihood of withdrawal include white race, female gender, and increased age, though not all studies have found a gender association [26] and one study noted an association with cerebrovascular disease [27]. Increasing rates of medical events and hospitalization in patients immediately prior to withdrawal [26] suggest that declining health and accelerated clinical morbidity are motivating factors for withdrawal. A number of system-level barriers, including financial incentives for continuing dialysis, eligibility issues with hospice, lack of outpatient systems for providing palliative care, and a lack of communication and prognostication skills of the nephrologist, have been cited as important factors driving lower rates of withdrawal [28]. These factors will be explored further in the context of decision-making discussed below.

Decision-making around CKM and Dialysis Withdrawal

It is important to emphasize that decisions for CKM, dialysis, and dialysis withdrawal should be proactive, deliberate, and directed by patient preferences and values. It must also be emphasized that neither CKM nor dialysis withdrawal mandates a cessation of care [29, 30]. Explaining treatment options to patients includes the assurance that they will

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

receive care to optimize QOL, including active symptom management and assistance with care coordination and communication with all involved healthcare providers. This will help reassure patients that receiving the treatment and care that matters most to them is of primary importance, regardless of the care pathway they choose.

Unique Aspects of Informed Consent in Patients with CKD

Informed consent and the practice of advance care planning (discussed further in Chapter 54) empowers patients, families, and physicians by aligning decisions about future treatment with patient values, wishes, and evolving clinical circumstances. Reports that patients regret having started dialysis [1], along with the high prevalence of both cognitive impairment [31] and depression [32] in patients with CKD, underscore the importance of assuring that a patient's consent is based on an informed decision. Furthermore, concerns that patients with ESKD receive life-sustaining therapies more often than patients with other terminal illnesses [2] and that many initiate dialysis by default rather than by deliberate decision point to the need for proactive discussion and a dialogue that explores patients' goals, values, and preferences for care, including end-of-life care.

The initiation of dialysis presumes that a process of communication between the patient and physician has taken place, that sufficient information has been provided that describes all the potential harms and benefits of each available treatment option, and that consent to undergo the dialysis procedure has been given. Provision of informed consent for dialysis therefore involves much more than the completion of a legal document that authorizes kidney replacement therapy or the presence of basic documentation stating that the patient accepts the risks associated with the actual dialysis procedure such as low blood pressure and pain with access cannulation. In a healthcare culture where the distinction between the opportunity to extend life and the obligation to do so is often blurred, the informed consent conversation commands attention to a number of pertinent and unique considerations (Table 55.2).

The ethical and legal elements of a valid informed consent to initiate dialysis include the requirements that a patient have decision-making capacity, that consent be voluntary, that information is provided in an understandable manner, and that the risks be presented and alternative options explored [33]. Although application to practice may differ by country, the essence of these requirements transcends geography and international differences in the provision of care.

Table 55.2 Unique aspects of informed consent for patients contemplating CKM or dialysis.

- Patients with significant comorbid illness may not live long enough to progress to the need for dialysis.
- CKM may confer a survival benefit similar to or greater than dialysis for a select group of patients.
- CKM may be preferable to dialysis in some patients for whom the anticipated burdens of dialysis are expected to detract from QOL.
- Functional and cognitive decline may occur rapidly in many older patients starting dialysis, which will impact the overall experience of dialysis.
- Patients' preferences and wishes may change as their clinical or social context evolves.

Preferences and a decision to pursue, continue or withdraw from dialysis may be dynamic, requiring ongoing discussion and the acceptance that emotional, cultural, and social contextual factors will impact the decision-making process [29, 30]. Emotions such as fear or denial may impact a patient's ability to engage in a discussion of what they might perceive is a choice between life and self-imposed death. Specific issues to address include the impact of dialysis on daily life, anticipated clinical course and prognosis, potential for changes in functional status, and alternative treatment choices such as choosing to forego dialysis altogether [12, 34, 35]. The clinical implications of this is that physicians have ethical and legal obligations to present an individualized, patient-centered approach that for some patients includes the likelihood that dialysis may increase suffering while not prolonging life [35–37].

Shared decision-making, recognized as the "pinnacle" of patient-centered care and the accepted model for medical decision-making, is a key component of informed consent and particularly relevant to patients with ESKD contemplating the initiation of renal replacement therapy (further discussed in Chapter 81) [38]. Even for older patients or those with substantial comorbidity, some may be willing to accept a high symptom burden with dialysis as well as its attendant complications based on the hope that it will extend their lives while personal preferences and values may direct others toward a conservative care pathway that does not include dialysis [39–41]. Changes in patient status must be anticipated to ensure that the informed consent process is dynamic and that contextual issues are monitored and considered as life and clinical circumstances evolve. Independent of unique circumstances, patients' preferences may also change over time [42]. Given all these factors, providing informed consent to patients with advanced CKD is complex and can be extremely challenging [43]. Patients' consent or

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. refusal for dialysis commands attention and respect, and nephrologists are well poised to take responsibility for ensuring the integrity of this process.

For Whom is CKM Most Appropriate?

The evidence around the benefits and outcomes with CKM is limited and has been well summarized in two systematic reviews [44, 45] with a more recent large Canadian study [46]. These data are observational with numerous limitations making it difficult to pool data and assess the impact of dialysis vs. CKM. These limitations have been well described [47] and include small numbers of patients receiving CKM, mostly limited to those managed by nephrologists, wide variation in the estimated glomerular filtration rate (eGFR) cutoff inclusion criteria with lead-time bias, and significant differences between patients receiving dialysis vs. CKM resulting in mortality biases. By random effects meta-analysis, patients choosing CKM are older (80.0 years vs. 71.5 years) and are less likely to be able to care independently for themselves with lower Karnofsky scores (62.8 vs. 73.0) compared to patients choosing dialysis [45]. They are also more likely to have diabetes and be women than those choosing dialysis. It is unclear how decisions for dialysis or no dialysis are made in these studies. As a result patients receiving what is termed CKM are a heterogeneous population, including at least three groups of patients whose survival will be very different. These groups include (i) patients suitable for dialysis who choose not to receive it, (ii) older people with multimorbidity who are not offered dialysis, and (iii) patients who lack capacity and may not be offered dialysis [47]. There is also a lack of standardization or clarity in reporting of the care provided for patients who are labeled as receiving CKM.

Keeping in mind these limitations, the evidence to date demonstrates a survival advantage with dialysis for most patients compared to CKM. A retrospective Canadian cohort study used linked administrative and laboratory data to identify adults ≥65 years in Alberta with two outpatient eGFR < 10 ml/min/1.73 m^2, spanning ≥90 days (2002–2012). Overall, 838 patients were identified with a mean age of 79 years, 48.6% male, and mean eGFR of 7.8 ml/min/1.73 m^2. Receiving dialysis vs. no dialysis was associated with a significantly lower risk of death for the first 3 years of follow-up (hazard ratio [HR] 0.59), but not thereafter (HR 1.22) [46]. Dialysis, however, was associated with a significantly higher risk of hospitalization (HR 1.40). This population study included all three groups of CKM patients identified above, cared for by non-nephrologists as well as nephrologists. For patients not on dialysis, the care they received is unknown and may not include the core components of CKM as previously defined.

In the nine studies that examined patients cared for by nephrologists and which performed multivariable Cox proportional hazards regression models, five showed a survival advantage for dialysis vs. CKM, although four of these five studies concluded that the survival advantage with dialysis was reduced substantially by older age and the presence of comorbidities [45]. In a meta-analysis limited to the three cohorts that included patients ≥65 years and eGFR < 15ml/min/1.73 m^2, patients choosing dialysis had a pooled adjusted hazards ratio for mortality of 0.53 ($P = 0.02$) relative to CKM, after accounting for both age and comorbidities. The survival benefit with dialysis was no longer significant when restricted to patients ≥75 years. Frail patients often experience accelerated functional and cognitive decline after starting dialysis [48, 49] and those residing in long-term care facilities at the time of starting dialysis have especially poor outcomes [49].

To summarize, while age alone is a poor predictor of survival, patients older than 75 or 80 years with functional and cognitive impairment and multimorbidity, especially heart disease, are at an increased risk for poor outcomes on dialysis with limited if any survival advantage. These are the people most likely to benefit from CKM. Patients who receive CKM spend less time in hospital [45] and are more likely to access timely palliative care services [50].

Decision Aids to Facilitate Educating Patients and Families about the Option for CKM

Although decisions to forego or stop dialysis are often difficult, few patient decision aids (PDAs) present CKM with any depth. The most comprehensive PDA currently available is the freely accessible CKM PDA from the collaborative effort of the Kidney Supportive Care Research Group (University of Alberta) and Alberta Health Services in Canada [51]. Based on state-of-the-art implementation science and patient-orientated research with high stakeholder engagement, this tool provides patients, families, and care providers with information on CKM and dialysis. It is a highly interactive, online resource that incorporates patients' values, preferences, and overall goals of care with patient-specific prognostic markers of age, functional status, comorbid conditions, cognitive function, and living circumstances to compare dialysis versus CKM [51, 52]. A similar but paper-based tool was developed by the Ottawa Hospital CKD team in Ontario, Canada. The Ottawa PDA also provides patient-specific risks and benefits in the context of the patient's personal values and is designed to be used one-on-one with a decision coach trained in decision support.

An upcoming PDA for the decision between CKM and dialysis is the OPTIONS tool from Australia. This tool will be an illustrated workbook with detailed help on making

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. care decisions around CKM, although it is unclear if it includes an individualized prognostic component similar to the above two PDAs [52].

For any PDA to be effective, clinicians must introduce the PDA to patients and families as well as have the communication skills and knowledge to facilitate decision-making. Translations into non-English languages are needed for all.

When to Consider Dialysis Withdrawal

As dialysis transforms from a therapy that is life-enhancing to one that is life-prolonging, patients as well as loved ones may see decreasing value in continuing to dialyse. Symptoms that worsen or are not alleviated as hoped may prompt some patients to request discontinuation of dialysis, believing that the burdens of dialysis are no longer worth the benefits they receive [53]. Others experience such poor QOL that they feel little or no hope for an experience that is better than status quo. Severe, unrelenting depression or loss of the will to live may constitute sufficient rationale for certain patients to withdraw [12, 34]. Withdrawal from dialysis is an appropriate treatment option for any patient in whom the burden of treatment becomes irreversibly greater than their perceived benefits.

Unfortunately patients may not discuss end-of-life issues, including wishes to withdraw from dialysis with their families. Patients may also not state independently or explicitly the extent of their suffering or their desire to consider dialysis withdrawal to their care team. Instead, they often look to their healthcare providers for guidance [1, 54], with the expectation that their provider will raise these issues when they become relevant for each individual [55]. This raises the importance of ensuring all patients and their caregivers are aware of the treatment option to withdraw if the burden of dialysis care becomes irreversibly greater than the benefits as perceived by the patient. Despite evolving knowledge of the trajectory of illness in ESKD, identifying this particular point in time can be difficult when clinical decline is subtle [56, 57]. However, when recognized and acknowledged, it may serve as an indication for considering withdrawal (Figure 55.1). Clinicians must also be vigilant for clinical cues in their communications with patients such as expressions of unrelenting suffering.

Consideration of dialysis withdrawal is also appropriate for patients who no longer have decision-making capacity and whose properly appointed agent requests dialysis discontinuation based on the patient's best interests, patients with irreversible, profound neurological impairment who lack signs of thought, sensation, purposeful behavior or awareness of self or environment, patients whose condition no longer renders them able to cooperate with the technical process of dialysis, and patients with terminal illness from nonrenal causes (where no benefit from continued dialysis is anticipated) (Table 55.3) [12, 34].

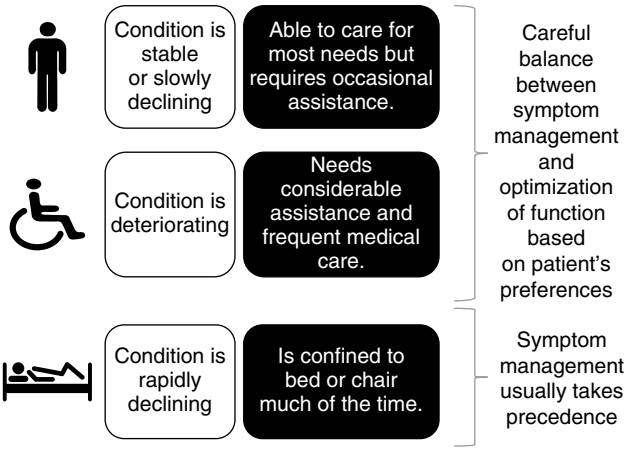

Figure 55.1 CKM should take into consideration the patient's general condition and prognosis.

Educating Patients and Families about the Option of Dialysis Withdrawal

Unfortunately no PDAs currently exist to facilitate conversations and decision-making around dialysis withdrawal. Barriers to this process include patient, family, and physician factors. If not informed, patients may be unaware of the option to withdraw or feel that their decision will be deemed unacceptable and/or unsupported by the medical team. Others may consider withdrawal spiritually unacceptable, "a sin" or an act of suicide. Others may believe that withdrawal constitutes "giving up" and/or fear that their loved ones will not accept their decision. Patients may be fearful of the dying process following withdrawal and uncertain of the care they will receive.

Table 55.3 When to consider discussing dialysis withdrawal.

- Patients in whom the burden of treatment becomes irreversibly greater than its perceived benefit
- Patients who no longer have decision-making capacity and who appear to no longer be benefitting from dialysis
- Patients with irreversible, profound neurological impairment who lack signs of thought, sensation, purposeful behavior, or awareness of self or environment
- Patients whose condition renders them unable to cooperate with dialysis
- Patients with terminal illness from nonrenal causes without anticipated benefit from continued dialysis

Sources: Davison et al. [12] and Renal Physicians Association [34].

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

These issues must be explicitly addressed, including reassurance that patients will be cared for and not abandoned. Patients and families may also differ in their motivation to stop dialysis, a scenario that further complicates the decision-making process and underscores the importance of discussing the option for dialysis withdrawal in early advance care planning conversations that include family and surrogate caregivers [30, 57].

Physicians and other healthcare providers may be reticent about instituting discussions because of uncertainty in estimating patient-specific prognosis, a lack of understanding of patients' wishes, and/or the perception that these conversations will be overly distressing to patients and destroy hope. However, patients tend to understand and accept the inherent uncertainty in predicting individualized outcomes. Moreover, proactive discussions about options for end-of-life care have been reported to reinforce trust and promote hope [58] while impacting patient choice [59, 60]. Lack of training and inexperience on the part of healthcare providers has been cited as a barrier to this conversation and some physicians may harbor an ethical opposition to dialysis withdrawal or be unwilling to communicate this option for other personal reasons [61–63].

Setting the stage for patients experiencing clinical decline requires an honest evaluation and assessment of an individual patient's current clinical status, their prognosis and potential for further decline and an acknowledgement that ongoing dialysis may further reduce the benefit–burden balance. In situations where a patient lacks decision-making capacity, the patient's designated surrogate decision-maker must understand clearly the patient's clinical situation. Without this support, patients and families may struggle with what they perceive as choosing death rather than allowing death to occur [64].

It is important to discuss the option of withdrawal at the outset of renal replacement therapy discussions in all patients, but it is particularly pertinent in those who initiate dialysis despite a poor prognosis. Key points of education for patients and families considering withdrawal of dialysis are outlined in Table 55.4. First and foremost, this includes the promise that withdrawing from dialysis will not result in abandonment and does not mean "no care." Clinicians must acknowledge the role of patients' fears and emotions, social factors, depression, and/or high symptom burden in the decision-making process and address potentially remedial factors contributing to the decision. The specifics of the dying process after withdrawal, especially with regards to potential symptoms patients may experience, how these can be treated, and a time frame, are key components of the conversation. Patients should be made aware that palliative care is available irrespective of a decision to withdraw from dialysis. Serial conversations and incremental introduction of available palliative interventions may be needed in patients who are conflicted or where reversible factors contributing to suffering are driving patient choice. Wishes for and the availability of hospice care to relieve suffering and provide support can also be discussed and may be factored into the decision. While hospice may be an appropriate consideration following withdrawal of dialysis, it may also be available for patients who remain on dialysis with an extremely limited expectation for survival.

Table 55.4 Key education points for patients and families contemplating whether to pursue, forego, or withdraw from dialysis.

- Conservative kidney management without dialysis is every patient's option and choice.
- Choosing to forego or withdraw from dialysis does not mean "no care."
- Palliative and supportive care is available irrespective of whether dialysis is chosen, continued or withdrawn.
- Hospice is an appropriate consideration for patients following withdrawal of dialysis or for patients who have chosen CKM in the terminal phase of their illness.
- Estimates of survival individualized to the patient are important to patients and families. For patients withdrawing from dialysis this should be given in days.
- Anticipatory plans for dealing with distressing symptoms are important for patients choosing CKM or deciding to withdraw from dialysis to avoid unnecessary suffering.
- Preparing for acute symptom management may pre-empt the need for heat of the moment decisions in patients contemplating their options and prevent the unnecessary use of acute care resources.

When CKM is the Chosen Treatment Option

The Illness Trajectory from the Decision for CKM through to Death

Prognostication for patients with CKD is challenging given the great variation in individual illness trajectories and accurate prognostic models are limited. This is particularly true for patients with ESKD receiving CKM. Patients are anticipated to pass through several stages, as outlined in Figure 55.1. The patient's eGFR does not necessarily predict their overall clinical picture or their survival. Patients with an eGFR of 6–15 ml/min/1.73 m^2 may experience minimal symptom burden and remain functional and stable for years, although some may have high symptom burden and/or deteriorate rapidly over a few months [44, 50]. Patients with an eGFR of ≤5 ml/min/1.73 m^2 typically have a life expectancy measured in weeks to a few months. Understanding the overall health

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

status of the patient is a better predictor of outcome and provides a more reliable guide to determining appropriate care. For patients who remain relatively stable and functional, maximizing their QOL requires a careful balance between promoting function and addressing symptom burden. For patients who spend much of their time confined to bed or have a life expectancy limited to weeks, comfort and control of symptoms generally takes precedence.

Standards for Clinical Care for Patients Receiving CKM: CKD Complications

There are minimal studies that address specifically how to optimize CKM. As a result there is great variation in how this care is both conceptualized and delivered. Most clinical guidelines for patients with advanced CKD focus on slowing the progression of CKD and minimizing morbidity and mortality. This is done through strategies such as optimizing blood pressure control, normalizing biochemical parameters, and primary prevention through the use of certain medications such as statins and angiotensin converting enzyme inhibitors or angiotensin receptor blockers. However, this is not the focus of care for most patients who have chosen CKM. Rather the aim is to optimize clinical outcomes such QOL and physical and cognitive function. To accomplish this in patients who tend to be frail, CKD clinical standards and expectations need to be adjusted. Despite a lack of robust evidence specific to CKM, recommendations were developed that integrate the existing evidence and expert opinion from nephrology, geriatric medicine, and palliative care. These recommendations are part of an integrated CKM clinical pathway that is freely accessible (www.ckmcare.com) and they have been recently published [65]. The key elements of these recommendations are outlined in Table 55.5. They reflect the priorities of comfort, QOL, and safety, ensuring that all treatment decisions align with patient's values and preferences, and are intended as a starting point toward reaching consensus and generating further evidence for optimal CKM.

Table 55.5 Recommendations for managing the progression and metabolic complications of CKD for patients receiving CKM.

Rationale for recommendations	Recommended interventions
Blood pressure (Musini VM, Muller M, Benetos A)	
The primary goal of blood pressure control in CKM is to optimize QOL by preserving physical and cognitive function, minimizing the risk of falls from hypotension or orthostatic hypotension, while avoiding very high readings that might precipitate an acute cardiovascular event. Decisions about specific medications will depend on the patient's comorbidities.	Blood pressure targets can be relaxed for *most* CKM patients to <160/90 mmHg. This applies to patients with diabetes as well. The geriatric literature suggests a target systolic blood pressure of 160–190 mmHg is reasonable for frail patients near the end of life [66]. Based on expert opinion, the lower end of this target has been identified as being appropriate for CKM.
Dyslipidemia (Benetos A, Kutner JS, Silveira MJ)	
There is no evidence that statins provide benefit in the context of significant frailty or in the last year or two of life. Statin therapy takes years to accrue benefits. Advanced age and multimorbidity are risk factors for adverse effects of statins, including myopathy and a potential link to cognitive deficits. A randomized trial of discontinuing statin therapy in patients with life-limiting illness suggested that cessation was not only safe, but it improved QOL.	Care providers, in discussion with the patient, can discontinue statins.
Sodium restriction	
Sodium intake may be associated with volume overload leading to breathlessness and symptomatic peripheral edema. Sodium restriction, however, influences palatability. Strategies should balance symptom management and the patient's enjoyment of food and nutritional status.	Diuretics and dietary sodium restriction is recommended to assist with volume control if volume overload is contributing to symptoms such as breathlessness or symptomatic peripheral edema.
Anemia (Rogers SD)	
Anemia can contribute to fatigue and breathlessness. The purpose of treating anemia would be to reduce these symptoms as opposed to reducing cardiac mortality or morbidity.	Interventions include the use of erythropoiesis stimulating agents and iron supplements. Anemia-related blood work every 3 months is appropriate but should be based on patient preference and symptoms. When a patient starts spending most of their time confined to bed or chair and/or is near the end of life, it is no longer appropriate to manage fatigue and breathlessness by addressing anemia and anemia treatment can be stopped.

(*Continued*)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 55.5 (Continued)

Rationale for recommendations	Recommended interventions
Acidosis (Kopple JD [79], Raphael KL [80])	
Metabolic acidosis can contribute to fatigue, bone loss, muscle wasting, and malnutrition. Treatment is aimed at improving these symptoms.	Oral sodium bicarbonate. It is reasonable to monitor CO_2 every 3 months if the patient is being treated or is symptomatic. If the patient finds the pill burden too great, or when the patient can no longer swallow, treatment should be stopped.
Calcium and phosphorus balance (Rayner HC 2017, Shinaberger CS, 2008)	
Current CKD guidelines aim to normalize serum calcium, phosphate, and parathyroid hormone levels to prevent bone abnormalities and vascular calcification. However, it is not clear that there are benefits to normalizing these factors in CKM patients in the last years of life. Rather, there is the possibility of harm in promoting lower protein intake in patients already at high risk for protein malnutrition [67]. The focus is on promoting and maintaining adequate nutrition, avoiding malnutrition and inflammation, and liberalizing the diet. Changes in the metabolism of calcium and phosphorus may contribute to (i) myalgias, arthralgias, and pseudogout, and (ii) restless legs syndrome. Interventions would only be promoted for possible benefit of these symptoms.	The recommendation is to focus on adequate nutrition rather than normalizing biochemistry. If elevated phosphorus levels were felt to be contributing to pain or RLS, interventions would include a phosphorus-restricted diet and the use of phosphate binders, monitoring for the impact on overall QOL, symptom burden, and nutritional status. It is reasonable to check calcium and phosphorus levels every 3 months if patients are being treated or are symptomatic. Parathyroid hormone levels do not impact decision-making for patients being cared for with CKM, therefore there is no need to monitor.
Vitamin D	
Vitamin D deficiency may play a role in the symptoms of fatigue, weakness, and muscle loss. Supplementation should only be considered if deficiency was felt to be contributing to these symptoms.	Low-dose active vitamin D (vitamin D analogue) replacement. There is no additional benefit in monitoring parathyroid hormone levels.
Hyperkalemia	
Hyperkalemia predisposes patients to cardiac arrhythmias and sudden death. Acute treatment of hyperkalemia is appropriate if consistent with the patient's goals. If the patient wishes to liberalize their potassium intake, the risks of lifting the restriction must be explained clearly.	Interventions include a potassium-restricted diet and potassium-binding resins such as patiromer. Consider sodium polystyrene sulfonate for life-threatening hyperkalemia. For those aiming to maintain normal potassium levels, it is reasonable to monitor potassium levels monthly.

Symptom Assessment and Management for Patients Receiving CKM

Only a few studies have looked at symptoms in patients receiving CKM but the symptom burden appears to be high and similar to that of patients who intend to dialyze or are receiving dialysis (this is discussed further in Chapter 52) [44]. There are even fewer studies that look specifically at the impact of a CKM program on the symptom burden of patients. An Australian kidney clinic that integrates palliative care for patients receiving CKM found that although patients who chose CKM had a worse symptom burden and physical composite SF-36 QOL scores than others at their initial clinic visit, the majority maintained or improved symptom control and QOL at 12 months [68]. In 122 CKM patients, 57% had stable or improved symptoms and 58% had stable or improved QOL. This cohort of CKM patients had a median survival of 16 months with 68 (56%) patients dying over the study period. This was in comparison to the patients who intended to dialyze, of whom only 41% had stable or improved symptoms and only 55% had stable or improved QOL.

Patients underreport symptoms unless they are assessed explicitly [69, 70]. It is therefore critical to assess patients at each clinic visit for physical and emotional symptoms using a validated tool like the Edmonton Symptom Assessment System Revised: Renal (ESAS-r: R) or the Integrated Palliative Care Outcome Scale-Renal (IPOS-Renal) (see Chapter 52 for further discussion on available tools for symptom assessment).

The aim of treatment is to ameliorate symptoms that are adversely impacting the patient's QOL as it is not always possible or necessary to resolve them. It is important that clinicians explain this to patients in order to establish realistic expectations. The goal of therapy is to relive the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

overall symptom burden to a level that is tolerable for an individual patient. Care teams also need to take into consideration the overall health and function of their patient. Earlier in the illness trajectory the relief of symptoms may be aimed at promoting social and physical functioning, and the adverse effects of pharmacologic interventions will need to be balanced carefully between symptom relief and optimal cognitive and physical wellbeing. Symptoms may be experienced in complex clusters. It may not be necessary to target all the symptoms at once. For example, restless legs may interfere with sleep and be associated with daytime somnolence, fatigue, depression, anxiety, and an overall poor QOL. When assessing the patient, attempting to understand the root cause for a patient's distress will help guide appropriate management. In the above scenario, targeting the restless legs would be anticipated to improve sleep, energy, and ultimately mood and overall QOL.

The treatments of individual symptoms are outlined in Part 12: Patient-centered care and outcomes (see Chapters 84–89). They are summarized in Table 55.6 with considerations specific for CKM and can be accessed in detail through the integrated CKM pathway [51]. All recommendations follow a similar stepped approach that starts with assessing the patient to rule out contributing reversible factors. The second step is to consider nonpharmacological interventions. Given the frailty and multimorbidity of most CKM patients, these conservative measures are important to explore to promote patient safety before moving on to the third step, which involves pharmacological interventions. Good examples are the management of nausea, vomiting, and pain due to the adverse effects of many of the commonly used agents. For example, ondansetron can be constipating and the dopamine antagonists haloperidol, metoclopramide, and olanzapine cross the blood–brain barrier and can cause extrapyramidal symptoms and exacerbate restless legs syndrome. Opioids for the management of pain and shortness of breath can be extremely constipating and may exacerbate pruritus, restless legs, and terminal agitation.

These CKM recommendations tend to avoid the use of benzodiazepines given the significant risks risk of falls, fractures, and decreased cognition in the frail and older patient. However, they could be considered for patients experiencing significant anxiety. They may also be the only option for restless legs causing distress for patients near the end of life who can no longer swallow.

Table 55.6 Management of symptoms for patients receiving CKM.

Restless legs syndrome (Gopaluni S, 2016; Giannaki CD, 2014)		
Address possible contributing factors	Nonpharmacologic	Pharmacologic
• Anemia and iron deficiency • Hyperphosphatemia • Medications such as dopamine antagonists, antidepressants, and opioids	• Abstinence from stimulants (e.g. alcohol, caffeine, and nicotine) • Mental alerting activities (e.g. puzzles or games) • Optimized sleep hygiene • Exercise	**First line:** Gabapentinoids Gabapentin 50–300 mg nightly or pregabalin 25–75 mg nightly **Second line:** Nonergot-derived dopamine agonists Ropinirole 0.25–2 mg nightly Rotigotine transdermal patch 0.5–3 mg/nightly Pramipexole 0.125–0.5 mg nightly • All these medications should be taken 2 h before sleep
Uremic pruritus (Simonsen E, 2017)		
Address possible contributing factors	Nonpharmacologic	Pharmacologic
• Anemia and iron deficiency • Other: xerosis, drug hypersensitivities, allergies, infestations, contact dermatitis, or inflammation	• Appropriate skincare and moisturizers (e.g. baths with lukewarm water, pat dry, and moisturize with aqueous emollients within 2 min; gentle soaps with no fragrances or additives) • Keep skin cool • Humid environment • Avoid scratching: maintain short, smooth fingernails, encourage gentle massage, wear gloves at night • Very little evidence exists for complimentary therapies but consider phototherapy (UVB) three times weekly for a 3-week trial or acupuncture	**Topical** • Capsaicin 0.025% or 0.03% ointment • Pramoxine 1% • Menthol/camphor/phenol: 0.3% each, either separately or in combination with each other • Gamma-linolenic acid cream 2.2% **Systemic** **First line:** Gabapentin (50–300 mg daily) 1–2 h before sleep. Similarly, pregabalin before sleep (25–75 mg) is also an option. **Second line:** Tricyclic antidepressant such as doxepin 10 mg daily at night

Table 55.6 (Continued)

Nausea and vomiting (Collis E, 2015; Murray-Brown F, 2015)		
Address possible contributing factors	Nonpharmacologic	Pharmacologic
• Metabolic disturbances • Medications, e.g. opioids, antidepressants • Gastrointestinal disturbances, e.g. constipation, delayed gastric emptying	• Manage constipation • Encourage proper oral hygiene • Smaller, more frequent meals; eat slowly • Avoid alcohol • Avoid foods that are greasy, spicy or excessively sweet • Minimize aromas, e.g. cooking odors, perfumes, smoke • Encourage relaxed, upright position after eating to facilitate digestion • Loose-fitting clothing • Consider complementary therapies, e.g. relaxation techniques, acupressure, use of ginger	Recommendations are very specific depending on patient's status but include: **First line:** Ondansetron 4–8 mg every 8 h as needed **Second line:** Metoclopramide 2.5 mg every 4 h as needed. Due to the prokinetic properties, metoclopramide would be first-line treatment for patients with nausea and vomiting due to gastroparesis. **Third line:** Olanzapine 2.5 mg every 8 h as needed OR haloperidol 0.5 mg every 8 h as needed **Fourth line:** For persistent and severe nausea, consider increasing haloperidol to 1.0 mg (maximum 5 mg in 24 h) OR replacing with methotrimeprazine 5 mg orally or 6.25 mg subcutaneously every 8 h as needed. Methotrimeprazine may also be beneficial if there is concomitant anxiety, insomnia, or neuropathic pain.
Breathlessness (Booth S,, 2011; Barnes H, 2016		
Address possible contributing factors	Nonpharmacologic	Pharmacologic
• Anxiety • Anemia • Infection • Pulmonary edema	• Sit in an upright position, e.g. 45° • Position by a window or use a fan to blow air gently across the face • Maintain a humid environment • Pursed lip breathing • Supplemental oxygen • Complementary therapies, e.g. relaxation techniques, music • Consider role of diet: fluids and sodium	• If patient is intravascularly overloaded: furosemide • Low doses of opioids, especially nearer the end of life. Due to its fast action, fentanyl works well in cases where breathlessness is predictable. For shortness of breath that is more constant or unpredictable in nature, consider low-dose hydromorphone, e.g. 0.5 mg PO (0.2 mg subcutaneously) every 4 h around the clock and every hour as needed.
Fatigue and sleep disturbances (Canadian Agency for Drugs and Technologies in Health: 2016; Furey SA, 2014; Yennurajalingam S, 2007)		
Address possible contributing factors	Nonpharmacologic	Pharmacologic
Fatigue • Vitamin D deficiency • Metabolic acidosis • Hypothyroidism, hyperthyroidism, adrenal insufficiency • Anemia • Mood disorder, e.g. anxiety, depression • Medication toxicity, e.g. benzodiazepines, antidepressants, opioids • Sleep disorders Sleep disturbances • Other symptoms as described in this table • Cognitive impairment • Medications • Generalized insomnia • Mood disorders • Apnea	Fatigue and sleep disturbances • Exercise • Nutrition and hydration management • Cognitive and psychological approaches, e.g. relaxation therapy, delegating and setting limits • Energy conservation strategies • Optimized sleep hygiene, e.g. avoid stimulants later in the day, avoid napping, save the bedroom for sleep • Complementary treatments, e.g. acupressure, massage, acupuncture	Sleep Disturbances **First line:** Consider low-dose gabapentin (50–300 mg at night), especially if the patient has concomitant neuropathic pain, restless legs syndrome or uremic pruritus **Second line:** Doxepin 10 mg at bedtime, especially if concomitant pruritus or neuropathic pain **Third line:** Cautiously consider mirtazapine 7.5 mg or zopiclone 3.75–5 mg at night or melatonin 2–5 mg at night

When Withdrawal from Dialysis is the Chosen Treatment Option

When withdrawal is the chosen course, it is important to provide an explanation of the dying process, the symptoms a patient may anticipate, how these symptoms can be treated, other care requirements and family supports that are required, and an estimated time frame for survival [12, 34]. A suggested process is shown in Figure 55.2. Aligning care to meet patients' needs typically requires detailed attention to symptom management. Dietary restrictions, blood tests or adherence to medications no longer takes precedence. Coordinating care between the multidisciplinary care providers is a key component of providing supportive care. Offering patients the option to change their mind may give them comfort and a feeling of control. This care mirrors the care patients receive in the terminal phase of CKM as described above.

Patients and families should be provided with an estimate of survival following withdrawal from dialysis. Although individual estimates are often difficult to make, reported survival times are 7–14 days on average [24]. The occasional patient may live for over a month or two if there is still residual kidney function.

Prior to withdrawal, patients should clarify, document, and make available their advance directive, will and durable or medical power of attorney, and, as appropriate, an inventory of bank, brokerage, and financial accounts. Documentation of funeral preferences and/or a written, audio or video message to family and/or friends may be desired [12, 34]. Finally, translating the advance directive into actionable medical orders helps direct care. In some provinces in Canada this is done through Goals of Care Designations and in the United States through Physician Medical Orders for Life-Sustaining Treatment known as POLST, POST, MOLST, or MOST depending upon the state [71]. The patient's preferred location of care and site of death should be determined as death in the preferred location of care is not always feasible. The availability of palliative care services and the potential role of a hospice are important to discuss. Patients' desires for comprehensive symptom control (physical, emotional, and spiritual) and palliative sedation should symptoms become refractory to treatment are key components of these discussions.

Special Considerations for Terminal Symptom Management at the End of Life

For most patients, whether they have chosen CKM or have withdrawn from dialysis, control of symptoms becomes the primary focus in the last weeks or days of life. Management strategies for terminal symptoms are slightly different than chronic symptom management and are summarized in Figures 55.3–55.6.

Anticipatory prescribing is extremely important to avoid unnecessary suffering. This means that even if patients are not experiencing symptoms, they should still have rapid access to subcutaneous or sublingual medications for pain, shortness of breath, nausea, and agitation so that these symptoms can be addressed rapidly should they occur. For the treatment of nausea and vomiting (Figure 55.3), the dopamine antagonists haloperidol and metoclopramide should not be prescribed together and doses are typically reduced by 50% for patients with ESKD. This is an off-label use for both these medications. Patients should be monitored carefully for extrapyramidal symptoms. For the treatment of pain or shortness of breath at the end of life (Figure 55.4), opioids are the first-line pharmacologic treatment. Fentanyl or buprenorphine is preferred given the pharmacokinetics are minimally altered in ESKD. Hydromorphone is metabolized principally

to hydromorphone-3-glucuronide, which has no analgesic activity but possibly causes neuro-excitation resulting in agitation, confusion, and hallucinations. In patients receiving CKM or for those who have withdrawn from dialysis, this metabolite will accumulate and might cause toxicity. For this reason, we consider hydromorphone the second-line treatment for ESKD patients in the last days of life if not receiving dialysis. If terminal agitation, restlessness, or hallucinations occur, it is important to rule out medication toxicity (Figure 55.5). In the case of opioid toxicity, it may be necessary to reduce the opioid dose or consider switching to another opioid, i.e. opioid rotation. Terminal respiratory tract secretions can cause sounds colloquially known as a death rattle once a patient is no longer able to clear their saliva and bronchial secretions. This is normal but can be distressing to family members. It is important to educate the family that the patient is usually not disturbed by and is unaware of their noisy breathing. Repositioning the patient may be helpful but suctioning is to be avoided. Medications to reduce secretions can be provided to the patient in an attempt to provide emotional comfort for loved ones (Figure 55.6). Emotional and spiritual support for both the patient and family remain integral to comprehensive end-of-life care. Palliative care consultation and hospice referral may be appropriate for many patients.

Role of Hospice

Patients may benefit from hospice services that address and provide expert symptom management. In addition to clinical monitoring and support, hospice can provide significant social and emotional support to patients and families. Hospice promotes sharing the responsibility of caregiving through scheduled visits and education of loved ones, usually with around the clock availability for questions or concerns that may arise after hours. It is also important to understand that hospice services are not limited solely to patients who have chosen CKM or have withdrawn from dialysis but may be available for patients on dialysis who have an expected survival limited to only a few months.

Despite its broad availability in many countries, hospice care occurs much less frequently among patients with ESKD [56, 72–74] than the general population [75].

Several possible explanations for the underutilization of palliative and hospice care have been proposed and include a lack of knowledge and understanding of palliative care and related services among patients and their families, which may be socially and culturally patterned [76, 77]. Many patients with ESKD have very poor knowledge of palliative and hospice care. Perceptions are often negative, with a lack of appreciation of the types of services provided and of the potential benefits to patients and family [78]. ESKD patient and family education about the benefits of hospice is important in optimal use of these services.

Underutilization is also likely to be due to eligibility requirements and the common misconception that dialysis patients must stop dialysis to receive hospice care. For example, eligibility for the Medicare hospice benefit in the United States is contingent on the terminal diagnoses for which hospice is engaged and patients may not receive two distinct Medicare benefits for the same illness. Thus, patients may not concurrently receive both hospice and ESKD benefits based on a diagnosis of ESKD alone. Therefore those with ESKD as the sole terminal diagnosis who desire hospice must forego their ESKD benefit and discontinue dialysis. A minority of patients with the terminal illness of ESKD who do not wish to discontinue dialysis may be fortunate enough to find a hospice willing to pay for dialysis as part of the hospice services being provided. Alternatively, dialysis patients with non-ESKD terminal

diagnosis may retain their ESKD Medicare benefit and continue dialysis while they engage hospice. This diagnosis may be as simple as "failure to thrive."

Conclusion

Decision-making for patients and families facing ESKD can be challenging, particularly for older patients or those with complex multimorbidity whose prognosis and potential harms and benefits of dialysis are difficult to predict. However, it is critical that clinicians recognize the need to review all treatment options and provide their best advice based on patients' goals, values, and preferences and ensure the options for CKM and dialysis withdrawal are presented adequately. These care pathways will require a multidisciplinary care team well versed in symptom management and end-of-life care.

Evaluation of the Living Donor Kidney

Neil Boudville[1] *and Amit X. Garg*[2]

[2] *Western University, Institute for Clinical Evaluative Sciences Western Facility, Victoria Hospital, London, ON, Canada*

Introduction

For patients who develop end-stage kidney disease (ESKD), compared to dialysis, kidney transplantation provides the lowest morbidity and greatest survival if a person is deemed healthy enough to receive one [1, 2]. The two sources of kidneys for transplantation are either a living or a deceased donor [1–3]. To meet the needs for transplant organs, live donation is an important aspect of transplantation, providing shorter time to transplantation and better clinical outcomes for recipients [2, 3].

The primary premise of living kidney donation is that the positive outcomes for the recipient and potential positive psychological outcomes for the donor outweigh the short- and long-term medical, psychosocial, and financial risks to the donor [4]. In this chapter we will discuss the assessment of a potential living kidney donor as this requires an appreciation of the existing literature on the risks involved with donation. Similarly, an understanding of the risks involved with donating a kidney is a key component to obtaining fully informed consent from the donor prior to surgery [4, 5].

The assessment of the potential living kidney donor includes (i) an evaluation of their fitness to undergo the operation, (ii) their fitness to live the rest of their life with only one kidney, and (iii) ensuring that the donor has no medical issues that could compromise the recipient in the event of donation. This chapter will not provide a list of tests to be performed but rather discuss the principles behind the potential donor's evaluation and some of the current evidence.

Assessment of the Living Kidney Donor's Fitness to Undergo the Operation

This part of the evaluation is really an assessment of the living donor's short-term surgical risks. The recently published Kidney Disease Improving Global Outcomes (KDIGO) Guidelines appropriately describe a living kidney donor nephrectomy to be equivalent to a noncardiac surgery of "moderate-size" [6].

Perioperative Mortality

The perioperative risk of death within the first 90 days has been estimated at 0.031% (3.1 in 10 000 donors) based on data on 80 347 living kidney donors in the United States between 1 April 1994 and 31 March 2009 [7]. Despite considerable changes in practice and donor selection over this 15-year period, there does not appear to be any change in the mortality rate [7]. The most common causes of death seem to be related to the development of pulmonary embolism and bleeding at the operative site, fundamentally diametrically opposite complications where the prevention of one may increase the risk of the other.

Perioperative Morbidity

Total rate of perioperative complications is estimated to be between 8% and 18%, with the relatively high variation likely reflecting differences in the method of ascertainment of complications [8–12]. The largest publication to

date ($n = 69\,117$) had an incidence of 7.9%, but was limited by only collecting procedure-related complications [11]. Another prospective cohort study of 1042 living kidney donors in Canada and Australia who donated between 2004 and 2014 detected a complication rate of 13% [13]. With the recognition of the importance to monitor living kidney donor outcomes, some jurisdictions have attempted to keep a record of perioperative complications.

Venous thromboembolism (VTE) (including pulmonary emboli) occurs in less than 2% of cases, with increased awareness leading to recommendations of tailored VTE prevention depending upon the risk for the individual donor [14]. Risk stratification of a potential living kidney donor's VTE risk includes a preoperative evaluation of risk factors such as past history of VTE, older age, obesity, and medications [14]. Hemorrhage is the most common intraoperative complication but is also seen postoperatively.

Other common perioperative complications include urinary tract infections, gastrointestinal dysfunction, low-grade fever, wound infections, and pain [12]. The average length of stay following living kidney donation is dependent on the surgical technique (open versus laparoscopic) and local practices but averages 3–6 days. Risk factors for complications seem to include African Americans, predonation obesity, hypertension, hematological condition, and psychiatric condition [12].

In view of the extent of this operation, routine preoperative assessment should include an evaluation of the risks for cardiovascular, pulmonary, bleeding, anesthesia, and other perioperative complications. Besides smoking cessation, there is limited evidence to direct the most appropriate evaluations to make and practitioners should be guided by the information in this chapter and local practices.

Assessment of the Long-term Medical Outcomes for Living Kidney Donors

The decision to approve a potential living kidney donor to donate a kidney is predicated on understanding the long-term risk of living with a single kidney and assimilating that with the donor's preoperative characteristics that may add to these risks [6]. The difficulty with this process is that there still exists uncertainty about what precisely are the long-term risks of donating a kidney [15]. Below we will try to summarize the existing literature with respect to specific patient-level outcomes.

Blood Pressure

The kidneys are a key mediator of blood pressure control and so mechanistically it is easy to suspect that removal of one of two kidneys may lead to an increase in the patient's blood pressure [16]. Hypertension in turn can lead to progression of chronic kidney disease (CKD) and other adverse outcomes. A key study by Lentine et al. linked Organ Procurement and Transplantation Network (OPTN) records of all living kidney donors in the United States from a large, single national private US health insurer between October 1987 and July 2007 with a median follow-up of 7.7 years [17]. They described a prevalence of hypertension at 5 years of 17.8% and that for diabetes mellitus of 4.0% [17].

However, the main issue with the majority of studies to date on the long-term outcomes of people who donate a kidney is around what proportion of comorbidities that develop after donation is attributable to the donation itself, and how much would have happened as part of the normal aging process. The study by Lentine et al. compared the prevalence of the development of disease in the living kidney donor cohort with that from a general population cohort sampled from the National Health and Nutrition Examination Survey (NHANES) data (2005–2006 cohort) [17]. Using this methodology they still detected a higher prevalence of hypertension in the living kidney donor cohort than their general population cohort, but with similar prevalence of diabetes. This still raises the question on whether this comparator group is the correct one, as living kidney donors undergo rigorous testing prior to donating to ensure that they are very healthy.

A previous systematic review and meta-analysis assessed blood pressure changes in studies that included healthy nondonor controls along with living kidney donors [18]. Their pooled estimate of four trials with controls at least 5 years after kidney donation revealed a significantly higher systolic blood pressure of 6 mmHg (95% confidence interval [CI] 1.6–10.5) compared to a 4 mmHg (95% CI 0.9, 6.7) higher diastolic blood pressure in the donors from the five trials identified [18]. A more recent systematic review still identified a higher diastolic blood pressure in donors compared to controls but no difference in systolic blood pressure or the development of hypertension [19].

Proteinuria

Proteinuria in the general population is a predictor of renal outcomes, cardiovascular disease, and mortality [20]. Amongst living kidney donors it has been noted to occur in up to 20% on follow-up [21–23]. In a systematic review and meta-analysis of studies the incidence of proteinuria was 12% (95% CI 8–16%) amongst 42 studies with 4793 living

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

kidney donors followed up for an average of 7 years postdonation [23]. In the small number of studies that included a control comparator group, there also was found an increased amount of proteinuria (mean difference of 66 mg/day (95% CI 24–108) at an average of 11 years postdonation) [23]. However, the prognostic significance of this increased proteinuria in living kidney donors is unknown and may not necessarily be similar to that seen in the general population.

Cardiovascular Disease

As CKD, even from a glomerular filtration rate (GFR) <75 ml/min/1.73 m^2, has been associated with cardiovascular disease, it has been a concern that this may be increased with donating a kidney [24]. There have been four studies to date that have examined this with a comparator group of healthy controls. While one study did document an increased incidence of cardiovascular mortality compared to the control population, the other three studies did not and a meta-analysis of the four studies showed no significant difference in this outcome amongst living kidney donors [19, 22, 24–27].

Survival

The initial investigations into survival amongst living kidney donors were reassuring, with the most notable and often quoted study being from the Swedish group [28]. This study followed a cohort of 430 living kidney donors from Stockholm, Sweden between 1964 and 1994, and compared their survival with that of the general population. They found a 29% (95% CI 20–38%) better survival amongst living kidney donors (attributed to the careful selection process donors undergo compared to the general population), a finding that reassured many in the transplant community at the time. In a single-center study of 3698 living kidney donors from the University of Minnesota, there were 268 deaths in the follow-up period with similar survival rates when compared to the general population [22].

With increasing recognition that the general population may not be an appropriate comparator group, four publications have subsequently been published with healthy controls as the comparator group. The healthy controls were generated by selecting a "healthy" subgroup of an existing cohort, e.g. Segev et al. used the NHANES III cohort and excluded those that had existing kidney disease, diabetes mellitus, hypertension or ischaemic heart disease [7]. This information was attained from the previously obtained 30 screening questions performed at baseline for NHANES III. Two of the other four studies also found a higher survival amongst living kidney donors compared to their "healthy" control group [25, 29]. There was one study from Norway, where all kidney transplants for the country are performed in a single transplant unit in Oslo, that followed up 2269 living kidney donors [26]. The authors matched the living donors to people identified from a preexisting cohort identified from a population-based survey performed between 1984 and 1987 in Norway. They only included those people who had normal blood pressure, body mass index (BMI) <30 kg/m^2, and self-rated their health as "good" or "excellent." They demonstrated a statistically significant increase in mortality amongst the living kidney donors compared to the "healthy" controls, with a hazard ratio of 1.30 (95% CI 1.17–1.88). Notably, they did not detect this increased mortality rate until after 10 years of follow-up, which is longer than most existing studies. A meta-analysis of all four studies showed no significant difference in survival though CIs remain a little wide and there was a trend toward improved survival [19].

End-stage Kidney Disease

In the study from Norway, nine of the living kidney donors developed ESKD, resulting in a crude incidence of 302 per million person years [26]. This compared to 100 per million patient years for the general population of Norway and a hazard ratio of 11.38 (95% CI 4.37–29.63) compared to the matched "healthy" controls. Muzaale et al. published on the US OPTN database, identifying 96 217 living kidney donors between April 1994 and November 2011 [30]. They compared outcomes with a matched cohort of "healthy" controls generated from the NHANES III dataset and demonstrated a cumulative incidence of ESKD 15 years postdonation of 30.8 per 10 000 donors versus 3.9 per 10 000 healthy nondonors, $P < 0.001$ [30]. Similar to the Norwegian study, they also demonstrated that living donors still had a statistically significant lower incidence of ESKD than the general population. On systematic review and meta-analysis, donors were found to have a significantly increased incidence of ESKD (relative risk [RR] 8.83, 95% CI 1.02–20.93) [19].

Pregnancy-related Complications

There have been three publications on pregnancy-related outcomes in living kidney donors [31–33]. The most recent publication demonstrated a statistically significant increase in the incidence of gestational hypertension or preeclampsia in 181 living kidney donors compared to 788 matched healthy women (odds ratio [OR] 2.4, 95% CI 1.2–5.0) and absolute incidence of 11% versus 5%. This finding was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

maintained on meta-analysis [19]. No significant increased incidence could be found with the development of low birth weight or preterm birth.

Psychosocial Considerations for Living Kidney Donors

All potential living kidney donors should have a detailed psychosocial evaluation to ensure that their risk of adverse psychological outcomes can be estimated and a plan devised to minimize them and manage any that may occur. Discussion and consideration of how the potential living kidney donor may react if there is a bad perioperative outcome should be made. A wide variation currently exists in how this evaluation is made with no preferred method proven to be more effective than another [34, 35].

Most studies of the psychosocial outcomes of living kidney donors have generally shown positive findings with minimal adverse outcomes. A recent study examined prospectively a cohort of 193 living kidney donors and 20 healthy controls, and measured an array of psychosocial outcomes predonation and at 1, 6, 12, and 24 months postdonation [36]. They used validated questionnaires to measure these outcomes. Overall, there was the development in a small proportion of donors of new adverse psychosocial outcomes but not significantly more than in the healthy controls. It was also noted that a proportion of donors did demonstrate an improvement in their psychosocial wellbeing postdonation. These findings were supported in a systematic review and meta-analysis that examined 10 studies that used the short-form 12 or short-form 36 health survey to measure quality of life in donors and controls [19]. This study found no important or statistically significant difference in mental or physical scores between the two groups.

Selection of the Living Kidney Donor

The evidence to date still maintains some uncertainty about the long-term complications following living kidney donation. With the information above noted, plus the knowledge that CKD does lead to increased cardiovascular morbidity, plus cardiovascular and all-cause mortality, the evaluation of potential living kidney donors should be performed with this in mind. KDIGO guidelines nicely describe the long-standing intuitive assessments that have been made to date when deciding on a potential living kidney donor's suitability to donate (Figure 56.1). The potential donor's risks are quantified and if the risks are above a certain threshold they are not accepted and if they are below a certain threshold then they are able to donate. The issue with this is that it is very hard to quantify an individual's overall risk and it is also hard for a transplant unit to agree on a threshold level for all types of potential donors.

Kidney Function

The lack of adequate evidence to fully quantify the risk for a potential donor has continued to make this process an art

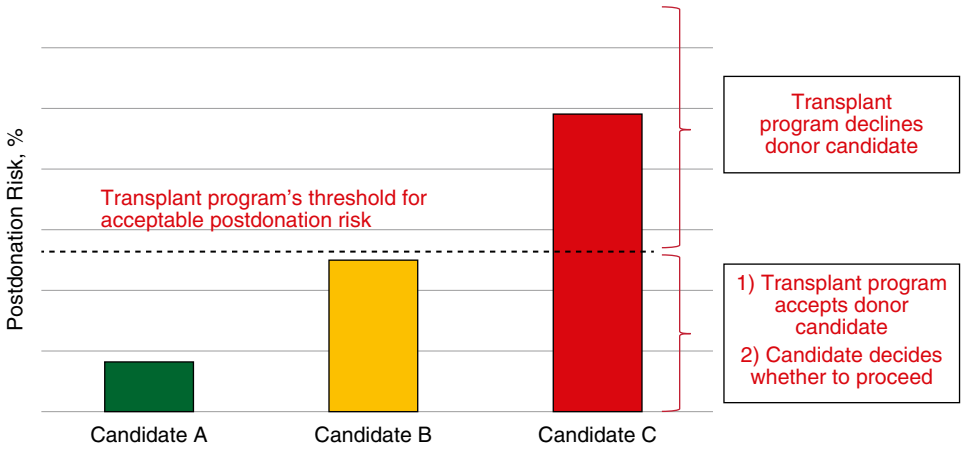

Figure 56.1 Framework to accept or decline donor candidates based on a transplant program's threshold of acceptable postdonation risk. The decision by the transplant program to accept or decline a donor candidate is grounded on whether an individual's estimated postdonation risk is above or below the threshold set (dotted line) by the transplant program. The threshold may vary across transplant programs, but the same threshold should apply to all donor candidates at each program. For example, candidate A (green) would be acceptable because the estimated projected postdonation risk is far below the threshold. Candidate B (yellow) could be accepted with caution because the estimated projected postdonation risk is close but below the threshold, and candidate C (red) would be unacceptable because the estimated postdonation projected risk is far above the threshold. *Source:* Lentine et al. form rather than a pure science. Kidney function is probably the one area with the most information to guide our decision-making. Many jurisdictions have traditionally set a threshold level of kidney function below which a potential donor would be deemed unacceptable for donation, for many this has been 80 ml/min/1.73 m^2 [37, 38]. The two main concerns are leaving the donor with reduced kidney function that in turn leads to adverse outcomes for the donor, in addition to leaving the kidney transplant recipient with inadequate kidney function for long-term benefits. While the donor has their kidney function immediately postoperatively reduced to approximately 50% of the predonation level, with compensatory hyperfiltration the donors usually finishes with 30% reduction in kidney function compared to predonation [21–23]. The rationale behind this threshold is largely based on tradition and dogma rather than evidence [39].

KDIGO described the concept of lifetime risk, such that the younger the living donor the longer their expected life expectancy and so the greater their exposure to risk. This has been developed further by the Chronic Kidney Disease Prognosis Consortium, who focused on the development of ESKD [40]. They combined data from multiple North American general population studies, with almost five million participants, to develop a risk calculator to estimate the long-term incidence of ESKD. They propose that this can be used in the assessment of potential living kidney donors to estimate their 15-year and lifetime risk of developing ESKD if they were to not donate a kidney. As you can see from Figure 56.1, the younger the donor, the greater the cumulative risk for ESKD. The proposal is that a transplant unit can decide on what threshold risk they would accept for a potential living kidney donor and if their risk is above this threshold then decline them for donation. Ongoing efforts to better quantify risk in this way may lead to a more transparent and equitable process.

One of the things that this equation does not take into account is the amount of added risk the individual will have if they were to donate a kidney – attributable risk. Grams et al. attempted to provide an estimate of the attributable risk of donation by applying the same equation to almost 53 000 previous living kidney donors in the United States and comparing the 15-year predicted incidence of ESKD with the actual incidence. Here they found a 3.5- to 5.3-fold higher observed incidence of ESKD compared to that predicted by their equation, potentially providing us with a means to estimate attributable risk for the donation process. These equations need to be validated in other populations before being used outside of North America.

The KDIGO Guidelines have recommended against a single threshold for acceptable kidney function for all potential donors [6]. Instead they have set a few thresholds: >90 ml/min/1.73 m^2 being acceptable for donation, <60 ml/min/1.73 m^2 being unacceptable for donation, and 60–90 ml/min/1.73 m^2 being up for discussion. This would be dependent on the individual's longer term risk of ESKD dependent upon their baseline demographics and comorbidities plus the added attributable risk of donation. For example, an older potential donor has a lower lifetime risk of ESKD and therefore it is possible to accept a lower level of kidney function predonation.

This example of predicting the lifetime risk of kidney failure in a potential living kidney donor needs to be applied to multiple clinical outcomes in every potential donor: cardiovascular disease, all-cause mortality, diabetes, mental illness, quality of life, and others. Hence the complexity of this evaluation process and the difficulty in describing the evaluation in concrete and transparent terms for each individual donor evaluation.

Transmission of Disease from the Donor to the Kidney Transplant Recipient

The other aspect of the evaluation of a potential living kidney donor is to ensure that they do not have a disease that could be transferred to the kidney transplant recipient. Especially in the context of immunosuppression, any such condition transmitted may have dire consequences. These diseases are typically neoplastic or infective. Screening for cancers according to local guidelines is recommended [6]. If the potential donor has a history of neoplasms, there have been guidelines developed with respect to years of remission prior to being deemed suitable for donation. These are largely based on case reports, case series, cohort, and registry studies [41]. The Organ Procurement and Transplantation Network Disease Transmission Advisory Committee Malignancy Subcommittee published different neoplasms into six levels of risk stratification which may be used as a guide to decision-making but it should be remembered that further data is still required to confirm this classification system [42].

Infections also need to be screened for, with some infections being "acceptable" as potential/likely transmissible agents, e.g. cytomegalovirus (CMV) and Epstein-Barr virus (EBV) (potentially) [6]. More recently, with the development of successful curative treatments for hepatitis C, it is being mooted that this may also become an acceptable infection for a donor to have, though in a living kidney donor attempts should be made to cure this prior to donation [43]. There are some other infections which continue to be (relative/absolute) contraindications for donation: human immunodeficiency virus, tuberculosis, hepatitis B,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and syphilis [6]. Consideration for local endemic infections or those of the potential donor's original place of residence needs to be made [44].

Recent Trend Toward Accepting Living Kidney Donors with Medical Conditions

For much of the time since the first living kidney donation in 1952, donors have been selected based on a very high standard of good health. As we have become more comfortable with this procedure, confident in our belief that donors are not significantly affected by donation, and continue to have a shortage of deceased kidney donors, there has been an increasing tendency to accept donors with some conditions that may previously have precluded them from donation [45].

In the ANZDATA Living Kidney Donor Registry it was noted that in the period between 2004 and 2012 there were 2932 donors in Australia and New Zealand [45]. When some of the living kidney donors' demographic details were compared to national guidelines on selection of living kidney donors, it was identified that 26% had at least one relative contraindication to donation and 9% had at least one absolute contraindication to donation. This included donors that had hypertension (20%), diabetes (0.3%), and impaired glucose tolerance (2%) at the time of donation.

Similarly in the United States, Muzaale et al. demonstrated that amongst the 96 217 living kidney donors between 1 April 1994 and 30 November 2011, 25.2% had a BMI > 30 kg/m^2, 9% had a systolic blood pressure over 140 mmHg, and 24.2% were smokers at the time of donation [30]. The fact that we are accepted donors that we previously were not suggests that we need to consider this when reviewing data on long-term outcomes of living kidney donors. Such long-term outcomes may only be applicable to similarly healthy donors to our historical donors.

Informed Consent

An essential component of any medical procedure is to ensure that the person is adequately informed about what the procedure entails and understands the risks involved. For living kidney donation these risks include short-term (those within the first 90 days of the donation) plus long-term risks (for the rest of the donor's life). While the short-term risks are relatively well defined, there is still a large amount of uncertainty with the long-term outcomes. This. however. does not discount our ability to present the current level of evidence that exists (along with the uncertainty) and behooves us to ensure we continue to grow the evidence.

Postdonation Follow-up

Traditionally, living kidney donors have not routinely been followed-up by kidney transplant units and are discharged back to their primary physician after postoperative recovery is assured. This is in keeping with the message that we try to convey to donors – that they are still healthy postdonation. However, it has led to the uncertainty of precisely what the long-term risks are and recent evidence suggests that there may be some increased risk, albeit small in absolute terms. Maybe because of this uncertainty, the potential of increased risk of poor outcomes, and the premise that the transplanting team has some responsibility to provide life-long care of a kidney donor's remaining kidney function, many units are providing ongoing follow-up of living kidney donors. This is often in the form of an annual review which would include blood pressure measurement, serum creatinine, estimation of albuminuria, and emphasis on healthy lifestyle behaviors.

The Impact of Deceased Donor Quality and Outcomes after Kidney Transplantation

Margaux N. Mustian and Jayme E. Locke

Department of Surgery, Division of Transplantation,, University of Alabama at Birmingham, Birmingham, AL, USA

Introduction

Although kidney transplantation is the standard of care for patients with end-stage renal disease (ESRD) [1, 2], there is a worldwide shortage of organs available for kidney transplantation. In the United States, despite a kidney transplant waiting list of nearly 90 000 candidates, there are fewer than 20 000 kidney transplants performed annually [3]. Limited deceased donor pools serve as a barrier to transplantation throughout many other countries as well [4–6]. Attempts have been made to mitigate the scarcity of available organs and enlarge the donor pool by expanding acceptance criteria for potential deceased kidney donors (Figure 57.1.), including utilization of expanded criteria brain dead donors (ECD), the Kidney Donor Profile Index (KDPI) >0.85, and donation after cardiac death (DCD) as well as donors labeled as increased risk for infectious diseases and those with documented infections, such as hepatitis C virus (HCV) and/or human immunodeficiency virus (HIV).

However, the quality of the deceased donor kidney has been shown to influence both patient and graft survival for the recipient [7, 8], and as such must be considered during the selection of both kidney transplant recipients and donors. Consequently, standardized assessments of donor quality have been established, including the designation of ECD and KDPI scores. Transplant provider understanding of donor quality and subsequent risks and potential outcomes for recipients is paramount, as appraisal and approval of donors and recipients for transplantation lies with the transplant team of surgeons and nephrologists (Table 57.1).

Pathophysiology of Deceased Donors

Donation after Brain Death

Brain death is diagnosed as lack of responsiveness or coma accompanied by apnea and an absence of brain stem reflexes, despite standardized conditions (e.g. normothermia, lack of electrolyte/acid-base/endocrine disturbance, blood alcohol content <0.08, systolic blood pressure greater than 100 mm Hg, and lack of medications that cause central nervous system depression) [9]. Brain death occurs after severe brain injury, which causes increased intracranial pressure and cerebral edema, leading to decreased brain perfusion and ultimately the termination of cerebral blood flow [10]. Large animal models have demonstrated the physiologic responses that occur following brain death, such as hypertension and bradycardia, which are then followed by hyperdynamic state due to catecholamine surge [11]. After this initial increase, there is a drop in the catecholamine level, which then leads to cardiovascular instability and poor visceral perfusion [11]. Following brain death, there is also a shift from aerobic to anaerobic metabolism, evidenced by elevated serum lactic acid levels [11]. Hormonal changes due to disruptions in the hypothalamic-pituitary axis also occur, including the development of diabetes insipidus and decreased cortisol levels, which further propagate hemodynamic instability and inflammatory responses [11]. The inflammatory response also leads to endothelial, complement, and coagulation pathway activation, which can all lead to organ damage [11]. Furthermore, the diagnosis of brain death may lag behind these pathophysiological changes, leading

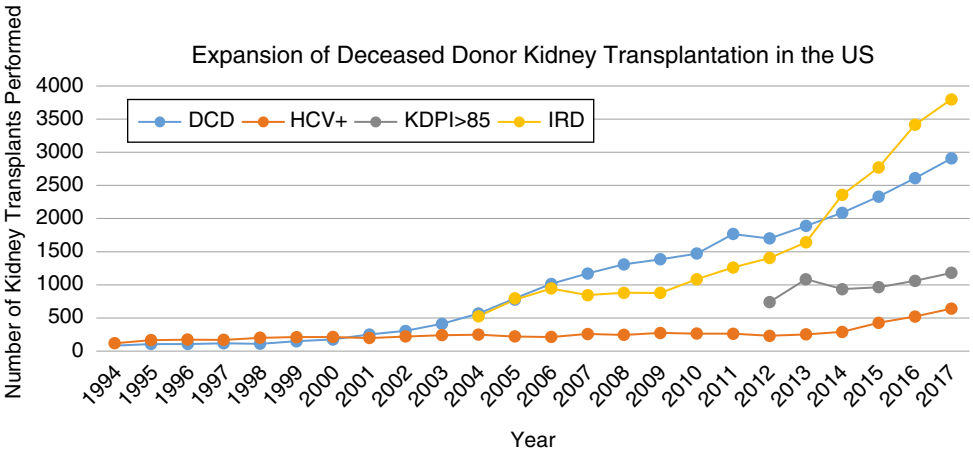

Figure 57.1. Utilization of deceased donor kidney transplantation in the United States, based on OPTN data as of 3 August 2018.

to organ compromise prior to confirmation of brain death [11]. These pathophysiologic changes further highlight the need for transplant surgeons and physicians to critically evaluate organ quality prior to transplantation.

Donation after Cardiac Death

DCD donors are typically those who do not meet brain death criteria, but for whom further medical intervention is deemed futile [10]. DCD donation is not associated with an inflammatory response as robust as that elicited by donation after brain death (DBD) [11]. However, there is a longer warm ischemia time associated with DCD, resulting from the time period between withdrawal of respiratory/circulatory support and time of death [12]. The prolonged warm ischemia can then lead to higher rates of primary nonfunction and delayed graft function (DGF) in kidney transplant recipients [11]. As a result, there are established maximum warm ischemia times after which organ procurement is not typically pursued. The warm ischemia time permissible for kidney procurement varies by country, with a 60-minute time period commonly used in the United States, a 90-minute period used in Australia, and a 1–4-hour period used in the UK [13, 14].

Expanded Criteria Donors/High Kidney Donor Profile Index (KDPI > 0.85)

Epidemiology

In Spain, where living donor kidney transplantation accounted for less than 1% of all kidney transplants, there was a great need to improve the utilization of deceased donor kidneys for transplantation [15]. As such, they began to transplant kidneys from older donors and those with hypertension, aiming to decrease their discard rates. Over the course of a decade, Spain was able to increase their organ donor annual rate from 14 donors per million population pmp (per million population) to 34 donors pmp as of the early 2000s [15, 16]. Following suit, in the United States, the Kidney Work Group created the Crystal City Kidney proposal for determining ECD status in 2001, in which they compared the discard rate for older donors in the United States to the practices in Spain [17]. The authors found that if the utilization of kidneys recovered from donors over the age of 45 in the United States mirrored the trends in Spain, this would correlate with an increase in the rate of deceased donors in the United States by 38% [17]. The following year, a definition was put forth describing ECD in the United States, including characteristics that were associated with a 1.7-fold increased relative risk for allograft loss in the recipient [18, 19]. Then in 2009, KDPI was introduced by Rao et al. in an attempt to further quantify the risk of graft loss due to donor characteristics, yielding a percentile which corresponded to the predicted allograft longevity in lieu of the dichotomous ECD status [20].

Diagnosis

The characterization and determination of "marginal" or "expanded criteria" donors have undergone multiple iterations over time. Ojo et al. defined marginal donors as those with one or more of the following characteristics: age over 55 years, greater than 10-year history of hypertension or diabetes mellitus, DCD donation, or cold preservation time of greater than 36 hours [21]. Port et al. established ECD donors as those with a relative risk of graft loss greater than 1.7 compared with standard criteria brain dead donors [18]. The authors described standard criteria donors (SCD) as those who were 10–39 years of age, had terminal serum

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 57.1 Deceased donor kidney transplantation (KT) recommendations.

Deceased donor classification	Recommendation	Certainty of evidence	Strength of recommendation
Expanded criteria/high KDPI donors	We suggest KT with high KDPI organs for older recipients, or those at centers with longer waiting times, or patients with both older age and longer waiting times due to the survival benefit derived compared with continuing to wait for a low-KDPI organ.	Low	Weak [33]
Infectious risk donors	We suggest KT with IRD kidneys for older candidates, with higher PRA, previous KT, or those who face long waiting times due to the observed survival benefit compared with declining IRD kidneys.	Low	Weak [39]
HCV+ donors	We suggest KT with HCV+ organs for HCV+ recipients, followed by post-transplantation DAA therapy. Likewise, there may be a role for HCV+ KT for HCV- recipients.	Low	Weak [73]
HIV+ donors	We suggest KT with HIV+ organs for HIV+ recipients. However, in the United States this is currently limited to research protocols. Recipients should have a CD4 count greater than 200/μl and be on a stable antiretroviral regimen, with viral load <50 copies/ml. Among younger HIV recipients with low panel reactive antibodies, patient and graft survival is similar to HIV− recipients.	Low	Weak [81, 107]
Donation after cardiac death	We suggest the use of DCD organs for kidney transplantation. However, increasing donor and recipient age, prior transplantation, and increased cold ischemia time are associated with poor graft and patient survival among recipients of DCD kidneys.	Low	Weak [108]

DAA, direct-acting antiviral; DCD, donation after cardiac death; HCV, hepatitis C virus; HIV, human immunodeficiency virus; IRD, infectious risk donor; KDPI, kidney donor profile index; KT, kidney transplantation; PRA, panel reactive antibody.

creatinine 1.5 mg/dl or less, had cause of death other than cerebrovascular accident, and had no history of hypertension [18]. Based on these findings, the US Organ Procurement and Transplantation Network (OPTN) created the designation of ECD donors as brain death donors over the age of 60 years, or over the age of 50 with two of the following: history of hypertension, serum creatinine 1.5 mg/dl or greater, or cerebrovascular accident as cause of death [19].

Rao et al. further delineated the risk of graft loss according to deceased donor characteristics through the creation of the kidney donor risk index (KDRI), which was developed among a cohort of donors in the United States from 1995 to 2005 transplanted into ABO compatible, first-time solitary kidney recipients [20] (Table 57.2). Importantly, the KDRI accounts for type of donor death, with a higher risk index associated with cardiac death compared to brain death. The KDRI, which gives the relative risk of graft loss, is then remapped and given a percentile, also known as KDPI, such that a score of 10 indicates that the allograft will likely last longer than 90% of other kidney allografts transplanted in the same year (OPTN website). Furthermore, kidneys with KDPI of 0.85 or greater, thought to be similar to ECD kidneys, are usually reserved for recipients with high-risk features ([22], OPTN website). Additionally, with the advent of KDPI, which describes both DCD and DBD donors, ECD is now also used to describe donors following cardiac and brain death, and the ECD designation now is more synonymous with "marginal" donors.

Prognosis

Although ECD kidneys pose a greater risk of graft loss based on the nature of the designation, the prognosis for recipients

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of ECD kidneys is not uniformly poor. Ojo et al. found a survival benefit for transplant recipients of marginal kidney donors compared with remaining waitlisted on dialysis [21]. Alternatively, Saidi et al. found that recipients of ECD kidneys had longer lengths of stay, higher readmissions, and increased DGF compared with SCD recipients [23]. The authors also noted decreased graft survival among ECD recipients after a mean follow-up of 50 months, with significantly increased graft loss noted at 2 years post transplant [23]. In reality, not all aspects of ECD kidneys carry the same weight in respect to risk of graft loss, and therefore selecting the best recipient for an ECD kidney is pivotal. Several studies haves shown that older donor age was associated with increased DGF and poor graft survival among ECD donors [21, 24]. Stratta et al. stressed the importance of recipient selection for ECD kidneys and demonstrated no statistically significant differences in ECD and SCD outcomes, including DGF, acute rejection, and 4-year patient and graft survival [25]. Furthermore, additional information from kidney biopsies, such as the severity of histological damage, may be useful to aid in the determination of organ suitability for transplantation among deceased donors meeting ECD criteria [26].

The United Network for Organ Sharing (UNOS) ECD designation may not be uniformly applicable throughout the world, and when employed in different patient populations may yield different results. In Japan, Nakagawa et al. found that using the UNOS ECD classification categorized 84% of their deceased donors as ECD, despite no differences in outcomes between SCD and ECD donor recipients [6]. A study from Korea showed that ECD recipients had increased DGF and longer wait times on dialysis but no differences in patient or graft survival compared to both SCD recipients of DDKT (deceased donor kidney transplant) and living kidney donor recipients [27]. Similarly, Palkoci et al. found no difference in long-term patient and graft survival for ECD donor recipients compared with SCD recipients despite poorer graft function in the first 6 months post transplant [28]. In Poland, authors found an increased risk of graft failure but similar patient survival and DGF using ECD donors compared with SCD donors [29].

Since the KDPI was developed to predict which deceased donor kidney transplants were predisposed to allograft failure on the basis of donor characteristics, it is not surprising that as the KDPI increases, graft failure rates also increase (Figure 57.2.) (OPTN website). Recipients of kidneys with low KDPI (≤0.20) are expected to have a mean half-life of 11 years, nearly the same expectancy as recipients of living donor kidneys, while high KDPI kidneys have an estimated graft life of about 5.5 years [30]. Consequently, kidneys with a KDPI of >0.90 had a discard rate of over 60% in the United States between 2001 and 2012 [30]. Furthermore, Bae et al. demonstrated that in the KDPI era, there was a paradoxically higher discard rate for kidneys meeting the conditions for ECD [31]. Other countries have also utilized KDPI to assess deceased donor quality, and in Spain although the SCD/ECD classification was not predictive of graft function, increased KDPI was associated with poor

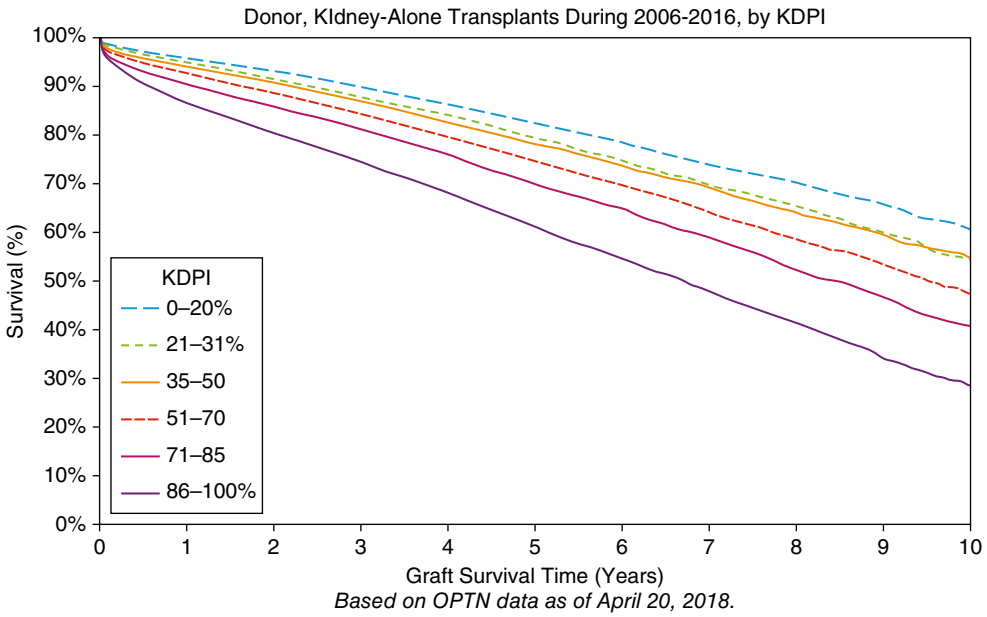

Figure 57.2. Kaplan–Meier graft survival estimates for adult deceased donor kidney transplant recipients, stratified by KDPI [94]. *Source:* A Guide to Calculating and Interpreting the Kidney Donor Profile Index (KDPI), 23 March 2020, US Department of Health and Human Services.

graft survival [32]. However, despite the increased risk of allograft loss with high KDPI kidneys, Massie et al. found a survival benefit for receiving high KDPI kidneys compared with remaining on the waitlist for some patient subgroups, including diabetic recipients over the age of 50 years listed at centers with long waiting times [33].

Treatment

Compared with IL2 receptor antibodies (IL2RA), antithymocyte globulin (ATG) has been associated with decreased acute rejection among recipients of ECD kidneys [34]. Furthermore, for ECD kidney recipients who were African American, had high panel reactive antibodies (>20%), or had previous kidney transplants ATG was also associated with improved graft survival compared with IL2RA [34]. Alternatively, another study compared outcomes between ATG and daclizumab in this patient population and found no statistically significant differences in patient or graft survival [35]. It should be noted, however, that daclizumab is no longer used in the United States. Maintenance immunosuppression for ECD kidney recipients has not been established through randomized trials, but regimens that avoided calcineurin inhibitors (CNIs) were originally proposed to avoid potential nephrotoxicity, although these regimens have been associated with increased risk of acute rejection [36, 37]. Therefore, standard triple therapy maintenance immunosuppression is recommended for recipients of ECD kidneys, with CNIs, mycophenolate mofetil (MMF), and steroids. However, reduced CNI exposure via lowered target serum levels may be beneficial in this recipient population [36].

Donors Labeled High Infectious Risk

Epidemiology

In 1994, the US Centers for Disease Control (CDC) established guidelines to prevent potential unknown transmission of infectious diseases, such as HIV, through organ transplantation [38]. They recommended the implementation of certain exclusionary criteria for organ donation, including previous intravenous drug use, incarceration, men who have sex with men, and prostitution, unless the risk of infectious disease for the recipient was deemed less than the risk of not undergoing transplantation (Table 57.3) [38]. These "CDC high risk donors," also known as infectious risk donors (IRDs), represent donors with no documented infection despite behavioral risks for infection and accounted for 10% of deceased donors in the United States as of 2011 [39]. However, the disease transmission risk is generally low, with the risk of HIV or HCV transmission from high-risk donors estimated to range from 0.09 to 300.6 per 10 000 donors, based on serologic testing [40]. In reality, the risk of disease transmission following transplantation from IRDs is exceedingly low, with a transmission risk of 46 per 100 000 IRD transplant recipients compared with 2.4 per 100 000 transplant recipients of all donor types [41]. In fact, assuming a 100% mortality following HIV transmission, the predicted mortality risk due to HIV transmission following IRD kidney transplantation has been shown to be comparable to the mortality risk associated with living kidney donation [41]. Likewise, the incremental mortality risk associated with IRD kidneys is very small compared with the risk of waitlist mortality [41]. Additionally, there has only been one documented deceased kidney donor transmission of HIV in the United States since 1988 after more than 200 000 deceased donor transplants have been performed [41].

Diagnosis

Donors at high risk for infectious diseases were described by the exclusionary criteria created and distributed by the CDC in 1994, as shown in Table 57.3 [38]. Although these donors are tested for HIV and HCV prior to donation, the window period, or time between disease acquisition and detection via serology, allows for potential transmission of infectious diseases to the recipient [42]. Using enzyme-linked immunosorbent assays (ELISA), the window period is typically 22 days for HIV and 66 days for HCV, while using nucleic acid testing (NAT) decreases the window period to 9 days for HIV and 3–7 days for HCV [42–46]. Therefore, given the smaller window period available with NAT testing, there is a decreased risk of infectious disease

Table 57.3 High-risk criteria, described by CDC in 1994 [38].

Behavior/history exclusionary criteria/high-risk criteria
Men who have had sex with another man in the last 5 years
Persons reporting nonmedical intravenous, intramuscular, or subcutaneous drug use in the last 5 years
Hemophilia or other clotting disorders, or those who have received clotting factor concentrates
Persons who have engaged in sex in exchange for money or drugs in the last 5 years
Persons who have had sex in last year with anyone listed above, or with anyone known/suspected to have HIV
Persons who have been exposed to known or suspected HIV in the last year
Inmates of correctional facilities

transmission from high-risk donors compared to earlier eras secondary to the improved testing [47]. Based on NAT testing, the risk of HIV transmission during the window period is estimated to be 0.04–4.9 per 10 000 donors, while the risk of HCV transmission is 0.027–32.4 per 10 000 donors [40]. The risk for disease transmission is highest among intravenous drug users, and lowest in hemophiliacs and those who were previously incarcerated [48, 49].

The importance of NAT testing for infectious diseases among blood and tissue donors has become increasingly apparent over the past decade. Roth et al. administered an international survey of 37 countries on NAT screening for whole blood and platelet donors, finding that over a 10-year period, 300 million donors were screened for HCV and HIV [50]. Of those donors, nearly 1000 were NAT-only positive, which would have been missed by other serologic screening methods [50]. Similarly, in 2015, UNOS mandated the inclusion of NAT testing for reporting HCV status for transplant donors, which correlates with a 10-fold decrease in the risk of unintended transmission of HCV at time of transplant [46].

Prognosis

Studies have shown that recipients of IRD kidneys have had similar short-term patient survival compared to recipients of standard risk kidneys [51–53]. This is not surprising given that these high-risk donors are typically younger, with lower terminal serum creatinine, and are less likely to have other comorbidities such as hypertension [45, 54]. However, at longer term follow-up, higher risks of mortality have been reported for recipients of IRD kidneys [55]. Despite the majority of studies yielding positive reports regarding the outcomes following the transplantation of kidneys from IRDs, kidneys from IRDs are one-third less likely to be utilized for transplantation [54].

Recipient selection for IRD kidneys is pivotal. Chow et al. developed a Markov model to aid in the decision-making process, finding that recipient age, sensitization as measured by panel reactive antibodies, previous transplant, and waitlist times were predictive of survival differences [39]. Furthermore, recipient education and understanding of IRD kidney donation is also critical. A qualitative study that sought to capture patients' understanding of high-risk organs demonstrated that many candidates were confused about what constituted CDC high risk [56]. Although the waitlist candidates had a general lack of understanding, the authors also established the candidates' interest in learning more about high-risk donors [56]. Informed consent for IRDs is therefore critical, ensuring that patients understand the risks associated with these organs, and consequently in the United States the OPTN mandated a separate consent form for recipients of these donor organs [57]. Another qualitative study confirmed candidates' trepidation regarding high-risk donor kidneys due to concerns of disease transmission, finding that patients' feelings toward these organs were negative and that they were often viewed as "last resort" options if death was forthcoming [42].

Treatment

Induction immunosuppression does not need to be specifically tailored for recipients of IRD kidneys on the basis of their infectious risk. The induction agent selection should be based on the recipient characteristics. Standard triple therapy maintenance immunosuppression, with CNI, MMF, and steroids, should follow induction therapy.

Donors with Hepatitis C

Epidemiology

In part due to the opioid crisis yielding higher numbers of overdose deaths and also secondary to the introduction of direct-acting antiviral (DAA) agents, there has been an increase in the use of HCV+ deceased donors since 2014 [58]. Li et al. demonstrated that the number of transplants from HCV+ donors in the United States increased from 247 in 2013 to 520 in 2016 [58]. Although this represents improvement, a great need still remains to expand the utilization of HCV+ organs, as Kucirka et al. demonstrated that the discard rate for HCV+ kidneys was nearly three-times the discard rate for HCV− kidneys [59].

Diagnosis

HCV status is confirmed via antibody and NAT testing. Historically, HCV+ kidneys were reserved for HCV+ recipients who were viremic to reduce the possibility of worsening the HCV disease or disease progression. However, with DAA therapy, HCV+ organs are no longer limited to viremic HCV+ recipients. Recently, Gentile et al. demonstrated that genotyping of HCV+ deceased donors was possible, and may help in the future to guide decision-making regarding recipient selection and treatment regimens [60].

Prognosis

Maluf et al. demonstrated that among HCV+ transplant recipients, those who received HCV+ donor kidneys had decreased waiting times (mean time of 440.5 days vs. 735.0 days) but also poorer patient and graft survival,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

compared with their counterparts receiving HCV− organs [61]. Similarly, Cohen et al. described an increased risk of death and allograft loss among HCV+ recipients of HCV+ kidneys, compared to recipients of HCV− organs [62]. Other studies have demonstrated acceptable graft survival for HCV+ recipients (90% at median follow-up 14 months, compared with 92% for HCV+ recipients of HCV− organs) [63]. When assessing long-term outcomes, Morales et al., in their single-center study, found that there was no increased risk of graft failure at 5 and 10 years post-transplant, death or severe liver disease among HCV+ recipients of HCV+ donor kidneys compared to HCV+ recipients of HCV− kidneys [64]. However, among HCV+ recipients, Kucirka et al. found an increased risk of being added to the liver transplant waitlist for those who received HCV+ kidneys compared with recipients of HCV− kidneys, although the difference in listing rates between the two groups was less than 2% [65]. Sawinksi et al. found that there was no difference in response to DAA therapy among HCV+ recipients of HCV− and HCV+ kidney transplants, while recipients of HCV+ organs were afforded shorter wait times to transplantation, leading the authors to advocate for the use of HCV+ organs and post-transplant DAA therapy [66].

Given the success of DAA therapy for HCV, some have also promoted the use of HCV+ organs for HCV – recipients. Gupta et al. found that for kidney transplantation among HCV+ donors and HCV− recipients, seroconversion occurred for roughly half of the recipients [67]. Although graft survival was worse among these recipients compared to their matched counterparts receiving HCV− organs, graft survival did not differ on the basis of seroconversion, leading the authors to believe that other factors aside from HCV status may have contributed to the differences in graft survival for recipients of HCV+ kidneys [67]. Additionally, Goldberg et al. conducted a pilot study among HCV− recipients of HCV genotype-1 viremic donor kidneys, finding that despite detectable viral load at 3 days post-transplant, all recipients were cured of HCV with DAA therapy [68]. Furthermore, the authors demonstrated excellent allograft function for HCV− recipients of HCV+ kidneys as well, with a median serum creatinine of 1.1 mg/dl at 6-month follow-up [68]. However, it should be noted that HCV+ to HCV− kidney transplantation is currently only performed under research protocols in the United States, as insurers will not reimburse or pay for prophylactic DAA therapy in HCV− patients.

Treatment

Vivanco et al. demonstrated that the utilization of induction therapy, including depleting agents (alemtuzumab or ATG) or IL2R, for HCV+ recipients was associated with improved patient and graft survival, compared with no induction treatment [69]. Sureshkumar et al. compared outcomes of HCV+ recipients using depleting and nondepleting regimens (basiliximab or daclizumab), and the authors found no difference in graft or patient survival, leading them to recommend selecting induction therapy independent of HCV serostatus [70]. However, another study demonstrated that fibrosis progression was faster among HCV+ transplant recipients receiving induction with daclizumab compared with depleting regimens [71]. As both HCV+ status and CNIs are associated with increased risk of post-transplant insulin resistance, one study assessed the role of converting from tacrolimus to cyclosporine A with the authors finding that HCV+ recipients may benefit from cyclosporine-based maintenance immunosuppression [72]. Maintenance immunosuppression also consists of steroids and MMF. Post-transplantation, HCV should then be treated with DAAs, which have excellent sustained viral response (SVR) and are safe and effective for kidney transplant recipients [66]. A recent Monte Carlo microsimulation by Shelton et al. demonstrated that among HCV+ recipients, liver fibrosis stage and access to HCV+ organs are important for determining optimal timing of kidney transplant and HCV treatment [73]. The authors found that for HCV+ kidney transplant candidates with further progression of liver disease (as evidenced by METAVIR (Meta-analysis of histological data in viral hepatitis) fibrosis score of F3), it was more cost-effective to treat HCV pretransplant, while for all other candidates, it was more cost-effective to pursue kidney transplantation with HCV+ organs followed by HCV treatment post-transplant [73].

Donors with Human Immunodeficiency Virus

Epidemiology

The utilization of HIV positive (HIV+) deceased donors for kidney transplantation began in South Africa in 2008, and over the course of a decade 43 kidney transplants from HIV+ donors were performed [74]. In the United States, 1.5% of patients with ESRD are HIV+, and among African Americans with ESRD the prevalence of HIV is even higher [75]. Despite this need, kidney transplantation from HIV+ donors was initially banned in the United States in 1988, but the HIV Organ Policy Equity (HOPE) Act, passed by US Congress in 2013 and implemented in 2015, now allows for transplantation of HIV+ kidneys into HIV+ recipients [76]. However, HIV+ to HIV− kidney transplantation in the United States can only be performed under research protocols.

Diagnosis

In South Africa, HIV+ deceased donors have been used for kidney transplantation, and the diagnosis of HIV was confirmed by ELISA [77]. Some of the exclusionary criteria for these donors were severe sepsis, active tuberculosis, proteinuria, and elevated serum creatinine [77]. Because HIV serostatus of the deceased donors in South Africa as not known until time of death only two out of 43 donors were previously on antiretroviral therapy (ART) prior to donation [74]. The viral load for donors in South Africa varied from <960 to >150 000 [74]. However, characteristics of HIV+ donors who pose higher risk for recipients include history of drug resistance, detectable viral load (>200 copies/ml), X4 tropic virus, requirement of protease inhibitor therapy, history of virologic failure with ART therapy or no history of ART, and lower CD4+ count [78]. Similarly, candidate selection for HIV+ to HIV+ kidney transplantation is very important. In the multisite NIH study, as well as in South Africa, the criteria for recipients included viral load <50 copies/ml, CD4 count <200 cells/mm^2, stable ART regimen, and no active opportunistic infections [78].

Prognosis

Following HIV+ to HIV+ kidney transplantation, there have been concerns for infectious risks, particularly secondary to immunosuppression. However, reports utilizing kidneys from HIV-negative (HIV−) deceased donors to transplant HIV+ KT recipients have demonstrated that immunosuppression regimens necessary for transplantation can be safely administered in the setting of HIV given appropriate candidates selection [79–82]. Similarly, kidney transplantation for HIV+ recipients has been proven to provide a survival benefit compared with remaining on dialysis [83]. In their early experience of HIV+ to HIV+ kidney transplantation, Muller et al. reported two episodes of DGF among 27 recipients with 84% patient survival and 93% graft survival at 1 year post-transplant compared with 91% and 88% patient and graft survival among HIV− recipients, respectively [77].

Recurrence of HIV-associated nephropathy (HIVAN) was noted in 16% of recipients of HIV+ kidneys in South Africa [74]. However, another study, using HIV− organs, demonstrated HIVAN recurrence in nearly 70% of allograft biopsies despite undetectable viral loads at time of transplant [84]. The risk of HIVAN recurrence was thought to be related to the HIV viral reservoir residing within the kidney [85]. Additionally, there were concerns of HIV superinfection for HIV+ recipients of HIV+ organs due to a second viral strain being introduced, which could possibly become more resistant to ART treatment [74]. However, in the South African population, these potential risks have not been observed [74].

Treatment

Much of the research on immunosuppression regimens for HIV+ recipients has been based on transplantation of HIV+ recipients with HIV− kidneys, but the knowledge gained from this population may be used to influence decision making in the HIV+ to HIV+ kidney transplant population as well. Stock et al. did not initially use any induction treatment, and their maintenance immunosuppression consisted of MMF, steroids, and either cyclosporine or sirolimus [79]. In a subsequent study, Stock et al. found that the use of sirolimus for maintenance immunosuppression was associated with lower levels of HIV DNA, indicating a smaller reservoir size for these recipients [85]. Tan et al. used standard triple therapy for recipients of deceased donors with no induction therapy [86]. Others have used anti-CD25 for induction therapy [80–82, 87], while some studies have also used ATG for induction [88, 89]. Locke et al. found that HIV+ kidney transplant recipients who underwent induction therapy with ATG had 2.6-fold lower risk of acute rejection compared with their counterparts who had received no induction therapy [90]. The authors also demonstrated an increased risk for acute rejection associated with sirolimus-based maintenance immunosuppression regimens [90]. For HIV+ recipients of HIV+ organs, Muller et al. employed an immunosuppression regimen including ATG for induction, coupled with standard triple therapy [77]. Due to concerns of CNI toxicity when used in conjunction with protease inhibitors, protease inhibitor-based ART regimens are not optimal in the post-transplant setting [77]. Similarly, among HIV+ KT recipients of HIV− organs protease inhibitors should also be avoided if possible given associated increased risks of graft loss and mortality compared with other ART regimens [91].

Donation after Cardiac Death

Epidemiology

Although the majority of deceased donor kidneys are retrieved following brain death, the use of DCD donors has also been on the rise in several countries. As of 2013, in the United Kingdom, the Netherlands, and Belgium DCD donors accounted for 7.5–9 donors pmp (per million population) [92]. DCD donors now account for nearly 40% of all deceased donor kidney transplants in the UK [93]. In the United States, the number of DCD donors for kidney transplantation continues to increase as well, and as of 2017,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nearly 3000 kidneys were transplanted from DCD donors, while fewer than 800 DCD kidneys were discarded [94]. In Japan, DCD donors account for 85% of deceased donor kidney transplants performed [6].

Diagnosis

There is some variation in the criteria to diagnose death for DCD donors internationally, but the overarching principles are the same [95]. Irreversible cardiopulmonary arrest must be confirmed, and irreversibility is defined as cardiac or respiratory function that cannot return spontaneously without medical intervention [95]. While in the United States and the UK there are no specific recommendations regarding medical personnel to confirm death (although the physician cannot be part of the retrieval team), in Canada two physicians are required and in Australia an intensivist is mandatory [95]. Likewise the observation period varies between 2 and 5 minutes, with the Institute of Medicine in the United States recommending 5 minutes [95]. In Australia, the retrieval team may reintubate the patient, but other measures such as mechanical ventilation and cardiac compressions cannot be pursued until after the organ procurement surgery has begun [95]. However, in other countries such as Canada, the United States, and the UK, such interventions are not permissible [95].

DCD donors are also divided into Maastricht categories (Table 57.4), according to the location and time of their death [96]. Controlled DCD donation refers to donors in categories III and IV, in which circulatory support is withdrawn in a planned setting, while categories I, II, and V refer to donors with unexpected, irreversible, cardiopulmonary arrest [13]. While some countries utilize controlled DCD donors (i.e. Australia, the UK, and the United States), in France and Spain uncontrolled DCD donors are more commonly used, and other countries such as the Netherlands support both controlled and uncontrolled DCD donors [93].

Table 57.4 Maastricht classification of donation after cardiac death [96].

Category	Description
I	Dead on arrival
II	Unsuccessful resuscitation
III	Anticipated cardiac arrest
IV	Cardiac arrest in a brain-dead donor
V	Unexpected arrest in an ICU patient

Prognosis

The increased warm ischemia times for DCD kidneys have been thought to contribute to poor outcomes for DCD kidney transplant recipients. Soneijs et al. demonstrated that although DCD donors allowed for a substantial increase in the number of kidney transplants performed, they also carried a sevenfold increase in odds of primary nonfunction and 10-fold increased odds of DGF compared with recipients of DBD kidneys [97]. Other studies have shown that despite the increased risk of DGF, there is similar patient and graft survival for recipients of DCD kidneys compared with DBD donor recipients [92]. These results may be secondary to improved graft and patient survival following DGF for DCD kidney recipients compared with DBD transplant recipients who have experienced DGF [98]. Moreover, Wadei et al. also found similar kidney function between recipients of DCD and DBD donors [99]. Additionally, DCD kidneys from donors under the age of 50 years have been shown to have similar long-term graft function compared to SCD donors [100]. Furthermore, kidney transplantation from DCD donors has been proven to be more cost-effective than remaining on dialysis [101].

Because living kidney donation accounts for 80–85% of kidney transplantation in Japan, the utilization of deceased donor kidneys is limited [102]. However, of the deceased donors, many are Maastricht grade III or IV DCD donors, and of those many meet ECD criteria as well [102]. In this patient population, Tomita et al. described a graft survival of 74.8% at 5 years for DCD ECD kidneys compared with 95.6% for DCD SCD kidneys, although the difference was not statistically significant ($P = 0.102$, 102). In the UK, Nagaraja et al. found that DCD-ECD kidneys had equivalent short-term graft survival to DCD-SCD kidneys and DBD-ECD kidneys [103]. Likewise, the authors reported that increasing donor age was the only aspect of the ECD criteria that was significantly associated with decreased renal function in recipients of DCD kidneys [103].

Treatment

For recipients of DCD kidneys, ATG has been established as a cost-effective induction agent and was also associated with lower rates of DGF and acute rejection compared with IL2R therapy [104]. Mai et al. demonstrated that with the use of ATG followed by maintenance immunosuppression, including tacrolimus, MMF, and rapid steroid taper, yielded 3 years graft survival that was comparable to recipients of DBD kidneys [105]. Another study used a mammalian target of rapamycin inhibitor for uncontrolled DCD donors, and although there was no difference in graft function compared to CNI treatment, nearly 50% of the cohort was converted to CNI therapy [106] (Table 57.5).

Table 57.5 Summary of findings: patient and graft survival for deceased donor kidney transplantation, stratified by deceased donor classification.

Deceased donor classification	No. of participants in study	Patient survival (follow-up time, months)	Graft survival (follow-up time, months)	Certainty of the evidence (GRADE)	Conclusion
Expanded criteria/ high KDPI donors	29 068	–	84.5% (12) 68.0 (36)	Low [18]	The use of expanded criteria/high KDPI donors is associated with acceptable patient and graft survival in selected recipients
	109 127	77%	93.7% (12) 66.4% (60)	Low [2]	
	170 668	–	66.9% (60)	Low [100]	
	244	97% (12) 86% (48)	89% (12) 70% (48)	Low [25]	
	298	98% (12) 95% (60)	95% (12) 83% (60)	Low [109]	
Infectious risk donors	622	97% (12) 91% (36) 84% (60)	93% (12) 83% (36) 84% (60)	Low [52]	IRD kidneys provide graft and patient survival similar to those of standard criteria donors
HCV+ donors	24	100% (6)	92% (6)	Low [63]	HCV+ donors provide acceptable opportunities for kidney transplantation
	6 250	66% (156)	57% (156)	Low [65]	
HIV+ donors	27	84% (12) 74% (60)	93% (12) 84% (60)	Low [77]	HIV+ donors provide acceptable opportunities for kidney transplantation
Donation after cardiac death	170 668	–	77.9% (60)	Low [100]	DCD kidneys offer acceptable short-term outcomes
	312	100% (12) 79% (60)	97% (12) 58% (60)	Low [99]	
	182	–	90% (36)	Low [105]	

DCD, donation after cardiac death; HCV, hepatitis C virus; HIV, human immunodeficiency virus; IRD, infectious risk donor; KDPI, kidney donor profile index.

Conclusions

In summary, the utilization of deceased donor kidneys from ECD donors, those with high KDPI, DCD donors, and donors at risk for infectious diseases or with documented infections provide acceptable outcomes and improved patient survival compared with the alternative of remaining on dialysis. The decision to accept one of these organs should be preceded by an informative conversation between the recipient and members of the transplant team. Additionally, recipient selection for deceased donor kidney transplantation is very important. Bridging the gap between organ supply and demand may be partially achieved through the expansion of deceased donor kidney transplantation in the appropriate clinical setting in which recipients' risks and possible outcomes are clearly communicated.

- Kidney transplantation is the treatment of choice in patients with end-stage kidney disease (ESKD) because it confers a significant survival advantage compared to dialysis treatment [1, 2]. However, the survival remains poorer compared to the age-matched general population without ESKD [3]. Whilst there has been substantial improvement in the short- and intermediate-term allograft survival after kidney transplantation, there has been a lesser improvement in longer-term allograft survival, attributed to differences in etiology of short-term, compared to longer-term allograft failure. In this chapter, we will discuss the short-term medical and surgical complications that can potentially cause allograft failure within 1 year post kidney transplantation (Table 58.1), focusing on the practical approach, investigations, and treatment of these complications.
- Over the last two decades, the improvements in allograft and patient survivals after kidney transplantation have largely been attributed to the availability of more potent immunosuppressive agents (resulting in reduced incidence of acute rejection), improved stratification of immunological risk through the utilization of novel tissue typing technology (molecular human leukocyte antigen [HLA] typing and detection of donor-specific anti-HLA antibodies using Luminex technology), and better management of vascular risk factors prior to and after kidney transplantation [4–11]. Even though early mortality post-transplantation is relatively infrequent (5% at 1 year), the risk of mortality up to 6 months post-transplantation is three times higher compared to wait-listed patients on maintenance dialysis. Cardiovascular disease (CVD) and infections remain the two most common causes of early mortality post-transplantation, particularly among older patients, patients from socioeconomically deprived areas, and those with prevalent vascular disease or a long duration of ESKD [12, 13]. In addition, donor types and characteristics are likely to influence allograft and patient survival such that recipients of older live and deceased donor kidneys experience poorer allograft and patient survival compared to recipients of younger donor kidneys, with the magnitude of the survival differences more apparent in younger recipients [14, 15].
- The 1-year allograft survival in deceased and live donor kidney transplantation has improved substantially in the last decade. In Australia, primary allograft survival has increased from 80% to 94% between 1991–1992 and 2015–2016, respectively, for deceased donor transplants, and from 92% to 98% between 1991–1992 and 2015–2016, respectively, for live donor transplants [16, 17]. Similar trends have been observed in the United States (1-year allograft survival: deceased donor 87% in 1998 to 93% in 2014, live-donor 93% in 1998 to 97% in 2014) [18], Canada (1-year allograft survival: deceased donor 93% in 2007 to 94% in 2014, live-donor 96% in 2007 to 99% in 2014) [19], and the UK (1-year allograft survival: deceased donor 93% in 2005 to 94% in 2016, live-donor 95% in 2005 to 98% in 2016) [20, 21].
- Nonetheless, despite the improvement in short- and intermediate-term allograft survival, there has been little improvement in long-term allograft survival beyond 10 years post kidney transplantation, likely related to the lack of effective therapies for the common causes of late allograft failure including recurrent/de novo glomerulonephritis (GN), chronic antibody mediated rejections, and death with a functioning graft (particularly from CVD and cancer) [22, 23]. These trends have been observed in several countries, including Australia, Europe, and the United States [24–27].

Table 58.1 Potential surgical and medical complications occurring in the first 12 months after kidney transplantation.

	0–3 months	>3–6 months	>6–12 months
Surgical complications			
Wound complications			
Renal vein/artery thrombosis			
Renal artery stenosis			
Ureteric (urine leak/obstruction/ischemia)			
Lymphocoele			
Medical complications			
Acute rejection/allograft failure			
Delayed graft function			
Disease recurrence			
BK viral infection/allograft nephropathy			

Grey, high likelihood of complications within the time frame after kidney transplantation; black, low likelihood of complications within the time frame after kidney transplantation.

Early Surgical Complications

Although our knowledge and understanding of the immune system has transformed the practice of renal transplantation since the first successful attempt in 1954, it is somewhat humbling to admit that our surgical techniques are still based on Alexis Carel's work at the very beginning of the twentieth century [28]. However, we have also refined those techniques to achieve 1-year allograft survival rates in excess of 97%, despite the perils of the immune system and ABO blood groups, not to mention the hurdles of morbid obesity, which has become the surgeons' greatest challenge in the twenty-first century [29].

Vascular Complications

Although the early pioneers attempted anastomoses in the forearm, a heterotopic position, such that the transplanted ureter can reach the bladder, was more logical. This has become standard practice, utilizing the recipient's iliac vessels. Usually the kidney is placed in an extraperitoneal pocket or space, which has the added advantage of both avoiding any risk of intraperitoneal adhesion formation and bowel obstruction, as well as avoiding any potential torsion of an intraperitoneal kidney, which can rotate around on its vascular pedicle, resulting in acute infarction [30]. This rare but catastrophic complication can occur if a kidney is placed within the peritoneal cavity, where immunosuppression reduces adhesion formation and bladder distension can push the lower pole up and lead to torsion. Nevertheless, this potential early complication remains possible, particularly in very thin recipients, and may explain why allograft failure secondary to technical complications is relatively more common in patients with a low body mass index (BMI) compared with those with higher BMI [31].

Even with the advent of minimally invasive laparoscopic kidney transplantation, early allograft failures secondary to torsion of a laparoscopically placed intraperitoneal kidney have been reported [32]. Consequently, refinement of the implantation technique by creating an extraperitoneal pocket postreperfusion, which "fixes" the kidney in place, has minimized this devastating early complication. Early allograft failures attributed to vascular mishaps are associated with significant morbidity, with the need for allograft nephrectomy as well as the risk of developing sensitization to exposed HLA-antigens.

Over the years, the availability of novel immunosuppressive agents such as the calcineurin-inhibitor (CNI) of tacrolimus has reduced the rates of early surgical complications, including a reduction in the incidence of renal vein thrombosis. Clinically, renal vein thrombosis would be heralded by dark-colored urine, followed by macroscopic hematuria and frequently accompanied by acute severe pain over the allograft as the capsule overlying the allograft stretches and subsequently ruptures. This vascular complication is now infrequent, but remains life-threatening in the early post-transplant period if unidentified. The risk factors for renal vein thrombosis are likely multifactorial, with vascular anatomy (of the allograft), surgical technique, and expertise likely contributing factors [33–36]. However, these findings have to be

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. interpreted with caution as granular information such as the length of the renal vein, anastomosis site, or whether a caval extension was used in the setting of a right-sided deceased donor kidney were not available and may have modified the study findings. It is conceivable that venous thrombosis may occur because the length of the renal vein was left too long or indeed made even longer with the use of the attached inferior vena cava. Nevertheless, several registry-based observational studies have shown that recipients of kidney transplants using right-sided deceased donor or live donor kidneys were more likely to experience an increased risk of delayed graft function (DGF) and/or greater risk of early allograft failure attributed to surgical complications compared to left-sided donor kidneys [37]. While there is little doubt that right-sided kidneys pose a greater challenge to the surgical team, it is likely that a shorter renal vein combined with the longer renal artery on the right may contribute to the kinking of the vessels, resulting in the complication of renal vein thrombosis and premature allograft failure associated with the utilization of right-sided kidneys for transplantation. Smoking has also been shown to be a significant risk factor for renal vein thrombosis and therefore many transplanting centers have advocated that current smoking is considered an absolute contraindication to kidney transplantation [38].

These thoughts provide a convenient segue into complications from the arterial side of the renal allograft. Transplant renal artery stenosis is a well-recognized complication after kidney transplantation, with reported incidence varying between 1% and 25%. A recent cohort series of over 500 live donor kidney transplants reported an incidence of 3.8% for computer tomography (CT) angiography confirmed transplant renal artery stenosis, with total ischemic time and use of an arterial conduit identified as independent risk factors for this complication [39]. Transplant renal artery stenosis can be managed successfully with angioplasty and/or stent insertion, and rarely surgical exploration, but this complication has been associated with reduced 5-year allograft survival when compared with allografts without this complication.

Even though the direct visualization of renal vessels using digital subtraction angiography is considered the reference standard in detecting renal artery stenosis, less invasive techniques of Doppler ultrasound, CT angiography, and magnetic resonance (MR) angiography have largely superseded direct angiography in the screening for arterial stenosis [40].

Early allograft failure is usually deemed technical and assumed to be arterial or inflow in origin, rather than the rarely seen venous thrombosis. However, the details and cause of these early complications are often difficult to ascertain and are likely multifactorial in nature, with data from personal series and cohort studies adding little to the current understanding of the pathogenesis and subsequent prevention of allograft thrombosis [41].

Accelerated atherosclerosis and arterial calcification are highly prevalent in patients with ESKD, which are associated with significant morbidity and mortality. Widespread arterial disease is often considered a relative contraindication to kidney transplantation and therefore careful surgical evaluation by an experienced transplant surgeon is an essential aspect of determining surgical transplant suitability. In patients with or without arterial disease, dissection of the intima from the media of the recipient's iliac artery following arteriotomy during transplantation can lead to acute limb ischemia, in addition to the possibility of eliciting acute allograft thrombosis and failure [42]. Consequently, the careful selection of an appropriate anastomotic site avoiding calcified areas of atherosclerosis may mitigate this rare complication, but it can also occur in apparently healthy vessels. Dissection of the donor renal artery is an even less frequently reported complication that may be attributed to poor surgical technique or donor injury. If this is evident following reperfusion, urgent excision of the dissected segment where possible and re-anastomosis may lead to graft salvage, although successful angioplasty and surgical repair, as well as synthetic and autologous vein graft replacement have all been reported [43]. If left unrecognized, acute allograft ischemia will ensue, leading to early allograft failure.

Deceased donor kidneys usually have the added surgical advantage of an arterial patch which facilitates a wide arterial anastomosis, thereby reducing the risk of stenosis at the anastomotic site. However, the acute kinking of a long donor renal artery beyond the anastomotic site may occur, which may not become evident until after wound closure. For this reason, many transplanting units often advocate for early or immediate post-transplant Doppler ultrasound to assess renal vasculature, with patients returning immediately to theater for re-exploration if evidence is found of any compromised arterial flow within the allograft.

The appropriate positioning of the allograft within the extraperitoneal space following completion of vascular anastomoses is an important component of transplant surgery. The malposition of the allograft could lead to kinking or occlusion of the renal vasculature, but may also potentially cause torsion, resulting in acute vascular thrombosis and premature allograft failure. The authors advocate turning the allograft medially and, if necessary, creating a further extraperitoneal pocket beneath the rectus abdominis muscle such that the wound can be closed without compressing the allograft down on the recently created anastomoses. This medial placement may be more appropriate for thin recipients, as it requires only a simple technique

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. modification and may avoid the intraperitoneal placement of the allograft that is often advocated for thin adult recipients.

A rare but potentially life-threatening complication is mycotic aneurysm, with an extremely low incidence reported in published series [44, 45]. The etiology of this complication is frequently attributed to *Candida species*, with the potential to cause catastrophic bleeding if unrecognized. The clinical team must have a high index of suspicion, particularly in patients presenting with acute abdominal pain and allograft dysfunction in an otherwise stable post-transplant setting. The primary goal of treating the mycotic aneurysm is excision of the infected aneurysm and re-establishing distal arterial flow. The management of a suspected ruptured mycotic aneurysm will focus on halting the hemorrhage, which will often require allograft nephrectomy as the infected arterial anastomosis ruptures into the extraperitoneal space. Ideally, all the allogeneic vasculature should be removed, with repair of the anastomotic site with autologous vein to patch the site or replacing a short segment of the infected iliac artery. Use of the recipient's own internal iliac artery, such that the mycotic segment can be excised and replaced, has been reported, but often these cases are undertaken under life-threatening circumstances, with covered synthetic stents placed within the external and common iliac artery to limit ongoing hemorrhage [46]. However, this approach may lead to an infected stent and in the context of an immunosuppressed patient now recently returned to dialysis following allograft removal may result in complicated infectious complications. If this occurs, the entire iliac arterial system can be replaced with deceased donor iliac artery such that an infected stent could be removed without losing the blood supply to the lower limb (unpublished observation), although an autologous long saphenous vein when available would be the preferred conduit. The management of the mycotic aneurysm has evolved from surgical reconstruction to an endovascular approach, the latter thought likely to be associated with lower risk of morbidity and immediate mortality. Even though there is no high-level evidence comparing the efficacy and safety of open surgery versus endovascular stenting in this rare and unique setting, it does allow clinicians to select the most appropriate approach depending on the acuteness of the presentation, clinical circumstances, and expertise of the treating surgical teams.

Over the last decade, there is a greater focus on the timing of the surgery, particularly the time taken for vascular anastomoses (i.e. warm ischemic time) as well as preservation of the allografts using cold or normothermic perfusion machines [47]. Data from the United Network of Organ Sharing (UNOS) and Eurotransplant registries have shown an inverse association between warm ischemic time and allograft survival independent of cold ischemic time, such that for every 10 minutes increase in warm ischemic time, there was up to an 8% increased risk of allograft failure [48]. A smaller cohort study, also from Eurotransplant, similarly showed a direct relationship between warm ischemic time and risk of DGF and allograft fibrosis, independent of the duration of cold ischemic time [49]. Despite the recognition that shorter warm ischemic time is associated with better allograft outcome, it is somewhat surprising that almost 30% of the kidney transplants in these studies have reported times of over 45 minutes, reinforcing the need for careful speed under stressful circumstances. With the evolution of laparoscopic and more recently robotic kidney transplantation techniques, it will become ever more important to protect the kidney from prolonged warm ischemic injury, highlighting the critical role in the learning curve of the surgeon [50].

Ureteric Complications

The incidence of ureteric complications after kidney transplantation is estimated at between 2% and 12%, predominantly related to urine leak and obstruction [51]. The role of intra-operative ureteric stenting (versus no stenting) remains a subject of debate among transplant surgeons and urologists. One of the largest published randomized controlled trials (RCTs) of 300 kidney transplant recipients showed that these major urological complications could be completely avoided in the early transplant period with stent usage [52]. A systematic review of seven studies showed that routine prophylactic stenting of the ureter significantly reduced the risk of major urological complications, at the expense of an increased risk of urinary tract infection, unless prophylactic cotrimoxazole was prescribed [53]. In addition, there is a suggestion that ureteric stents may increase the risk of developing BK viral allograft nephropathy (BKVAN), although a definitive causal relationship has not been established [54]. Given these findings, the majority of the transplanting units have advocated for the routine prophylactic placement of ureteric stent to reduce the risk of early urine leak or obstruction. Nevertheless, ureteric stent avoidance does not necessarily result in greater rates of urological complications, with several authors advocating selective stent usage to avoid the increased risk of urinary tract infection [55]. Meticulous surgical technique remains an important facet of reducing the risk of post-transplant urological complications.

There is considerable interest among transplant urologists regarding the optimal timing of ureteric stent removal post-transplant. Several small randomized controlled trials have shown early stent removal to be beneficial. A recent

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

systematic review of five studies comprising 1127 kidney transplant recipients has shown that early stent removal within the first 2 weeks significantly reduced the incidence of urinary tract infection, provided the stent was not sutured to the urinary catheter [56]. However, the quality of evidence supporting these findings is poor. Consequently, there is substantial variation in the timing of ureteric stent removal between transplanting sites, which may also depend on several nontransplant-related factors such as theater availability and expertise in cystoscopy.

Urine leak in the early post-transplant period is often difficult to diagnose, but may be suspected when there is an unexpected worsening of allograft function in the setting of a new perinephric collection. This can be confirmed by a high creatinine concentration in the drain fluid when compared with serum creatinine concentration. There are several risk factors for urine leak, including ureteric stent migration out through the renal hilum, urine leak post biopsy, or leak from an infarcted area of kidney cortex, although prolonged surgical procedure beyond 3 hours has also been identified as a risk factor. Management of confirmed urine leak in the early post-transplant period is often surgical re-exploration even though anastomotic dehiscence is unusual, particularly if the ureteric stent and urinary catheter remains in situ. However, percutaneous drainage may have a role, particularly if the volume of urine leak is small and providing infection can be avoided. If a urine leak has occurred later post-transplant, conservative treatment with bladder decompression by prolonged catheterization and management of the contributing factors may be sufficient to ensure spontaneous resolution of these leaks without surgical intervention [57].

Ureteric obstruction is an infrequent occurrence in the era of routine placement of ureteric stents. Nevertheless, ureteric stenosis or obstruction may occur following routine removal of the stent and therefore must be excluded in situations where there is an acute deterioration of allograft function following stent removal. A dedicated ultrasound assessment is the initial imaging modality of choice and is usually sufficient to exclude ureteric obstruction. Management of ureteric obstruction does depend on the cause of the obstruction and local expertise, but often involves an antegrade percutaneous nephrostomy and subsequent stent insertion, unless the ureteric anastomosis can be accessed satisfactorily via cystoscopy. Many urologists advocate placement of the ureteric anastomosis at the lowest possible part of the bladder wall, rather than on the much more accessible bladder dome. However, the former is rarely practical in patients with a long history of anuria with a shrunken bladder.

Ureteric infarction can occur when the blood supply to the transplanted ureter is compromised, often in the setting of a ligated or thrombosed lower polar artery. The only available salvage treatment option is surgical ureteric reconstruction by anastomosing the renal pelvis of the allograft to the ipsilateral native ureter, which if successful can offer reasonable long-term allograft outcome. However, more distal strictures can be managed by raising a Boari flap from the bladder, as has been reported in 14 patients from a cohort study [58].

Lymphocele

Lymphocele formation occurs in approximately 4% of kidney transplant recipients [59] and, if of sufficient size, may lead to compression of the vasculature and/or transplant ureter causing acute or subacute allograft dysfunction and venous obstruction. Multiple risk factors for lymphcoele development have been reported, including the use of mammalian target of rapamycin (mTOR) inhibitors, although causal relationships have not been clearly established [60]. There is currently no consensus regarding the optimal management of lymphoceles, and it is likely to depend on the size, unit protocol, the pressure effect on surrounding structures, and the degree of allograft dysfunction attributed to the lymphocele. In a systematic review of 52 studies evaluating the different treatment strategies for post-transplant lymphocoeles, percutaneous drainage was reported to be effective in 25% of cases and is often considered the first-line treatment option in most transplanting units. The alternative option, particularly following failure of percutaneous drainage, is laparoscopic or open surgical drainage; the latter may be preferred for inferiorly placed lymphocele (and therefore difficult to identify the ureter) given the potential risk of ureteric injury [59].

Wound Complications

The incidence of wound complications such as wound dehiscence and infection following kidney transplantation may be up to 25%, particularly in high-risk groups with morbid obesity and low functional status [61]. This complication often leads to prolonged hospitalization or readmissions, requiring additional nursing/wound care, adjustment of immunosuppression, and excess healthcare resource utilization.

In a single institution study of over 2200 kidney transplant recipients, the incidence of incisional hernia formation was 5% at 5 years, increasing to 7% at 10 years. Both recipient obesity and surgical site infection were risk factors for subsequent hernia formation in this large series, with surgical site infection associated with almost a 30 times the risk of developing incisional hernia [62]. Patients

should be adequately informed of these potential complications prior to transplantation, although informed consent should not abrogate the need for careful aseptic technique and tissue handling to minimize such wound complications.

Conclusion

There is an evolution of minimally invasive surgical techniques for kidney transplantation, including the creation of anastomoses using laparoscopic and now robotic-assisted surgery but the long-term allograft outcomes of these approaches remain unknown. The challenge for transplant surgeons going forward is how to minimize the effects of the learning curve associated with these new minimally invasive techniques in morbidly obese recipients, particularly when slow anastomoses increases the risk of DGF and jeopardizes long-term allograft survival. Perhaps one of the greatest challenges is the transplantation of an allograft with multiple arteries and veins, as well as a bifid ureter, which will always challenge the experienced surgical team to minimize early surgical complications.

Early Medical Complications

Acute Rejection

Acute rejection of the kidney allografts following transplantation continues to be a major impediment to long-term allograft survival [63]. Even though the incidence of early acute rejection has decreased substantially over the last few decades with the introduction of more potent induction and maintenance immunosuppression (resulting in improvement of short- and intermediate-term allograft survivals), the incidence of acute rejections within the first 12 months post-transplantation is reported to be between 8% and 20% in most countries, with one in five allograft failures within the first year post-transplant attributed to acute rejection [17, 18, 64]. Compared to kidney transplant recipients who have not experienced acute rejection, recipients who have experienced cellular rejection have over a 1.5-fold greater risk of allograft failure, with those experiencing more severe rejections such as antibody-mediated rejections and/or vascular rejection associated with the poorest prognosis [63, 65, 66]. The most effective treatment strategies (combination of treatments and dosing of treatments) for cellular and antibody-mediated rejections remain uncertain, although interventions to eliminate circulating T cells (e.g. antithymocyte and antilymphocyte antibodies, alemtuzumab) and/or remove circulating donor-specific anti-HLA antibodies (plasmapheresis, intravenous immunoglobulin, anti-B cell, and anti-plasma cell therapies) are often required in the treatment of steroid-resistant cellular/vascular rejections and antibody-mediated rejections, respectively [67–72].

The risk of hyperacute rejection has largely disappeared with the evolution of novel immunological assays to detect for the presence of pretransplant donor-specific anti-HLA antibodies including luminex assays and flow cytometric cross-matching technique, which has facilitated a more accurate assessment of pretransplant immunological risk and appropriate selection of immunologically compatible donor kidneys. Even though pretransplant donor-specific anti-HLA antibodies are known to be associated with poorer outcome, including a 40 times greater risk of antibody-mediated rejection and premature allograft failure [73], the recognized limitations of the Luminex assays combined with the uncertainty regarding the differential adverse impact of the type, quantity, and quality of the donor-specific anti-HLA antibodies have led to a cautious but varying approach to the interpretation of these assays [7]. Consequently, there continues to be considerable debate regarding the acceptance (and nonacceptance) of donor kidneys for transplantation in patients with pre-existing donor-specific anti-HLA antibodies. There is an increasing number of non-HLA alloantibodies targeting vascular and angiotensin receptors or proteins expressed on endothelial cells (e.g. anti-endothelin-1 type A receptor antibody, antivimentin antibody, anti-angiotensin II type 1 receptor antibody) that are recognized to influence the development of antibody-mediated rejection and allograft failure [74–77], but the additional clinical significance of these non-HLA antibodies beyond the routine detection of donor-specific anti-HLA antibodies, combined with the cost of these assays, has preclude the inclusion of non-HLA antibodies in the standard immunological risk assessment for potential kidney transplant candidates.

Desensitization techniques designed to deplete anti-A or -B and donor-specific anti-HLA allo-antibodies prior to kidney transplantation have facilitated successful transplantation across the ABO barrier and in patients with pretransplant donor-specific anti-HLA antibodies, respectively. Even though the outcomes of ABO-incompatible kidney transplantation were similar or slightly reduced compared to ABO-compatible transplants [78, 79], the optimal desensitizing regimen remains unclear but typically comprises interventions aimed to remove circulating anti-A or -B antibodies and treatment strategies to suppress antibody production by B cells/plasma cells. A systematic review of 83 cohort, case-controls/reports, and registry studies comprising 4810 ABO-incompatible recipients showed that allograft and patient survivals exceeded 90%, with low-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

level evidence suggesting that preconditioning therapies consisting of immunoadsorptive therapy and rituximab may be associated with better allograft outcomes [80]. The risk of acute rejection after ABO-incompatible kidney transplantation varies between studies (3–52%), with the majority of rejections attributed to antibody-mediated rejections [80] and likely related to pre- and post-transplant anti-A/B titers such that patients with high levels of anti--A/B titers prior to transplantation or who experienced a rapid rebound in anti-A/B titers post-transplant were more likely to experience antibody-mediated rejections. Nevertheless, these associations remained inconsistent, possibly related to differences in desensitization regimens/intensity of immunosuppressive agents, differences in the absolute levels of anti-A/B titers pretransplant, differences in measurement assays of anti-A/B titers, and the possibility of utilizing A2 donor kidney for blood group O or B patients [81–85]. Even though death-censored allograft survival following ABO-incompatible kidney transplantation is similar to that of ABO-compatible kidney transplantation, these recipients may have a greater risk of mortality at 1-year post-transplant, attributable to infectious complications presumably related to the greater burden of immunosuppression from desensitization treatments [86].

There is a general reluctance among clinicians to consider transplantation across the ABO barrier and pretransplant donor-specific anti-HLA antibodies because of the perceived incremental risk of adverse allograft outcome, but the impact on allograft outcome may be similar to transplants with pretransplant donor-specific anti-HLA antibody [87]. A recent cohort study of 681 live donor kidney transplant recipients showed that ABO-incompatible kidney transplant may reduce the likelihood of developing de novo donor-specific anti-HLA antibodies, independent of the use of rituximab, but the exact mechanism of this favorable effect remains unknown and conflicting [88].

Highly sensitized patients often experience prolonged waiting time, lower transplantation rate, and a greater risk of mortality and adverse allograft outcomes following transplantation [89]. Desensitization strategies to remove circulating donor-specific anti-HLA antibodies have resulted in successful live-donor kidney transplantation in HLA-sensitized patients, with patient survival superior compared to dialysis treatment and waiting for a compatible donor kidney [90]. However, the longer-term outcome of cross-match positive kidney transplant recipients remains inferior compared that for to cross-match negative recipients [91]. The optimal desensitization regimen in cross-match positive HLA-sensitized live donor kidney transplant remains unknown, but typically comprises plasmapheresis, intravenous immunoglobulin and/or anti-B cell therapy/splenectomy [90, 92]. Similar regimens have also enabled the successful transplantation of these sensitized patients, with significant reduction in waiting time on the deceased donor transplant wait-list [93, 94]. A recent study of 25 highly sensitized patients showed that an endopeptidase, IgG-degrading enzyme derived from *Streptococcus pyogenes* (IdeS), substantially reduced donor-specific anti-HLA antibodies therefore allowing HLA-incompatible transplantation in 96% of these patients [95]. Even though this therapy appears promising, longer-term prospective trials including larger numbers of patients are required for better appraisal of this molecule.

The availability of high-resolution molecular HLA-typing methods has allowed for a more accurate assessment of HLA compatibility at the structural (or epitope) level, which has revolutionized our understanding of immunological compatibility in kidney transplantation. The importance of epitope matching has been highlighted in multiple cohort studies such that incremental mismatched epitope load is associated with a greater risk of acute rejection and poorer longer-term allograft outcome [8, 96–100]. Consequently, several countries have implemented allocation programs designed to preferentially allocate donor kidneys with a lower number of donor/patient epitope mismatched load, which may ultimately reduce the long-term risk of acute and chronic antibody-mediated rejection and improve long-term allograft survival [101, 102].

Over the last two decades there have been several clinical trials designed to examine the efficacy of different induction and maintenance immunosuppressive regimens. Even though the optimal induction regimen remains debatable, it is widely accepted that an immunosuppressive regimen comprising of tacrolimus and mycophenolate is the preferred maintenance immunosuppressive regimen, with other novel immunosuppressive agents inferior to or at most comparable to the efficacy of this regimen. Table 58.2 summarizes the important multicenter clinical trials comparing the efficacy of different de novo induction and maintenance immunosuppressive regimens on short-term allograft outcomes after kidney transplantation (only RCTs of more than 150 randomized patients since 2005 are shown).

Delayed Graft Function

DGF is a common complication after kidney transplantation (20–50%), with the highest incidence observed after donation after circulatory death (DCD) kidney transplants [116]. DGF is a pathophysiological process of ischemia-reperfusion injury following organ procurement, leading to excess inflammatory response, including indirect activation of the innate and adaptive immunity [117].

Table 58.2 Summary of the randomized controlled trials comparing the short-term efficacy of different immunosuppressive regimens in de novo kidney transplant recipients.

Trial	Design	*N*	Primary endpoint	Outcome	Adverse events
Induction therapy randomized controlled trials					
Brennan et al. [103]	RCT, superiority study of basiliximab vs. antithymocyte globulin	278	Composite of acute rejection, delayed graft function, graft loss, and death at 12 months	Composite endpoint: basiliximab 56% vs. antithymocyte globulin 50% ($P = 0.34$) Less BPAR in antithymocyte globulin group	Similar
Thomusch et al. [104]	RCT, superiority study Basiliximab + Tac/MMF ± P withdrawal day +8 vs. rATG + Tac/MMF/P + withdrawal P day +8	615	BPAR 12 months	BPAR rates similar: basiliximab (11% with or without P withdrawal) vs. rATG (10%)	Less PTDM (post-transplant diabetes mellitus) in steroid withdrawal groups
3C Study Collaborative Group [105]	RCT, superiority study of alemtuzumab vs. basiliximab	852	BPAR at 6 months	BPAR: alemtuzumab 7% vs. basiliximab 16% ($P < 0.01$)	More BK infection with alemtuzumab
Maintenance therapy randomized controlled trials					
Ekberg et al. (ELITE-Symphony study) [106]	RCT, superiority study of four regimens: (i) standard-dose CsA + MMF + P, daclizumab induction with MMF + P, (ii) low-dose tacrolimus, (iii) low-dose CsA, and (iv) low-dose sirolimus	1645	eGFR at 12 months	eGFR higher in low-dose tacrolimus vs. all other groups ($P < 0.01$) 6 months BPAR/12 months allograft survival: low-dose tacrolimus 11%/96%, low-dose CsA 22%/94%, low-dose sirolimus 35%/92%, standard-dose CsA 24%/92%	SAE more common in low-dose sirolimus group, incidence PTDM (post-transplant diabetes mellitus) higher in low-dose tacrolimus group (8%)
Vincenti et al. (BENEFIT study) [107]	RCT (phase 3), noninferiority study of MMF + P with (i) low-intensity (LI) belatacept, (ii) more intensive (MI) belatacept, and (iii) CsA	686	Three endpoints: 12 months composite graft and patient survival, composite renal impairment, and BPAR	Compared to CsA, belatacept was noninferior for graft/patient survival, superior in 12 months renal function, noninferior in BPAR (except MI belatacept was inferior)	Similar, more cases of PTLD (particularly brain) in belatacept groups
Durrbach et al. (BENEFIT-EXT study) [108]	RCT (phase 3) in expanded criteria donor kidney transplants, noninferiority/superiority study of LI and MI belatacept vs. CsA	578	12 months composite graft and patient survival (noninferiority), composite renal impairment (superiority)	Compared to CsA, belatacept was noninferior for graft/patient survival, superior in 12 months renal function BPAR similar	Similar, more cases of PTLD in belatacept groups
Russ et al. [109]	RCT (phase 2), noninferiority study of three doses of sotrastaurin + standard/reduced-dose tacrolimus + P vs. standard-dose tacrolimus + MPA + P	298	6 months composite of BPAR, graft loss, death or lost to follow-up	Similar outcomes (sotrastaurin 100 mg group discontinued because of high event rate) Median eGFR similar	Similar, but more gastrointestinal events and transient increase in heart rate in sotrastaurin groups

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Tedesco-Silva et al [110]	RCT (phase 2), noninferiority study of CsA + everolimus vs. sotrastaurin + everolimus (stage 1 efficacy study), then dose-finding study for sotrastaurin (stage 2)	311 (both stages)	Composite of BPAR, graft loss, death or lost to follow-up	Stage 1: composite efficacy failures at 3 months similar, higher in sotrastaurin group at 12 months (17% vs. 11%) Stage 2: composite efficacy failures higher in sotrastaurin groups (27–35%) vs. CsA group (19%) at 12 months	Similar, but more gastrointestinal events and transient increase in heart rate in sotrastaurin groups
Lebranchu et al (Concept study) [111]	RCT, superiority study of CsA + MMF + P, randomized at week 12 to continue CsA or change to sirolimus P stopped month 8	193	52 weeks adjusted CrCl	Mean (95%CI) CrCl: sirolimus 68.9 (65.9, 71.8) vs. CsA 64.4 (61.7, 67.1) ml/min/1.73 m^2; $P = 0.02$ Numerically more BPAR in sirolimus group	More adverse events in sirolimus group (aphthous stomatitis, diarrhea and acne)
Weir et al. (Spare-the-Nephron trial) [112]	RCT, superiority study of MMF + CNI, randomized days 30–180 post-transplant to MMF + CNI vs. MMF + sirolimus	299	Mean % change in measured renal function from baseline to 12 months	Mean % change greater in MMF + sirolimus group vs. MMF + CNI group at 12 months (24% vs. 5%, $P = 0.01$) Not significant between groups at 24 months	Similar in both groups, numerically higher rate of discontinuation MMF + sirolimus group
Tedesco Silva Jr. et al. (A2309 study) [113]	RCT, noninferiority study of everolimus + reduced exposure CsA vs. standard-exposure CsA + MPA	833	12 months composite of BPAR, graft loss, death or lost to follow-up	12 months efficacy failure rates were noninferior in the everolimus 1.5 mg (25%) and 3.0 mg (22%) vs. MPA (24%) groups Similar eGFR	Higher discontinuation in the everolimus groups
Flechner et al. (Orion study) [114]	RCT, superiority study of sirolimus + tacrolimus elimination + P, sirolimus + MMF + P vs. tacrolimus + MMF + P	469	12 months eGFR	Similar eGFR at 12 months Group 2 discontinued due to high rate of BPAR Similar rate of BPAR in remaining two groups	Higher rate of discontinuation in sirolimus + tacrolimus elimination group (34%) vs. tacrolimus + MMF (22%)

In the ensuing ischemic injury, there is osmotic injury to cells in addition to an accumulation of reactive oxygen species [118, 119], the damage of which can be reduced with appropriate preservation fluids, optimal storage conditions, and adequate intra- and post-operative fluid balance [120–122]. After reperfusion, the combination of vasoconstriction, activation, and recruitment of innate and adaptive immune cells contributes to sustained epithelial cell damage and inflammatory response, manifesting clinically as DGF [116, 123]. In a prospective longitudinal study of 318 kidney transplant recipients, kidneys that were complicated by DGF showed significantly higher degrees of tubulo-interstitial inflammation (i.e. higher Banff *t* and *i* scores) and higher Banff cumulative chronicity scores in protocol biopsy at 3 months compared to kidneys without DGF, suggesting a potential role of inflammation in determining the longer-term allograft outcomes in recipients with DGF [124].

The clinical manifestations of DGF vary in severity, with definitions of DGF ranging from an asymptomatic slowing in the improvement of allograft function to sustained oligoanuria and hyperkaliemia resulting in the need for dialytic support. The optimal definition for DGF remains unknown and there is no single definition of DGF that has been shown to be superior in predicting the risk of adverse allograft outcome after kidney transplantation. Even though the requirement of dialysis within the first week of transplant remains the most preferred and accepted definition of DGF [125, 126], there is likely to be a dose-dependent effect between DGF duration and allograft failure, with DGF duration of beyond 7 days consistently associated with the highest risk of allograft failure [127–129].

Risk factors associated with ischemia reperfusion or excess inflammatory response such as prolonged ischemic time, older donors and recipients, higher recipient BMI, and longer dialysis duration have been shown to increase the probability of DGF [130, 131]. The consequences of DGF are substantial, with short- and long-term adverse outcomes leading to prolonged hospitalization and excess utilization of healthcare resources [132]. Even though the association between DGF and adverse longer-term allograft survival is well established, there continues to be uncertainty as to whether this association remains consistent in both donation after brain death (DBD) and DCD kidney transplantation. One of the main limitations when interpreting the study findings regarding the "true" incidence of DGF and the association between DGF and allograft outcomes is the significant heterogeneity in the definition of DGF, which is present even after adjustment for patient- and center-level characteristics, and therefore caution must be exercised when interpreting these findings or when considering the most appropriate definition of DGF for clinical trials [133]. In a meta-analysis of 33 studies totaling 151 594 kidney transplant recipients, DGF was associated with over 40% greater risk of allograft failure and poorer allograft function, with the majority of these studies confined to DBD kidney transplant recipients [134]. However, the association between DGF and allograft outcome in DCD kidney transplants remains indeterminate, with several cohort studies showing a lack of association between DGF and allograft survival [135, 136]. This observation is thought to be related to a differential susceptibility between DBD and DCD kidneys to the deleterious effects of cold ischemic injury, such that brain death induces a greater upregulation of inflammatory gene expression profile in the DBD kidneys compared to DCD kidneys, which may to some extent explain why DGF in DCD kidneys may not have the same deleterious effects on allograft survival as DBD kidneys [137]. However, a paired-kidney registry analysis from Australia and New Zealand showed that recipients of DCD kidneys with DGF experienced a fourfold increased risk of allograft failure at 3 years post-transplant compared with those without DGF, suggesting that the deleterious effect of DGF in DBD transplants may also be extended to recipients of DCD kidneys [138].

Several population cohort studies have shown that DGF may predispose to an increased risk of acute rejection, possibly related to reduction in immunosuppression and the excess immunological reactivity resulting from an indirect activation of the innate and adaptive immune responses [116, 139, 140]. There is, however, uncertainty as to whether the adverse association between DGF and allograft outcome is related to the presence of acute rejection or the presence of "susceptible" donor types but it does suggest the need for careful monitoring and evaluation for acute rejection in recipients who have experienced DGF [129, 141, 142].

The presence of DGF increases the complexity in post-transplant management, with clinicians requiring to differentiate DGF from other acute pathology, particularly early acute rejection, which requires an increase in the intensity of immunosuppression, compared to the judicious reduction in CNI (which causes vasoconstriction and may exacerbate DGF) in the presence of DGF. The practical approach to DGF is to determine whether dialysis is clinically indicated after exclusion of competing pre- and postrenal complications and early consideration for allograft biopsy to discern acute tubular necrosis (suggesting DGF) from acute rejection. Repeated imaging of the allograft vasculature and frequent biopsies may be necessary in the presence of prolonged DGF. There is little data to guide the management of prolonged DGF in the absence of acute rejection. Other than avoiding nephrotoxins, pre-emptive

delaying the introduction of CNI (where there is a high pretransplant probability of DGF) and substituting CNI for mTOR-inhibitors or antilymphocyte therapy are unproven strategies, although the latter approach may be practical in the concurrent presence of acute rejection or in highly sensitized recipients at high risk of acute rejection [143–147]. Figure 58.1 shows a practical algorithm in the management of recipients with DGF. Given the greater understanding of the risk factors and complexity of the pathophysiological mechanisms contributing to the development of DGF, there have been multiple clinical trials utilizing promising therapies (e.g. belatacept, toll-like receptor monoclonal antibody, pegylated carboxyhemoglobin bovine) that may lead to a reduction in the burden of DGF and consequently improve longer-term allograft outcome. In addition, normothermic machine perfusion has been shown to effectively assess and potentially ameliorate the ischemia reperfusion injury prior to implantation [148]. A large multicenter RCT comparing the efficacy of normothermic perfusion with standard cold storage is currently underway in the UK which may help in defining the role of this technology in the future [149].

Early Disease Recurrence

Primary glomerulonephritis (GN) is one of the leading causes of ESKD worldwide [150–152]. In Australia and New Zealand, primary GN accounts for 20% of incident ESKD and is the most common indication for kidney transplantation (ANZDATA registry 2017 report). In the United States, Canada, and the UK, ESKD attributed to primary GN contributes to between 10% and 20% of overall burden of ESKD. All GN subtypes can potentially recur after transplantation, with the prevalence of GN recurrence between 3% and 15%, although patients with IgA nephropathy, membranoproliferative GN (MPGN), focal segmental glomerulosclerosis (FSGS), and idiopathic membranous nephropathy (IMN) are more likely to experience disease recurrence compared to other GN subtypes, including those with presumed or advanced GN without a clear histological diagnosis [152]. Even though the risk of GN recurrence is directly proportional to time post-transplant, early GN recurrence resulting in allograft failure within 12 months is more common in patients with FSGS and MPGN. Up to 30% of patients with FSGS experience disease recurrence post-transplant [152–155], particularly those with primary FSGS whereby the presence of a circulating glomerular permeability factor might directly induce podocyte damage and early recurrence [156]. In contrast, patients with familial FSGS have low risk of disease recurrence, with the belief that the intrinsic genetic defect of the host kidney is corrected by receiving a donor kidney without this defect [157]. The treatment of recurrent FSGS remains largely unproven, with plasmapheresis, immu-

noadsorption, and alternative immunosuppressant (e.g. cyclophosphamide, abatacept) used with varying successes, but the optimal treatment strategy remains unknown [158–161].

Disease recurrence from primary MPGN is relatively common, with high rates of recurrence (up to 100%) and allograft failure (50%) observed for those with type I and II MPGN (majority were reclassified as immune complex-mediated GN according to the new classification [162]) and over 50% of recurrence occurring within 12 months post-transplant [152, 163–165]. Similar to FSGS, the optimal treatment for recurrent disease is not established, limited to case reports of successful treatment with the use of plasmapheresis and other immunosuppressants, including cyclophosphamide, eculizumab, and rituximab [166–169]. Although the recurrence rate of IgA nephropathy and IMN may be up to 50% post-transplant, early recurrence is unusual and the progression of disease recurrence to allograft failure is typically slow [170]. It is likely that the incidence of GN recurrence or allograft failure attributed to GN recurrence may be underestimated because of the likelihood of selection bias (i.e. systematic differences in the selection and listing of ESKD patients with different GN subtypes), misclassification and indication bias (where kidney biopsy may be carried out only for specific clinical indication and therefore may fail to identify asymptomatic incidental cases of disease recurrence) and the competing risk of other causes of allograft failures.

Patients with systemic diseases and ESKD resulting from secondary GN (such as atypical hemolytic uremic syndrome [aHUS], systemic lupus erythematosus [SLE], anti-glomerular basement membrane [GBM] disease, and crescentic GN [e.g. from systemic vasculitis]) may experience GN recurrence after kidney transplantation but these relapses are often late and infrequently lead to allograft failure [170]. In patients with antineutrophil cytoplasmic antibody (ANCA)-associated vasculitis, the relapse rate (often at nonrenal systems) has been reported to be 0.02 per patient-year, with no consistent association found between ANCA subtypes or disease severity pretransplantation and risk of relapse [171–173]. The incidence and outcome of patients with recurrent lupus nephritis post-kidney transplantation are unclear, with the majority of the reports from single-center and registry studies. The reported incidence of recurrent lupus nephritis varies between 0% and 44% [174], with patients who had experienced recurrent lupus nephritis at a greater risk of allograft failure and mortality [175–178]. However, this association remains inconsistent [179]. In patients with anti-GBM disease, disease recurrence after kidney transplant is less than 5% in the era of modern immunosuppression, and allograft failure from disease recurrence is exceedingly rare [180, 181]. Prior to the availability of the C5-inhibitor eculizumab (Soliris®), the risk of disease recurrence following transplantation of patients with aHUS was up to 80%, and a substantial proportion of patients would lose their allograft from recurrent disease within the first year post-transplant, therefore kidney transplantation is considered a contraindication for patients with aHUS [182]. With prophylactic use of eculizumab, kidney transplantation appears safe and associated with excellent allograft outcome, even in those with pathogenic mutations known to be associated with a high risk of disease recurrence [183–185]. There have been reports of successful live donor kidney transplantation without the use of prophylactic eculizumab but this is generally not recommended or undertaken with extreme caution in patients with certain genetic mutations (e.g. membrane-associated complement regulator membrane cofactor protein mutation) and frequent monitoring [186, 187].

Table 58.3 shows the primary causes of ESKD that are known to recur post-transplant, stratified by the timing of disease recurrence and available treatment options.

BK Viral Infections

BK viral infection is common after kidney transplantation, and early recognition and treatment can prevent progression to allograft failure from BKVAN [188]. Because cellular adaptive antiviral immunity is critical in the control of BK viral infection and BKVAN, the overall intensity and cumulative exposure to chronic immunosuppression is the most consistent risk factor for the development of BK viral infection and related BKVAN [189]. Population cohort studies have identified the use of T-cell depleting antibody, and tacrolimus and mycophenolate-based immunosuppressive regimen associated with a greater risk of BK viral infection, but other donor (e.g. BK-seropositivity of donor), recipient (age, male gender, presence of diabetes), and transplant-related risk factors (e.g. HLA-matching, acute rejection, DGF) have also been shown to be associated with BKVAN [190, 191]. In a prospective multicenter RCT of 682 kidney transplant recipients, cyclosporine--mycophenolic acid (MPA) regimen was associated with almost a 70% reduction in the risk of BK viremia at 12 months post-transplant compared to tacrolimus-MPA regimen, showing for the first time the differential relationship between CNI type and risk of BK viral infection [192].

Primary infection of BK virus is often subclinical, with the virus remaining latent in renal tubular epithelial cells and uro-epithelium. As a result of immunosuppression, BK viral replication may occur, resulting in BK viruria and viremia, and if untreated up to 10% of patients can pro-

gress to BKVAN [193]. In the absence of effective treatment strategies for BKVAN, screening for BK viral replication (i.e. presence of decoy cells, BK viruria or viremia) is critical to facilitate early intervention prior to the development of overt BKVAN. The true incidence of BK viral infection remains unclear, but prospective screening studies have shown that the peak incidence of BK viremia occurred at 3 and 12 months post-transplant (up to 11–28%), with the majority of BKVAN occurring within the first 12 months post-transplant [193–195]. The optimal and most cost-effective screening method for BK viral replication remains unclear, although the test performances of urinary haufen and BK viremia screening methods appear to be superior to other screening methods [196–198]. As new onset BK viral infection tends to occur within the first 24 months post-transplant, the general recommendation is to consider regular screening for BK virus from 1 month up to 24 months post-transplant, with the frequency and duration of screening determined by the prevalence of the BK viral infection/BKVAN in each transplant center [199]. Renal allograft biopsy remains the gold standard for the diagnosis of BKVN and should be considered in the presence of sustained BK viremia (particularly if serum BK viral load >4 log copies/ml). There is currently no universal grading system for BKVAN and although each of these grading systems is slightly different, the presence of severe inflammation and fibrosis is consistently associated with poorer allograft prognosis. Nevertheless, the establishment and validation of a single standardized grading system for BKVAN will be important to guide treatment (and response to treatment in trial setting) and to assess prognosis [199–201].

The mainstay of treatment for BKVAN remains a reduction of the intensity of immunosuppression [202–204], but the optimal immunosuppressive regimen remains unknown. A dilemma facing clinicians is to decide the balance between reducing immunosuppression versus maintaining an adequate level of immunosuppression to prevent acute rejection (incidence of acute rejection post-immunosuppression reduction reported at 8–12%). As interstitial inflammation is a common histological finding in patients with BKVAN, clinicians are often reluctant to consider aggressive reduction of overall immunosuppression. If allograft failure attributed to BKVAN ensues, retransplantation is largely successful, but requires close monitoring for recurrent BK viremia [199]. Allograft nephrectomy is generally advocated prior to retransplantation in an attempt to reduce the latent BK virus load within the failed allografts urothelium. A management flow-chart of the diagnosis and treatment of BK viral infection and BKVAN is shown in Figure 58.2.

There is inconclusive evidence as to the efficacy of adjunctive treatment options for BKVAN, including the use of leflunomide and cidofovir. In a systematic review comprising 40 studies (RCT, case series, prospective, and retrospective cohort studies) examining the effect of immunosuppression reduction alone or in combination with other treatment strategies, the addition of the adjunctive therapies including intravenous immunoglobulin, leflunomide, cidofovir or ciprofloxacin did not alter the observed rate of allograft failure. However, the quality of the evidence was poor, with the estimates provided predominantly from uncontrolled case series [205]. A summary of the available treatment options for BKVAN is given in Table 58.4.

Severity of BK infection	Decoy cells/BK viruria	BK viraemia	Class A BKVAN	Class B BKVAN	Class C BKVAN
Likelihood of kidney kidney dysfunction	None	None/Mind	Mild/Moderate	Moderate	Moderate/Severe
Risk of allograft failure	0% →				70%
Treatment strategies:					
Observation	+	–	–	–	–
Reduction IS	–	+	+	+	+
Antibiotics	–	+/–	+	+	+
Leflunomide	–	+/–	+	+	+
Cidofovir	–	–	+/–	+	+/–
IVIg	–	–	–	+	+/–

Table 58.4 Treatment options and level of evidence for BK viral allograft nephropathy.

Treatment options	Mechanism of action	Adverse events	Level of evidence
Essential treatment			
Reduction of immunosuppression	Improving cellular and humoral immune responses ± in vitro inhibition of BK viral replication	Increase risk of acute rejection	
Target lower CNI levels	Improving cellular and humoral immune responses	Increase risk of acute rejection	
Reduce MMF dose	Improving cellular and humoral immune responses	Increase risk of acute rejection	
Target lower CNI levels and reduce MMF dose	Improving cellular and humoral immune responses	Increase risk of acute rejection	
Change tacrolimus → cyclosporin	Improving cellular and humoral immune responses	Increase risk of acute rejection	
Change MMF → azathioprine	Improving cellular and humoral immune responses	Increase risk of acute rejection	
Change MMF → leflunomide	Improving cellular and humoral immune responses + in vitro inhibition of BK viral replication	Increase risk of acute rejection + adverse events of leflunomide (hemolysis, abnormal liver function, thrombocytopenia)	
Change to mTORi-based regimen	Improving cellular and humoral immune responses + in vitro inhibition of BK viral replication	Increase risk of acute rejection + adverse events of mTORi (mouth ulcers, oedema, proteinuria, pneumonitis)	
Combination of above	Improving cellular and humoral immune responses + in vitro inhibition of BK viral replication	Increase risk of acute rejection and other drug-specific adverse events	
Discretionary treatments			
Cidofovir (low dose)	in vitro inhibition of BK viral replication	Nephrotoxicity, peripheral oedema, proteinuria, uveitis, neutropenia, metabolic acidosis	
Brincidofovir	in vitro inhibition of BK viral replication	Gastrointestinal adverse events	
Fluroquinolone (ciprofloxacin and levofloxacin)	in vitro inhibition of BK viral replication	Possible emergence of bacterial resistance, headache, skin reactions, Achilles tendon rupture, gastrointestinal intolerance	
Intravenous immunoglobulin	Immuno-modulatory (neutralizing anti-BK virus antibodies and interaction of Fc fragment of pooled IgG antibodies with Fcγ receptors of target immune cells)	Possible paradoxical increase in viral load, thrombo-embolic complications, constitutional symptoms	
Adoptive T-cell therapy	BK-reactive cytotoxic T cells	None	

black, good level of evidence; orange, medium risk; gray, poor level of evidence.

Conclusion

Even though short-term allograft survival has substantially improved over the last few decades, early surgical and medical complications are not infrequent and can result in significant morbidity and adversely impact on longer-term allograft and patient outcomes if unrecognized or inadequately treated. This chapter has highlighted the potential complications that clinicians should be cognizant of within the first 12 months post-transplant, emphasizing the importance of undertaking vigilant surveillance and clinical monitoring to identify and treat these early transplant-related complications.

Infections After Kidney Transplantation

Elmi Muller

Faculty of Medicine and Health Science & Dept of Surgery Stellenbosch University

Introduction

Kidney transplantation requires significant immunosuppression to maximize graft outcomes and reduce the risk of rejection.

Infection post-transplantation can be either routine infections, as experienced by nonimmunosuppressed patients, or true opportunistic infections (OIs), mostly experienced by immunocompromised patients. Immunosuppression should be tailored according to immunological risk, as all patients who receive a transplant should weigh up the risk for rejection versus the risk for opportunistic infection.

Infection can be further classified as donor-derived or nondonor-derived. Detection of donor-derived infections may be well after the transplant has taken place or may be early after transplantation (within weeks to months). It is also possible for solid organ recipients to experience a reactivation of an infection that occurred prior to transplantation.

The physician identifying the donor and working up both donor and recipient should bear in mind the risk of these different infections based on timing in relation to transplantation and make informed choices about infection avoidance, prophylaxis, and early and late treatment options. In live donor transplantation, there is more capacity to consider and discuss these issues. All donors should be assessed for infectious risk.

In general, transplant patients should be treated aggressively and early to avoid poor clinical outcomes. Evidence for this is not always available in the form of randomized trials and is based on case studies and meta-analysis of previous reports in the literature. Immunosuppressed patients often lack the usual clinical responses such as fever or raised white cell count.

Definitions

Community-acquired Infection

The lack of a valid standard approach for defining sepsis makes it difficult to determine the true incidence of community-acquired infection and sepsis. Differences in case ascertainment contribute to the variation in reported incidence of community-acquired infection and sepsis. A working definition would be the presence of a positive blood culture and systemic inflammatory response syndrome (SIRS) before or within 48 hours of hospital admission [1].

Hospital-acquired Infection

Hospital-acquired infection is defined as an infection present at hospital admission or within 48 hours after admission in patients that fulfilled any of the following criteria:

- received intravenous therapy at home, wound care or specialized nursing care through a healthcare agency, family or friends, or had self-administered intravenous medical therapy in the 30 days before the infection (excluding patients whose only home therapy was oxygen use)
- attended a hospital or hemodialysis clinic or received intravenous chemotherapy in the previous 30 days
- were hospitalized in an acute care hospital for two or more days in the previous 90 days
- resided in a nursing home or long-term care facility [2].

Opportunistic Infection

Most studies reporting opportunistic infection (OI) lack a formal definition of this term and when present, heteroge-

neity between studies was noted with regard to the types of infections considered or reported as opportunistic.

In a large systematic review, pathogens and/or specific presentations of certain pathogens were considered an OI, as they indicate an alteration in host immunity [3]. This list is included as.

Epidemiology

Previous exposure to pathogens is very important, both for the recipient but also for the organ donor. Transmitting a donor organism to a recipient might result in a donor-derived infection. The physician needs to have a clear understanding of this risk for the recipient and has to weigh up the potential benefit of the organ against this risk. In cases of deceased donation the risk for the donor does not need to be considered. In the case of a living donor the health of the person who donates the organ should be considered first.

Transplant patients are at normal to slightly higher risk of contracting community-acquired infections. These include viruses, bacterial, and fungal infections.

Respiratory Viruses

Influenza

Influenza is usually a community-acquired infection [4]. Vaccine immunogenicity for influenza in immunocompromised patients is low. Consideration should be given to vaccination in all transplanted patients.

Other Respiratory Viruses (Respiratory Syncytial Virus, Adenovirus, Parainfluenza)

Several clinical cases have been reported but no specific studies have been done [5]. Incidence is reported to be higher in immunocompromised patients.

Chikungunya, Dengue, and Zika

In endemic areas, the assessment of epidemiological risk is mandatory [6]. Donor deferral for 120 days in suspected or confirmed ZIKV+ has been recommended, while CHIKV+ donors should wait 30 days. No deferral is recommended for DENV+ donors. Evidence is based on individual case studies.

Bacterial Infections

Bacterial Pneumonia

Bacterial pathogens are the most frequent cause of pneumonia after transplantation [7]. Early after transplantation, recipients are at higher risk for nosocomial infections. The most commonly encountered pathogens during this period are gram-negative bacilli (*Klebsiella pneumoniae*, *Escherichia coli*, *Pseudomonas aeruginosa*), but gram-positive coccus such as *Staphylococcus aureus* or *Streptococcus pneumoniae* and anaerobic bacteria can also be found.

Six months after transplantation, pneumonias are mostly due to community-acquired bacteria (*S. pneumonia*, *Haemophilus influenza*, *Mycoplasma*, *Chlamydia*, and others).

Opportunistic pathogens take advantage of the state of immunosuppression, which is usually highest from 1 to 6 months after transplantation. During this period, but also occurring many years later in the setting of a chronically depressed immune system, bacterial pathogens with low intrinsic virulence can cause pneumonia.

Community-acquired Pneumonia Secondary to Intracellular Pathogens

Intracellular bacteria are common causes of community-acquired pneumonia (CAP) in immunocompromised patients [8]. There is considerable variation in the reported incidence between countries and change over time. The intracellular pathogens that are well established as causes of pneumonia are *Legionella pneumophila*, *Mycoplasma pneumoniae*, *Chlamydophila pneumoniae*, *Chlamydophila psittaci*, and *Coxiella burnetii*.

Gastrointestinal Infections

Common Organisms Affecting the Gastrointestinal Tract

Diarrhea is one of the most commonly occurring diseases in immunocompromised patients [9]. Patients suffering from diarrhea should be considered for salmonellosis, shigellosis, and *Campylobacter* infections, as well as infections with pathogenic *E. coli* strains, yersiniosis, and cholera. Diarrhea caused by toxigenic *Clostridium difficile* strains has a severe impact in immunocompromised patients.

Fungal Infections

Histoplasma capsulatum

Histoplasma capsulatum is a dimorphic fungus that most often causes asymptomatic infection in the immunocompetent population [10, 11]. In immunocompromised patients, it is likely to cause severe life-threatening infection. Incidence is rare (≤1%) and may result from endogenous reactivation of latent infection, de novo post-transplant acquisition, or donor-derived infection. Disseminated infection is common. Fever is the most common symptom and clinical features are often nonspecific, but patients with disseminated infection may present with a septic picture. Other features, including pancytopenia and hepatosplenomegaly, may not be prominent early in the course of

illness. Routine screening of donors and recipients is not currently recommended.

Coccidioides

Donor-derived coccidioidomycosis causes unexpected morbidity and mortality in transplant recipients. Six reports of proven or probable coccidioidomycosis in immunocompromised patients were reviewed in a meta-analysis published in 2016 [12]. In four of the six studies, the infection was first detected at autopsy in the recipient. In two cases it was first identified in the donor. Twenty-one recipients received organs from these six donors. Transmission occurred in 43% at a median of 30 days post-transplant with a mortality rate of 28.5%.

Other Invasive Fungal Diseases

Opportunistic fungal pathogens such as *Aspergillus*, *Candida*, *Cryptococcus*, *Rhizopus*, and *Pneumocystis jiroveci* are distributed worldwide and constitute the majority of invasive fungal infections in immunocompromised patients [13]. Dimorphic fungi such as *Histoplasma capsulatum*, *Coccidioides* spp., *Paracoccidioides* spp., *Blastomyces dermatiditis*, *Sporothrix schenckii*, *Talaromyces (Penicillium) marneffei*, and *Emmonsia* spp. are geographically restricted to their respective habitats and cause endemic mycoses. Disseminated histoplasmosis and *T. marneffei* infection are recognized to cause a high rate of morbidities and mortalities in immunocompromised patients.

Mold Infections

Mold infections carry a substantial risk in solid organ transplant recipients, with a high overall mortality of near 30% [14]. The most important pathogens include *Aspergillus*, the Zygomycetes, *Fusarium*, *Scedosporium/Pseudallescheria*, and the dematiaceous (dark) molds. Risk factors for the infections vary by transplant type but include a degree of immune suppression and loss of skin or mucosal integrity. Correct diagnosis usually requires histopathology and/or culture. Management often requires a multidisciplinary team approach with combined antifungal and surgical therapies.

Other Pulmonary Opportunistic Infections

Tuberculosis

Solid organ transplant recipients are at an increased risk of tuberculosis [15]. Tuberculosis after solid organ transplantation generally occurs after months or years; early infections should raise the possibility of donor-derived infections. Tuberculosis is endemic in certain geographical areas and in these areas clinicians should have a low threshold to screen.

Cytomegalovirus

Human cytomegalovirus (CMV) represents the most common infection among recipients of solid organ transplants [16–19]. CMV disease ranges from asymptomatic viremia to CMV syndrome, to tissue-invasive disease. As CMV prophylaxis, treatment, diagnostics, and overall awareness have improved, the general trend has been toward earlier diagnosis of CMV disease and more mild clinical presentations in solid organ transplant recipients.

Previous meta-analysis showed 0.8% of solid organ transplant recipients developed CMV disease whilst receiving valganciclovir prophylaxis.

Donor-derived Infection

Donor-derived infections are important as they might give more severe and serious complications in recipients [20]. Screening potential donors for infection remains crucial to improving the safety of organ transplantation.

Donor-derived infection is usually suspected in the first 6 weeks after the transplant. As the immunocompromised recipient received an organ carrying an infection, there is an increased risk of developing systemic symptoms and diseases secondary to this event.

It is especially important to consider whether there is any multidrug-resistant organism that could potentially infect the recipient. Donors may also harbor latent infections (e.g. *Histoplasma*, *Coccidioides immitis*, *Mycobacterium tuberculosis*, and strongyloidiasis) based on their epidemiologic exposures.

Recommended Minimum Screening Policy for all Donors

- Serology for human immunodeficiency virus (HIV), hepatitis B, and hepatitis C (repeat within 28 days of donation in living donors)
- CMV IgG
- Epstein-Barr virus IgG
- HIV-1/2 antibody or HIV antigen/antibody assay
- Hepatitis B surface antigen and core antibody; consider nucleic acid testing (NAT)
- Hepatitis C NAT
- Syphilis screening
- Toxoplasma IgG
- Blood, urine, and sputum cultures

Recommended Additional Screening

- Tuberculosis screening (purified protein derivative or interferon-γ release assay)
- Testing based on prior history of living in an endemic area

- *Strongyloides* antibody
- *Trypanosoma cruzi* antibody
- *Histoplasma* antibody
- *Blastomyces* antibody
- *Coccidioides immitis* antibody
- Hepatitis E antibody

- Testing based on epidemiologic exposures
  - *Brucella* antibody
  - *Cryptococcus* antigen
  - West Nile virus antibody

- Organ-specific testing: urine culture for kidney donors, bronchoalveolar lavage fluid/sputum culture for lung donors

Pathophysiology

Patients with bacterial infections have an increased risk of developing systemic symptoms, including sepsis and septic shock. Urinary tract and chest infections are common and prognosis in immunocompromised patients is similar to nonimmunosuppressed patients if treated early and correctly [21, 22].

An important risk factors for bacterial as well as fungal infections is neutropenia. Resistance rates against antibiotic vary between regions, especially for *E. coli*, *K. pneumonia*, and *P. aeruginosa*. Resistance rates should be carefully assessed in each region when antibiotic therapy is chosen.

Immunosuppressive therapy has dramatically reduced the incidence of acute rejection and improved graft survival in kidney transplant patients. However, viral infection as well as tuberculosis secondary to T-cell depleting therapy remains an important issue. T-cell depleting therapy may induce prolonged CD4 T-cell lymphopenia and trigger lymphocyte activation in some patients. Transplanted patients have an increased susceptibility to chronic viral challenges secondary to these immune alterations [23, 24].

In all immunocompromised patients the reactivation of latent infections remains an important consideration. This is especially important in the case of *M. tuberculosis*. The immune system seeks to control the infection by containing the bacteria in a granuloma, where it is exposed to stressful anaerobic and nutrient-deprived conditions. It is thought to be these environmental conditions that trigger the nonreplicating persistent state. A number of in vitro models have been developed that mimic conditions within the granuloma to a lesser or greater extent. These different models have all been utilized for the research of different characteristics of NRP *M. tuberculosis*, however their disparity in approach and physiological relevance often results in inconsistencies and a lack of consensus between studies [25].

Diagnosis

Clinical diagnosis can be more difficult in immunocompromised patients as they are usually slower to respond to pathogens with signs of inflammation and fever. Radiological investigations, nuclear medicine, and magnetic resonance imaging (MRI) might be useful to the clinical decision maker.

Blood tests involve:

- serological testing
- immuno assays
- antigen-based tests
- enzyme-linked immunosorbent assays
- nucleic-based acid-based test
- polymerase chain reaction.

Cultures remain the mainstay for diagnostic purposes, although patients often need treatment before culture results are available. Clinicians are advised to start broad-spectrum treatment while waiting for specific results and then narrow the treatment down to be as specific to the organism as possible. Routine tissue, blood, and urine culture can be extremely helpful.

Treatment

Transplant patients often have foreign material present in the form of dialysis liners, stents, and catheters. It is advisable to remove these as early as possible. Surgical management of collections, obstructions, or leaks is very important and should be done early, as patients deteriorate quickly because of their immunosuppressed status.

Reduction of Immunosuppression

To prevent infections flaring up or in the case of severe sepsis, patients might require a reduction in immunosuppression. This should be done with caution as it might result in a rejection episode.

Resistance Rates and Choice of Antibiotic if Resistance Is Suspected

Empirical antibiotic treatment is always needed in immunocompromised neutropenic patients. Consider treating with an antibiotic that will cover *P. aeruginosa*. Monotherapy regimens can be cefepime (ceftazidime), piperacillin/tazobactam or meropenem. Combination therapy could include a combination of aminoglycoaside (amikacin), glycopeptide (vancomycin), and a quinolone (ciprofloxacin) [26]. Although resistance rates vary across

Table 59.1 Resistance rates reported in the literature for common gram negative bacteria [25–31].

Organism	ESBL (%)	Cefepime (Ceftazidime) (%)	Piperacillin/ Tazobactam (%)	Carbapenem (Meropenem)	Multiresistant (%)	Overall incidence of resistance
Escherichia coli	11–69	30–85	0–51	0–18%		21% (18–46%)
Klebsiella pneumoniae	23–69	50–71	25–63	0–31%		11% (4–20%)
Pseudomonas aeruginosa				44% (3–66%)	30–70	10% (3–30%)

different regions, a summary form the literature is given in Table 59.1 [27–33].

Influenza

There is low evidence that influenza vaccine has demonstrated effectiveness in reducing severe disease in immunosuppressed patients. Various strategies to improve influenza vaccine immunogenicity have been attempted, including two vaccine doses in the same influenza season and intradermal, adjuvanted, and high-dose vaccines. The timing of influenza vaccine is also important to achieve optimal immunogenicity. Given the suboptimal immunogenicity, family members and healthcare professionals involved in the care of these populations should be vaccinated. Healthcare professional recommendation for vaccination is an important factor in vaccine coverage.

Conclusions

It is difficult to make recommendations over a wide spectrum of infections as every infection could possibly warrant a meta-analysis on its own. However, certain key principles are important:

- Treatment should start early and be empirical.
- Remove all sources of infection, such as foreign material, stents, or collections, at an early stage.
- Immunosuppressed patients deteriorate rapidly and treatment should be aggressive.
- Assess the specific infection after cultures and sensitivity, and adjust antibiotic treatment accordingly as early as possible.
- Always consider donor-derived infection and if suspected all other recipients from the same donor should be considered for treatment.

Introduction

- Electrolytes are involved in numerous intra- and extracellular biological and physiological functions, including maintenance of cell volume, cellular ionic strength, and enzymatic activities, critical for sustaining life. A narrow physiological range for each electrolyte is actively secured by multiple, often overlapping, regulatory and homeostatic systems, ensuring an optimal cellular and extracellular ionic environment for normal tissue and organ function. It is not surprising that most electrolyte alterations are associated with increased morbidity and mortality.
- Hyponatremia is by far the most common electrolyte disorder encountered in practice. Hyperkalemia is among the most common electrolyte disorders in patients with impaired kidney function. The prevalence of dysmagnesemia is unclear but is likely underdiagnosed as magnesium (Mg^{2+}) intake is insufficient in ~60% of the US adult population [1]. Advances have been made in understanding the underlying pathogenesis and in the management of these electrolyte alterations. This chapter will integrate existing and new advances in the area.

Dysnatremia

Definitions

Hyponatremia is defined as a serum $[Na^+] < 135$ mmol/l. Based on the measured blood osmolality, hyponatremia can be categorized as hypotonic, isotonic, or hypertonic hyponatremia. Hypotonic hyponatremia can be further divided into hypovolemic and euvolemic or hypervolemic hyponatremia. Serum $[Na^+]$ in the range 125–129 mEq/l is, in general, considered moderate and <125 mmol/l is considered severe hyponatremia.

Differentiating acute hyponatremia (developing within 48 hours) versus chronic hyponatremia (having hyponatremia for >48 hours) is critical. Rapidity in the development and severity of hyponatremia dictates the clinical manifestations. All of the above groupings are critical parts of diagnosis and directly impact the treatment strategy.

Hypernatremia is defined as a serum $[Na^+] > 145$ mmol/l. It occurs when total body water is disproportionately reduced in relation to extracellular fluid Na^+. Hypernatremia can result from pure water loss (e.g. diabetes insipidus [DI, central or nephrogenic], large insensible losses), hypotonic fluid loss (e.g. gastrointestinal losses [diarrhea] and renal osmotic diuresis), or hypertonic Na^+ gain (e.g. hypertonic NaCl or $NaHCO_3$ administration). Hypernatremia may be hypervolemic, euvolemic or hypovolemic. Unlike hyponatremia in which a hypertonic or hyperosmolar state can potentially be present, hypernatremia nearly always predicts a hyperosmolar state. Ideally, serum $[Na^+]$ should be kept in the range of 138–142 mmol/l, as this range is considered most physiological [17].

Epidemiology

Hyponatremia is the most common electrolyte disorder in both the community-dwelling population [18] and in hospitalized patients [19], with occurrence rates of 8–15% and 44%, respectively [20]. It is well-known to be associated with increased morbidity and mortality [21]. The

older adult population and women are more susceptible to hyponatremia. Hyponatremia can also occur following strenuous exercise, known as exercise-associated hyponatremia (EAH).

Hypernatremia is less common than hyponatremia, with a reported incidence of 1–3% in hospitalized patients [18, 22]. At-risk populations include pediatric, older adult, and critically ill patients. One study showed that in the last two decades, the incidence of hypernatremia in critically ill patients has doubled [23], possibly related to more frequent use of loop diuretics and high concentration Na^+-containing fluids. Patients with chronic kidney failure (CKD) are, in general, considered to be at a higher risk of dysnatremia than the general population due to diminished glomerular filtration rate (GFR) and impaired tubular regulation [24]. With kidney disease progression from stage 1 to stage 5 (nondialysis), the incidence of hyponatremia declines slightly, while that of hypernatremia increases [24].

Clinical Manifestations

The clinical manifestations of hypo- and hypernatremia depend on the rapidity of the development and magnitude of $[Na^+]$ alterations [25, 26]. The brain is the dominant organ manifesting morbidity of hypo- and hypernatremia due primarily to the rigid confines of the brain and exquisite sensitivity of neurons to volume change (shrinkage or swell). When developing gradually (in days), the clinical manifestations of hyponatremia can be subtle, ranging from headache, lethargy, and restlessness to gait disturbance. When developed more rapidly or severe ($[Na^+] < 125$ mEq/l), confusion, respiratory distress, seizures, coma, and death can ensue [27]. Hypernatremia can manifest as excessive thirst, lethargy, and irritability, and, when severe, can progress to muscle spasms, vomiting, dyspnea, seizure, coma, and death. Delayed treatment of dysnatremia can cause irreversible neurological sequelae and increased mortality.

Pathophysiology

Sodium and Water Regulation

Serum Na^+ concentration represents water balance and is the primary determinant of serum osmolality. In the kidney, arginine vasopressin (AVP) and tonicity enhancer element binding protein (TonEBP, also known as transcription factor nuclear factor of activated T-cells 5, NFAT5) independently and synergistically regulate water absorption, maintaining serum $[Na^+]$ in the range 135–145 mEq/l. In addition to regulating water absorption, AVP also retains Na^+, thus influencing volume balance.

AVP binds to V2 receptors in the basolateral membrane of the collecting ducts and activates adenylyl cyclase-mediated cyclic AMP (cAMP) generation and protein kinase A-mediated signaling pathways, leading to phosphorylation and the apical membrane insertion of aquaporin 2 (AQP2) water channels. This, in turn, causes water absorption from tubular lumen to the circulation, driven by the tubulomedullary osmotic gradient. TonEBP, responding to increasing extracellular interstitial tonicity, forms homodimers. The latter preferentially binds TonE (tone consensus sequence) in its target gene promoters to increase the transcription of the target genes, including those involved in the synthesis and transport of organic osmolytes [28]. When activated, both AVP and TonEBP increase AQP2 gene expression and apical membrane AQP2 distribution. The stabilizing effect of organic osmolytes allows medullary tubular cells under osmostress to survive and perform vital functions. Excessive water absorption due to hyperactivation of the above water absorption system leads to the development of hyponatremia. On the contrary, mutations in the V2 receptor and AQP2 genes and acquired dysfunction of these proteins (e.g. chronic lithium exposure) can cause nephrogenic DI [3, 29].

On a high-salt diet (≥12 g/day), healthy adults are able to raise the amount of urine Na^+ excretion, typically without triggering extra water intake (lacking thirst stimulation) [30]. The kidneys are responsible for the excretion of concentrated Na^+ and simultaneously conserve water. This process requires the kidneys to absorb extra Na^+ and urea from tubular fluids to strengthen the intramedullary hypertonicity to facilitate water absorption/conservation. Indeed, recent studies show that a high-salt diet activates an array of metabolic processes, including enhanced hepatic urea genesis and muscle catabolism through at least in part activating glucocorticoid receptors [30, 31]. Also seen in association with a high-salt diet is elevation of circulating AVP. AVP is known to causes intraglomerular hypertension, mesangial contraction, and proliferation and stimulates intrarenal activation of the renin-angiotensin-aldosterone system (RAAS) [32]. When persistent and habitual, these homeostatic adaptive processes can become maladaptive [33]. Consistently, a recent population-based study showed that plasma copeptin (a surrogate marker of AVP) is a predictor for the occurrence of CKD [34], a chronic disease of ~13.4% population worldwide [35]. With the advent of Na^+ imaging nuclear magnetic resonance [36], a volume-independent pool of Na^+ in the skin and muscle has been revealed; heavy epidermal and dermal Na^+ signal is associated with refractory hypertension and risk for cardiac hypertrophy [37, 38].

Special Considerations

Female Susceptibility to Hyponatremia

Most, but not all, studies show a female susceptibility to hyponatremia and hyponatremia-associated symptoms. For example, females are more susceptible to hyponatremia among marathon runners [39]. On the other hand, conflicting results were shown regarding a female predilection for postoperative hyponatremia [40, 41], possibly related to varying degrees of stress and care styles. The potential mechanisms of female susceptibility include (i) inhibitory effects of estrogen on Na^+,K^+-ATPase, which reduces the cells homeostatic regulation in the setting of hypo or hypernatremia, (ii) lower muscle mass, which can reduce the buffering capacity for the water shift, (iii) lower baseline serum [Na^+] than their male counterparts, which renders serum [Na^+] in female easier to fall into a hyponatremic range, and (iv) more pronounced AVP-induced cerebral vasoconstriction than that in males, rendering females at a greater risk for reduced central nervous system oxygen delivery [42].

Exercise-associated Hyponatremia

Exercise-associated hyponatremia (EAH) in recent decades has become increasingly recognized [43, 44] following a number of death cases in athletes after strenuous exercise. It has become clear, however, that EAH can also occur in nonprofessional athletes and in association with a variety of physical exertions, including running, hiking, long-distance swimming, mountain cycling, weightlifting, and even tennis and yoga. Patients with cystic fibrosis are at increased risk and can develop EAH with low-intensity exertion [44]. Mechanisms of EAH are complex. Overconsumption of water plus nonosmotic (stress-related) AVP secretion are important contributors in the genesis of hyponatremia.

Symptoms of EAH include bloating, dizziness, mild nausea, headache, vomiting, progressing to confusion, dyspnea, altered mental status, obtundation, further progressing to seizure, coma, decorticating posturing, mydriasis, and death. These symptoms could occur shortly after exercise and, as detailed above, women tend to be more susceptible.

For symptomatic patients, intravenous administration of 3% NaCl (typically 100 ml every 10 minutes, several times) can effectively correct hyponatremia and eliminate the symptoms. Recent studies show that similar efficacy can be achieved through an equivalent amount of hypertonic saline given orally [2]. The oral sodium treatment resulted in a comparable blood [Na^+] increase but a higher degree of urine Na^+ excretion. There was no difference in plasma AVP in both groups pre- and postintervention, consistent with the known phenomenon of the nonsuppressible nature of stress-related AVP. Of importance, calculated plasma [Na^+] increase based on the best-known formula was 1.3 mEq/l with the amount of NaCl administration, markedly differing from the actual plasma [Na^+] changes, 2.0 ± 0.9 mEq/l in the intravenous group, and 1.9 ± 1.6 mEq/l in the oral group. These observations underscore the importance of avoiding the reliance on calculations but rather measuring [Na^+] to monitor the degree of [Na^+] correction. It also suggests the possibility of tissue Na^+ mobilization. Consistent data were reported recently [45] showing formulae cannot correctly predict [Na^+] change following a known quantity of high percentage saline loading in healthy adults.

The nonsuppression of AVP has been shown in hypo, euvolemic, and hypervolemic EAH. Among factors that cause nonsuppressible AVP could be interleukin-6 release, nausea, vomiting, and acute stress. There have been studies showing that patients on a baseline low-salt diet seem to be more susceptible to this condition, suggesting a role of tissue Na^+ load in the genesis of EAH. Consistently, overhydration contributes only in part to the EAH; hyponatremia can occur in euhydration even hypohydration states. Conversely, hypernatremia can develop in overhydration or the euhydration state. These observations again suggest a role of tissue Na^+ sequestration or release into the body fluids in the genesis of dysnatremia.

Hypernatremia indicates the presence of total body water deficiency in relation to body fluid Na^+. It can result from (i) loss of water or hypotonic fluid (loss of water > loss of Na^+) or (ii) gain of Na^+, such as receiving hypertonic saline or salt tablets without taking in water. Renal loss of water can be caused by diabetes insipidus, hypercalcemia, hyperglycemia, chronic hypokalemia, and medications such as loop and osmotic diuretics, lithium, and vasopressin V2 receptor blockers. Hypernatremia can also be caused by water loss from the gastrointestinal tract due to osmotic diarrhea and vomiting. In the setting of excessive sweating or burns, skin loss of hypotonic fluids can be responsible for hypernatremia. Sustained hypernatremia is typically associated with lacking access to water or the presence of impaired thirst mechanism. The elderly, children, and critically ill patients are especially vulnerable to hypernatremia.

Special Consideration

Lithium-associated Kidney Effects

Lithium gains entry to renal epithelial cells through competing with Na^+. In the distal nephron, lithium enters renal tubular cells through the apical membrane epithelial sodium channels (ENaCs). Lithium has a 1.5–2-fold stronger affinity to ENaC, making it preferentially absorbed over Na^+ via the ENaC. Its exit from the cells is, however,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

not readily supported by Na^+,K^+-ATPase as lithium is a poor substrate for this ATPase. Lithium, therefore, accumulates in the renal epithelial cells, competing with Na^+ and Mg^{2+} for their protein binding and causing a variety of adverse cytotoxic effects through interfering with multiple cellular signaling pathways. One of the major effects of lithium is the inhibition of glycogen synthase kinase-3β (GSK3β), which relays the actions of aldosterone and AVP. The inhibition of GSK3β causes impairment of adenylyl cyclase activity, leading to reduced cAMP generation. GSK3β inhibition also releases the normally inhibitory effect of GSK3β on Cox-2, which causes hyperactivation of Cox-2 and a robust generation of prostaglandins. Both the reduction of cAMP and increased generation of prostaglandins impair renal water absorption, causing a nephrogenic type of DI.

Because lithium interferes with Na^+ reabsorption from tubular fluids, it compromises the maintenance of medullary concurrent mechanism and the steep osmotic gradient for renal water absorption. Increased solute content in the tubular fluids also enhances tubuloglomerular feedback (TGF), inducing constriction of afferent renal arterioles, and thus risking renal underperfusion and ischemia.

Patients on chronic lithium treatment have an increased risk for developing CKD. This phenomenon has been confirmed by epidemiological, clinical, and histopathological studies. Longer lithium use (>20 years), older age, and episodes of lithium intoxication are some of the risk factors for the development of lithium-induced nephropathy and CKD [46, 47]. CKD in patients on lithium is typically asymptomatic. Their blood pressure tends to be low normal or normal. Urine sedimentation is generally normal with and without proteinuria. Renal biopsy is typically characterized by evidence of tubulointerstitial fibrosis and multiple renal microcysts, and is often associated with focal segmental glomerulosclerosis. Interestingly, GSK3β is involved in the maintenance of primary cilia which, in its malfunction, contributes to kidney cyst formation, revealed in the investigation of polycystic kidney disease [48].

Renal monitoring for patients with chronic lithium exposure is important to assess the degree of polyuria, electrolyte and acid-base alterations, and kidney dysfunction. Preventive therapy (i.e. amiloride addition) to deter lithium entry to the renal epithelial cells has shown some encouraging results in terms of reducing the degree of polyuria [49, 50]. However, long-term effects of lithium exposure, especially with regard to lithium-associated CKD, have yet to be studied in detail. General guidelines for minimizing the risk of renal damage in lithium-treated patients include (i) monitor serum creatinine and estimated glomerular filtration rate (eGFR) regularly every 6 months to 1 year, and (ii) avoid lithium toxicity and maintain lithium levels at the lowest effective level and consider once-daily dosing. Lithium discontinuation and nephrology consultation should be considered when the serum creatinine reaches ~1.6 mg/dl (140 mmol/l).

Up to 30% of lithium-treated patients develop a mild degree of hypercalcemia. This tends to become problematic in patients with CKD and reduced capacity of urine calcium excretion. The underlying mechanisms for hypercalcemia are multiple, often associated with hyperparathyroidism related to either parathyroid adenoma or multinodular hyperplasia. Surgery for adenoma can be effective and cinacalcet treatment can be tried for patients with multinodular lesions. Hypothyroidism is another common adverse effect of chronic lithium exposure. Maintenance hormone replacement is the treatment of choice.

Significant Tests

For hyponatremia

Measurement of serum osmolality (normal serum osmolality: 275–295 mOsm/kg water) is required to determine the body-fluid tonicity and to rule out (i) pseudohyponatremia (isotonic hyponatremia) in the setting of hyperlipidemia and paraproteinemias, and (ii) hyperosmolar (>295 mOsm/kg) hyponatremia mostly in the setting of hyperglycemia or after mannitol or other solute administration. True hypotonic hyponatremia typically shows a reduced serum osmolality (<280 mOsm/kg).

For hypernatremia

As hypernatremia represents a hyperosmolar state, measurement of serum osmolality is generally not required. Urine osmolality is a useful test to differentiate renal water loss (e.g. diabetes insipidus, which is a state of inappropriately dilute urine) from extrarenal water loss (concentrated urine representing appropriate renal water conservation). Urine osmolality may not be informative in patients taking diuretics and with CKD.

For polyuria

Central DI, nephrogenic DI, and primary polydipsia can all present with polyuria and polydipsia. Central and nephrogenic DI, however, even at a compensated state, typically present with high normal levels of serum [Na^+] (>140 mEq/l) while primary polydipsia including beer potomania and psychogenic polydipsia typically present with low normal serum [Na^+] (<140 mEq/l).

DI tends to have more frequent nocturia compared to those with primary polydipsia. DI could be idiopathic, especially central DI (~50% of central DI cases are idiopathic). Nephrogenic DI could be due to medications

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(lithium being the most common cause) or genetic defects related to mutations in the genes encoding vasopressin V2 receptor or AQP2 channel [51].

To differentiate central vs. nephrogenic DI, a water deprivation study has classically been the test of choice. With water deprivation, if urine can concentrate to 800 mOsm/kg or greater in patients with conserved kidney function, DI is excluded. Polyuria in such patients is likely due to primary polydipsia. Patients tend to have a low normal serum [Na^+] as water-drinking drives the symptom. In patients who fail to concentrate urine despite serum [Na^+] elevation to ~150 mEq/l, a dose of desmopressin (typically 2 μg intravenously) is given to differentiate central vs. nephrogenic DI. If the patient's urine remains diluted (<300 mOsm/l) a diagnosis of nephrogenic DI could be made. However, if the patient is able to respond to a degree and urine concentrates ~300–500 mOsm/l, a partial central DI is present. For patients who are able to concentrate urine to >600 mOsm/kg in response to desmopressin, a diagnosis of central DI can be made. During the study, patients should be carefully monitored, and blood and urine should be sampled as often as every 30 minutes to 2 hours. Approximately 2–3% of weight loss is often present during the water deprivation.

In recent years, serum copeptin determination has emerged as a greatly simplified diagnostic test for DI. A baseline unstimulated (nonwater-deprived) serum copeptin level of >21.4 pmol/l in a polyuric patient is diagnostic for nephrogenic DI, with sensitivity and specificity of 100% [29], more accurate than the water deprivation study [52]. Copeptin response to hypertonic Na^+ administration demonstrates a superior diagnostic sensitivity and specificity in diagnosing central DI and in the differentiation of central DI from primary polydipsia [53].

Prognosis: Complications

Both hypo- and hypernatremia increase mortality [54–57]. In the community patient population, hyponatremia can be minimally symptomatic. Nonetheless, these patients, compared to eunatremic populations, tend to have a higher rate of all-cause mortality and a higher rate of fracture and its related morbidity [54, 55]. In hospitalized patients with mild hyponatremia, clinical settings seem to determine the patient outcomes [58]. In almost all comorbid settings (end-stage liver and with end-stage heart failure), occurrence of hyponatremia elevates mortality [56, 59]. Pulmonary edema in the setting of hyponatremia can be neurogenic. It may reflect central nervous system hypoxia and should be treated urgently, as combined hypoxia and hyponatremia impair brain adaptation, leading to worsening brain edema and can markedly increase mortality [60].

Hypernatremia carries a high rate of morbidity and mortality. In a large multicenter study of critically ill patients, Darmon et al. showed that fully adjusted 30-day mortality increases from 22.5% up to 54.5% from mild (145–150 mEq/l) to more severe hypernatremia [61]. In patients with acute cardiovascular disease, especially those with cerebrovascular accident, serum [Na^+] outside the range of 141–146 mEq/l has been shown to increase hospital and 28-day mortality [62, 63].

Treatment

Hyponatremia

For patients with volume depletion, restoration of volume with isotonic fluids should turn off AVP release, leading to renal water excretion and correction of hyponatremia. For patients with euvolemic hyponatremia, select appropriate treatment options (outlined in Table 60.1) based on clinical scenarios and identify the underlying causes (Table 60.2). Eliminating the causes will in general lead to the resolution of hyponatremia. A registry study involving 225 sites in the United States and European Union showed that initial treatment for hyponatremia often employs modalities of limited efficacy. A significant portion of hyponatremic patients discharged from hospital remained hyponatremic [64]. Hypervolemic hyponatremia typically occurs in patients with hepatic cirrhosis or congestive heart failure. Liver or heart transplant will eliminate the Na^+ abnormality. For exercise-induced hyponatremia, there has been no standard prophylactic measure to date. Forcing fluids is likely harmful and is not advised. In general, athletes are advised to drink to their thirst. Close monitoring and treating those with even mild symptoms and with biochemical hyponatremia are essential. Oral administration of hypertonic saline has recently been shown to be effective, convenient, and noninferior to intravenous administration of an equivalent amount of hypertonic saline [2]. Given the consequences of untreated hyponatremia in endurance runners and potential for progression (to obtundation, coma, and death), oral hypertonic saline seems advisable, especially in those with mild symptoms.

Regardless of the etiology, the rate of serum Na^+ correction depends on (i) whether the patient is symptomatic and (ii) onset rapidity (<48 hours or >48 hours). For symptomatic hyponatremia, the predominant current practice is 3% saline in 100–300 ml bolus administered intravenously over 10–45 minutes with the goal of raising serum [Na^+] by 4–5 mmol/l initially. Repeated bolus may be used when appropriate to achieve this goal [65, 66].

For patients with chronic hyponatremia (onset >48 hours) who are relatively asymptomatic, serum [Na^+] should be corrected slowly to prevent neurological damage such as

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Table 60.1 Evidence table: sodium disorders.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Hyponatremia			
Hypertonic saline (3% NaCl)	For symptomatic hyponatremia, we recommend 100–300 ml 3% saline be given parenterally over 10–30 min with the goal to raise serum [Na+] by ~5–6 mEq/l Oral administration may have similar efficacy based on lower certainty evidence [2]	High	Strong
Isotonic fluids (0.9% saline or balanced fluids)	For patients with hypovolemia, we recommend that volume restoration with isotonic fluids diminishes AVP stimulatory force, and clinicians should avoid overcorrection of volume depletion	High	Strong
Oral water restriction (800 ml/day)	We recommend oral water restriction be used for patients with syndrome of inappropriate antidiuretic hormone (SIADH) or other euvolemic and high volume hyponatremia Clinicians should be aware of low patient adherence and that restriction will not be sufficient when urine osmolality is >500 mOsm/kg, or the sum of urine Na^+ and K^+ is >serum [Na^+], water restriction alone will not be sufficient Additional measures will be required	Moderate	Strong [3]
Eliminate causes	We recommend that agents with hyponatremic potential should be replaced or discontinued if possible (e.g. hydrochlorothiazide, antidepressants [mainly selective serotonin reuptake inhibitors], anticonvulsants, antipsychotics, cytotoxic agents, pain medications [4], ecstasy) For patients with cancer as the cause of hyponatremia (e.g. small cell lung cancer), treatment should be focused on cancer eradication in addition to the other corrective strategies outlined in this table (treatment plan should be individualized)	High	Strong
Salt tablets + oral furosemide	We recommend that salt tablets combined with oral furosemide be used for euvolemia patients refractory to the above measures	Moderate	High
Vaptans (V1A/V2R antagonist Conivaptan; V2R antagonists Lixivaptan, Mozavaptan, Satavaptan, Tolvaptan)	We suggest avoiding use of vaptans for symptomatic hyponatremia due to the risk of overcorrection, even at lower than 15 mg/day dosage [5] We suggest avoiding use of vaptans for hypovolemic hyponatremia We suggest vaptans may be tried for SIADH and other euvolemic and hypervolemic hyponatremia refractory to other measures and should not be expected to be used long term (>1 month) We suggest watching for overcorrection and other adverse effects with vaptan therapy, including liver dysfunction [6, 7]	High	Low to moderate [8]
Urea, oral administration	We suggest urea (oral administration) is useful for critically ill [9] and subarachnoid hemorrhage [10, 127] patients We suggest oral urea administration may be effective for chronic milder and relatively asymptomatic hyponatremia We suggest oral urea may have similar efficacy and tolerability to vaptans [11]	Moderate	Moderate
Intravenous DDAVP + dextrose if serum [Na^+] is overcorrected (typically >8 mEq/day)	We recommend intravenous DDAVP + dextrose be used if serum sodium is overcorrected (typically >8 mEq/day) if water alone is insufficient to slowing the rate of correction We recommend that the 24-h serum [Na^+] increment (not hourly increment) is critical and should be ~6 mEq/l within the first day for chronic hyponatremia	Moderate	Strong [12]
DDAVP IV + 3% saline	We suggest DDAVP + 3% saline be used when controlling the rate of [Na^+] correction	Moderate	Moderate [13, 14]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 60.1 (Continued)

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Hyponatremia			
Lithium	We suggest lithium be considered in eu- and hypervolumic patients, although many patients may reasonably choose to refuse due to low certainty evidence and risk of multiple adverse events	Moderate	Weak [15]
Demeclocycline	We suggest demeocycline may be used in eu- and hypervolumic patients, although many patients may reasonably choose to refuse due to low certainty evidence, low onset of action, nephrotoxicity, unpredictable increases in sodium, gastric intolerance, and skin photosensitivity	Low	Weak [16]
Hypernatremia			
Isotonic fluids	We recommend isotonic fluids for patients with hypovolemia, as restoration of volume should take clinical precedence We recommend that once the volume is restored, hypotonic fluids should be initiated to correct hypernatremia	High	Strong
Hypotonic fluids	We recommend for patients with adequate volume, dextrose water or hypotonic Na^+-containing fluids be used (to account for ongoing Na^+ losses)	High	Strong
Diuretics + dextrose water or water	We recommend for patients with expanded volume a combination of diuretics (volume reduction) and dextrose water (or water) be used	Moderate	Strong

V1A/V2R; Vasopressin receptor subtypes V1a /V2; V2R Vasopressin receptor subtype V2; DDAVP diamino D-arginine vasopressin; SIADH syndrome of inappropriate antidiuretic hormone.

Table 60.2 Causes of euvolemic hyponatremia.

Severe hypothyroidism
Adrenal insufficiency
Low solute intake: beer potomania, tea and toast diet
Psychogenic polydipsia
SIADH

- Idiopathic/aging related
- Nausea/vomiting
- Pain
- Cancer (small cell lung cancer)
- Lung: abscess/empyema/chronic obstructive pulmonary disease
- Central nervous system: meningitis/encephalitis/ stroke
- Medications: antidepressents (mainly SSRIs), anticonvulsants, antipsychotics, cytotoxic agents, some pain medications [4], and rarely amiodarone
- Ecstasy (3,4-methylenedioxy-methamphetamine, MDMA)

osmotic demyelination syndrome (ODS) [129]. For patients with ODS risk factors, i.e. malnutrition, alcohol addiction, and hepatic cirrhosis, target serum [Na^+] increase should be in the range of 4–6 mEq/l in the first 24 hours. For those without the risk factors, target serum [Na^+] increase should be in the range of 6–8 mEq/l in the first 24 hours and should not exceed 18 mEq/l in 48 hours. In general, the magnitude of [Na^+] correction in 24 hours is more important than an hourly correction rate [67].

Inadvertent overcorrection is not rare. A recent study shows that the overcorrection rate in the first 24 hours is over 40% [68]. Younger age, being a woman, schizophrenia, lower Charlson comorbidity index, lower presentation serum sodium, and urine sodium <30 mEq/l are risk factors for rapid overcorrection [68]. Overcorrection should be reversed with either hypotonic fluids or deamino D-arginine vasopressin (DDAVP) combined with hypotonic fluids, preferably within 12 hours. DDAVP use was associated with effective slowing in the rate of [Na^+] correction in a retrospective study of 1450 patients admitted for severe hyponatremia (serum [Na^+] <123 mEq/l). Longer durations of hyponatremia and length of hospital stay, however, were noted [69]. For patients with a high risk for ODS, DDAVP could potentially be used to slow the rate of correction [68, 69]. Serial serum [Na^+] measurements (every 2–6 hours) are required to evaluate treatment adequacy, especially during the initial 24 hours. A role for urea in the management of overcorrection is under investigation [128].

Hypernatremia

Management of hypernatremia should start with assessing the patient volume status and eliminating or treating potential causes/contributors of hypernatremia. For patients with hypovolemia, isotonic fluids should be used to restore

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

volume status. After euvolemic status is achieved, hypotonic fluids should be initiated to correct hypernatremia. The rate of correction depends on the rapidity of hypernatremia development. If hypernatremia is developed over 48 hours or of unknown duration, serum [Na^+] correction should not exceed 10–12 mEq/l in the first 24 hours. Overly rapid correction can cause cerebral edema [34]. On the other hand, acute (onset <48 hours) hypernatremia can be corrected more rapidly (up to 0.5–1.0 mEq/l per hour) when appropriate.

Correction of hypernatremia should be timely. Studies have shown that if hypernatremia fails to be corrected fully within 4 days, the rate of irreversible brain damage and mortality can increase considerably [70]. It is therefore advisable to complete the correction within 3–4 days.

Risk factors for demyelination include malnutrition, alcoholism, and liver failure. Brain compression due to parenchymal edema can cause neurogenic pulmonary edema and hypoxia [60]. Pulmonary edema in patients with symptomatic hyponatremia may thus signify pending herniation. The outcome could change with prompt treatment of hyponatremia [71].

Total body free water deficit in hypernatremia can be estimated by calculating estimated total body water (total body water = body weight × [0.6 for men, 0.5 for women]). It is important to recognize, however, that the osmo-active pool of body fluid Na^+ may not be static. Studies have revealed tissue (skin and muscle) storage pools of osm-independent Na^+ that can exert a role in the Na^+ homeostasis [37, 45, 72]. The rate and amount of water replacement in correcting dysnatremia should thus be based on repeated serum [Na^+] measurements. In one study, observed increase in [Na^+] exceeded the increase predicted by the calculation by 74.2% of the cases studied [73]. Reliance on existing formulae to predict [Na^+] correction should therefore be avoided. Frequent serum [Na^+] measurement is imperative.

Dyskalemia

Table 60.3 summarizes the quality of evidence and strength of recommendations for the various components of the management of potassium disorders.

Definitions

Hypokalemia is defined as a serum K^+ concentration [K^+] < 3.5 mEq/l, and hyperkalemia as serum [K^+] > 5.3 mEq/l. It is often further arbitrarily classified as mild (5.4 to <6 mEq/l), moderate (6 to <7 mEq/l), and severe (≥7 mEq/l) [86].

Epidemiology

While dyskalemia, hypokalemia, and hyperkalemia can develop in both normal and CKD populations, hyperkalemia occurs predominantly in patients with CKD. In a 2018 international meta-analysis of 1,217,986 (mean age 55 ± 16 years) subjects, followed up for an average of 6.9 years [87], the prevalence of reduced serum [K^+] was 23.6% (<4.0 mmol/l) and 1.91% (<3.5 mmol/l). The prevalence of [K^+] elevation in non-CKD individuals was 3.31% (>5.0 mmol/l) and 0.49% (>5.5 mmol/l). In patients with CKD, the prevalence of low [K^+] was 12.6% (<4.0 mmol/l) and 2.03% (<3.5 mmol/l), and prevalence of high [K^+] was 17.9% (>5.0 mmol/l) and 4.23% (>5.5 mmol/l).

Hyperkalemia develops most often in the settings of (i) reduced GFR, which is the most powerful determinant of hyperkalemia generation, (ii) increased K^+ intake (often in combination with GFR reduction), (iii) on medications that reduce kidney K^+ excretion (Table 60.4), (iv) hyperkalemic (type IV) renal tubular acidosis and voltage-dependent renal tubular acidosis, and (v) transcellular potassium shift, i.e. cellular/tissue breakdown in rhabdomyolysis and hemolysis, insulin deficiency, and hyperosmolar state.

Hyperkalemia is the most common electrolyte disorder in patients with CKD [86]. Its prevalence increases as CKD progresses [88]. In a nested case-control study of 180 diabetic and 180 nondiabetic CKD patients followed in a nephrology outpatient clinic [89], matched for gender, age, and eGFR, the prevalence of hyperkalemia was higher in diabetics CKD3 (28.6% vs. 17.5%, $P = 0.036$). In CKD4, it was equally high in both groups (35.5% vs. 32.3%, $P = 0.788$). In CKD4, the use of angiotensin-converting enzyme inhibitors (ACEIs; odds ratio [OR] 2.228, 95% confidence interval [CI] 1.254–3.958) and smoking (OR 2.254, 95% CI 1.218–4.171) were independently associated with hyperkalemia in fully adjusted models.

Diabetic patients are at high risk for hyperkalemia [88] due to a combination of (i) insulin deficiency, (ii) episodes of hyperosmolality related to hyperglycemia, and (iii) frequent occurrence of hyporeninemic hypoaldosteronism (type IV renal tubular acidosis). Patients with chronic urinary tract obstruction can develop defects in Na^+ absorption via ENaC in the collecting duct, leading to failure in the generation of the luminal negative voltage. The voltage defect impairs tubular K^+ and H^+ secretion, leading to hyperkalemic normal anion gap acidosis [90], known as voltage-dependent renal tubular acidosis. Such tubular defects can resolve with timely reversal of obstruction. Patients with a family history of hyperkalemia and salt-sensitive hypertension should be investigated for familial hyperkalemia and hypertension (FHHt) (also known as pseudohypoaldosteronism type II [PHA II] or Gordon syndrome) [91–93].

Table 60.3 Evidence table: potassium disorders.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Hypokalemia			
Increasing dietary K^+	We recommend increasing dietary potassium intake	High	Strong
Oral K^+ supplementation	We recommend oral potassium supplementation be used	High	Strong
IV K^+ supplementation	We recommend avoiding use of dextrose-containing solution for K^+ infusion We recommend a central line be used to infuse K^+ We recommend K^+ infusion should not exceed 10 mEq/h (if 10–20 mEq/h is deemed necessary, cardiac monitoring is required; >20 mEq/h is not recommended)	High	Strong
Hyperkalemia			
Multipronged: adjust dietary K^+	We suggest a low K^+ diet (<40 mEq/day) be used in combination with other strategies	Weak (no data on the efficacy of dietary counseling [74])	Strong
Medications For CKD: kidney and GI effects of RAAS inhibitors For dialysis patients: GI effects	We recommend that medication regimens be reviewed to minimize the exposure of drugs that may induce hyperkalemia We recommend avoiding hyperkalemic medications, but balance the relative pros and cons (e.g. RAAS inhibitors [75])	Strong	Strong
Intravenous Ca infusion	We recommend intravenous calcium be used to stabilize myocardium and prevent malignant cardiac excitability We recommend that other strategies are considered for longer-term effects on hyperkalemia be used in conjunction with intravenous calcium We recommend for digoxin-associated hyperkalemia that Ca^{2+} infusion not be used due to risk of cardiotoxicity and dysrhythmias [76]	Moderate	Strong
Insulin (intravenous route with glucose)	We recommend that insulin administered intravenously in combination with glucose be used for severe and symptomatic hyperkalemia We recommend low-dose intravenous insulin be used to reduce the occurrence of hypoglycemia in CKD and end-stage renal disease [77]	High	Strong
β2 receptor agonist (albuterol inhaler)	We suggest inhaled β2 receptor agonist be used for severe and symptomatic hyperkalemia	Moderate	Medium
$NaHCO_3$ infusion	We recommend sodium bicarbonate infusion be used when metabolic acidosis is present The clinician should be aware of the risk of volume overload, hypocalcemia (ionized form), and, when using undiluted, hypernatremia	Moderate	Strong
Loop and thiazide diuretics	We recommend that loop and thiazide diuretics be used to promote kaliuresis This evidence may be more applicable for patients with CKD [78] Clinicians should monitor for individual diuretic-associated adverse events	High	Strong

Table 60.3 (Continued)

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Patiromer: oral agent, onset of action within ~7 h [79]	We recommend that patiromer (a nonabsorbable, Ca^{2+}-K^+ exchange polymer that selectively binds K^+ mainly in the colon) be used to treat chronic hyperkalemia in patients with nondialysis CKD Patients need to be aware of potential side effects, including constipation and mild hypomagnesemia and take the medication spaced at least 1 h apart from other medications due to a potential risk of drug–drug interaction	High	Strong [80, 81]
Sodium zirconium cyclosilicate: oral agent, onset of action within 2 h	We recommend that sodium zirconium cyclosilicate (a nonabsorbable, insoluble crystal that traps gut K^+ in exchange for Na^+ and H^+) be used to treat acute or chronic hyperkalemia in patients with nondialysis CKD Patients should be aware that edema is a potential side effect	High	Strong [82]
Kayexalate (sodium polystyrene sulfonate)	We suggest sodium polystyrene sulfonate be used to treat acute hyperkalemia as a temporizing measure Patients may reasonably choose not to take this medication due to low certainty evidence and multiple case reports of causing gut ischemia and necrosis	Low	Weak [83]
Fludrocortisone	We recommend fludrocortisone be used in selected patients with mineral corticoid deficiency and without a high risk of volume retention	Moderate [84]	Strong
Hemodialysis	We recommend hemodialysis be used for life-threatening, intractable, and refractory hyperkalemia	Strong	Strong
Oral glucose	We recommend oral glucose be used for nondiabetic hemodialysis patients [85]	Moderate	Strong

RAAS; renin-angiotensin-aldosterone system

Table 60.4 Commonly used medication known to induce hyperkalemia.

- RAAS inhibitors (angiotensin converting enzyme inhibitors, angiotensin receptor blockers, renin inhibitors)
- Mineralocorticoid receptor inhibitors (spironolactone and eplerenone)
- β2 receptor blockers
- K^+ sparing diuretics (triamterene, amiloride)
- Heparin (inhibiting aldosterone production)
- Digitalis glycosides (blocking Na^+-K^+-ATPase, impairing intracellular K^+ distribution)
- Calcineurin inhibitors (cyclosporine, tacrolimus)

The modern diet lacks sufficient K^+ [94]. Intake of less than the recommended 4.7 g (120 mmol/day) or a minimum of 3.5 g (~90 mmol/day) [95] is common due to a reduced consumption of plant foods (fruits and vegetables) [94]. The modern diet has a K^+/Na^+ ratio of ~0.4 whereas in the premodern era the ratio was >3 and often near 10. As plant foods are also a rich source of base or base-equivalents and fiber, a low K^+ diet is coupled with a net acid accumulation (positive net endogenous acid production) and sluggish bowel transit from lacking fiber, which can alter gut microbiota [96]. In healthy adults, mild or low-normal serum [K^+] is common and could be linked to risks of many common and noncommunicable chronic diseases [33]. In addition to diet, kaluretic diuretic use (furosemide, hydrochlorothiazide, and osmotic diuresis), alkalosis, and hypomagnesemia can exacerbate K^+ depletion. Vomiting and diarrhea associated with acute illness can superimpose on the baseline deficiency and cause clinically significant hypokalemia. Patients with hypertension and hypokalemia should be investigated for primary hyperaldosteronism (Conn's syndrome). Persistent or recurrent hypokalemia onset in teens and younger should be investigated for potential genetic abnormalities, i.e. Gitelman syndrome, Bartter syndrome, and Liddle syndrome [97]. Hypokalemia can often be associated with hypomagnesemia. Hypomagnesium lifts the magnesium-mediated inhibition to the apical K^+ (renal outer medullary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

potassium, ROMK) channel, causing increased distal tubular K^+ excretion [98]. Failure to correct hypomagnesemia renders hypokalemia refractory to treatment.

Pathophysiology

Potassium Regulation

Potassium (K^+) is the dominant intracellular cation, with >98% of total body K^+ (~3500 mmol) being distributed in the intracellular compartment and <2% (~65–70 mmol) in the extracellular fluids. The sharp intracellular-to-extracellular K^+ gradient is critical to the maintenance of plasma membrane potential and normal functions of multiple tissues, especially the heart, nerves, and skeletal muscle. K^+ also participates in the regulation of cell volume and cellular pH. The kidneys are the major K^+ regularly organ. K^+ is freely filtered through glomeruli. The proximal tubules reabsorb ~65% of the filtered K^+, while the thick ascending limb of the Loop of Henle reabsorbs ~25%. The distal nephron (the distal convoluted tubule and collecting duct) is the major site of renal K^+ regulation. The distal nephron can either excrete or absorb K^+ to control K^+ balance. Major factors that increase distal nephron K^+ excretion are (i) serum K^+ elevation, (ii) distal tubular Na^+ delivery, (iii) tubular fluid flow, (iv) serum aldosterone elevation, and (v) alkalosis (HCO_3^- coupled K^+ excretion) or the presence of nonabsorbable anions [86]. Acidemia and hypokalemia stimulate proximal tubular ammonia genesis while alkalemia and hyperkalemia exert an inhibitory effect on ammoniagenesis.

Effects of Inadequate Dietary Potassium

A low or low-normal serum or plasma K^+ concentration, mostly a consequence of insufficient intake, can stimulate kidney NH_3/NH_4^+ genesis and RAAS activation, contributing to systemic inflammation, protein catabolism, development of CKD, and, in patients with preexisting CKD, promoting CKD progression [99]. Kaluretic diuretics, commonly used in hypertensive and CKD patients, can further exacerbate K^+ deficiency and its adverse effects [100]. Abundance of dietary K^+ is epidemiologically associated with a reduction in hypertension, stroke, and other cardiovascular diseases [101]. A recent metaanalysis of randomized controlled trials showed a mortality benefit of aldosterone antagonists in postmyocardial infarction patients with preserved ejection faction, supporting the notion of antiinflammation and K^+-sparing benefits [102].

Potassium has been shown to reduce vascular smooth muscle cell proliferation and migration. It also reduced neointimal formation following balloon angioplasty associated vessel injury. These effects were implied in a population-based study, showing an association of reduced proliferation of vascular smooth muscle cells and reduced monocyte adherence through the vessel walls [103]. Recently, Sun et al. [104] demonstrated a causal role of dietary K^+ in the regulation of osteogenic differentiation and calcification of vascular smooth muscle cells, both *in vitro* and in atherosclerotic animal models. Specifically, lower levels of extracellular fluid K^+ induce vascular smooth muscle cell osteogenic transformation by elevating intracellular calcium. The latter activates cyclic AMP response element-binding protein (CREB), leading to an enhanced expression of osteogenic markers, e.g. runt-related transcription factor 2, and, simultaneously, diminished smooth muscle cell markers, e.g. α-actin. Remarkably, even a slight serum K^+ reduction (mean K^+ level 3.70 ± 0.21 mEq/l) in mice could trigger a significant vessel calcification associated with elevated pulse-wave velocity, a reliable indicator of aortic stiffness. On the contrary, when K^+ levels are raised to ~4.73 mEq/l by dietary modification, signs of osteogenic differentiation are abrogated and vascular calcification prevented. Consistent with the notion of K^+ being protective to vasculature, a high ratio of urine Na^+/K^+ excretion (indicative of high Na^+ and low K^+ intake) has recently been linked to the genesis of hypertension [105].

Significant Tests

Pseudohypokalemia due to active cellular uptake of extracellular K^+ in the test-tube should be ruled out when the clinical setting is appropriate. It often occurs in samples from patients with severe leukocytosis or leukemia. Immediate separation of plasma from the whole-blood sample can minimize such occurrence. Pseudohyperkalemia due to cell lysis can occur during or after blood sampling from use of a small needle and inadequate technique. These possibilities can be ruled out by using an appropriate-sized needle and optimal technique.

Prognosis: Complications

Both hypo- and hyperkalemia across the spectrum of kidney function are associated with increased all-course and cardiovascular mortality [87]. Hypokalemia is also associated with an increased risk of developing CKD and CKD progression. In the PREVED (prospective, population-based) study involving 5215 adults (ages, 28–75 years) with a median follow-up of 10.3 years [106], CKD risk increased significantly in those with a lower urine K^+ content, reflecting a low K^+ diet. For each 21 mEq decrement of daily urine K^+ excretion, there was a 16% higher risk of developing CKD (defined as eGFR <60 ml/min/1.73 m^2 or albuminuria >30 mg/24 h or both). This is consistent with a prior

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cross-sectional study of dietary K^+ intake [107] and urine K^+ excretion on the risk of CKD development and progression [108, 109]. In dialysis patients (hemodialysis or peritoneal dialysis), hyperkalemia is a well-known risk for mortality. Recent studies have also shown a significant increase in morbidity and mortality associated with serum [K^+] reduction [110, 111].

Treatment

Treatment for hypokalemia includes correcting the underlying causes and K^+ replacement.

K^+ repletion can be achieved with oral or intravenous supplementation. Intravenous K^+ infusion is appropriate for patients with severe and symptomatic hypokalemia or without adequate gut function. Intravenous K^+ should not be given in a dextrose-containing solution because sugar can stimulate insulin secretion and potentially exacerbate hypokalemia by shifting K^+ intracellularly. A central line is preferred for K^+ infusion due to the vessel corrosive effect of K^+; the rate of K^+ infusion should generally not exceed 10 mEq/h (mmol/h). Hypokalemia can precipitate digoxin toxicity. Close monitoring and withholding digoxin may be necessary.

Hyperkalemia should also be managed in a multipronged manner. Dietary modification to limit dietary K^+ intake (<75 mmol/day) is an important part of intervention. The medication regimen should be reviewed to minimize exposure of drugs that may induce hyperkalemia. Loop and thiazide diuretics can be used to promote kaliuresis. In CKD patients, lack of diuretic use is associated with increased occurrence of hyperkalemia [78].

Patiromer is a nonabsorbable compound containing a Ca^{2+}–K^+ exchange polymer that selectively binds K^+, mainly in the colon. Its onset of action is 7 hours. Placebo-controlled clinical trials [80, 81] have demonstrated its efficacy and safety in lowering (normalizing) serum K^+ levels. It is Food and Drug Administration (FDA)-approved for the treatment of hyperkalemia in nondialysis CKD patients in a nonacute setting. Patiromer comes as a powder (in three strengths of 8.4, 16.2, and 25.2 g) with a recommended starting dose of 8.4 g daily. Dosage may be titrated up to a maximum daily dose of 25.2 g. Ingestion of patiromer should be spaced at least 3 hours away from intake of other medications due to a potential risk of drug–drug interaction. The most common known side effects are constipation and mild hypomagnesemia. There is a small study of hyperkalemic hemodialysis patients ($n = 6$) showing effective control of hyperkalemia with oral patiromer (12.6 g daily in divided doses) for 7 days [112].

Sodium zirconium cyclosilicate (ZS-9) is another nonabsorbable, insoluble crystal that traps gut K^+ in exchange for Na^+ and H^+. It has been shown to be effective in correcting hyperkalemia within 48 hours [82, 113]. The FDA has recently approved its use as an oral agent for hyperkalemia in patients with CKD. ZS-9 has an onset of action at ~1 hour and can be dosed 5 or 10 g/day in divided dosage. There has been no reported drug–drug interaction. Because of its gut Na^+ exchange, edema is a noted adverse effect. Other common side effects are constipation, nausea, and vomiting.

Management of acute and symptomatic hyperkalemia requires cardiovascular monitoring. In the presence of electrocardiogram (ECG) changes, intravenous calcium should be administered to stabilize the myocardium. Temporizing measures to shift K^+ into the cell interior are indicated, including albuterol (10 mg) inhalation and intravenous infusion of regular insulin (5–10 units) combined with dextrose. $NaHCO_3$ (oral or intravenous) can be added when there is coexistent metabolic acidosis. Definitive measures to excrete K^+ include loop diuretics and/or thiazide to promote renal excretion and hemodialysis. Given its relatively quick (1 hour) onset of K^+-lowering action, ZS-9 can also be used. Hemodialysis is the most effective and reliable treatment modality, especially in the setting of renal failure.

Medications that confer cardiovascular protection in heart failure patients, i.e. ACEIs, angiotensin receptor blockers, and mineralocorticoid blockers, could induce hyperkalemia and become a serious therapeutic barrier. Measures to lower serum [K^+] while keeping at-risk patients on these agents should be carried out, as limiting the use of these agents could portend to a higher all-cause and cardiovascular mortality [114].

Hypo- and Hypermagnesemia

[Mg^{2+}].

Definitions

Hypermagnesemia is defined as a serum Mg^{2+} concentration [Mg^{2+}] > 2.3 mg/dl (0.95 mmol/l) and hypomagnesemia has serum [Mg^{2+}] < 1.7 mg/dl (0.70 mmol/l).

Epidemiology

Both hyper- and hypomagnesemia are relatively common, with reported prevalences of ~31% and ~20%, respectively, in hospitalized patients [115]. In one study, oral intake of sevelamer carbonate as phosphate binder in patients with kidney failure receiving hemodialysis was associated with a lower risk of hypomagnesemia [116].

Pathophysiology

Mg^{2+} is the second (after K^+) most abundant intracellular cation. It is a cofactor for numerous (>600) intracellular enzymes and has multiple functions in oxidative phosphorylation, DNA synthesis repair and replication, RNA and protein synthesis, and signaling pathways [1].

Daily Mg^{2+} intake in an adult should be ~350–450 mg (14.4–18.5 mmol). It is absorbed predominantly in the distal small intestine through a paracellular process and in the cecum and colon by a transcellular process involving TRPM6 (Transient Receptor Potential *cation channel,* subfamily M, member 6). Intestinal Mg^{2+} absorption can vary significantly from 25% to 75% depending on the Mg^{2+} intake. Notably, ~60% of the US population show insufficient dietary Mg^{2+} intake [117].

Greater than 99% of the total body Mg^{2+} is distributed in the intracellular compartment with ~1% or less distributed in the extracellular fluid. Approximately 20–30% of circulating Mg^{2+} is protein-bound (mainly to albumin). Unbound Mg^{2+} (70–80%) is freely filtered through glomeruli in the kidneys. The kidneys filter ~2400 mg (98.7 mmol) of Mg^{2+} daily. Unlike Na^+, K^+, and Ca^{2+}, the largest part of the filtered Mg^{2+} (70%) is absorbed, not in the proximal tubules (20% Mg^{2+} absorption), but in the thick ascending limb of the Loop of Henle (TALH), where claudins 16 and 19 facilitate paracellular Mg^{2+} absorption. The major driving force for Mg^{2+} absorption is the lumen-positive transepithelial voltage, generated primarily by the reabsorption of Na^+, K^+, and Cl^- in the TALH. The remaining 5–10% of filtered Mg^{2+} is reabsorbed in the distal tubule through a transcellular process involving TRPM6. When in balance, ~100 mg (4.1 mmol) of filtered Mg^{2+} is excreted in the urine daily (reviewed in [118, 119]). Causes of hypo- and hypermagnesemia are listed below [86]. Mg^{2+} repletion improves clinical symptoms. In patients with diabetes, Mg^{2+} repletion has been shown to improve insulin sensitivity [120]. Causes of pathologic states of hypo-and hypermagnesemia are shown in table 60.5.

Table 60.5 Major Causes of Hypo- and Hypermagnesemia.

	Hypomagnesemia	Hypermagnesemia
Hereditary	• Maturity onset diabetes of young (MODY) • Gitelman syndrome • Barter syndrome-type V	• Familial hypocalciuric hypercalcemia (FHH) (autosomal dominant inheritance)
Acquired	• Gut causes (malabsorption, chronic diarrhea) • Kidney causes (recovery phase of obstructive uropathy and acute tubular necrosis)	• Advanced renal failure + high Mg^{2+} intake
Hormonal deficiency	• Parathyroid hormone • Insulin • Estrogen • Vitamin D	
Medications	• Loop/thiazide diuretics • Proton pump inhibitors • Calcineurin inhibitors (cyclosporin, tacrolimus) • EGFR (epidermal growth factor receptor) antibodies (cetuximab, panitumumab, and matuzumab) • Platinum-containing agents (cisplatin, carboplatin) • Tyrosine kinase inhibitors • Aminoglycosides • Amphotericin • Patiromer • Non-Mg^{2+}-containing osmotic laxatives	Mg^{2+}-containing oral agents • Mg^{2+}-containing laxatives (milk of magnesium) • Epsom salt water • Mg^{2+}-containing antacids Intravenous Mg^{2+} infusion: • Magnesium chloride • Magnesium sulfate
Electrolyte disturbances	• Hypercalcemia • Hyperphosphatemia • Chronic metabolic acidosis

Table 60.6 Evidence table: magnesium disorders.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Hypomagnesemia			
Correcting the underlying causes	We recommend control of hyperglycemia, replacement or discontinuation of Mg^{2+} wasting diuretics and proton pump inhibitors, and correction conditions that lead to Mg^{2+} loss be used to management hypomagnesemia	High	Strong
Mg^{2+}-rich diet	We recommend intake of a diet rich in dark green leafy vegetables, beans, nuts, seeds, fish, avocados, dark chocolate, etc.	Moderate	Strong
Oral Mg^{2+} salts	We recommend use of magnesium replacement alone or in combination	Moderate	Strong
Parenteral Mg^{2+} administration	Recommend intravenous magnesium replacement for symptomatic hypomagnesemia as a temporizing measure Oral magnesium salt administration is required to replace total body Mg^{2+} store	High	Strong
Hypermagnesemia			
Self-correct through urine Mg^{2+} excretion	We recommend self-correct through urine Mg^{2+} excretion for patients with adequate renal function	High	Strong
Loop diuretics	We recommend use of loop diuretics if necessary to enhance renal Mg^{2+} excretion	Moderate	Strong
Intravenous calcium	We suggest intravenous calcium be used for symptomatic hypermagnesemia to temporarily stabilize the myocardium	Moderate	Medium
Dialysis	We recommend dialysis be used as the most effective and definitive treatment of hypermagnesemia, especially for patients with compromised kidney function	Strong	High

Diagnostic Tests

Because albumin binds ~15–20% of circulating Mg [121], alterations in serum albumin concentration could, to a degree, alter the serum [Mg^{2+}]. As serum Mg represents <1% of the total body Mg^{2+}, the [Mg^{2+}] may not reflect the intracellular and tissue Mg^{2+} content. However, when chronic, serum Mg^{2+} could be in equilibration with the tissue Mg^{2+}, and a reduced serum [Mg^{2+}] thus signifies a significant intracellular and tissue Mg^{2+} depletion. Measuring red blood cell Mg^{2+} has not been reliably reflective of total body Mg^{2+} status. More precise methods are Mg^{2+} tolerance test and Mg^{2+} loading study [121–123]. These methods, however, are time-consuming and impractical in the setting of hospital admission.

Prognosis: Complications

Both hypo- and hypermagnesemia adversely impact patient outcomes, including increased mortality and duration of hospital stay [115, 124–126].

Treatment

Treatment of dysmagnesemia involves eliminating the underlying causes if possible and normalizing blood and tissue Mg^{2+}. For severe symptomatic hypomagnesemia, parenteral Mg^{2+} administration is indicated. Oral Mg^{2+} preparations in divided doses daily, however, are the only effective method for total body Mg^{2+} repletion. Hypermagnesemia in patients with adequate renal function is typically transient and can mostly self-correct with urine Mg^{2+} excretion. If necessary, Mg^{2+} losing diuretics (loop and thiazide) can be used to enhance renal Mg^{2+} excretion. In patients with advanced renal failure and symptomatic hypermagnesemia, intravenous calcium should be considered to stabilize the myocardium. Dialysis in such settings is the most effective and definitive treatment of hypermagnesemia. Table 60.6 summarizes the quality of evidence and strength of recommendations for the various components of the management of magnesium disorders.

Metabolic Evaluation and Prevention of Kidney Stone Disease

Neera K Dahl[1] *and David S Goldfarb*[2]

[1] *Section of Nephrology, Yale University School of Medicine, New Haven, CT, USA*
[2] *Nephrology Section, New York Harbor VA Medical Center, and Nephrology Division, NYU Grossman School of Medicine, New York, New York, USA*

Introduction

The field of kidney stone prevention is still in its infancy, with a relative paucity of high-grade data suitable for inclusion in this textbook which promotes evidence-based medicine (Table 61.1). Numerous studies regarding treatment and patient outcomes are underway and robust, evidence-based data should become increasingly available [2]. Insights from genetics, understanding of microbiota, and an appreciation of the "exposome," the accumulation of environmental exposures during a lifetime, are contributing to our understanding of kidney stone disease as a chronic metabolic condition marked by acute episodes [2].

Kidney stones are becoming more common. The overall prevalence of kidney stones has increased from affecting 3.8% of the population in 1976–1980 to 8.8% of the population in 2007–2010 based on National Health and Nutrition Examination Survey (NHANES) data. Non-Hispanic white men have the highest prevalence of stones, followed by Hispanic men, non-Hispanic white women, and Hispanic women. Non-Hispanic black men and women have the lowest prevalence of stones at 4.8% and 4.2%, respectively [3]. The prevalence of kidney stones increases with age: 16% of men and 7% of women over the age of 70 had passed at least one stone. The prevalence of kidney stones increases in men until the age of 65, and in women until the age of 70 [4].

Besides causing episodes of acute nephrolithiasis, stones are associated with significant morbidity, which may be attributed to shared risk factors. In a group of calcium oxalate stone formers, the prevalence of diabetes mellitus, hypertension, and increasing body mass index (BMI), all risk factors for stone disease, increases from age 18 to 69 prior to declining in those aged 70+ [5].

There is a higher risk of cardiovascular disease in women stone formers compared to nonstone formers [6]. A larger cohort study of over three million people in Alberta, Canada found a higher risk of acute myocardial infarction, higher risk of PTCA (percutaneous transluminal coronary angioplasty)/coronary artery bypass graft (CABG), and higher risk of stroke in patients with at least one kidney stone compared to patients without stones [7], particularly in young people and women. Nephrolithiasis is also associated with a twofold higher risk of end-stage renal disease (ESRD) [8]. Thus, kidney stones may be considered a risk factor for other metabolic derangements and part of a complex of other chronic diseases.

Nontraditional risk factors for stones include consideration of the patient's microbiome, the environment created by the microorganisms associated with the patient. For example, *Oxalobacter formigenes* degrades oxalate in the intestinal tract. Patients who are colonized with this organism have fewer stones and lower urinary oxalate levels [9]. Antibiotics are known to affect the prevalence of this organism in the human intestinal tract [10]. Antibiotic use is also associated with an increased risk of kidney stones [11]. Antibiotic use could affect stone risk by altering a patient's microbiome.

This chapter will focus on the evaluation of stone formers and the measures taken to prevent stone recurrence. Topics that will be covered only briefly here are the urologic aspects of stone disease, including the differential diagnosis of renal colic, the management of renal colic, and surgical management of ureteral stones.

Table 61.1 Interventions for calcium stones.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Thiazide diuretics	We suggest thiazide diuretic therapy may be used to reduce stone formation in people with calcium-based stones Some patients may reasonably choose not to take thiazide diuretics due to the low certainty of the available evidence	Low	Weak
Potassium citrate	We suggest potassium citrate may be used for the secondary prevention of calcium stones, although patients may reasonably choose not to due to the paucity of high-quality evidence	Very low	Weak
Fluid intake	We suggest increased fluid intake of 2.5–3 l per day to prevent stone recurrence	Moderate	Weak

Source: Based on Seliger and Kestenbaum [1].

Urologic Aspects of Stone Disease

Imaging plays an important role in the evaluation of kidney stones. A KUB (kidney, ureter and bladder x-ray) will show larger, calcium-containing stones, which are radio-opaque, but may miss small calcium-containing stones, or radiolucent uric acid or cystine stones.

Noncontrast, helical, computed tomography (CT) is considered the imaging modality of choice for the evaluation of nephrolithiasis [12]. CT has several advantages. The size of a stone can be accurately determined. Small stones and/or ureteral stones are easily visualized. Stone density, expressed in Hounsfield units (HU), may also be measured by CT. In general, HU < 500 is consistent with a uric acid stone, which may be amenable to medical dissolution therapy regardless of size [13]. Dual emission CT scanning uses X-ray beams of two frequencies to better calculate stone density and suggest stone composition. The only stones so radiolucent that they are not visualized by CT scanning are those composed of protease inhibitors used in the treatment of human immunodeficiency virus (HIV) infection [14].

Although less sensitive and specific than CT scanning, ultrasound is also helpful for the diagnosis of nephrolithiasis. Lower cost and no radiation make ultrasound a reasonable and preferable imaging modality, especially in younger patients [15]. When patients with suspected renal colic were evaluated in emergency rooms, point-of-care ultrasound approached the positive predictive value of CT scanning [15]. Patients with an initial negative ultrasound who still had signs and symptoms of renal colic then underwent CT scanning for a definitive diagnosis. This approach, however, is controversial, especially among urologists who are concerned with delayed and inaccurate diagnosis. Low-dose, noncontrast CT scans are a nice option, when available, for minimizing radiation exposure and are becoming more widely available with lower radiation exposure [16]. Other options for minimizing use of CT scans include incorporating the use of a predictive algorithm such as the STONE score to determine which patients have a high probability of an uncomplicated ureteral stone (based on male sex, acute onset of pain, nonblack race, presence of nausea, or vomiting and microscopic hematuria) [17]. Appropriately selected patients, particularly among those with a prior history, may initially be managed without CT scanning.

While facilitation of stone passage has been widely studied, the optimal prescription remains uncertain. Forced diuresis with administration of oral or intravenous fluids is not effective, probably because the affected kidney has a reduced glomerular filtration rate, with most of the fluid administered excreted by the contralateral kidney [18]. Alpha-blockers have been popular for promoting stone expulsion, but the most recent randomized controlled trials (RCTs) have not shown clear benefit of these drugs, which are thought to relax ureteral smooth muscle [19]. Despite conflicting data on benefit, recent guidelines include the use of alpha-blockers to facilitate passage of ureteric stones in a shared decision-making approach [20]. Nonsteroidal anti-inflammatory drugs may have a positive effect but have not been tested adequately.

Guidelines on Evaluation and Management of Stone Formers

Stone disease is highly recurrent. The overall risk of a second kidney stone is about 10% per year and about 50% in 5 years. However, some individuals are much more likely to develop a second stone. Table 61.2 reviews the guidelines from the American Urologic Association (AUA), which are founded on the biological reasoning that for the individual patient, management and prevention of stone recurrence can be based on the individual's unique characteristics. The overall utility of the recommended comprehensive evaluation of the patient with renal stones has not been evaluated with rigorous RCTs.

Table 61.2 AUA guidelines for evaluation of risk of kidney stones.

- A clinician should perform a screening evaluation consisting of a detailed medical and dietary history, serum chemistries, and urinalysis on a patient with newly diagnosed kidney or ureteral stones.
- When a stone is available, clinicians should obtain a stone analysis at least once.
- Clinicians should review available imaging to quantify stone burden.
- Clinicians should perform additional metabolic testing in high-risk or interested first-time stone formers and recurrent stone formers.
- Metabolic testing should consist of one or two 24-h urine collections obtained on a random diet and analyzed at a minimum for total volume, pH, calcium, oxalate, uric acid, citrate, sodium, potassium, and creatinine.

Source: Based on Pearle et al. [21].

Evaluation of Stone Formers

Kidney stones are the result of both genetic and environmental risk factors. The hereditability of the risk of stones is high, as indicated by a near doubling of concordance for stones among monozygotic versus dizygotic twins [22]. However, the specific genes that account for this finding remain uncertain. When stone formers in a highly selected stone clinic are screened for genes known to confer risk, about 10% of pediatric patients are found to have a mutation responsible for a monogenic disorder [23].

Obesity, diabetes mellitus, and gout are increasingly common conditions and are associated with an increased risk of kidney stones [3]. Increasing prevalence of these disorders may be in part responsible for increasing prevalence of stones. Other metabolic conditions such as hyperparathyroidism increase risk of stones. Hypertension and low bone density are associated risk factors [24].

Certain occupations may also increase risk of kidney stones. For example, taxicab drivers [25] have infrequent access to rest rooms, reduce fluid intake, and urine volume, developing higher risk. Those who work in hot environments [26] or have infrequent access to fluids also have more concentrated urine and a risk for stones. Stones are more frequent at lower latitudes [27] and may increase as global warming ensues [28].

Many of these risk factors may act to promote stone formation by changing urine chemistry. Increased urinary calcium is a frequent finding in patients with calcium oxalate and calcium phosphate stones. Increased urinary oxalate promotes the former. Reduced urinary citrate excretion is frequently noted in calcium stone formers, as citrate can be thought of as a competitive antagonist for oxalate and phosphate binding to calcium. Low urine pH is seen with obesity, metabolic syndrome, and diabetes, conferring a risk of uric acid stones. The likelihood of all stones increases with higher relative supersaturations of the relevant solutes, as calculated from 24-hour urine collections [29].

The AUA guidelines recommend performing 24-hour urine collections to further evaluate patients at greater risk, though convincing evidence of the benefit of this strategy has not been produced [30]. There are reasons for and against such a diagnostic plan, with many stone specialists promoting such collections in order to select appropriate patients for various regimens. The Recurrence of Kidney Stone (ROKS) nomogram for predicting stone recurrence [31] was developed to help determine which first-time stone formers were at high risk of recurrence. Factors associated with an increased likelihood of a second stone include first stone at a young age, white race, male, and positive family history of kidney stones. Uric acid stones are most likely to recur. A stone at the renal pelvis or lower pole is associated with a higher risk of recurrence than a stone at the ureterovesicular junction (UVJ). Having any other incidentally noted stones will increase the risk of a second stone. The nomogram did not include the results of 24-hour urine collections.

Patients with multiple stones are at high risk of recurrence and should be counseled to undergo a more thorough evaluation to identify stone risk factors. Similarly, patients with stones affecting a solitary kidney should also undergo further evaluation and close follow-up. Finally, evidence of nephrocalcinosis or reduced glomerular filtration rate might suggest distal renal tubular acidosis (RTA), primary hyperparathyroidism or medullary sponge kidney, for which further evaluation is necessary.

Table 61.3 outlines some specific conditions which may increase risk for stone formation and the likely associated stone type.

Nonspecific Prevention of Stones

Drinking an adequate amount of fluid to maintain a higher urine output is the single most important preventive measure for most stones. We recommend drinking at least 2.5 l to maintain a urine volume of 2 l. This simple measure has been shown by RCT to have significant efficacy [33]. Observational studies suggest protective effects of coffee and alcohol.

Dietary intake is also a modifiable risk factor in the development of kidney stones. In observational studies, maintaining a normal BMI, eating a diet high in fruits and vegetables, and high in low fat dairy products (such as the Dietary Approaches to Stop Hypertension [DASH] diet),

Table 61.3 Specific concerns for stone formers which increase risk for recurrent stones.

Condition	Metabolic risk	Stone type
Inflammatory bowel disease or chronic diarrhea	Hyperoxaluria Acidic urine	Calcium oxalate Uric acid
Intestinal surgery, including ileostomy or colectomy	Volume depletion, bicarbonate loss	Calcium oxalate or uric acid
Roux-en-Y, gastric bypass	Hyperoxaluria	Calcium oxalate
Sarcoidosis, primary hyperparathyroidism, immobilization, hyperthyroidism	Hypercalciuria	Calcium phosphate and calcium oxalate
Distal renal tubular acidosis	Low urine citrate, high urine pH	Calcium phosphate
Gout	High serum uric acid Overweight	Uric acid stones Calcium oxalate
Metabolic syndrome, obesity, diabetes mellitus	Low urine citrate, low urine pH	Uric acid stones, calcium oxalate stones
Renal anomaly (e.g. horse-shoe kidney)	Urine stasis	Multiple stone types
Recurrent UTI with urea-splitting organisms (e.g. *Proteus)*	High urine pH	Struvite
Medications		
Topiramate	Low urine citrate, high urine pH	Calcium phosphate
Sulfa-containing drugs	Crystallization in urine	Sulfa (medication)
Antiretroviral therapy	Crystallization in urine	Antiretrovirals (e.g. atazanavir)
Nephrocalcinosis	Hyperparathyroidism, distal RTA	Calcium phosphate or calcium oxalate
Medullary calcification with ductal ectasia (medullary sponge kidney)	Urine stasis, hypocitraturia	Calcium oxalate or calcium phosphate

Source: Based on Worcester and Coe [32].

with adequate calcium intake, and low intake of sugar-sweetened beverages were factors associated with a significantly lower risk of incident kidney stones [34]. The only positive RCT of diet for calcium stone prevention showed that a diet with restricted salt, animal protein, and oxalate content, and with an increase in calcium ingestion, was superior to a calcium-restricted diet [35]. The effect of increasing calcium intake is attributed to binding of oxalate in the intestinal lumen, limiting its absorption. In general, lower protein intake is associated with lower urinary stone risk [36], but an RCT did not show an effect [37]. Kidney stone risk may also vary by protein type, with a lower risk from dairy-based proteins and a higher risk from other animal-based proteins. Diets high in potassium or with high potassium to animal protein ratios were beneficial [38], possibly because of their greater citrate content.

Based on the findings of population-based studies and review of existing clinical trials, both the AUA [21] and the European Association of Urology (EAU) [39] recommend "normal" (not restricted) dietary calcium intake, limited sodium, and limited animal protein for patients with calcium-containing stones (Table 61.4). A recent Cochrane review also found a benefit from a normal calcium, low protein, and low-salt diet for stone patients with higher urine calcium excretion [40]. The EAU recommends general preventative measures for all stone formers, including specific dietary management based on the results of a 24-hour urine collection.

In contrast, the American College of Physicians (ACP), which limits recommendations to those backed by rigorous RCTs, only has a single guideline for dietary management of kidney stones, noting a goal of increased fluid spread throughout the day to achieve a daily urine volume of at least 2 l. Beyond stating that sodas acidified with phosphoric acid should be avoided, there were no specifics for additional dietary interventions [41]. In the absence of better RCT-derived data, we consider limiting prescriptions in this manner inappropriate.

Calcium Stones

In general, we use the appropriate medical intervention to treat the appropriate metabolic risk in calcium stone formers at high risk of recurrence. For example, thiazides would be used in recurrent stone formers or high-risk patients

Table 61.4 AUA and EUA dietary guidelines for management of kidney stones.

AUA guidelines	General preventative measures (EAU)
All stone formers should have fluid intake that will achieve a urine volume of 2.5 l daily	Fluid intake of 2.5–3.0 l/day Circadian drinking Neutral pH beverages Goal: urine output of 2.0–2.5 l/day Goal: specific gravity <1.010
Patients with calcium stones and high urinary calcium should limit sodium intake and consume 1000–1200 mg daily of dietary calcium	Nutritional advice: balanced diet Rich in vegetables and fiber Normal calcium content (1–1.2 g/day) Limited sodium chloride (4–5 g/day) Limited animal protein 0.8–1.0 g/kg/day
Patients with calcium oxalate stones and high urinary oxalate should limit intake of oxalate-rich foods and maintain normal, or higher, calcium consumption	If a 24-h urine shows hyperoxaluria, oxalate should be restricted
Patients with calcium stones and low urinary citrate should increase intake of fruits and vegetables, and limit nondairy animal protein	If a 24-h urine shows high sodium excretion, sodium should be restricted
Patients with uric acid stones or calcium stones with high urinary uric acid should limit nondairy animal protein	If a 24-h urine shows a small urine volume, fluid intake should be increased
Patients with cystine stones should limit sodium and protein intake	If a 24-h urine shows high intake of animal protein, excess animal protein intake should be avoided
	Lifestyle advice BMI for adults: 18–25 kg/m^2 Stress limitation measures Adequate physical activity Balancing excessive fluid loss

with higher urinary calcium. Potassium citrate would be used in patients with hypocitraturia. The RCTs demonstrating benefit may be imperfect and sparse but do suggest clinically meaningful benefits with or without the use of 24-hour urine measurements to guide treatment decisions.

The current state of the art for evidence-based management of calcium-containing stones is outlined in the Table 61.5.

Table 61.5 Summary of evidence-based interventions for calcium stones.

Summary of evidence-based interventions for prevention of calcium-containing kidney stone recurrence.
Thiazide diuretics: Several RCTs show a benefit in calcium stone formers. Not all trials showed a significant benefit. Most trials involved small numbers (<100) of participants. Typical doses were higher than those commonly used to treat high blood pressure and higher than those used today for stone disease. Higher urine calcium was not required.
Potassium citrate: Five trials evaluated the effect of citrate for secondary prevention of calcium stones. Two reported a significant risk reduction. All studies had small participant numbers. Sodium citrate does not appear effective. Lower urinary citrate was not required for benefit.
Fluid: Observational data from multiple cohorts and a single RCT favor increased fluid intake to reduce stone recurrence.

Source: Based on Seliger and Kestenbaum [1].

Medications

The AUA and EAU note that high-risk stone formers are likely to benefit from medical therapy and have issued guidelines regarding appropriate treatment based on stone composition or metabolic factors. Both guidelines were based on the best available published evidence and expert opinion.

Thiazides

The AUA guidelines state that clinicians should offer thiazide diuretics to patients with high or relatively high urinary calcium and recurrent calcium stones to reduce urine calcium excretion (guideline 14, evidence strength Grade B) [21]. Appropriate doses of thiazide type diuretics include hydrochlorothiazide 25 mg twice daily, chlorthalidone 25 mg

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

daily, and indapamide 2.5 mg daily. Potassium balance may be maintained with use of potassium supplements, including potassium citrate, or with spironolactone or amiloride [21]. Triamterene, which is poorly soluble, should be avoided.

The ACP guideline recommends monotherapy with a thiazide diuretic, citrate, or allopurinol to prevent recurrent stones in patients with active disease in whom increased fluid intake fails to reduce the formation of stones [41]. However, they fail to specify when these drugs are appropriate.

The EAU guidelines suggest either thiazide or potassium citrate for management of hypercalciuria, with more specific recommendations based on 24-hour urine measurements [39].

Use of thiazides may lead to hyponatremia or orthostatic hypotension, increasing fall risk. Thiazides may also cause erectile dysfunction, fatigue, and muscle symptoms [41], further limiting use. On the other hand, thiazides are associated with increased bone mineral density, a condition often associated with calcium stones.

Citrate

Potassium citrate may be used to treat hypocitraturia (e.g. as seen in distal RTA) in patients with calcium stones. Because citrate is metabolized to bicarbonate, leading to an increase in urinary pH, it can also limit the precipitation of crystals which are insoluble in a low pH environment such as uric acid and cystine. Potassium citrate or potassium bicarbonate is preferred over sodium citrate or sodium bicarbonate as the additional sodium load may lead to increasing urinary calcium.

The AUA guidelines recommend giving potassium citrate for patients with recurrent calcium stones and low or relatively low urinary citrate (guideline 15, evidence strength Grade B). It may also be appropriate in patients with normal citrate excretion when all else fails, and in those "unselected" patients who have not done 24-hour urine collections. Potassium citrate should also be offered to patients with uric acid stones (with a goal urine pH of 6.5) and cystine stones (with a goal urine pH of >7.0) [21].

The EAU recommends using alkaline citrate or sodium bicarbonate for uric acid stone formers with a urine pH < 6.0, for patients with cystine stones, and for patients with distal RTA [39]; in general, sodium should be avoided in calcium and cystine stone formers.

Potassium citrate may cause gastrointestinal symptoms like dyspepsia. Some patients have better gastrointestinal tolerance of potassium bicarbonate compared with potassium citrate. Careful monitoring is advised in patients with mild renal impairment, particularly those who are adherent to low-salt diets (which will further limit potassium excretion) or on medications which impair potassium excretion such as an angiotensin converting enzyme inhibitors, angiotensin receptor blockers, or mineralocorticoid antagonists.

Allopurinol

The AUA suggests limiting use of allopurinol as first-line therapy for management of uric acid stones [21], as most patients have low urine pH as the predominant urinary risk factor rather than hyperuricosuria. Of the four RCTs which evaluated the role of allopurinol in management of calcium oxalate stones, the only one which showed a benefit enrolled patients with hyperuricosuria and excluded those with higher urine calcium excretion [42]. Thus, patients with recurrent calcium oxalate stones with hyperuricosuria may benefit from allopurinol therapy.

Allopurinol must be used with caution, starting with low doses and increasing gradually in patients with chronic kidney disease [43]. Whether febuxostat, which is excreted by the kidneys, has the same benefit has not been evaluated.

Other Treatments for Kidney Stones

The EAU guidelines suggest use of magnesium supplements in calcium oxalate stone formers with hypomagnesuria. For patients with enteric hyperoxaluria, the result of steatorrhea, calcium supplementation (200–400 mg daily), is recommended to bind oxalate in the intestinal lumen. For some patients with primary hyperoxaluria due to primary hyperoxaluria type 1, pyridoxine is effective in reducing urinary oxalate and therefore recommended [39]. Patients with a common missense mutation may particularly benefit from pyridoxine [44].

Calcium Phosphate Stones

Young women have a higher prevalence of calcium phosphate stones. This decreases with age, as calcium oxalate becomes the predominant stone type [45]. Although calcium oxalate stones remain the most common type of stone, both men and women show an increased prevalence of uric acid and struvite stones with age. The percentage of uric acid stones shows significant increase after the age of 50. Calcium phosphate stones are also associated with hyperparathyroidism, distal RTA, and use of drugs with carbonic anhydrase activity such as topiramate.

EAU guidelines recommend evaluation for hyperparathyroidism and distal RTA (especially if the urine pH is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

elevated) in patients with calcium phosphate stones, including carbonate apatite, or brushite stones [39].

Distal RTA (type 1 RTA) is suggested by a higher urinary pH (6.5) and low urinary citrate. Complete distal RTA may be accompanied by a low or low normal serum bicarbonate and/or a low serum potassium. If the serum values are normal, an incomplete distal RTA may be diagnosed. A diagnosis of distal RTA, or incomplete RTA, may be confirmed by response to an ammonium chloride load or to a challenge with furosemide and fludrocortisone, a maneuver that maximizes urinary acidification [46]; patients with distal RTA will not be able to acidify the urine (<5.5) in response to these maneuvers. The furosemide/fludrocortisone test has a positive predictive value of 30% and a negative predictive value of 98% in incomplete RTA. The addition of fasting urine pH and serum potassium parameters improved the sensitivity of the test to 85% and specificity to 77% [47]. Using these maneuvers to make the diagnosis is probably not necessary, since citrate supplementation will be appropriate whether urinary acidification does or does not occur [48]. Hypercalciuria and osteoporosis are often present because of acidosis-induced stimulation of osteoclast activity and inhibition of renal calcium reabsorption [49].

Potassium citrate or potassium bicarbonate, at doses sufficient to titrate the daily acid load (1 mEq/kg body weight/day) are generally sufficient. A corresponding increase in the urine citrate may not be appreciated but the serum bicarbonate should improve.

Patients with primary hyperparathyroidism have multiple abnormalities that increase risk for stone formation. These include a marked increase in urinary calcium, while urinary oxalate, phosphate, and pH may also increase. In turn, this leads to a higher supersaturation for both calcium oxalate and calcium phosphate stones, even though urine volume is also increased [50]. It is important to know that patients with primary hyperparathyroidism may have predominantly calcium oxalate stones. Initial treatment for primary hyperparathyroidism consists of surgical resection.

Struvite Stones

Struvite stones are composed of magnesium ammonium phosphate. Carbonate apatite is often present in these stones as well. Urinalysis discloses high urine pH (>8.0) and classic "coffin lid" shaped crystals. Patients with recurrent upper tract infections with a urea-splitting bacterium such as *Proteus* or *Klebsiella* are at high risk of struvite stones. Women and patients with a neurogenic bladder or with a urinary diversion are at higher risk. Since stone fragments remaining in the kidneys may form a nidus for recurrent infection, the goal of surgical therapy is to completely remove all stones. For patients in whom effective surgical treatment is not possible, acetohydroxamic acid, a urease inhibitor, or antibiotic suppressive therapy may be considered [21]. Since struvite stones can occur in combination with other stone types, particularly calcium phosphate, full metabolic evaluation is still important to minimize other risk factors.

The EAU guidelines also recommend antibiotics, urinary acidification with either ammonium chloride or methionine, or acetohydroxamic acid [39].

Uric Acid Stones

Uric acid stones are most often radiolucent by plain film. They are readily identifiable by CT, as generally the HU are <500. Uric acid stones, even those that are quite large, may respond to medical dissolution therapy that consists of increasing the urine pH, generally with potassium citrate. Uric acid is insoluble and will precipitate, leading to stone formation or growth at an acid pH. The solubility increases with increasing pH. The goal is a pH above 6.5, which may require 20 mEq of potassium citrate two or three times each day. Repeat imaging after several months of dissolution therapy will help determine if treatment has been successful or if surgical intervention is needed. Since uric acid stones have an increased tendency to recur, life-long prophylactic therapy may be considered. One dose of potassium citrate at night, to achieve one daily urinary alkalinization, may be sufficient to prevent stones when none are present [51]. All patients should be counseled on following an alkali-rich (or fruit- and vegetable-rich) diet with good fluid intake. Drugs such as allopurinol or febuxostat are considered second-line therapy as the primary risk for most patients is a low urine pH rather than hyperuricosuria. These xanthine oxidase inhibitors are reserved for patients who have trouble achieving higher urine pH values, such as those with chronic diarrhea or other bowel disorders.

The EAU suggests adjusting dosing with potassium citrate depending on whether or not further uric acid stone prevention or dissolution is desired. The target pH depends on whether it is used for prevention (goal pH of 6.2–6.8) or dissolution therapy (goal pH of 6.5–7.2) [39].

Cystine Stones

Patients with cystinuria have an autosomal recessive disorder leading to defective proximal tubular reabsorption of cystine, ornithine, lysine, and arginine (COLA), and are at

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk of forming cystine stones. Patients with autosomal recessive disease have defects in *SLC3A1*, while patients with autosomal dominant disease (with variable and incomplete penetrance) have defects in *SLC7A9* [52]. A typical presentation for a cystine stone former would be the presence of unilateral or bilateral staghorn calculi, often at a young age. Urine microscopy may show classic hexagonal crystals. Addition of cyanide-nitroprusside, a useful screening test performed by laboratories specializing in stone risk factors, will be positive, yielding a purple color.

Cystine is the oxidized homodimer of the amino acid cysteine. Cystine is relatively insoluble in urine, particularly at low pH. The goals of therapy for cystine stones include alkalinizing the urine to increase cystine solubility, reducing the concentration of cystine in the urine below the threshold for precipitation (generally about 243 mg/l or 1 mmol/l) by increasing fluid intake, and maintaining cysteine in a monomeric state [53].

The goal for cystine stones is a urine pH > 7.0. This is usually achieved with potassium citrate at a dose of 20–30 mEq two or three times daily. The urinary excretion of cystine should be measured by 24-hour urine collection, and an individualized fluid prescription should be determined to maintain the urine concentration of cystine below 243 mg/l. For example, a patient who excretes 1000 mg of cystine in a 24-hour collection should be instructed to drink at least 4 l of fluid a day.

If urinary alkalinization and increased fluid intake are not sufficient to limit further cystine stone formation then treatment with thiol-containing drugs should be considered [54]. Thiol-containing drugs reduce cystine to more soluble cysteine-drug compounds. D-penicillamine or tiopronin are typically used. Tiopronin is currently the first-line thiol for cystinuria because of lower adverse event rates. Both drugs may infrequently cause diarrhea, dysgeusia, skin rash, proteinuria, thrombocytopenia, leukopenia, and nausea, which may limit use.

Since cystine stones are caused by a genetic defect in cystine transport, life-long adherence to therapy is required. Multiple urological interventions may be required, with some risk of chronic kidney disease and end-stage kidney disease.

Summary

There are no RCTs evaluating treatment options for secondary prevention of uric acid, struvite, or cystine stones. Strategies for treatment are based on observational studies and uncontrolled case series [1]. Treatment based on chemical composition of an initial stone with therapeutic strategies aimed at lowering the supersaturation for that stone type are biologically sound but have never been adequately examined in the clinical trial setting [55].

The development of kidney stones is determined by underlying genetics, the patient's microbiome, exposures, and the existence of other comorbid conditions, including diabetes mellitus, hypertension, and obesity. [2]

Optimal management of a recurrent stone former thus requires addressing diet, fluid intake, management of known metabolic risks relevant to the type of stones produced (e.g. thiazides to lower urinary calcium in a patient with recurrent calcium oxalate and calcium phosphate stones), and addressing factors such as climate and occupation as well as management of other diseases (e.g. diabetes mellitus).

Since much treatment data in kidney stone management is based on strong associations with limited availability of robust RCTs, we counsel patients to make the simplest changes first, modifying diet and fluid intake, and achieving good control of other chronic conditions. For patients at higher risk of recurrence, including those with genetic predispositions, we engage in more intense medical management and monitoring.

Part 11

Pediatrics

Dedication

We dedicate the Pediatric section of this book to our friend and colleague, Professor Lesley Rees, who sadly passed away on 23 May 2022. Lesley's professional life focussed on improving the lives of infants and children with chronic kidney disease (CKD). Her contributions to the fields of CKD, dialysis and nutrition have changed the way a generation of children were treated. She helped train paediatric nephrologists globally, always emphasizing the importance of clinical expertise informed by best evidence, dedication to excellence and compassion.

Professor Rees was awarded the IPNA Lifetime Achievement Award in 2016, our society's highest honour. She will be remembered for her humanity, generosity and graciousness as much as for her many brilliant academic contributions.

Growth, Nutrition, and Development

Lesley Rees†

Paediatric Nephrology, Great Ormond Street Hospital NHS Foundation Trust and UCL Great Ormond Street Institute of Child Health, London, UK

Table 62.1 is a summary of the management of growth and nutrition in children with chronic kidney disease

Introduction

Poor growth is an important complication of chronic kidney disease (CKD). Normal growth can be divided into four important phases: prenatal, infantile, childhood, and pubertal. Factors affecting growth at different phases vary, but influences on the growth process have their most dramatic effect when growth is at its fastest.

Phases of Normal Growth and the Influence of Renal Disease

The Prenatal Phase

Growth in utero is more rapid than at any other time; around 30% of final height is achieved by birth. Intrauterine growth retardation (IUGR) has a profound effect on postnatal growth: children remain small and catch-up is rare. There is an increased incidence of prematurity and IUGR in patients with renal disease [1–3]. An adverse environment in utero impairs kidney development and makes it more vulnerable to damage from a range of pathological processes [4–7].

The Infantile Phase

The extremely rapid prenatal rate of growth gradually decreases from >25 cm/year at birth to an average of 18 cm/year at age 1 year and 10 cm/year at age 2. Half of adult height is achieved by the age of 2 years. This phase is highly dependent on nutrition: 170 kcal/day is stored in new tissue in the newborn term infant, falling to 50–60 kcal/day at 6 months, 30–40 kcal/day by 1 year, and 20–30 kcal/day by age 2 years. Maintenance of normal growth is extremely difficult in the young child with CKD: poor feeding and vomiting are common and urological complications, the commonest cause of CKD in infancy, may result in sepsis, further aggravating the feeding problems or necessitating investigation and treatments with associated periods of fasting [1, 8–14].

The Childhood Phase

Growth during this phase becomes more dependent on the growth hormone (GH)–insulin-like growth factor-1(IGF-1) axis. GH is secreted in pulses, particularly at night, and this is important for its actions. Growth rate decelerates throughout childhood and will continue to do so until the onset of sex hormone production. Continuing slowing of growth in association with lack of development of secondary sexual characteristics (prepubertal deceleration) often causes concern and is a particular problem in children who have been on long-term steroid therapy [15, 16]. Growth will not resume until the onset of puberty.

The Phase of Puberty

Acceleration of growth during puberty is dependent upon the coordination of GH and sex steroid production, which together with nutrition and general health modify the genetic growth potential. Rising sex steroid concentrations stimulate GH production by increasing the amplitude of GH secretory pulses. Together they have an anabolic effect

Table 62.1 Management of growth and nutrition in children with chronic kidney disease

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
rhGH	We recommend the use of rhGH in children with CKD 3–5 of all ages if there is still growth potential, if they have a HtSDS <3rd centile and a Ht velocity SDS <25th centile, and all other potential causes have been treated	Moderate	Moderate
rhGH dose	We recommend 45–50 μg/kg or 1.4 mg/m^2 daily	Moderate	Moderate
Gastrostomy feeding at <2 years of age	We recommend gastrostomy feeding in infants who are not gaining appropriate weight. Benefit of improved/stable growth exceeds reported harms.	Moderate	Strong
Gastrostomy feeding at >2 years of age	We recommend the use of enteral feeding if there is poor nutritional intake with low serum albumin	Very low	Weak
EAA supplements	We are unable to recommend EAA supplements as they are of uncertain benefit. There is no evidence on harms.	Very low	Weak
Amino acid PD solutions	We are unable to recommend amino acid PD solutions as there is no demonstrated benefit. There is no evidence of harms.	Very low	Weak
Intradialytic parenteral nutrition	Uncertain benefit. There is no evidence of harms.	Very low	Weak
Increase in dialysis adequacy	We recommend the use of intensified hemodialysis. No harms reported. No evidence to recommend increasing *Kt/V* in peritoneal dialysis.	Very low	Moderate
Alternate-day steroids	We recommend the use of alternate-day steroids in selected patients. No increase in harms.	Weak	Moderate
Steroid withdrawal or a no-steroid regimen post-transplant	We recommend steroid withdrawal post-transplant in selected patients no increase in harms.	Weak	Moderate

CKD, chronic kidney disease; EAA, essential amino acid; PD peritoneal dialysis; rhGH, recombinant human growth hormone.
GRADE assessment of the certainty of the evidence [9]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

on muscle mass, bone mineralization, and body proportions. Rates of growth may reach as high as 12 cm/year. The pubertal growth spurt will not take place until the appearance of secondary sexual characteristics. In girls it occurs early, soon after the onset of breast development; in boys it occurs later, after the onset of penile and pubic hair development, and not until the testes have grown to 10–12 ml. It is therefore impossible to interpret growth rates without knowledge of the corresponding pubertal stage. Pubertal development and growth may be affected by CKD and steroid therapy (see below) [15–18].

Definitions

Short Stature

Height standard deviation score (HtSDS) of more than 2 SD below the mean for age and sex (<2.5th centile).

Poor Longitudinal Growth

Ht velocity SDS > 1 SD below the mean.

Malnutrition

Inadequate intake of nutrients resulting in weight loss associated with protective metabolic responses: a decreased basic metabolic rate and preservation of lean body mass at the expense of fat mass.

Protein Energy Wasting

In protein energy wasting (PEW) appetite is decreased and there is an increase in the metabolism of fat and lean body mass.

Lean tissues are wasted preferentially to fat stores. Cachexia is the term used when PEW is severe.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Table 62.2 The differences between malnutrition and protein energy wasting (PEW)

Malnutrition	Protein energy wasting
Inadequate intake of nutrients	Inadequate intake only partially responsible
Body fat is decreased	Normal or increased fat mass
Lean body mass is initially preserved; loss of muscle mass occurs later	Loss of lean body mass
Low resting energy expenditure	High resting energy expenditure
Can be reversed with dietary intake	Inadequate response to dietary intake

The differences between malnutrition and PEW are shown in Table 62.2 [19].

Obesity

Body mass index (BMI, weight [kilograms] divided by the square of height [meters]) is used as a measure of body fat and centile charts for children are available for age and sex.

Weight category	BMI percentile range
Underweight	<5th
Normal weight	5th to <85th
Overweight	85th to <95th
Obese	≥95th

Epidemiology of Growth Disorders in CKD

Growth in children with CKD is principally influenced by age of onset and CKD stage, i.e. those in the infantile phase of growth and those on dialysis are the worst affected. The problem is of variable severity around the world, with extremes of mean HtSDS per country ranging from −1.4 to −3.5, presumably affected by local policies on CKD management and financial resources [20]. However, overall nowhere is the mean HtSDS normal.

The effect of age has been clearly shown by the United States Renal Data System (USRDS) registry: in 2015 the percentage of incident end-stage renal disease (ESRD) patients with short stature was highest in the youngest patients, at 52.7% in the 0–4 age group, 33% in the 5–9 age group, 29.4% in the 10–13 age group, and 23.8% in the 14–17 age group [21].

The effect of CKD stage has also been recently shown by the Chronic Kidney Disease in Children Study (CKiD), a US registry of children with a glomerular filtration rate (GFR) <75 ml/min/1.73 m^2. The 2014 report identified a fall in HtSDS of 0.12–0.16 for each decline in GFR of 10 ml/min/1.73 m^2 [22]. The 2006 North American Pediatric Transplant Cooperative Study (NAPRTCS) report of a very large cohort of over 5000 children with GFRs of up to 75 ml/min/1.73 m^2, covering the 10 years between 1994 and 2004, also found a correlation between GFR and HtSDS, being −3.2, −1.9, −1.5, and −0.9 for GFR < 10, 10–25, 25–50, and > 50 ml/min/1.73 m^2, respectively [23].

There is evidence that the situation has improved since two decades ago, particularly in well-resourced areas, for example in Germany the overall mean HtSDS in children on renal replacement therapy (RRT) has increased over the past 20 years from −3.0 SD to −1.8 SD. However, in the last decade the situation seems to have stabilized, with no further demonstrable improvement [24].

Effect on each Phase of Growth in Children with Conservatively Managed CKD

Prenatal Phase

Prematurity, low birth weight, and a requirement for neonatal intensive care are common, and along with these go all the associated difficulties that are known to influence growth [1–3]. Even normal infants who are growth retarded at birth frequently do not achieve catch-up growth and this has also been shown to be true for such infants with CKD [3].

Infantile Phase

Many infants are already growth retarded by the time they are first seen in a pediatric nephrology service, with losses as high as −1.68 SD from birth (−5 SD/year) [25]. HtSDS is below the normal range in most studies [1, 8–14]. Approximately one-third of the fall in HtSDS occurs during fetal life and one-third during the first 3 months of life, accompanied by a similar fall in head circumference [8, 9, 26]. Interestingly, infants who grew well continued with catch-up in early childhood [12, 25]. As well as IUGR, a proportion of infants has comorbidity and associated syndromes which may in themselves affect growth. Although half of those with GFR < 35 ml/min/1.73 m^2 showed catch-up growth, many that grew poorly had IUGR [1].

Childhood phase

By this phase many patients with CKD from infancy are growth retarded; growth parallels the centiles but without catch-up [8, 9, 25] or may fall progressively. HtSDS fell from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

−1.6 to −2.1 over 3.5 ± 3.3 years in 22 patients aged <14 years with a GFR of 32.6 ± 24.8 ml/min/1.73 m^2 [27]. However, this is not the case in all studies. Other studies have shown an improvement: +0.3 SD over 2 years in 99 children with a median GFR of 22 ml/min/1.73 m^2 and HtSDS of −1.73 [28]; a smaller study had similar findings [29]. Growth is improving over the decades: of 799 children (median age 11.0 years) participating in the CKiD (a US registry of children with a GFR < 75 ml/min/1.73 m^2) the median HtSDS was −0.55 [22], whereas in 1996 it was −1.5 in 1725 patients, −1.4 (one-third > −1.88) in 1998 with 3863 patients, and −1.4 in 2001 with 4666 patients aged <20 years and GFR < 75 ml/min/1.73 m^2 [23]. One-third of patients were below the third centile for height in the NAPRTCS 2006 study, whereas in 2014 this percentage was only 12%.

Pubertal Phase

This phase of rapid growth is another period when loss of height potential can occur. Early studies demonstrated that puberty was delayed by approximately 2.5 years in both sexes, with an irreversible decline in HtSDS [30]. However, others report normal pubertal progression and growth [24, 25, 26, 28, 31, 32]. This problem seems to be much less common now, with reports showing normal pubertal growth and development [24].

Effect on each Phase of Growth in Children on Dialysis

Many studies combine children of all ages and dialysis modality (peritoneal dialysis [PD] and haemodialysis [HD]): of 651 patients aged <18 years, 266 (41%) had a HtSDS < −1.88 [33] and 57% of over 200 on PD were growth retarded [34]. Growth has been reported to be best on CAPD compared to CCPD and HD: changes in HtSDS were −0.55, −1.69, and −1.80, respectively, over 6–12 months [35], although this effect was most noticeable in older children [36].

Infantile phase: Reports vary considerably, although overall infants either show no change in growth or a deterioration without nutritional support. No change in HtSDS was reported (−2.51 to −2.74) in 15 children <2 years treated with CAPD [37]. Deterioration in HtSDS occurred in 17 infants on PD [38] and a decline in HtSDS by −0.29 SD/year has also been reported, along with a significant improvement between the first (−0.50) and second (+0.23) years in 22 starting PD in infancy [39]. However, it appears that an early and more intensive approach to nutrition is able to maintain or even improve height SDS [1, 2, 10, 12], especially if given via gastrostomy and alongside the use of physiological pH PD solutions and recombinant human growth hormone (rhGH) [40]. The benefits of nutrition in the infantile phase have also been illustrated in a study of 101 children presenting with chronic CKD stage 4 or 5 before the age of 2 years of whom 89% were enterally fed. In this cohort, the mean height SDS improved from −2.18 at age 6 months to −0.87 at 5 years. Those without a comorbid condition achieved a mean normal adult height without the administration of rhGH [2, 12].

There are fewer studies of growth in infants on HD. In those aged 0–1 and 2–5 years at the start of HD and/or PD HtSDS was −1.99 and −2.05, respectively, falling to −2.46 and −2.32 at 1 year and −2.06 and −2.00 at 2 years [32]. There are two studies of HD, one reporting no change from −1.6 in 18 infants on HD for up to 2 years [41] and another reporting HtSDS of −3.59 in 10 infants of <10 kg, only one of whom showed any improvement in HtSDS over a mean duration of 8.5 months [42].

Growth at this phase is improving: children who started dialysis at <18 months of age between 1983 and 1995 had a height SDS of −3 compared with −1.4 in those patients who initiated HD between 1996 and 2008. This improvement appears to be due to better control of renal bone disease and the increased use of enteral feeding (including both tube and gastrostomy feeding) and rhGH [19, 40].

Childhood Phase

Reports vary from improvement from −2.13 to −1.66 in 34 patients on PD for 6 months [43] to no change over 1 year [44, 45], to a declining HtSDS from −1.71 to −1.86 at 1 year and −2.12 at 2 years in children on PD or HD aged 6–12 years [32].

Pubertal Phase

Puberty may be delayed with poor growth [46]: HtSDS fell from −1.97 to −2.36 in 94 adolescents on HD for 3 years [47] and from −1.39 to −1.59 at 1 year and −1.83 at 2 years in those on PD or HD [32]. In two recent studies, age at pubertal onset and at menarche did not differ between children on RRT and healthy children, and the serum levels of pubertal reproductive hormones were normal in the great majority of patients [24, 48].

Effect on Each Phase of Growth in Children Post Transplant

In the NAPRTCS 2014 annual report, the mean height deficits for all patients at transplantation were −1.73: −1.77 for males and −1.68 for females. Younger subjects between 2 and 5 years at transplant (−2.22) and those with prior transplants (−2.09) also had greater height deficits at the time of transplantation. Overall, mean height SDS remain relatively constant over the available follow-up period, increasing 0.1 SD every 2 years [49].

Some, but not all, studies show growth post-transplant to be superior to growth on dialysis, particularly in younger

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

children [36, 50, 51]. However, comparison is difficult because as well as age at transplant, growth is influenced by pretransplant height deficit (the greater the height deficit the greater the catch-up), which is in turn influenced by diagnosis and duration of dialysis [50]. Several studies have demonstrated the importance of GFR [50, 51]: each increase in serum creatinine of 90 μmol/l (1 mg/dl) is associated with −0.17 SD [52]. The steroid regimen also affects growth (see below).

However, growth patterns differ by age at transplant, with younger subjects (less than 6 years of age) experiencing improvement in growth deficit.

Infantile Phase

Small size precludes transplantation for most children at this age. Those who do receive transplants before 2 years of age have the greatest improvement in HtSDS, with gains of +1 SD overall [53]. In the NAPRTCS 2014 report there was an increase in HtSDS of 0.26 in the first 6 months post-transplant in under 2s, with increases thereafter of 0.53 by 12 months and 0.70 by 2 years post-transplant [49].

Childhood Phase

Improvement in growth diminishes throughout childhood: 47% <6 years at transplant and 22% >6 years gained 1 SD [53]. HtSDS changed from −2.1 to −1.0 at 1 year, −1.1 at 5 years, and to −0.14 at 10 years in 54 children transplanted before age 5 years [53], from −2.0 to −1.8, −1.5, and −1.5 at 1, 2, and 5 years post-transplant in 39 children <6 years of age [54], and from −1.71 to −1.14 at 1 year and −0.55 at 5 years in 20 children <8.5 years of age [53].

In the NAPRTCS 2014 annual report, those with functioning grafts who were aged 2–5 years at transplant had similar gains in HtSDS to younger children, and a mean increase in HtSDS of 0.57 at 2 years. However, after this age (6–12 years), linear growth was stable, at about −1.9 SD. The oldest subjects also had no increase in HtSDS, the mean for which was −1.4 SD throughout [49].

Pubertal Phase

Historically, the onset of puberty has been reported to be delayed, although in accordance with bone age: in 68 patients mean chronological age and peak height velocity were 14.6 ± 1.9 years and 13.3 ± 1.9 years and 6.6 ± 1.6 cm/year and 6.5 ± 2.9 cm/year in boys and girls, respectively, menarche was achieved at 15.9 years and the duration of pubertal development was within normal limits [46]. Steroids may contribute to this delay [17]. HtSDS increased by 1.3 SD and 0.7 SD until final height (FH) in children transplanted before and after start of puberty, respectively, although pubertal height gain was reduced by 20% [50]. Ht SDS increased from −1.8 to −1.6, −1.5, −1.0, −0.7, and −0.6 over 5 years in 54 adolescents [55]. Total pubertal height gain was better in younger children, those transplanted before the onset of puberty, and those with better graft function [50, 55]. The age at onset of puberty and pubertal height gain has been positively correlated with the age at transplantation [50]. However, more recent reports are much more positive, demonstrating normal pubertal development and growth, particularly if post-transplant a steroid-free regimen is used [48]

Final Height

In all reports, conservative management is associated with a better FH than those on RRT (−1.15 vs. −2.1) [56]. For children on RRT, young age at start of dialysis and at transplant, short stature at transplant [57, 58], and graft function [57] predict FH. FH may be reached later than expected, particularly in those on long-term steroid therapy. FH was not reached until 20.2 ± 1.8 years in males and 18.8 ± 2 years in females [46, 56], with a gain of +0.87 and +0.3 SD, respectively, after the age of 18 years [56].

Final adult height is improving with time. Of 1612 patients in the European Dialysis and Transplant Association-European Renal Association (EDTA-ERA) registry who started RRT before age 19 years and reached FH between 1990 and 2011, the median FH was −1.65 (168 cm in boys and 155 cm in girls). Overall FH was within the normal range in 55% of patients. This improved to 62% between 2006 and 2011. When results were stratified for age and decade of commencement of RRT, FH increased significantly from −1.93 in those starting RRT before 1990 to −1.78 between 1990 and 1999, and to −1.61 in those starting RRT after 1999. This improvement was independent of age at the start of RRT [59].

A similar improvement with time has been shown in the United States. NAPRTCS 2014 reported the mean HtSDS of those aged >19 years to be −1.37. Twenty-five percent had HtSDS of −2.20 or worse, and 10% were over 3.22 SD below the mean. The FH improved from −1.93 in the 1987–1991 cohort, to −1.51 in the 1992–1996 cohort, − 1.06 in the 1997–2001 cohort, −0.98 in the 2002–2006 cohort and −0.89 for the most recent cohort [49].

Obesity

In accordance with the worldwide epidemic, obesity has become a problem in CKD too. Data from the International Peritoneal Dialysis Network (IPDN) from 25 countries between 1995 and 2101 showed an incidence of overweight in 32% and 12% obesity in 4474 patients under 16 years of age. When looked at according to treatment modality, 15% were overweight on HD, 12% on PD, and 43% post-transplant. Similar measures for obesity were 8%, 6%, and 17%, respectively. Overweight increased with age with a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

proportionate decrease in underweight: malnutrition was 15% in under-1s and <2% in the oldest children [60].

Patients in the NAPRTCS 2014 report gained an average of 0.83 SD in weight in the first year following transplantation and 0.90 SD by 2 years with no change over the next 5 years [49].

Obesity is associated with young age, males, short stature, duration of dialysis, and number of transplants [61, 62]. However, obesity may not be more common than in the normal population, and is strongly related to the BMI of the mother [57].

Pathophysiology of Poor Growth in CKD

Nutrition

One of the best described causes of poor growth is inadequate intake of calories and protein. This is particularly the case during the infantile phase, when growth is more rapid than at any other time and so demands relative to body size exceed any other age. The infant with CKD is often anorexic and prone to vomiting. This can also be true of older children, but effects are proportionately less [63].

PEW

PEW is associated with metabolic abnormalities (particularly acidosis) and chronic inflammation (elevated IL-1, IL-8, and TNF alpha). There is a decreased response to the anabolic hormones insulin, IGF1, and GH [19].

Sodium

A state of sodium deficiency, as occurs in tubular salt wasting disorders such as cystinosis, can lead to chronic volume contraction. This can affect growth. Salt depletion also occurs in the tubulopathy associated with CAKUT [19, 63].

PTH

Bone deformities associated with uncontrolled hyperparathyroidism (HPT) can clearly result in growth problems. Less severe HPT is also associated with poor growth due to disruption of the growth plate architecture [64].

Dialysis Adequacy

Poor clearance of toxins, fluid overload, and chronic inflammation affect the growth process [65].

GH Resistance

There is GH resistance in CKD as levels are high and IgF1 is low [66].

Steroid Therapy

Steroids adversely affect growth: they suppress pulsatile GH release from the pituitary gland mainly by reduction of pulse amplitude, interfere with GH/IGF-I receptor signaling, and modulate paracrine IGF-I synthesis and binding by IGF binding proteins [15, 17, 66].

Diagnosis/Evaluation

What to Measure to Assess Growth

Classical measures of height (Ht), weight (Wt), and head circumference along with calculation of BMI and plotting on growth charts remain the mainstay of growth assessment in children with CKD.

Available Guidelines and Systematic Reviews

Nutrition

The Kidney Disease Outcomes Quality Initiative (K/DOQI) has published guidelines for the nutritional management of children with renal disease, including methods of assessment of nutritional status, management of acid-base status, role of urea kinetic modeling, interval measurements for assessment of nutritional status, energy, protein, vitamin, and mineral intakes, dietetic input, nutritional supplements, and use of rhGH [67, 68].

CKD-MBD

There are US guidelines on diagnosis, evaluation, prevention, and treatment [69] and a Cochrane review on interventions [70].

rhGH in CKD and Post-transplant

This has been the subject of a Cochrane review [71].

Evidence for the Benefit of Interventions on Nutrition and Growth

Nutrition

Dietary supplementation, input by a dietician, and nasogastric/gastrostomy feeds are shown in Table 62.3.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The benefits of supplemental feeds in CKD and dialysis have been studied using case and cohort series (1, 2, 10–13, 42, 44, 75–87; Table 62.3). All but two concentrate on children <2 years of age, who might be expected to benefit most from intensive nutrition. In 14 studies there is an improvement in HtSDS [1, 2, 10–13, 40, 72–79], in three there is an initial decline followed by normalization of growth [11, 80, 81], in three there is no change [41, 83, 84], and in one there is a decline in HtSDS [85]. Six studies include older children; of these three show an improvement in growth [10, 73, 75], two show no change [81, 84], and one shows a decline in HtSDS [85]. At least the normal age-related requirements for energy and protein seem to be needed for growth improvement, with an increased protein allowance for children on PD and a smaller supplement for those on HD to allow for losses in dialysate. The intensity of input required and advantage of input from a dietician has been specifically demonstrated in two studies [81, 82], but it is likely that all studies could not have been achieved without dietetic input. Administration of supplements was by nasogastric tube or gastrostomy in all but one study; complications are not specified, but are principally in children on PD. Post-gastrostomy there is an initial post-surgical peritonitis risk but thereafter there is no increased risk [86]. There is, however, an increased incidence of exit site infection and catheter removal from infection when the gastrostomy is inserted after PD has started, a risk that may be reduced if open rather than percutaneous surgery is used. Paraoesophageal hernias have been reported [86, 87]. Successful track closure on removal and normal feeding post-transplant are the usual outcomes [88, 89].

Essential Amino Acid Supplements

Serum essential amino acids (EAAs) may be low in CKD, particularly during PD [90] (Table 62.4). It has been suggested that a low protein diet supplemented with EAAs might ensure adequate intake and reduce protein toxicity, thereby benefiting growth. The small cohort studies available are inconclusive [91–94].

Amino Acid Containing Peritoneal Dialysis Solutions

Excessive glucose absorption and dialysate amino acid and protein losses contribute to malnutrition during PD. It has therefore been suggested that using an amino acid dialysate might both decrease glucose load and replace amino acid losses (Table 62.5). However, although amino acids are absorbed in proportion to the concentration difference between dialysate and plasma [95, 96], there is no evidence for long-term nutritional benefit [97]. In addition, such solutions are more expensive than standard ones. There are no disadvantages compared with glucose as equal amounts of urea and creatinine are removed and normoglycemia is maintained although ultrafiltration is variable [98, 99, 101]. It may be that using a combination of glucose and amino acid solutions increases protein synthesis [100]. There were no reported adverse effects.

Intradialytic Parenteral Nutrition

Papers describing the effects of intradialytic parenteral nutrition on growth are summarized in Table 62.6. Losses of amino acids occur into the dialysate during HD depending on their plasma concentrations and molecular weights. Body weight but not serum albumin improved and there were no reported complications, but numbers are very small [102–105].

Dialysis Adequacy

Papers describing the effects of dialysis adequacy on growth are shown in Table 62.7. Increasing dialysis dose might be expected to benefit appetite, nutrition, and growth, and

Table 62.4 EAA supplements and growth

Study [reference]	No. of patients	GFR (ml/min/1.73 m^2)	Diet	Duration (months)	Outcome
Jones 1980 [91]	7	Severe CKF	Protein RDA for Ht age, half as EAAs	6–8	Improved nitrogen balance but no increase in HtSDS
Jureidini 1990 [92]	10	Severe CKF	Low protein and EAAs	36	Increase in Ht and WtVel
Mir 2005 [93]	20	<50	0.6 g/kg protein and ketoacids	30	HtSDS from −1.93 to −1.37
Zachwieja 1994 [94]	10	HD	AAs 0.25 g/kg body weight i.v. with dialysis	2 of 3	No improvement in plasma amino acids

Ht, height; i.v., intravenous; RDA, recommended dietary allowance; Vel, velocity; Wt, weight.

Table 62.5 Amino acid-containing PD solutions and growth

Study [reference]	No. of patients	Dialysis	Dialysate	Duration	Outcome
Canepa 1990 [95]	7	CAPD	1% AA exchange compared to glucose 1.36%	1 exchange	Rise in plasma AAs proportional to amount of AA in dialysate; amount of AA absorbed 66% after 1 h, 86% after 4 and 6 h; loss of 116 ± 69 μmol/kg body Wt with glucose
Hanning 1987 [96]	8	CAPD	AA-based dialysate	1 exchange	Absorption of 70–73% of AAs peaking at 1 h and varied with concentration difference; levels at pre-exchange at end of cycle
Canepa 1991 [97]	8	CAPD	First morning exchange of 1% AA dialysate	12–18 months	No improvement in any plasma or anthropometric parameter of nutrition; plasma urea increased; plasma EAAs improved but intracellular pool did not
Qamar 1994 [98]	7	CAPD	AA or dextrose dialysate	3 months, crossover	No nutritional benefit from AA dialysis
Qamar 1999 [99]	7	CCPD	AA or dextrose dialysate	3 months, crossover	During AA, appetite, calorie, and protein intake improved and total body nitrogen increased in half of children; plasma albumin did not change; fasting AAs were comparable to baseline; plasma urea was higher
Canepa 2001 [100]	10	CCPD	3 : 1 ratio of glucose to AA	8 infusions	Glucose absorption was 33.7%, AA 55.2%; plasma AA levels high but plasma urea did not increase

AA, amino acid; CAPD, continuous ambulatory PD; CCPD, continuous cycling PD.

Table 62.6 Intradialytic parenteral nutrition and growth

Study [reference]	No. of patients	Intradialytic (HD) treatment	Outcome
Abitbol 1984 [102]	3	AAs added to dialysate in increasing concentrations	Zero flux of AA nitrogen when 22 mg/100 ml of AA additive in the dialysate; increase in plasma non-EAAs but not of EAAs
Krause 2002 [103]	4, malnourished	8.5% AA solution, 10–15% dextrose, 20% fat emulsion for 7–12 weeks	Oral intake improved; Wt did not improve during treatment, but did subsequently; albumin did not change
Goldstein 2002 [104]	3, malnourished adolescents	70% dextrose, 15% AAs, 20% lipids, 6 weeks	Wt improved but not albumin
Orellana 2005 [105]	9 with >10% Wt loss and <90th percentile of ideal body Wt	Thrice weekly for 3–22 months	In six patients, BMI and PCR increased, serum albumin did not change

AA, amino acid; EAA, essential amino acid; Wt, weight; PCR, protein catabolic rate.

indeed this is the case in some studies [106–108]. However, this has to be balanced against increasing dialysate albumin losses during PD [109] and increasing amino acid losses during HD [110]; it may be possible to overcome this with careful attention to diet. PD causes an influx of glucose which can contribute to obesity. High transporter status was associated negatively with HtSDS and positively with BMISDS in 51 children on PD. Large dialysate volumes also increase BMISDS [115]. For HD it is not clear if there is a maximum optimum dose. Studies of daily HD, which is likely to offer most benefit, are promising [116].

Residual renal function (RRF) has an important positive effect on clearance and growth. HtSDS improved from −1.78 to −1.64 over a year of PD in 12 patients with RRF, but declined from −1.37 to −1.90 in 12 patients without. Weekly Kt/V was not different, and only the native kidney Kt/V and creatinine clearance correlated with growth, suggesting that clearance obtained by PD cannot be equated

with that obtained by native kidneys [117]. Eleven of 20 patients on PD with a minimum *Kt/V* of 2.1, daily protein intake of 3.25 g/kg/day, and HtSDS of −2.3 improved their HtSDS by 0.55, while in nine it declined by −0.50. Variables affecting growth were nitrogen balance and residual *Kt/V* [118].

Reports of intensive in center hemodiafiltration and more frequent dialysis (in center or at home) have been associated with growth acceleration. The dietary intake and growth rate of children on maintenance hemodialysis significantly improves with increased duration of hemodialysis sessions, such as hemodiafiltration six times per week or nocturnal hemodialysis [112, 113]. Daily HD was also superior to conventional HD [111].

Although there are no demonstrable differences in growth between those on PD and those children who receive three times a week in-center hemodialysis, intensified regimens such as short daily HDF or slow overnight dialysis show particular promise, with attainment of centiles predicted from parental heights [65, 114].

Recombinant Human Growth Hormone

Papers describing the effects of rhGH on growth are shown in Table 62.8. The efficacy of recombinant human growth hormone (rhGH) in CKD and post-transplant has been the subject of a Cochrane review [130]. Fifteen randomized controlled trials involving 629 children were identified [119–129, 131–134]. rhGH at 28 IU/m^2/week resulted in a significant increase in HtSDS at 1 year (weighted mean difference [WMD] 0.78 SDS, 95% CI 0.52–1.04) and a significant increase in height velocity at 6 months (WMD 2.85 cm/6 months, 95% CI 2.22–3.48) and 1 year (WMD

Table 62.8 Effects of rhGH on growth versus placebo or no treatment

Study [reference]	No. of patients	Type of patients	Experimental intervention (rhGH dose)	Control intervention	Ht velocity, cm/year (SD), with 1 year of rhGH [treated (T) vs. control (C)]	ΔHtSDS[a] (SD) with 1 year of rhGH [treated (T) vs. control (C)]
Fine 1994 [119]	82	Predialysis, prepuberty	28 IU/m^2/week s.c. for 24 months	Placebo injection s.c. for 24 mos	T: 10.7 (3.1); C: 6.5 (2.6)	T: 1.01 (0.94); C: −0.08 (0.96)

3.80 cm/year, 95% CI 3.20–4.39) [130]. Results were independent of pubertal stage or treatment modality (CKD, dialysis, or transplant). The frequency of reported side effects was similar for the rhGH-treated group and the controls. However, there was no further improvement in subsequent years of treatment. It is not certain whether rhGH therapy improves FH, but data from cohort studies suggests that it does [130]. The remaining five trials compared two different doses of rhGH: four trials compared 28 IU/m^2/week with 14 IU/m^2/week in CKD [131–133], dialysis [131–133], and post-transplant [132–134]. They showed a 1.34 cm/year (0.55–2.13) increase in height velocity in the group treated with 28 IU/m^2/week compared to those given 14 IU/m^2/week. However, increasing the dose to 56 IU/m^2/week showed no further benefit over 28 IU/m^2/week [133]. An updated Cochrane review in 2010 [71] identified one further RCT showing a significant benefit from the use of rhGH for 1 year even in the very young [129]. There is some evidence that rhGH may also improve FH [135].

Alternate Day Steroids and Steroid Withdrawal Post-Transplant

Papers describing the effects of steroid regimen on growth are shown in Table 62.9. Better growth occurs in children on alternate-day versus daily steroids, with no detriment to graft function [136–139]. However, there may be bias toward selection of better graft function in alternate-day treated patients [134, 138, 139].

Some have advocated no steroids or their withdrawal [141, 142]. Steroid withdrawal over 2–12 months benefited growth in six out of seven studies [143–149], but again selection bias applies. The same is true for patients managed with steroid-free immunosuppression [142, 150, 151]. A recent (2017) meta-analysis of corticosteroid use and growth post-transplant identified five RCTS in renal transplants. Steroid withdrawal and/or avoidance was associated with significantly improved growth compared with those who were on steroids without any rejection or other complications [140].

A study from Germany gives impressive data on the final height of 74 patients transplanted between 1981 and 2001 and in whom steroids were withdrawn by 4–6 months post-transplant. Mean follow-up was 8.5 years. The mean final HtSDS values were −0.5 and −1.0 in prepubertal and pubertal patients and were within the normal range (>−2 SD) in 94% and 80% of them. Age and HtSDS at transplant were independent predictors of adult height [152]. The mean final heights were 177 and 175 cm in males transplanted prepubertally and postpubertally, respectively, with similar figures of 165 and 162 cm for females. These compare favorably with previous studies [24, 50, 59, 66, 153] which vary from 148 to 158 cm for females and from 162 to 168 cm for males (second centiles 151 and 163 cm, respectively).

Deflazacort is derived from prednisolone and is said to have equivalent immunosuppressive effects with less toxicity. It has been shown to improve growth and body composition post renal transplant when used in an equivalent dose to prednisolone in four studies by the same group [154–157]. However, a blinded controlled trial over 1 year in 40 patients with SSNS showed no benefit for growth [158].

Table 62.9 Effects of alternate-day steroids post-transplantation on growth

Study [reference]	No. of patients on daily/no. on alternate-day steroids	Steroid regimen	Outcome
Broyer 1992 [136]	18/17	Randomized to daily or alternate day for 1 yr; all on alternate day in second year	First year, −0.29 SD on daily, +0.49 SD alternate day; second year, +0.29 SD and +0.52 SD
Feldhoff 1984 [137]	15/15	15 switched to alternate day matched with 15 on daily	Increase in HtVel in the second but not the first year
Kaiser 1994 [138]	24/31	31 switched to alternate day, but daily group had worse graft function and higher dose	+0.94 SD alternate-day, −0.86 SD daily
Jabs 1996 [139]	1664/337	Not known how regimen selected	HtSDS up to 24 months +0.5 SD on alternate-day and +0.1 SD on daily
Tsampalieros 2017 [140]	124 patients, 138 controls 268 patients, 262 controls	5 observational studies 5 RCTs	Compared to those on steroids Δ +0.34 SD Δ +0.18 SD

Vel, velocity.

Effect of Height on Long-term Outcome

Malnutrition and poor growth are associated with increased morbidity and mortality. Patients <18 years of age initiating dialysis with hypoalbuminemia are at a higher risk for death: in 1723 children each fall of serum albumin by 10 g/l (1 g/dl) was associated with a 54% higher risk of death. This was independent of other potential confounding variables [159]. HtSDS < −2.5 at dialysis initiation is associated with poor school attendance, more time in hospital, and a twofold higher risk of death [160, 161]. Each decrease in HtSDS or Ht velocity by 1 SD was associated with a 14% and 12% increase in risk for death, respectively. There was a U-shaped association between BMI and death, with low and high BMIs associated with an increased risk for death [162, 163].

Conclusion

Short stature is common in children of all ages with renal disease and has an important influence on outcome. Adequate nutrition is vital, particularly in the first 2 years of life but also in older children. Feeds often need to be administered by nasogastric or gastrostomy tubes and require dietetic input for prescription adjustment. There is no evidence for any benefit from EAAs orally or as amino acis dialysate or for any benefit from IDPN. Dialysis prescription is likely to affect growth, but the ideal dose is unknown. The use of the lowest possible alternate-day steroid dose, or no steroids at all, offers the best chance of good growth post-transplant. One year of rhGH may improve growth by 4 cm/year for all treatment modalities and may improve FH. All these interventions have a very low complication rate.

Bone Disease in Children with Chronic Kidney Disease

Sevcan A. Bakkaloğlu

Department of Pediatric Nephrology, Gazi University, School of Medicine, Ankara, Turkey

Introduction

Abnormalities in mineral metabolism and bone structure are an almost universal finding in children with chronic kidney disease (CKD) and when left untreated may lead to significant complications including bone pain, avascular necrosis, and fractures which are similar to those seen in adults, as well as skeletal deformities resembling vitamin D deficiency rickets and most pertinently reduced growth rates, which are unique to children [1–3]. Such skeletal changes reflect disturbances in endochondral bone formation linked to longitudinal growth at the level of epiphyseal growth plate and alterations in remodeling process characterized by abnormalities of bone turnover, mineralization, and volume [2, 4]. In children with CKD, alterations in bone microarchitecture and quality and in vascular biology carry consequences that severely impact bone growth and strength, cardiovascular health, quality of life, and life span [5–10]. Thus, management of CKD-mineral and bone disorder is more challenging in children, which requires fine-tuning balance between promoting skeletal growth with optimum mineralization and preventing extraskeletal calcification with appropriate treatment.

Definition and Pathophysiology

In early stages of CKD, plasma levels of calcium (Ca) and phosphorus (P) are normal, and increased levels of the fibroblast growth factor 23 (FGF23) [11, 12] prevent hyperphosphatemia by enhancing renal phosphate excretion. FGF23 also decreases the synthesis of 1,25-dihydroxyvitamin D ($1,25(OH_2)D$) and increases the inactivation of vitamin D into 24-hydroxylated compounds [13]. FGF23 levels markedly increase as estimated glomerular filtration rate (eGFR) decreases. When renal function becomes severely impaired, phosphate levels rise. In parallel, reduced production of active vitamin D by the failing kidneys and by the inhibition of 1 alpha hydroxylase activity with FGF23 leads to hypocalcemia and hyperparathyroidism [14]. If hypocalcemia is not corrected, Ca is mobilized from the bone into the circulation via increased parathormone (PTH) [2, 15, 16]. Excess Ca and P are deposited in soft tissues, including blood vessels [17]. Alterations in mineral metabolism parameters, including calcitriol deficiency, hyperparathyroidism, hyperphosphatemia and elevations in FGF23 [2, 18], disordered bone remodeling, and cardiovascular calcifications accompanying CKD together point to a systemic disease, CKD-mineral bone disorders (MBD) [4]. Renal osteodystrophy (ROD) is one component of CKD-MBD. The historical nomenclature of ROD included categories such as osteitis fibrosa, adynamic bone, osteomalacia, and mixed uremic osteodystrophy (Figure 63.1a) [19]. Current guidelines favoring a unified classification that is based on bone turnover, mineralization, and volume (TMV) omit the categories above [4, 20] and ROD is now classified as low- or high-turnover ROD.

The predominant lesion on bone biopsy in children on dialysis is high bone turnover (in 57–61% of patients) and low turnover bone disease much less common (4% of patients) [19, 20]. In the largest pediatric bone biopsy study comprising 161 peritoneal dialysis (PD) patients, abnormal skeletal mineralization was even more common than turnover abnormalities (Figure 63.1b) [20]. In line with this, high turnover bone disease was seen in 29% of children with CKD stage 4, but was not seen in children with stage 2 disease, while mineralization abnormalities occurred in 42% of children with stage 2 CKD, in 80% of children with stage 4 CKD, and in over 90% of CKD stage 5D patients (Figure 63.1c) [12].

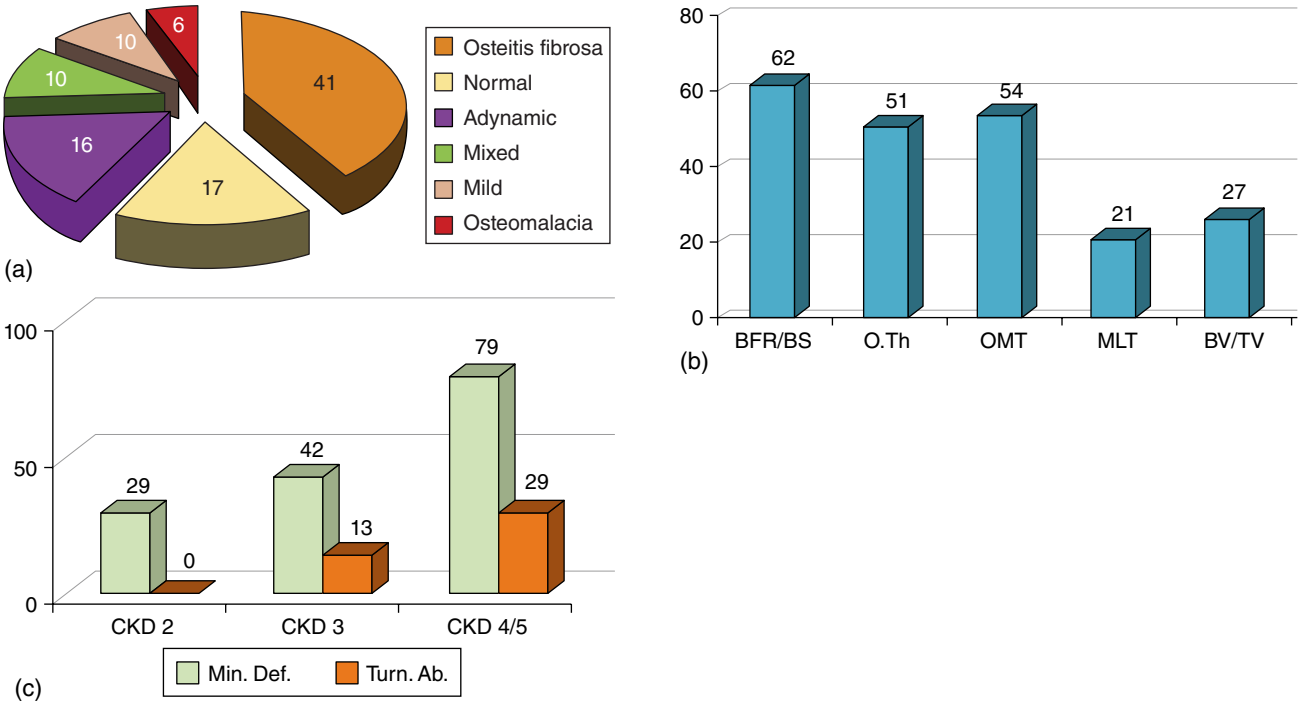

Figure 63.1 (a) Prevalence of histological types of renal osteodystrophy in children with CKD stages 5/5D. *Source:* Based on KDIGO [19]. (b) Abnormal bone histomorphometry parameters in children on PD (% cases). *Source:* Bakkaloglu et al. [20]. (c) Mineralization and turnover abnormalities in CKD 2–5 patients (% cases). *Source:* Based on Wesseling-Perry [12]. ROD, renal osteodystrophy; CKD, chronic kidney disease; D, dialysis; PD, peritoneal dialysis; BFR/BS, bone formation rate/bone surface; O.Th, osteoid thickness; OMT, osteoid maturation time; MLT, mineralization lag time; BV/TV, bone volume/tissue volume; Min. Def, mineralization defect; Turn. Ab, turnover abnormalities.

In contrast, mineralization defect was observed in only 3% of more than 600 adults on dialysis [21]. Due to modeling process and endochondral bone formation in the growing skeleton, there is a high demand for Ca to maintain bone mineral acquisition in children, including those with CKD. If this requirement is not met, mineralization defects become evident even in the early stages of CKD despite normal serum levels of Ca and P, and normal bone formation rate [12]. As such, in children undergoing PD, for any given level of bone turnover, high, normal or low, levels of PTH were higher and serum Ca values were lower in those with a concomitant mineralization defect [20]. Furthermore, lower serum Ca level was associated with lower cortical volumetric bone mineral density (BMD) and increased fracture risk in children with CKD [7, 8]. These data highlighted the importance of sufficient Ca for skeletal health during growth in CKD.

Clinical Findings

Growth Failure, Bone Deformities, and Fracture Risk

Childhood and adolescence are crucial times for the development of a healthy skeletal system. Unlike adults, skeletal growth occurs by processes of bone modeling and remodeling in children. Modeling, defined as simultaneous bone formation and resorption on different bone surfaces, is the basis of the large increase in bone size during growth. Remodeling, in which formation and resorption occur sequentially at the same location because of local coupling, allows for maintenance and repair of the skeleton [2]. Longitudinal growth is driven by the growth plate, whereas the periosteum drives bone growth in width by appositional modeling. During puberty and late adolescence, endosteal apposition and trabecular thickening provide maximum skeletal mass and strength, and therefore the growing skeleton is particularly vulnerable to the effects of CKD-MBD [2, 22]. Despite the traditional emphasis on bone turnover, significant abnormalities in skeletal mineralization have also been observed in patients with CKD and dialysis [12, 20]. Clinical implications of defective mineralization in patients with CKD remain to be further elucidated. These lesions persist despite adequate suppression of secondary hyperparathyroidism and may contribute to increased fracture rates, bone deformities, and growth retardation [7, 8, 22–24].

Growth failure: Approximately 40% of children with end-stage kidney disease (ESKD) have a reduced final height

Table 63.1 Treatment for chronic kidney disease mineral and bone disorder in children [115].

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Phosphate binder therapy	We suggest that phosphate lowering therapy be used to lower age-appropriate serum phosphorus levels in children with CKD. The choice of phosphate-lowering treatment based on age-appropriate serum calcium levels is emphasized. Calcium-based binders are suggested as first line based on very low certainty that low calcium levels are associated with mineralization defect and fracture risk in observational studies. If serum calcium measurements show a trend toward the age-adjusted upper limit of normal sevelamer may be considered.	*Moderate (lowering phosphate levels)* *Low* (hypercalcemia) *Very low* (mineralization, fracture risk)	Weak [56, 70]
Vitamin D	We suggest using vitamin D compounds in children with CKD stages 3a–5D who have persistently increased serum PTH concentrations above the CKD-specific target range. We suggest that oral calcitriol, 1α-hydroxyvitamin D, and paricalcitol are safe and well tolerated in children with CKD stages 3a–5D.	Moderate (decrease PTH secretion) Low (hypercalcemic episodes) Very low (the effect on bone morphology and growth is uncertain)	Weak [56, 81]
25-hydroxy vitamin D	Serum 25(OH)D concentrations are suggested to be maintained above 75 nmol/l (>30 ng/ml) in children with CKD stages 2–5D.	Moderate (time to development of secondary hyperparathyroidism) Very low (the effects of 25(OH) D concentrations on bone) Low (the optimal target level)	Weak [86]
Calcimimetic	We suggest that cinacalcet be initiated for the treatment of secondary hyperparathyroidism in children with ESKD in whom secondary hyperparathyroidism is not adequately controlled with conventional treatment.	Moderate (PTH lowering effect) Very low (growth, bone disease)	Weak [100–102, 104]
Serum biochemical targets	We suggest an individualized approach to management based on trends in biochemical values rather than treating to specific targets.	Very low (optimal identification of turnover type by PTH and other clinically used markers)	Weak

GRADE assessment of the certainty of the evidence [115]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

(<3 percentile), and thus growth failure is a hallmark of CKD in children [25]. In a cross-sectional study of 5615 pediatric CKD patients included in the North American Pediatric Renal Trials and Collaborative Studies registry, overall 37% of subjects had short stature [26]. There was an almost linear relationship between growth failure and eGFR decrease. Growth deficit was seen in 68% of those with an eGFR of <10 ml/min/1.73 m^2 and in 22% of those with an eGFR of 50–75 ml/min/1.73 m^2 [26]. In a cohort of 249 young Dutch adults with childhood onset of ESKD, 61% had severe growth retardation and 18% were disabled by bone disease [27]. Along with the psychosocial disadvantages of growth failure, uremic children with growth failure have been demonstrated to have an increased risk of death [28]. In the updated Kidney Disease: İmproving Global Outcomes (KDIGO) guidelines, it is recommended that infants with CKD stage G2–G5D have their length measured at least quarterly, while children with CKD stage G2–G5D should be assessed for linear growth at least annually [29].

Bone deformities: Children with CKD also experience bone deformities [2 ,3] and fractures [24] (Figure 63.2).

(a) (b) (c) (d) (e)

Figure 63.2 Skeletal findings of CKD-MBD: (a) coxa vara, (b) pathologic fracture, (c) genu valgum, (d) slipped capital femoral epyphysis and leg length discrepancy, (e) extensive soft tissue and vascular calcification.

Renal osteodystrophy may clinically manifest as slipped epiphyses of the femur, humerus, radius, and/or ulna, resulting not only in skeletal deformities, but also pain, abnormal gait, and/or inability to ambulate. Genu valgum, genu varum, and pes varus may also occur and, importantly, may persist despite long-term treatment with active vitamin D sterols [2, 3, 22]. In a review of 890 children on peritoneal dialysis, 9.4% had radiological signs of osteodystrophy/rickets, 5% had limb deformities, 1.4% had bone pain, and 1.5% had extraskeletal calcification [3]. Among 271 patients followed for 12 months, signs and symptoms of CKD–MBD persisted in 20 (7.4%), resolved in 32 (11.8%), and developed de novo in 17 (6.3%) [3].

Fractures: Children with CKD have a 2- to 3-fold higher gender-specific fracture risk compared to healthy children [23]. In a prospective study of 537 children with CKD (median age 11 years and mean eGFR 47 ml/min/1.73 m^2), 16% were reported to have a prior history of fracture, and over a median follow-up of 3.9 years 67 (12.5%) reported an incident fracture [23]. For fracture resistance, cortical bone is of vital importance because cortical bone represents nearly 80% of human bone mass and is the major determinant of bone strength in all individuals, including those with CKD. Prominent cortical changes of increased porosity and reduced cortical thickness occur in patients with CKD. A small adult study revealed deterioration of cortical microarchitecture contributing to bone fragility, despite predominantly normal trabecular parameters, which reinforces the importance of comprehensive cortical evaluation (not captured in the TMV system) in patients with CKD [30]. Cortical dimensions were correlated with bone strength in children [6, 7, 31]. A single-center pediatric bone biopsy study revealed a greater degree of erosion in cortical bone in CKD patients with secondary hyperparathyroidism than in those with normal or low trabecular bone turnover [32]. Progressive deficits of cortical bone have also been shown by peripheral quantitative computed tomography (pQCT) in 171 children and adolescents with CKD stages 2–5D. Importantly, greater increases in serum Ca levels were associated with greater increases in cortical BMD *Z*-scores in growing children and lower cortical BMD predicted future fracture events [7]. Therefore, in the updated KDIGO guidelines the higher Ca requirement of the growing skeleton is recognized and serum Ca levels are suggested to be maintained in the age-appropriate normal range in children and adolescents with CKD G3a–G5D [29].

Diagnostic Tests

Parathormone and Bone Turnover Markers

In early CKD, serum levels of Ca, P, and PTH are still within the normal range, while there are preceding alterations in hormonal and signaling molecules in bone such as FGF23 and sclerostin [12]. In advanced CKD, Ca, P, and PTH are routinely tested to titrate calcitriol and phosphate binder (PB) therapy. Where available ionized calcium levels should be measured [33, 34].

Abnormalities in turnover are largely driven by elevated PTH concentrations and no biomarker so far has clearly proved to be superior to PTH in predicting bone turnover in CKD [35]. However, PTH is not a bone turnover marker as it is neither involved in the process of, nor is a direct product of, bone resorption or formation. Additionally, PTH levels have proved unreliable to independently predict bone turnover, partly due to skeletal resistance to PTH and accumulation of long C-terminal fragments as well as PTH assay

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

variability [2, 36]. Low bone turnover is generally associated with low or low-normal PTH levels. However, low turnover may coexist with elevated levels of PTH and high turnover may coexist with low PTH levels [36]. Due to a complete lack of evidence, current guidelines in children markedly differ with respect to the recommended PTH target levels, ranging from two to three times the upper limit of normal (ULN) in the European guideline [37] to two to nine times ULN in the KDIGO guideline [19].

For the KDIGO 2017 Update, the Work Group encouraged the continued use of PTH trends (persistently above the ULN as well as progressively rising), rather than single time-point measurements to guide therapy [29]. Parallel to this statement, in children monitoring of serum levels of Ca, PTH, and alkaline phosphatase (ALP) activity beginning in CKD stage 2 and treatment decisions based on the serial measurements of these markers are suggested [29] because it is likely that a panel of bone biomarkers will always prove superior to a single bone biomarker. PTH values <400 pg/ml plus ALP <400 IU/l provided the highest prediction of normal bone turnover and mineralization in the largest pediatric bone biopsy study [20]. However, circulating ALP consists of mostly liver and bone isoforms, so the interindividual biological variation of ALP is large, in the order of 20%. Bone-specific ALP (B-ALP) is useful in concurrent liver disease and may have the advantage of specificity over total ALP [38, 39]. A large bone biopsy study reported that intact PTH, whole PTH, and bALP levels were associated with bone turnover; however, no biomarker singly or in combination was sufficiently robust to diagnose low, normal, and high bone turnover in an individual patient [35]. Other markers of bone formation (osteocalcin and intact procollagen type 1 N-terminal propeptide [P1NP]) and resorption (C-terminal telopeptide of type 1 collagen [CTX]) do not provide optimal discrimination of turnover type and mineralization status in ROD [40]. Therefore, KDIGO 2017 guidelines encourage using trends in PTH rather than absolute "target" values to guide therapy and when trends in PTH are inconsistent a bone biopsy should be considered [29]. Further basic research is needed to elucidate the biological processes involved in modulating these biomarkers, which might lead to more targeted therapies [41].

Bone Imaging

Dual-energy X-ray Absorptiometry

Dual-energy X-ray absorptiometry (DXA) is the most widely used noninvasive technique for measuring bone mineral content and evaluating bone mass. The 2017 KDIGO guidelines suggest DXA screening in adults with CKD stage 3–5D, if results will impact management decisions [12], i.e. individualized treatment strategies according to patients' clinical, biochemical, and BMD risk factors.

In children with CKD, DXA scans have significant limitations [33, 42, 43]. Specifically, DXA scans rely on areal (g/cm^2) rather than volumetric (g/cm^3) BMD, resulting in an artificial underestimation of bone density in children with short stature. Also, DXA scans cannot distinguish between cortical and trabecular bone, which may be differentially affected in CKD; trabecular bone mass increases and cortical bone mass decreases in response to increased PTH levels [44]. Posterior–anterior DXA projection of the spine captures the largely trabecular vertebral body, as well as the superimposed cortical spinous processes. However, the lateral projection allows a distinction to be made between the vertebral body and posterior elements. Despite these limitations, there is growing evidence that DXA BMD predicts fractures in healthy children and adolescents, and those with chronic diseases [7, 23, 45]. A recent cross-sectional multicentre study in 26 patients with CKD stage 4 and 5 (median age 11.9 years) and 77 on dialysis (median age 14.0 years) showed that routinely measured serum biomarkers Ca, PTH, and ALP taken together are moderate predictors of BMD, whereas DXA is not a useful measure [46]. Prospective studies are needed in children to determine whether DXA predicts fractures and to determine whether the International Society of Clinical Densitometry (ISCD) recommendations to measure whole-body and spine BMD in children with chronic diseases are appropriate in the context of CKD [45].

Trabecular bone score (TBS) derived from a DXA spine scan is increasingly being used in stratifying fracture risk but has yet to be validated as a measure of trabecular architecture in the setting of CKD. In a recent study, relationships between TBS and measures from DXA, HR-pQCT, and histomorphometry were determined in 50 adult CKD patients. It was suggested that TBS reflected trabecular microarchitecture and cortical width measured by bone biopsy [47].

Peripheral Quantitative Computed Tomography

Newer imaging options for stratifying fracture risk include pQCT and high-resolution (HR) pQCT [48]. Peripheral QCT is a three-dimensional method that distinguishes between trabecular and cortical bone, using a low radiation dedicated extremity scanner (distal radius or tibia), and provides volumetric measures of BMD (mg/cm^3) that are not confounded by bone size [6, 7]. The feasibility, safety, and utility of pQCT in children with CKD have been demonstrated [6, 7]. However, this imaging modality is not widely available in clinical practice, is largely operator dependent,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

different protocols are used around the world, and the reference data to calculate age-, height- and sex-adjusted Z-scores for healthy people are limited [46]. pQCT BMD measurements correlate with circulating mineral metabolism factors, including PTH, in pediatric CKD patients [7]. Hyperparathyroidism is associated with significant reductions in cortical BMD and bone size, and with greater trabecular BMD in younger children [6]. The ISCD pediatric task force recommends that pQCT "can be used clinically in children where appropriate reference data and expertise are available" [49]. On the other hand, the use of bone structural parameters to identify bone dynamic parameters is controversial and doubtful because the effects of bone turnover on bone structure require about 3–6 months to be detectable on HR-pQCT imaging [40].

Micro-MRI

Micro-MRI, a nonionizing method for in vivo quantification of bone microarchitecture, is performed using readily available clinical scanners but with customized pulse sequences and coils, and sophisticated post-processing and analysis [50]. It is not limited to peripheral bone sites and can image proximal femur [51]. Wehrli et al. evaluated the role of micro-MRI in assessing bone microstructure in 17 young adults on maintenance hemodialysis, demonstrating significantly lower cortical thickness and cross-sectional area and evidence of trabecular disruption in the dialysis patients compared to controls [52].

Currently, noninvasive high-resolution imaging is confined to the research setting. Despite limitations, including lack of standardized reference data and technical parameters, imaging to peripheral sites, high costs, very few studies, and lack of robust validation against histomorphometry in pediatric CKD, this modality has the potential to fill, at least partially, the significant gap between screening of BMD using DXA and comprehensive diagnosis by bone biopsy [53].

Bone Biopsy

Currently, double-labeled tetracycline transiliac crest bone biopsy with quantitative histomorphometry is the only way to assess three key histologic descriptors of bone histology (TMV) and to accurately assess responses to therapeutic interventions [4]. In a large pediatric bone biopsy series, approximately half of the peritoneal dialysis patients had increased bone turnover and/or abnormal mineralization [20]. This classification system focuses on trabecular bone and generally excludes an assessment of cortical microarchitecture and integrity related to fracture resistance. An adult bone biopsy study on 630 hemodialysis patients reported a high prevalence of low bone turnover and abnormal cortical parameters [21]. Significant cortical loss was shown to be mediated by hyperparathyroidism and elevated turnover [54] in adults and children with CKD [32].

Using micro-CT, bone biopsy samples from patients on dialysis often show severely thinned and porous cortices due to intracortical remodeling [54]. In a recent study, trabecular and cortical bone microarchitecture were evaluated by histomorphometry and micro-CT in 16 patients with CKD stage 5 and 5D. Deterioration of cortical microarchitecture despite predominantly normal trabecular parameters reinforces the importance of comprehensive cortical evaluation in patients with CKD [30]. Evaluation of 68 pediatric bone biopsy samples by micro-CT revealed that bone volume measurements were highly correlated between bone histomorphometry and micro-CT, whereas bone formation rate did not correlate with any micro-CT determinations [55].

For the present, bone biopsy represents an important adjunct to the clinical and biochemical evaluation of patients with CKD, particularly when patients present with bone pain or unexplained fractures [1, 19, 29]. Bone biopsy studies evaluating bone biology/physiology have emphasized the critical role of bone as an endocrine organ and improved our understanding of the pathophysiology of not only ROD but also bone/kidney/vascular axes [1, 2, 4, 19, 29]. However, bone biopsy is invasive, expensive, requires approximately 3 months for results, cannot be used for rapid decision making, is not easily implemented as a disease and treatment monitoring tool, and is available at only several centers worldwide. In addition, it assumes that iliac crest remodeling is representative of systemic turnover. It is also limited by its ability to provide a measure of bone quality at a single site and a single point in time. So, even with the availability of bone biopsy data, we may find that patients do not respond predictably to treatments [40]. Thus, a true understanding of the prevalence of abnormal turnover, defective mineralization, and altered bone volume throughout the course of CKD is limited and regular analysis of biochemical indices and attention to their trends will also be required [20, 29, 36].

Treatment

The goals of CKD-MBD treatment in children are to normalize mineral metabolism, minimize progression of extraskeletal calcification, and promote normal bone turnover and normal skeletal growth without deformities. Along with dietary interventions, PBs, active and native vitamin D sterols and calcimimetic agents for selected individuals are current practice for CKD-MBD treatment [2, 18].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The most common treatments used in children with CKD are PBs (calcium or noncalcium containing) and vitamin D sterols (calcitriol, 1α-hydroxyvitamin D, paricalcitol). Dietary measures are instituted to reduce phosphate intake while maintaining adequate calcium and vitamin D intake for healthy skeletal growth. Also calcium levels in the dialysis fluid can be manipulated to maintain normocalcemia. New agents include calcimimetic agents (cinacalcet, etelcalcetide), which control secondary hyperparathyroidism, and for medically unresponsive patients, parathyroidectomy may be required.

Guidelines for the management of CKD-MBD in children are largely opinion-based, and many of the recommendations are cautiously vague and extrapolated from data in adults. Limited pediatric data coming from randomized controlled trials (RCTs) with a limited number of patients are focused on PTH and biochemical values only instead of patient-important health-related outcome parameters like growth, bone deformities, physical activity level, fractures, and finally death. Evidence for treatments is summarized in Table 63.1.

A recent Cochrane review concluded that there is a lack of evidence to guide CKD-MBD treatment in children with CKD and on dialysis. Hyperparathyroidism is improved by all vitamin D preparations. However, no consistent differences between routes of administration, frequencies of dosing or vitamin D preparations were demonstrated. Although fewer episodes of high calcium levels occurred with sevelamer compared with calcium acetate, phosphorus values were reduced to similar extents with all PBs [56]. After this Cochrane review, there are only a few RCTs on the effects of PBs and vitamin D, and available data is summarized below.

Phosphate Binders

Since conventional dialytic modalities remove far less than the daily dietary intake of phosphorus, PBs are routinely prescribed to control hyperphosphatemia in patients with CKD. The first agents, aluminum-containing PBs, were replaced by calcium-based PBs in the 1980s because of toxicities associated with aluminum. Then the calcium- and aluminum-free PBs sevelamer and lanthanum were introduced. Now, calcium-free iron-based PBs are on the market as promising alternatives. In the International Pediatric Peritoneal Dialysis (IPPN) Registry, among 890 patients, 88.3% were using PBs and the great majority of them (68.8%) were using calcium carbonate or acetate, 7% sevelamer (mainly in the USA), 11.8% both Ca-based binders and sevelamer, and only 0.3% lanthanum [3].

The most recent Cochrane review, including 104 adult studies in 13 744 patients [57], supported previous meta-analysis [58] and concluded that in adult dialysis patients, compared to calcium-based binders, sevelamer may lower all-cause death and incur less treatment-related hypercalcemia. There were no clinically important benefits of any PB on cardiovascular death, myocardial infarction, stroke, fracture or coronary artery calcification.

Iron lowered serum phosphorus levels to the greatest extent compared with other binders [57]. In terms of tolerability, lanthanum had the highest probability of causing nausea and sevelamer increased constipation compared with calcium, lanthanum, and iron. Iron was worst for diarrhea compared to calcium and sevelamer [58]. For predialysis patients, evidence is lacking for an advantage of any PB over placebo [57], therefore in the most recent UK Renal Association guideline PBs are suggested to be reserved for advanced stage CKD patients with progressively rising or persistently elevated serum phosphate [59].

The phosphate lowering capacity of Ca-containing PB and sevelamer is comparable [57, 60, 61]. Iron-based PBs appear to be the most effective in binding phosphate [57] and lanthanum is second [61], but these binders' long-term effects on bone and cardiovascular health are not known. Based on adult studies showing that calcium-based PBs may promote ectopic calcification [62–64], restricting the dose of calcium-based PBs is proposed in the KDIGO 2017 guidelines for avoiding hypercalcemia [29]. However, controversial data are also available [57, 62]. The most recent Cochrane review concluded that in adults with CKD and dialysis, there were no clinically important benefits of any phosphate binder on coronary artery calcification, though sevelamer incurs less treatment-related hypercalcemia [57]. Baseline calcification status is a more important predictor of calcification progression than the type of P binder [65]. Therefore, a pragmatic and individualized approach to phosphate reduction toward the normal range and maintaining serum calcium below the upper limit of the reference range are suggested in adults [59].

Several studies in children on dialysis have shown an association between high phosphate levels and increased vessel thickness/stiffness and arterial calcification [66–68]. Active vitamin D sterols and PBs have also been shown to be associated with worsening of vascular calcification [65, 66]. However, the growing skeleton of children has a high demand for calcium, and low calcium levels reduce BMD and increase fracture risk [6, 7, 23]. Furthermore, a large prospective cohort revealed that use of PBs, largely calcium-based ones, was protective from fracture in pediatric CKD patients [23]. Therefore, in children with CKD G3a–G5D, maintaining serum calcium and phosphorus in the age-appropriate normal range is suggested and the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

choice of phosphate-lowering treatment based on serum calcium levels is emphasized [29]. A calcium-based PB as the first-line phosphate reduction therapy in children should be preferred. If a series of serum calcium measurements shows a trend toward the age-adjusted upper limit of normal, either combining with, or switching to, sevelamer is suggested [59].

Only three RCTs have examined phosphate-lowering therapy in children with CKD or on dialysis (Tables 63.2 and 63.3) [60, 69, 70]. The first RCT examined biochemical endpoints (decrease in serum P levels, Ca*P product level) only and showed equivalent phosphate control with calcium acetate and sevelamer hydrochloride in an 8-week cross-over trial. There was a lower rate of hypercalcemia and lower lipid levels with sevelamer [69]. In the second study, 29 children on PD were randomized to different combinations of PBs (sevelamer hydrochloride vs. calcium carbonate) and vitamin D analogues (doxercalciferol vs. calcitriol). Bone biopsies suggested that both the sevelamer and calcium carbonate-treated groups had equally reduced bone formation rate versus baseline at 8-month follow-up, and less hypercalcemia with sevelamer was also noted [60].

The most recent phase 2 study evaluated the efficacy and safety of sevelamer carbonate in 66 children with CKD (mean age 14.1 years and 77% on dialysis). Following a 2–4-week screening phase, pediatric patients with a serum phosphorus level higher than age-appropriate levels were randomized to receive either sevelamer carbonate or placebo as powder/tablets in 0.4–1.6 g doses, based on body surface area. Dose was titrated up or down based on serum P levels after the fixed dose period. Sevelamer carbonate was shown to be effective in reducing serum P levels without any significant side effects [70].

Lanthanum is a heavy metal minimally absorbed and eliminated via the hepatobiliary pathway. Despite concerns related to bone accumulation and cartilage toxicity in growing children, randomized prospective adult studies of paired bone biopsies revealed no evidence of accumulation or toxicity in patients treated with lanthanum carbonate. There is also no evidence that lanthanum carbonate is associated with adverse safety outcomes in patients with ESKD [71]. However, there are no pediatric RCTs and its use is highly limited in children [3].

Ferric citrate (FC), an iron-based PB, has been shown to improve both hyperphosphatemia and iron deficiency in adult CKD and dialysis patients [72, 73]. In line with this, a small pediatric retrospective study ($n = 11$ children on dialysis, median age 13 years, median duration 7 months, time-averaged FC dose 3.5 (1.5–8.4) tablets/day, and elemental iron 27 [10–38] mg/kg/day) showed decreased serum phosphate, improved iron parameters, and maintenance of hematocrit with FC treatment [74]. The effects of iron-based P binders on anemia and hyperphosphatemia should be studied in RCTs.

Active Vitamin D Compounds

Deficiency in $1,25(OH)_2D$ increases PTH synthesis and secretion, both directly and due to the associated hypocalcemia. According to IPPN registry, 75% of the pediatric dialysis patients were using different active vitamin D sterols, mainly calcitriol (45.6%) and alfacalcidol (25%), and only a few patients (1.3%) were using doxercalciferol or paricalcitol [3].

Calcitriol, doxercalciferol, and paricalcitol were evaluated in RCTs (Tables 63.4 and 63.5). Two RCTs showed a significant reduction in PTH with thrice-weekly intravenous calcitriol [75] and thrice-weekly intravenous paricalcitol [76] in hemodialysis patients. The only placebo-controlled randomized trial in patients with stages 3–5 CKD showed that oral paricalcitol with an initiating dose of 1 μg three times weekly in children aged 10–16 years was effective in decreasing the iPTH levels [81]. Oral thrice weekly paricalcitol has also been shown to be safe and effective in reducing PTH in children on dialysis in an open-label study [81]. A significantly increased risk of hypercalcemia was reported with intravenous calcitriol [75], but not with IV or oral paricalcitol [76, 81]. Therefore, oral paricalcitol was shown to be safe and effective not only in dialysis patients, but also in children with CKD stage 3–4 [81]. Another controlled trial demonstrated that calcitriol and doxercalciferol exhibit equal efficacy in lowering PTH levels and in controlling bone turnover [77]. Two RCTs of alfacalcidol or calcitriol versus native vitamin D in children with CKD stages 2–3 [82] and on dialysis [83] indicated a qualitative and quantitative improvement in histological indices of renal osteodystrophy with both native vitamin D and active vitamin D analogues. Studies comparing intermittent with daily oral calcitriol showed that the change in mean height SDS and the percentage fall in PTH levels in the short (8 weeks) or long term (12 months) did not differ between treatments. It has also been reported that intermittent high-dose calcitriol may adversely affect linear bone growth [84]. Available data based on a Cochrane review in 2015 including 18 studies and 576 enrolled patients concluded that vitamin D sterols are effective in reducing PTH levels in children with CKD and on dialysis, but their effects on bone and growth are uncertain due to the small number of patients and short-term follow-up in controlled trials [56]. Based on available data we suggest using vitamin D sterols, including oral calcitriol, 1α-hydroxyvitamin D, and paricalcitol, as safe, effective, and well-tolerated agents in

Table 63.3 Summary of findings: phosphate binder therapy.

Outcome	No. of participants (no. of studies)	Absolute no. of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Phosphate lowering effect	113 (3 studies)	Not estimable	Not estimable	Moderate	Phosphate binders significantly lowered serum phosphorus levels
Hypercalcemia	57 (2 studies)	Not estimable	Not estimable	Moderate	Sevelamer probably leads to less frequent hypercalcemia than calcium-based binders
Bone histology	29 (1 study)	Not estimable	Not estimable	Low	Sevelamer and calcium-based phosphate binders in combination with active vitamin D sterols may reduce bone formation rates

children with CKD stages 3a–5D who have persistently increased serum PTH concentrations above the CKD-specific target range [85].

Native Vitamin D

Vitamin D deficiency is widely prevalent and often severe in children and adults with CKD. According to the most recent clinical practice recommendations, 25-hydroxyvitamin D 25(OH)D status is classified as follows: sufficiency >75 nmol/l (>30 ng/ml), insufficiency 50–75 nmol/l (20–30 ng/ml), deficiency 12–50 nmol/l (5–20 ng/ml), severe deficiency <12 nmol/l (<5 ng/ml). It is suggested that serum 25(OH)D concentrations are maintained above 75 nmol/l (>30 ng/ml) in children with CKD stages 2–5D [86]. Levels are suggested to be monitored 6–12 months apart in patients not requiring vitamin D supplementation, when deficient 3–6 monthly measurements can be suggested according to the response to therapy [86].

There are few studies in children or adults with CKD that examine the effects of 25(OH)D concentrations on bone, and the optimal target level of 25(OH)D is unclear. In the only RCT of native vitamin D therapy in children with CKD, it was shown that children on ergocalciferol who achieved 25(OH)D levels >75 nmol/l had a significantly longer time to development of secondary hyperparathyroidism (Table 63.6) compared with those on placebo [87] Other nonrandomized prospective studies in children with CKD have also shown the effect of ergocalciferol or cholecalciferol in reducing PTH levels [88, 89].

A treatment regimen guided by age and vitamin D levels for the prevention and treatment of vitamin D deficiency in children with CKD stages 2–5D is suggested. Mega-dose vitamin D therapy is not recommended. None of the studies adjust vitamin D doses for body weight or body surface area [90]. Although the "stoss regimen" (i.e. 300 000 and 600 000 IU as single mega-dose vitamin D therapy) may overcome issues of compliance, this can cause hypercalcemia without an additional benefit to the improvement of rickets [91]. Intoxication from vitamin D is largely reported from the use of very high doses of ergocalciferol or cholecalciferol over prolonged periods of time [92]. Symptomatic toxicity from vitamin D is defined as serum 25(OH)D above 250 nmol/l with hypercalcemia, hypercalciuria, and suppressed PTH, and, if prolonged, nephrocalcinosis and renal failure. Vitamin D supplementation is therefore stopped at serum 25(OH)D concentrations of 120 nmol/l (48 ng/ml) (Table 63.7) [86].

Cinacalcet

Cinacalcet is an allosteric modulator of the calcium-sensing receptor (CaSR) expressed in the parathyroid glands. It enhances the CaSR sensitivity for extracellular calcium, resulting in reduced serum PTH, Ca, and serum inorganic phosphate levels, allowing better control of secondary hyperparathyroidism and CKD-associated mineral and bone disorders (CKD-MBD). The effect of cinacalcet therapy on reducing PTH levels and on the need for parathyroidectomy in adults is clearly shown in meta-analyses [93, 94] and its use, along with calcitriol or vitamin D analogs, or a combination thereof, is included in the KDIGO guidelines [12], but there are controversial data about its impact on mortality [93–96]. Additionally, cinacalcet increases risks of nausea, vomiting, and hypocalcemia, suggesting the harms may outweigh the benefits in this population [93].

In the IPPN registry, only 2.8% of 890 children were on cinacalcet and they were mainly from the USA [3]. There

Table 63.5 Summary of findings: active vitamin D therapy in children with CKD stage 2–5D.

Outcomes	No. of participants (no. of studies)	Absolute no. of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusions
Bone disease	Three studies	Not estimable	Not estimable	Moderate/ low	Bone histology indicated improvement in children treated with vitamin D sterols No significant differences in bone histology were detected in studies comparing calcitriol and doxercalciferol
Growth	Two studies	Not estimable	Not estimable	Very low	No significant differences in growth rates were detected in studies comparing different vitamin D sterols
PTH control	Four studies	Not estimable	Not estimable	Moderate	No differences in PTH levels were found between oral daily and oral intermittent calcitriol therapy Vitamin D sterols given orally or intravenously resulted in reduced PTH levels compared with placebo or no specific treatment
Hypercalcemia	Five studies	Not estimable	Not estimable	Moderate	No differences in the number of children with hypercalcemia or the number of hypercalcemic episodes were found between oral daily or oral intermittent calcitriol therapy Hypercalcemic episodes were more common with intravenous calcitriol when compared with placebo Increased risk of hypercalcemia was not reported with 1alpha-hydroxyvitamin D or paricalcitol

are no pediatric RCTs on the use of cinacalcet in pediatric CKD before dialysis. Most of the data reporting the use of cinacalcet in pediatric CKD come from observational studies and small series [97–99]. Industry-sponsored trials have also been performed in pediatric dialysis patients (Tables 63.88 and 63.99) [100, 103, 104]. The first open-label study evaluated the safety, tolerability, pharmacokinetics, and pharmacodynamics of a single oral 15-mg dose of cinacalcet in pediatric subjects 6–17 years of age with CKD. No serious adverse events developed as a result of hypocalcemia [103]. The second study was conducted in infants and children under 6 years of age and a 0.25 mg/kg starting dose of cinacalcet was found to be safe, well-tolerated, and would result in a clinically meaningful decrease in PTH levels (−11% at 2 hours and −30% at 8 hours, returning to baseline at 72 hours) [104].

The third and only pediatric double-blind placebo-controlled phase 3 trial, including 43 patients between 6 and 18 years of age, randomized either cinacalcet or placebo and revealed that the effect of cinacalcet in reducing plasma iPTH was clinically meaningful and statistically significant despite early termination of the study following a fatality in a subject with severe hypocalcemia receiving cinacalcet. The cause of death was determined to be multifactorial, but a causal role for hypocalcemia could not be excluded [100]. Other industry-sponsored studies have only been presented as abstracts at international conferences [101, 102]. A phase 3 multicenter randomized open-label controlled study did not demonstrated efficacy of CIN, likely due to inadequate exposure [101]. On the other hand, an open-label, single-arm phase 2 study in dialysis patients aged 28 days to 6 years showed significant benefit of cinacalcet in reducing PTH levels with a good safety profile [102]. All three studies and their main characteristics are summarized in Table 63.8. After its approval by the European Medical Agency in 2017, a position statement on

Table 63.9 Summary of findings: calcimimetic therapy.

Outcomes	No. of participants (no. of studies)	Absolute no. of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
Reduction in PTH level	66 patients (three studies)	Not estimable	Not estimable	Very low	Cinacalcet may lead to a reduction in serum PTH levels
Hypocalcemia	66 patients (three studies)	Not estimable	Not estimable	Moderate	Hypocalcemia is a significant side effect and may be fatal in children having predisposing factors

PTH, parathyroid hormone.

the use of cinacalcet in pediatric dialysis patients based on the available data and opinion of experts from the European Society for Paediatric Nephrology and the ERA-EDTA was published [105]. There are no studies with etelcalcetide, the new IV calcimimetic, in children on dialysis.

Parathyroidectomy

Parathyroidectomy is recommended for hyperparathyroidism unresponsive to pharmacological therapy, including failure of calcitriol (with or without cinacalcet) to limit PTH rise, unacceptable side effects from treatment or adverse biochemical responses [106]. However, there is a complete lack of evidence on this topic even in adults and this procedure has its own complications and morbidity [106]. A recent meta-analysis showed that compared with standard treatment, parathyroidectomy significantly decreased all-cause mortality (RR 0.74 [95% CI 0.66 to 0.83], 15 cohort studies, 24 048 participants) and cardiovascular mortality (RR 0.59 [95% CI 0.46 to 0.76], six observational studies, almost 10 000 patients). Properly conducted, RCT comparing surgery with medical therapy and featuring many different outcomes from mortality to quality of life is necessary [107].

Growth Hormone

Growth retardation is a common complication of CKD [108] and one of the measures of quality of care in children. Recombinant human GH (rhGH) has been used successfully for many years to compensate growth failure in children and adolescents with CKD who are on conservative treatment, are undergoing dialysis or after kidney transplantation [19, 108–111]. In a recent Cochrane review, the efficacy, safety, and long-term results of rhGH were extensively evaluated. Treatment with rhGH (28 IU/m^2/week) compared with placebo or no specific therapy resulted in a significant benefit in children with CKD and on dialysis. One year of 28 IU/m^2/week rhGH in children with CKD resulted in a 3.88 cm increase in height velocity above that of untreated patients. Compared to the 14 IU/m^2/week group, there was a 1.18 cm/year increase in height velocity in the 28 IU/m^2/week group. Side effects of rhGH were generally similar to those of the control group [112]. A bone biopsy study in 33 PD patients showed that compared to placebo, GH therapy improved height irrespective of underlying bone histologic features. Additionally, normalization in bone formation rate was observed in those receiving rhGH therapy [113]. On the other hand, studies were too short to determine if continuing treatment resulted in an increase in final adult height [112] (Table 63.10).

Based on available data and recently published clinical practice recommendations, children with stage 3–5 CKD or on dialysis are candidates for GH therapy (0.045–0.05 mg/kg/day, subcutaneously) if they have persistent growth failure, defined as a height below the third percentile for age and sex, and a height velocity below the 25th percentile [114]. Before rhGH treatment, all CKD-associated threats to growth, including protein-calorie malnutrition, metabolic acidosis, disturbances in fluid-electrolyte, and mineral metabolism, should be well controlled. Treatment is suggested to be maintained until the patient reaches the estimated target height or when epiphyseal growth plates fuse or until renal transplantation [114].

Conclusion

Systemic and bony manifestations of CKD-MBD are highly prevalent and lead to significant morbidity. Uniquely to children, in addition to remodeling abnormalities, modeling disturbances result in significant growth failure and skeletal deformities, which contribute to long-standing disability. The pathophysiology of CKD-MBD is incompletely understood and there are major gaps in the evidence for diagnosing the bone pathology and guiding treatment

Table 63.10 Summary of findings: GH therapy in children with CKD stage 2–5D and kidney transplantation.

Outcomes	No. of participants (no. of studies)	Absolute no. of patients affected per 1000 patients treated for 1 year (95% CI)	Relative risk (95% CI)	Certainty of the evidence (GRADE)	Conclusion
	809 enrolled patients (16 RCTs)	Not estimable	Not estimable	Low	One year of 28 IU/m^2/week rhGH in children with CKD resulted in a 3.88 cm increase in height velocity above that of untreated patients Studies were too short to determine if continuing treatment resulted in an increase in final adult height The frequency of reported side effects of GH was generally similar to that in control groups
rhGH (28 IU/m^2/week) vs. placebo or no specific therapy					
Height SDS at 12 months	391 children (eight studies)	Not estimable	MD 0.82, 95% CI 0.56–1.07	Moderate	Delta height SD at 1 year: 0.82 (95% CI 0.56–1.07) in CKD patients, including dialysis and kidney transplantation patients
Height velocity at 6 months	27 children (two studies)	Not estimable	MD 2.85 cm/6 months, 95% CI 2.22–3.48	Low	The mean height velocity at 6 months of GH in the intervention groups was 2.85 cm higher than in controls
Height velocity after 1 year	287 children (seven studies)	Not estimable	MD 3.88 higher (95% CI 3.32 to 4.44)	Moderate	The mean height velocity after 1 year of GH in the intervention groups was 3.88 cm higher than in controls
Height velocity after 2 years	82 children (one study)	Not estimable	MD 2.30 cm/year, 95% CI 1.39–3.21)	Moderate/Low	The mean height velocity after 2 years of GH in the intervention group was significantly greater than in untreated children (2.3 cm/year)
rhGH 28 IU/m^2/week vs. 14 IU/m^2/week					
Height velocity after 1 year	150 children (three studies)	Not estimable	MD 1.18 cm/year with high dose, 95% CI 0.52–1.84	Moderate	1.18 cm/year higher height velocity after 1 year with high dose
rhGH daily subcutaneously [113]					
Height SDS	33 PD patients (one study)	Not estimable	Delta height SDS, GH vs. no-GH 0.32 ± 0.08 ($P < 0.01$)	Low	GH therapy improves height in pediatric dialysis patients, irrespective of underlying bone histologic features Therapy with growth hormone enhanced bone turnover in patients with baseline low bone turnover, while skeletal lesions of secondary hyperparathyroidism persisted in patients with high bone turnover at baseline, despite the concomitant use of calcitriol
Bone formation rate			Decreased in patients with high bone turnover from 103.3 to 60.3 μm^2/μm^3/year without rhGH ($P = 0.05$) Increased in patients with low bone turnover with rhGH (from 15.0 to 154.6 μm^2/μm^3/year ($P = 0.03$)		

CKD, chronic kidney disease; GH, growth hormone; MD, mean difference; rhGH, recombinant human growth hormone; SDS, standard deviation score.

options. Measurement of PTH and biochemical bone remodeling markers is helpful but also lacks sensitivity and specificity, therefore therapeutic decisions should be based on to the trend in levels rather than single measurements. Also, there is a significant shift from treating to specific targets toward a more individualized approach to management. There is currently an absolute need for high-quality studies demonstrating the effectiveness of diagnostic and therapeutic interventions on patient-centered outcomes of children with CKD-MBD.

Introduction

Anemia is one of the most common comorbidities in children with chronic kidney disease (CKD) and is associated with a variety of adverse consequences. A number of factors contribute to the development of anemia in children and adults with kidney disease, mainly dysregulated erythropoietin (EPO) production and iron restriction. As kidney function declines, patients experience a decrease in circulating red blood cell mass, indicated by low blood hemoglobin (Hb) concentration. The mainstays of anemia therapy in children with CKD are treatment with recombinant human erythropoietin (rHuEPO) and iron supplementation. A number of evidence-based clinical practice guidelines and recommendations for the monitoring and management of anemia of CKD in children, including the Hb thresholds used to define anemia, have emerged over the last 10–15 years and are summarized in this chapter.

Epidemiology

Data from the North American Pediatric Renal Trials and Collaborative Studies (NAPRTCS) cohort has shown that the risk for anemia increases with advancing stage of CKD, with prevalence of 73% at stage 3, 87% at stage 4, and >95% at stage 5 [1, 2]. Within the Chronic Kidney Disease in Children (CKiD) cohort study, the median Hb declined as the measured glomerular filtration rate (GFR) decreased to <43 ml/min/1.73 m^2 [3]. In the International Pediatric Peritoneal Dialysis Network (IPPN) registry, low serum albumin, increased parathyroid hormone (PTH) levels, high serum ferritin, and the use of bio-incompatible dialysate were associated with low Hb [4, 5]. Race is also a recognized risk factor for anemia. Among children in CKiD, African American children demonstrated lower levels of Hb than white children, even after adjusting for level of kidney function [6]. Compared to adults on chronic dialysis in the United States, pediatric patients more often have mean annual Hb levels of <11 g/dl: (54% vs. 39.8% in pediatric compared to adult hemodialysis (HD) patients and 69.5% vs. 55.1% in pediatric compared to adult peritoneal dialysis patients [7]. Anemia remains a problem even after kidney transplantation. The prevalence of anemia post-transplant in one single-center study of 231 pediatric patients was 25.5% at 1 year after transplantation [8].

Pathophysiology

The kidneys play a central role in regulating red blood cell mass through the production of erythropoietin. Erythropoietin is synthesized by interstitial cells in the peritubular capillary bed of the renal cortex, but under conditions of injury these cells transdifferentiate in myofibroblasts that synthesize collagen and lose their erythropoietin-producing ability [9]. In addition to deficient erythropoietin production, it has been proposed that the kidney functions as a "critmeter" by sensing oxygen tension and extracellular volume, and translating a measure of plasma volume as tissue oxygen pressure to regulate erythropoietin production [10]. In CKD, diminished oxygen consumption by renal tissue leads to dysregulation of erythropoietin production independent of damage to erythropoietin-producing cells [10]. Nutritional problems during CKD and end-stage renal disease (ESRD) can lead

to folate and vitamin B_{12} deficiency, leading to disordered DNA synthesis, maturation arrest, and ineffective erythropoiesis. Iron availability is a rate-limiting step in the maturation of red blood cells, and iron deficiency also further impairs erythropoiesis.

Inflammation, another common problem in CKD, impairs both erythropoiesis and the utilization of iron in red blood cell production. Inflammatory cytokines inhibit erythropoietin production and impair the growth of red blood cell progenitors [10]. A study by Goldstein et al. in 2006 found that the proinflammatory cytokines IL-1β, IL-6, IL-8, and tumor necrosis factor (TNF)-α are increased in pediatric patients compared to age-matched controls [11]. Inflammation also stimulates production of the iron regulatory-protein hepcidin, which is the key mediator of iron-restricted erythropoiesis in CKD. Hepcidin regulates both intestinal iron absorption and bodily iron distribution via suppression of cell membrane expression of ferroportin, the sole cellular iron exporter, by degrading ferroportin and inhibiting the release of iron stored in ferritin [12]. In 2009, Zaritsky et al. demonstrated that hepcidin levels are significantly increased in pediatric patients with CKD stages 2–5 compared to their respective controls, and that transferrin saturation and ferritin were predictive of hepcidin levels [13]. In a cross-sectional and longitudinal study examining hepcidin and its role in the development and progression of anemia in children with CKD, Atkinson et al. found that higher hepcidin levels were associated with a decreased Hb and increased risk of incident anemia [14].

Evidence has emerged to suggest an association between 25-hydroxy vitamin D (25-OHD) levels and anemia. Studies of the adult CKD population have shown that 25-OHD concentration is significantly correlated with Hb and decreased erythropoiesis-stimulating agent (ESA) dosing requirements [15]. in vitro treatment of mouse monocytes or hepatocytes with 25-OHD or 1,25-dihydroxy vitamin D by Bacchetta et al. was found to decrease hepcidin mRNA expression [16]. Additionally, in a pilot study of healthy human volunteers, a single oral dose of vitamin D_2 (100 000 international units [IU]) increased serum 25-OHD levels and decreased serum hepcidin levels by 34% within 24 hours of dose administration [16]. In a retrospective cohort study of pediatric CKD patients, 25-OHD insufficient/deficient patients were twice as likely to be anemic and that there was a significant correlation between 25-OHD level and Hb [17]. However, a recent pilot randomized controlled trial showed that treatment of pediatric CKD patients with 4000 IU of cholecalciferol daily compared to 400 IU daily was not associated with a significant change in hepcidin level at 4 or 12 weeks, despite median C-reactive protein level decreasing significantly in the 4000 IU daily group [18]. Further randomized clinical trial (RCT)s may be useful to describe the relationship between vitamin D, hepcidin and anemia, and to continue to explore the effect of hepcidin modification on the treatment of anemia.

Diagnosis

Suggested Hb thresholds for the diagnosis of anemia in children with CKD are presented in Table 64.1. There have been a series of clinical practice guidelines for the diagnosis and management of the anemia of CKD published over the last 10–15 years, which are summarized in this section. In 2006 in the United States, the National Kidney Foundation Kidney Disease Outcomes Quality Initiative (KDOQI) published clinical practice guidelines for anemia in CKD based on an evidence-based review. The KDOQI pediatric workgroup defined anemia in a child as a reduction in Hb level to less than the fifth percentile for their age and sex, with the caveat that adjustment in normal levels should be done for children living at higher altitudes. The

Table 64.1 Definitions of anemia in children with CKD.

KDOQI		
	5th percentile Hb level (g/dl)	
Age group (years)	**Boys**	**Girls**

normative values for children older than 1 year of age published in the KDOQI guidelines were adapted from data from the National Health and Nutrition Evaluation Survey III reference data [22] (Table 64.1), whereas the values for children from birth to 1 year of age were derived from the textbook *Hematology of Infancy and Childhood* [23].

In 2012, the international Kidney Disease: Improving Global Outcomes (KDIGO) Anemia Workgroup published guidelines on diagnosis and management of anemia for both adult and pediatric patients with CKD. The diagnosis of anemia in pediatric CKD patients was recommended for Hb concentration <11 g/dl for children 6 months to 5 years old, <11.5 g/dl for 5–12 years old, and <12 g/dl for 12–15 years old [20]. The most recent clinical practice guidelines regarding anemia in CKD were published in 2017 by the Renal Association (RA) in the United Kingdom. The diagnosis of anemia in pediatric patients was recommended at a Hb level of 10.5 g/dl in children younger than 2 years old and at a Hb level of 11 g/dl in children >2 years old [21].

In the development of the KDOQI guidelines, a systematic literature review was performed of Hb thresholds for initiating therapy, Hb level therapeutic goals, iron status goals, and efficacy of adjuvants in achieving Hb goals. For the pediatric population, clinical practice recommendations were made in the absence of pediatric-specific evidence. As stated by the committee, "the only evidence of sufficient strength to support evidence based guidelines are available from studies of the adult population" [19]. The workgroup included clinical practice recommendations on evaluation of anemia in CKD (Table 64.2), target Hb range (>11 g/dl), use of ESAs and iron agents, as well as adjuvants, transfusion indications, and evaluation of persistent failure to reach or maintain intended Hb level.

In 2007 KDOQI, in response to data from adult trials in which use of ESA to target higher Hb levels was associated with adverse outcomes, published a revised recommendation advising that in patients receiving ESA the Hb target should generally be in the range of 11–12 g/dl and should not exceed 13 g/dl [19].The Caring for Australians with Renal Impairment (CARI) group [25] systematically reviewed the evidence and determined that no evidence-based recommendations were possible based on level 1 or 2 evidence in 2005. In suggestions for clinical care, they stated that there was no evidence to support that treatment of anemia improves growth in pediatric CKD cases; however, correction of anemia is indicated to improve quality of life (QoL) and cardiac performance. In 2003, the European Pediatric Peritoneal Dialysis Working Group published guidelines on the management of anemia in pediatric peritoneal dialysis patients. These guidelines stated that after a thorough diagnostic workup, anemia treatment should aim for a target Hb concentration of at least 11 g/dl through administration of erythropoietin and iron preparations. According to these guidelines, iron should preferably be prescribed as an oral preparation, and there is no place for carnitine supplementation in the treatment of anemia in pediatric peritoneal dialysis patients [26].

The National Institute for Health and Care Excellence (NICE) in the United Kingdom periodically updates its guidelines, most recently in 2015. The NICE group recommended that oral iron be trialed prior to intravenous (IV) iron in patients who are not on hemodialysis, and that iron deficiency be addressed prior to initiation of ESAs. For patients who are on ESAs, the recommended Hb target was 10–12 g/dl in children >2 years old and adults, and 9.5–11.5 g/dl in children younger than 2 years old [27].

The KDIGO guidelines were created from systematic literature searches and supplemental evidence from October 2010 to March 2012. The workgroup provided clinical practice recommendations for the diagnosis and evaluation of anemia in CKD, use of iron, use of ESAs, and use of red cell transfusions for treatment of anemia in CKD. For pediatric patients, oral iron (or IV iron in hemodialysis-dependent patients) was recommended for transferrin saturation ≤20% and ferritin ≤100 ng/ml. They did not recommend a Hb threshold for initiation of ESAs in pediatric patients, but recommended that providers consider all potential benefits and harms prior to starting ESA therapy. For pediatric patients on ESAs, the target Hb recommended was 11–12 g/dl [20]. Finally, the RA guidelines utilized systemic literature searches and a review of related guidelines including NICE, KDOQI, and KDIGO. Oral iron was recommended for all anemic patients not on hemodialysis, with reservation of IV iron for patients with severe iron deficiency or who are on hemodialysis. For patients on IV

iron therapy, a high-dose/low-frequency regimen was recommended. ESAs were recommended for patients who would benefit from them in terms of QoL, functioning, and to avoid blood transfusions. The target Hb for patients on ESAs was 10–12 g/dl for children >2 years and adults, and 9.5–11.5 g/dl for children <2 years [21]. The most recent specific recommendations for anemia treatment from KDIGO and the RA are presented in Table 64.3, including

Table 64.3 Anemia monitoring and treatment clinical practice recommendations from KDIGO and RA.

	KDIGO		RA	
Parameter	**Iron**	**ESAs**	**Iron**	**ESAs**
Frequency of monitoring	Hb monitored every 3 months in CKD stages 3–5 (nondialysis) and in PD patients; monthly in HD patients	Hb monitored monthly during initiation phase and every 3 months during maintenance phase for nondialysis patients, monthly for dialysis patients; TSAT and ferritin monitored every 3 months during ESA therapy or more frequently when initiating or increasing ESA dose, in case of blood loss, after course of IV iron	Hb monitored annually in CKD stage 3, twice/year in CKD stages 4–5; iron stores monitored every 1–3 months in patients on IV iron; ferritin >800 μg/l with normal CRP may suggest iron overload	Hb monitored every 2–4 weeks in correction phase and every 1–3 months for maintenance phase
Goals	TSAT >20%; ferritin >100 ng/ml; address correctable causes of anemia (including iron deficiency and inflammation) prior to starting ESA	Hb goals: 11–12 g/dl in all pediatric patients	%HRC < 6%, CHr > 29 pg/ferritin, TSAT > 20%, ferritin > 100 ng/ml; correct iron-deficiency prior to starting ESA	Hb goals: <2 years old 9.5–11.5 g/dl ≥2 years old 10–12 g/dl
Dosing	For pediatric patients, PO iron recommended in non-HD patients, IV iron recommended for HD patients	Determined by initial Hb concentration, body weight, and clinical scenario	High dose, low frequency recommended for IV iron	Determined by initial Hb level, target Hb level, and rate of increase in Hb
Contraindications	Active systemic infections	Provider to balance benefit of reducing blood transfusions with risk of stroke, loss of vascular access, hypertension; use caution with active or history of malignancy, history of stroke		Severe hypertension; use caution prescribing ESAs for history of stroke or malignancy
Route of administration	Determined by severity of iron deficiency, availability of venous access, response to prior PO iron, side effects, patient compliance, cost. For nondialysis patients, PO iron preferred; use IV iron for HD patients	Determined by treatment setting; SC ESA recommended for nondialysis and peritoneal dialysis patients; IV ESA recommended for HD patients	Determined by clinical condition and treatment setting; PO iron preferred in non-HD patients; IV iron reserved for severe iron deficiency and HD patients	Determined by clinical condition and treatment setting; SC ESA preferred in non-HD patients; IV ESA preferred in HD patients
Frequency		Determined by CKD stage, treatment setting, efficacy, patient tolerance, and preference, type of ESA	Low frequency recommended for IV iron	Determined by CKD stage, treatment setting, class of ESA; less frequent administrations with long-acting ESAs preferred in non-HD patients

IV, intravenous; HD, hemodialysis; PD, peritoneal dialysis; PO, by mouth; SC, subcutaneous; TSAT, transferrin saturation.

recommended frequency of Hb iron store monitoring and routes of therapy.

Prognosis

Risk of Death

Studies in adults with ESRD have consistently demonstrated reduced risk of death and hospitalization when Hb levels are ≥11 g/dl, but the upper limit of target Hb is more controversial [28–30]. In 2004, the Cochrane Renal Group performed a meta-analysis of RCTs to evaluate the harms and benefits of different Hb targets in adult patients with CKD; they found lower risk of all-cause mortality with Hb of <12 versus >13 g/dl (relative risk [RR] 0.84, 95% confidence interval [CI] 0.71–1.00) [31]. This Cochrane review was updated in August 2006, included 22 RCTs, and had similar results [32]. The authors indicated the need for more adequately powered and better-designed trials. In November 2006, two additional RCTs investigating optimal target Hb were published [33, 34]. Drueke et al. randomly assigned 603 patients with estimated GFRs of 15–35 mL/min/1.73 m^2 and Hb of 11–12.5 g/dl to a target Hb of 13–15 g/dl versus Hb of 10.5–11.5 g/dl. Over 3 years, they found that early complete correction of anemia did not reduce risk of cardiovascular events in patients with CKD.

In children, there is less systematic evidence concerning the risks of anemia in CKD, and clinical practice guidelines and recommendations for anemia management are often primarily based on adult studies. However, lower Hb levels in children on dialysis have been strongly and independently associated with increased risk for mortality in observational studies of children on dialysis. In the pediatric population, Warady and Ho demonstrated an association between baseline hematocrit of <33% at 30 days postinitiation of dialysis and increased risk of prolonged hospitalization and death in incident ESRD patients less than 18 years of age from the NAPRTCS registry [35]. Using data from the US Centers for Medicare and Medicaid Services' ESRD Clinical Performance Measures Project (October–December 1999 and 2000) linked with the US Renal Data System hospitalization and mortality records, Amaral et al. assessed whether achieving target Hb levels of >11 g/dl in 677 adolescents on HD was associated with decreased risk of death. In this retrospective cohort study, 11.7% with Hb of <11 g/dl at study entry died compared to 5% of those with initial Hb of ≥11 g/dl ($P < 0.0001$) [36]. In the multivariable analysis, Hb of ≥11 g/dl was associated with decreased risk of death (hazard ratio [HR] 0.38, 95% CI 0.20–0.72). When Hb was recategorized into Hb levels of <10, ≥10 to <11, ≥11 to ≤12, and >12 g/dl, risk of mortality declined as Hb level increased. At Hb levels of 11 to ≤12 g/dl versus <10 g/dl, mortality risk decreased by 70% (HR 0.30, 95% CI 0.19–0.74). Risk of mortality was similar for Hb levels of 11–12 g/dl and >12 g/dl. Hb of >12 g/dl remained strongly associated with decreased risk of mortality (HR 0.20, 95% CI 0.07–0.56) [36]. This observational study's findings were consistent with literature on adults, showing decreased mortality in ESRD patients who meet Hb targets of >11 g/dl for adolescents on HD.

In 2013 Borzych-Duzalka et al. found that anemia, defined as Hb <10 g/dl in children aged 2 and over and <9.5 g/dl in those younger than 24 months according to the NICE guideline, was associated with increased risk for mortality and that the risk for death on dialysis was independently inversely associated with Hb [5]. Examining the US pediatric peritoneal dialysis population, Dahlinghaus et al. found that Hb ≥11 g/dl was associated with lower hospitalization risk but not with decrease in mortality risk. Hb levels ≥12 g/dl were not associated with decreased risk of hospitalization compared to levels of 11–12 g/dl [37]. Published in 2017, a 40-year retrospective cohort study of children on renal replacement therapy (RRT) by Adamczuk et al. found that mean Hb level was higher among survivors compared to nonsurvivors and was a significant prognostic indicator. The survivors were more frequently treated with ESAs, suggesting that treatment of anemia is important in decreasing mortality in patients on RRT [38].

There are currently no pediatric clinical trial data to support a Hb target above the current target of 11 g/dl. Future studies in the form of RCTs are needed to assess optimal Hb levels for all adolescents with CKD and ESRD. The KDIGO Anemia Workgroup stated that pediatric Hb targets are based on adult studies due to limited pediatric evidence, but recognized that a Hb less than 9.9 g/dl has been associated with increased risk of mortality and left ventricular hypertrophy (LVH), and recommended a Hb target of 11–12 g/dl for pediatric patients [20]. The RA recommendations are slightly different, with the lower limit of acceptable Hb being 9.5 g/dl for children younger than 2 years old and 10 g/dl for children 2 years or older. The recommended upper limit of Hb also varies by age, with 11.5 g/dl recommended for children less than 2 years old and 12 g/dl for children 2 years or older [21]. However, recently in a retrospective cohort study, Rheault et al. found that a Hb above 12 g/dl was not associated with increased risk of arrhythmia, cardiac arrest, or cerebrovascular accident (compared to Hb of <10 or 10–12 g/dl). Compared to the groups with lower Hb levels, the group of patients with Hb >12 g/dl had a lower hazard ratio of all-cause mortality and rate of all-cause hospitalizations [39]. Given this information, an upper limit of 12 g/dl is reasonable, but further information from RCTs would be useful to find the optimal Hb target for pediatric CKD patients.

Risk of CKD Progression

A number of studies have suggested that anemia may accelerate decline in kidney function through decreased oxygen delivery to tissues, accelerating ischemic changes and increasing endothelial injury. It has been proposed that hypoxia of renal tubule cells may stimulate extracellular matrix production and release of profibrotic cytokines, thereby accelerating kidney disease progression. Several clinical trials in adults have suggested that EPO treatment and correction of anemia may ameliorate the progression of CKD [40]. In 2007 a prospective cohort study by Furth et al. demonstrated an association between anemia and accelerated progression of CKD in 23 adolescents enrolled in the CKiD study, independent of GFR [41]. However, a subsequent analysis performed in 398 CKiD subjects found that in multivariable analysis, glomerular disease, proteinuria, hypertension but not anemia were associated with accelerated GFR decline [42]. More evidence is needed to support the theory that treatment of anemia slows progression of CKD.

Anemia, Quality of Life, and Cognitive Function

Anemia of CKD has long been associated with a negative impact on QoL. Several studies have revealed that the treatment of anemia in CKD improves QoL in adults with CKD and ESRD [43–46]. One single, blinded, placebo-controlled crossover study in 11 children with ESRD showed improvement in exercise tolerance, physical performance and health, and better school attendance with correction of anemia [47]. Decreasing anemia using rHuEPO in a multicenter pediatric study of 44 children with chronic kidney failure undergoing HD also showed marked improvement in QoL, particularly in activity levels [48]. Another cross-sectional study, by Gerson et al., examined the link between QoL and anemia in a cross-section of 116 adolescents with renal insufficiency on dialysis and post kidney transplantation. The authors found that anemia was associated with poorer QoL [49]. By caregiver assessment, adolescents with kidney disease and anemia (defined as hematocrit of <36%) were less satisfied with their health, participated in fewer activities at school and with friends, and were less physically active. These findings mirrored findings of studies examining the correlation between anemia and QoL in adults with CKD.

Regarding cognitive function, one multicenter trial of subcutaneous erythropoietin showed increased Wechsler intelligence scores in 11 children with chronic kidney failure who were treated for anemia over a 12-month period [50]. In the adult literature, several studies have demonstrated significant improvement in electrophysiological markers of cognitive function with improvement of anemia in patients with chronic and ESRD [34, 51–55]. Further study in the pediatric population is needed.

Cardiac Function

In adults, observational evidence has shown an association between anemia and LVH [56, 57]. Optimal Hb levels to prevent LVH and cardiovascular events are not clear based on the current body of evidence [58, 59]; some studies have suggested increased risk at higher Hb levels. Volkova and Arab performed an evidence-based literature review of the relationship between Hb and/or hematocrit and mortality in dialysis patients. They included five trials and 13 observational studies. They showed either no effect or a benefit of Hb level target higher than 11 g/dl in a general dialysis population and increased mortality associated with greater Hb concentration in cardiac patients [60]. They concluded that "most observational studies supported the increased mortality associated with Hb levels less than the reference range of Hb 11–12 g/dl (110–120 g/l)," and that "evidence of risks or benefits of Hb levels greater than 11–12 g/dl (110–120 g/l) is variable" [60].

Evidence supporting cardiac benefits associated with the treatment of anemia in children with CKD is more limited, although cardiac-related events and LV remodeling have been reported in pediatric CKD and ESRD populations, including children after kidney transplantation [61–63]. According to the KDOQI reviews, a single blinded crossover trial of 11 children aged 2–12 years on dialysis demonstrated an improvement in cardiac index by 6 months and significant reduction in LV mass by 12 months in those treated with ESAs [64]. Two additional observational studies of patients with severe LVH demonstrated that children with lower Hb levels had more severe LVH and lower LV compliance [65, 66]. A 2-year longitudinal study of children with CKD showed that initial lower Hb level was associated with increased incident LVH and independently predicted an interval increase in LV mass index [67]. In 478 children in the CKiD cohort, anemia was found to be an independent predictor of LVH even when controlling for systolic and diastolic blood pressure [68].

Treatment

With the isolation of the human *EPO* gene in 1985 and the commercial production of rHuEPO soon after, ESA became a critical component of the treatment of the

anemia of CKD in patients of every age. The United States Food and Drug Administration approved epogen for the treatment of the anemia of CKD in 1989, and its widespread use virtually eliminated the dependence on red blood cell transfusions that previously plagued patients with kidney disease [69]. There are several types of short- and long-acting ESAs available worldwide. Among rHuEPO types, epoetin alfa is commonly used in the US and epoetin beta used in Europe. Darbepoetin alfa is an EPO analogue with two additional sialic-acid-containing carbohydrates resulting in extended *in vivo* biological activity [70, 71]. Epoetins are short-acting and are generally dosed one to three times per week. Darbopoetin is long-acting and can be dosed weekly or every 2 weeks. A more recently developed EPO analogue is the continuous EPO receptor activator (CERA), which integrates a large methoxy polyethylene glycol polymer chain into the EPO molecule, resulting in higher molecular weight and longer half-life, allowing for extended monthly doses [69].

Table 64.4 summarizes pediatric studies examining the safety and efficacy of ESAs in anemia of CKD and ESRD. In children who require ESA treatment, there are several types of both long- and short-acting ESAs, and new formulations continue to emerge; this requires ongoing attention to the relative safety and efficacy in children overall and compared to adults. In a study published in 2006 Warady et al. randomized 124 children on stable rHuEPO to either continue on rHuEPO or convert to darbepoetin. The authors detected no statistically significant difference in mean change in Hb between the two groups, and since that time darbepoetin has been frequently utilized for the treatment of anemia in children [72]. In 2018, Warady et al. reported that Hb response was equivalent when darbepoetin was dosed either weekly or every other week, confirming the efficacy of a less frequent and potentially more patient-friendly treatment regimen [74]. CERA agents are also emerging for the treatment of anemia of CKD in children. In a study of 16 children on peritoneal dialysis (PD) previously treated with twice-weekly rHuEPO, CERA effectively and safely maintained Hb > 11 g/dl when dosed once or twice per month [73]. Subsequently in a cohort of 64 children on HD aged 5–17 years of age, maintained on stable doses of epoetin alfa/beta or darbepoetin and converted to a CERA dosed once every 4 weeks, Hb levels were effectively maintained within the target range of 10–12 g/dl after conversion with no additions to known safety profile [75].

A summary of the clinical practice recommendations published by the KDIGO [20] UK-based RA [21] and pediatric workgroup of the KDOQI [24] groups is included in Table 64.5. There is little available evidence in the form of RCTs to assess differential efficacy between ESAs in children or adults with CKD (Tables 64.4 and 64.5). Thus, because there are some data in pediatrics supporting the adult findings and no data supporting differing recommendations, the current practice recommendations have often been adapted from the evidence-based recommendations in adults. Although there are several potential benefits associated with ESA use, clinical trials in adults have raised concern about the safety of using escalating ESA doses to normalize Hb. The Correction of Hemoglobin and Outcomes in Renal Insufficiency (CHOIR) trial performed in adults with nondialysis CKD found that using epoetin alfa to target higher Hb was associated with increased risk for death, myocardial infarctionI, stroke, or congestive heart failure [34]. In the 2009 TREAT trial, adults with CKD receiving darbepoetin to achieve Hb > 13 g/dl demonstrated increased risk for stroke [77]. Consequently, in 2001 the US FDA changed the ESA product labeling to recommend the lowest possible ESA dose to prevent red blood cell transfusions, and that the dose should be reduced or interrupted for Hb > 11 g/dl [78]. However, this label change did not distinguish between pediatric and adult CKD patients. Although no such randomized controlled trials have been conducted in pediatric patients, observational data has demonstrated that higher ESA doses are associated with increased risk for mortality in children on chronic dialysis [5, 37, 76] (Table 64.6). No clinical trials in adults have identified whether the higher Hb level or the higher ESA dose specifically contributes to increased risk for adverse outcomes, but a prospective study in adults on dialysis found that those with naturally occurring higher Hb levels >12 g/dl were not at increased risk for mortality [79, 80]. In a similar study conducted in children on dialysis, Rheault et al. demonstrated that Hb level >12 g/dl was not associated with increased risk for either mortality or hospitalization [39].

Hb Monitoring

In general, it is recommended that Hb be monitored monthly, with closer monitoring at 1–2-week intervals when initiating and/or making significant changes to the ESA dose. All pediatric providers are advised to carefully

Table 64.4 Pediatric studies examining safety and efficacy of erythropoiesis stimulating agents (ESAs) in anemia of CKD and ESRD for pediatric patients.

Reference[a]	Type	Population	Intervention	Sample Size	Follow-up	Outcome
Sinai-Trieman et al. [102]	Prospective cohort	Transfusion-dependent PD pts	SC rHuEpo: initial dose 150 units/kg thrice weekly	5 children, 12–18 years old	8 months	All patients had increase in Hb and reticulocyte count and none required further transfusions
Offner et al. [103]	Prospective cohort	CAPD and CCPD	300 units/kg IV rHuEpo once weekly	14 children, 6–22 years old	1 year	Mean HCT and retic. count increased within 1 month Dosage was decreased after 3 months to keep HCT > 30%.
Campos and Garin [104]	Prospective cohort	HD	IV rHuEpo: thrice weekly	11 children, 6 months to 20 years old	9 months	HCT rose after 8 weeks from 20.3% (mean) to 31.7%
Reddingius et al. [105]	Prospective cohort	CAPD	IP rHuEpo: initial dose 300 units/kg/week	16 children	8 months	Mean Hb increased No patients required blood transfusions after initiation of therapy
Montini et al. [106]	Prospective cohort	PD	SC rHuEPO: initial dose 25 IU/kg twice weekly	24 children	24 weeks	6 patients censored, 18 remaining patients all had increased Hb
Brandt et al. [107]	Prospective randomized study	CKD, PD, and HD patients	IV or SC rHuEPO: low-dose (150 units/kg/week) vs. high-dose (450 units/kg/week) divided thrice weekly	44 children <21 years old: 25 pre-dialysis, 10 PD, 9 HD	12 weeks or until "target" Hb was attained	82% patients reached "target" Hb by 8 weeks; 95% patients in high-dose group reached target vs. 66% in low-dose group HD patients required higher doses
De Palo et al. [108]	Prospective cohort	HD patients previously on epoietin alfa	Darbepoetin 1.59 ± 1.19 μg/kg/week	7 children	6 months	Increase of >1 g/dl Hb in first month By second month, dose reduced Mean Hb at 3 months 11.8 ± 1.4 g/dl and mean darbepoietin dose 0.51 ± 0.51 μg/kg/week
Geary et al. [109]	Prospective cohort	CKD with GFR <30 ml/min/1.73 m^2, HD and PD patients	Darbepoetin alfa 0.45 μg/kg/week	23 children	28 weeks	73% of patients were receiving darbepoetin less than once weekly by 12 weeks and 87% by 28 weeks to maintain Hb 10–12.5 g/day
Durkan et al. [110]	Prospective cohort	Infants with CKD <8 kg	Darbepoetin 0.5 μg/kg/week	6 infants	20 weeks	For 3 patients mean darbepoietin dose was decreased and dosing interval increased to 3–4 weeks 3 patients required increase in weekly dose

Warady et al. [72]	Randomized open-label, noninferiority study	CKD with GFR <30 ml/min/1.73m^2, HD and PD patients who were receiving stable rHuEpo treatment	Subjects randomized (1 : 2) to either continue rHuEpo or convert to darbepoetin alfa	124 children, aged 1–18 years, receiving stable rHuEpo	28 weeks	Adjusted mean change in Hb between baseline and evaluation period for rHuEpo vs. darbepoetin groups was not statistically different Darbopoetin was found to be noninferior to rHuEpo
Cano et al. [73]	Prospective cohort	PD patients previously stable (Hb > 10 g/dl) on epoetin alfa with ferritin > 100 μg/l and TSAT > 20%	Methoxy polyethylene glycol epoetin beta (Mircera®) administered SC, starting dose 0.5 μg/kg q 2 week, dose adjusted to achieve Hb ≥ 11 g/dl	16 patiens aged 2–14 years	6 months	Mircera effectively maintained Hb levels when administered once or twice monthly Doses required to reach target Hb were higher than published experiences in adults
Schaefer et al. [111]	Prospective cohort	Children ≤16 years on PD, HD, or with CKD (eGFR < 60 ml/min/1.73 m^2) and receiving darbepoetin alfa Withdrawal for transplant or cessation of darbepoetin alfa	Darbepoetin alfa treatment regimen altered by treating physicians	319 patients who received at least one dose of darbepoetin alfa	Up to 2 years	No new safety signals associated with darbepoetin alfa use were reported Weight-adjusted dose to maintain Hb was consistently higher in younger than older children
Warady et al. [74]	Double-blind, randomized controlled trial	ESA-naïve, anemic children with CKD aged 1–18 years, including stage 3–5 CKD, HD, and PD TSAT ≥ 20% and Hb < 10 g/dl at initiation	Initial dose of darbepoetin alfa of 0.45 μg/kg week vs. 0.75 μg/kg every other week Administered SC in CKD and PD, IV in HD Subsequent doses were titrated to achieve target Hb 10–12 g/dl	114 patients	25 weeks	Correction of Hb to ≥ 10 g/dl occurred in >80% of subjects in either the weekly or q 2-week dosing groups
Fischbach et al. [75]	Phase II open-label trial, multiple-dose study	HD 5–17 years with Hb 10–12 g/dl on epoetin or darbepoetin	IV CERA dosed every 4 weeks at two starting doses and titrated: −4 μg for each weekly dose of 250 IU epoetin alfa/beta or 1.1 μg darbepoetin OR −4 μg for each weekly dose of 125 IU epoetin alfa/beta or 0.55 μg darbepoetin	64 patients	20 weeks	Using CERA conversion factor of 4 μg for each weekly dose of 125 IU epoetin alfa/beta or 0.55 μg darbepoetin, 81% of patients maintained Hb in 10–12 g/dl range and 75% maintained Hb within 1.0 g/dl of baseline

HCT, hematocrit; IP, intraperitoneal; IV, intravenous; rHuEpo, recombinant human erythropoietin; SC, subcutaneous.

Table 64.5 Erythropoiesis stimulating agents

Intervention	Systematic review	Evidence rating[a]	Comment on rating	Recommendations[b]	Comment on recommendation
Initiation of ESA	No RCTs examining effects of ESA on hard outcomes (KDIGO)	Very low (KDIGO) Moderate (RA)	Upper and lower Hb targets are opinion based (KDIGO)	Hb concentration at which ESA is initiated should weigh potential benefits and harms (KDIGO) Should be offered to patients likely to benefit and to avoid RBC transfusion (RA)	No specific Hb threshold for ESA initiation identified, but limited data that children with Hb < 9.9 g/dl are at increased risk for adverse outcomes
Choice of ESA	No evidence that any given ESA brand is superior to another with regard to patient outcomes (KDIGO)	Very low (KDIGO) Moderate (RA)	In studies in adults and children, all available products are efficacious when administered according to manufacturer's recommendations (RA)	Choose ESA based on balance of safety, cost, and availability, using only agents approved by independent regulatory agency (KDIGO) Decision should be based on local availability (RA)	
Target Hb concentration on ESA	Observational data only that lower Hb associated with morbidity (KDIGO)	Very low (KDIGO) Moderate (RA)	Caution in targeting higher Hb based on data extrapolated from adult trials only (KDIGO)	Keep Hb in range of 11–12 g/dl (KDIGO) Keep Hb 10–12 g/dl in children 2 and older, 9.5–11.5 in <2 year-olds (RA)	Lower Hb target in <2 year-olds based on lower normal range in age group
ESA dose – initiation	No primarily pediatric studies	Very low (KDIGO) Moderate (RA)	Initial dosing information determined from adult studies	Determine initial ESA dose based on Hb, weight, and clinical circumstances (KDIGO) Initial dose baseline on Hb, Hb goal (RA)	EPO starting dose 20–50 IU/kg 3 times/week, DA 0.45 μg/kg/week. – IV or SC (KDIGO) Goal of initial therapy to raise Hb by 1–2 g/dl/month, route determined by patient and ESA factors (RA)
ESA dose – maintenance	No primarily pediatric studies	1) Moderate 2) Low (KDIGO) 3) Moderate 4) Ungraded (RA)	Extrapolated from adult studies	5) Adjust ESA dose based on Hb and rate of change 6) Decrease ESA dose done rather than withhold (KDIGO) 7) Adjust ESA dose for Hb < 10.5 or >11.5 in patiens ≥2 years 8) For <2 year-olds, adjust before level is outside range to avoid fluctuation (RA)	EPO dose can be increased q 4 weeks by weekly dose of 3 × 20 IU/kg If Hb is increasing and approaching 11.5 g/dl, dose should be reduced by ~25% (KDIGO) Children may require higher absolute ESA doses compared to adults

			KDOQI 2006		
rHuEpo once weekly vs. twice weekly in dialysis patients	Cochrane Review, 2005 : 11 RCT of 719 patients	Moderate	The duration and frequency of the studies differed and there were small numbers of participants	There is insufficient evidence to recommend one regimen of frequency of rHuEpo dosing	There was no significant difference between once weekly vs. twice weekly dosing Large RCTs with longer duration and greater numbers of subjects are needed
ESA vs. placebo in HD and PD patients	12 RCT, including one pediatric[c]	Moderate	The duration, dosing frequency, and outcomes of the studies differed	The current body of evidence is insufficient to recommend one ESA agent or dosing pattern and potential benefits and risk must be weighed for each patient	ESAs are effective for reducing the requirement for blood transfusions in ESRD patients on ESA therapy may have improved quality of life Use of ESAs may be associated with increased blood pressure and lower *Kt/V* It is difficult to assess the separate impact of ESAs from improved Hb and HCT
rHuEpo in predialysis patients vs. no treatment or placebo	Cochrane Review, 2005, 15 trials, including 461 patients	High for reduction in anemia Moderate for improved quality of life and exercise capacity Low for impact on progression of CKD	rHuEpo was shown to correct anemia and reduce need for blood transfusion Quality of life and exercise capacity also improved in the treatment group	rHuEpo may be used to reduce anemia for people with chronic kidney disease who do not yet require dialysis	Further study is needed to assess whether rHuEpo use can slow the progression of CKD
Epoetin vs. darbopoetin (short-acting vs. long-acting ESAs)	One RCT of 522 HD and PD patients One crossover study of 524 patients with CKD	Low	There is only one RCT currently published which compares darbopoetin and epoetin in the form of RCT. This study shows no statistically significant difference between the two types of ESA. For the crossover study, there was no control group.	There is insufficient evidence to recommend one ESA agent's use over another's	Darbopoetin alfa was found to maintain Hb as effectively as rHuEpo but with a reduced dose frequency for up to 52 weeks in both studies

evaluate the individual patient's response to ESA treatment and to adjust dosing regimens and frequency of monitoring accordingly.

ESA Dosing

Initial doses and dose adjustments can vary widely in pediatrics. The starting dose of epoetin alfa or beta is generally 20–50 IU/kg three times weekly given either intravenously or subcutaneously, and for darbepoetin alfa is 0.45 μg/kg weekly or 0.75 μg/kg every other week regardless of administration route [20]. ESA dose adjustments after initiation of treatment should generally be done after the first 4 weeks of therapy and no more often than every 2 weeks [20]. When a decrease in Hb is necessary, ESA dose should be decreased but ideally not discontinued, as the pattern of holding and reinitiating therapy may lead to cycling around the desired target Hb range [81]. It should be noted that the dosing requirements for ESA can differ substantially between children and adults. Observational data from the NAPRTCS registry have shown that younger children require higher weight-based rHuEPO doses than adults, ranging from 275–350 U/kg/week for infants to 200–250 U/kg/week for older children [82]. Children and adolescents on HD also require higher absolute doses than adults to maintain target Hb despite lower body weight [4, 83]. Absolute rHuEPO dose of 1000 U given IV to both adults and children can increase Hb by 0.4 g/dl, suggesting that dosing schemes based on Hb deficit rather than on weight may be useful [84]. Differential dose requirements have been noted for CERA agents as well, with children on PD and HD noted to require higher doses to maintain target Hb compared to doses derived from experience with adults receiving CERA [73, 75].

ESA hyporesponsiveness is defined by KDIGO as either no increase in Hb from baseline after the first month of appropriate weight-based dosing or as the requirement for two increases in ESA dose by up to 50% beyond the prior ESA dose at which Hb was previously maintained within goal range [20]. In the IPPN registry, ESA treatment resistance and escalated ESA dosing were associated with inflammation, fluid retention, and hyperparathyroidism [5].

Red Blood Cell Transfusions

Children with treatment-resistant anemia are more likely to require red blood cell transfusions, which are associated with increased risk for development of human leukocyte antigen (HLA) antibodies. In adults, leukoreduction of blood products is an ineffective means to decrease HLA sensitization, and red cell transfusions lead to clinically significant increases in HLA antibody strength and breadth [85, 86]. These antibodies serve as a barrier to future transplantation and may adversely affect graft outcomes [85, 86]. More studies are needed to define the risks associated with red cell transfusion in children with regard to HLA sensitization and graft outcomes.

Monitoring Iron Stores

Iron availability is a rate-limiting step in the maturation of red blood cells, and adequate iron supply is necessary for effective ESA therapy. Assessment of iron stores remains a clinical challenge in patients with CKD, as is distinguishing inflammation-associated impaired iron trafficking from absolute iron deficiency. Transferrin saturation (TSAT) and ferritin are commonly utilized biomarkers of iron available for erythropoiesis and stored iron, respectively, but both have limited sensitivity and specificity to predict bone marrow iron stores and erythropoietic response to iron supplementation [20]. In a cohort of children with nondialysis CKD, ferritin levels ≥100 ng/ml were associated with lower Hb compared to patients with lower serum ferritin, and a TSAT >20% was associated with only a modest increase in Hb [87]. Data from the IPPN registry demonstrates an inverse relationship between Hb and ferritin [5]. In a retrospective cohort study conducted in 45 children on chronic dialysis, reticulocyte Hb equivalent, a measure which reflects iron availability for incorporation into reticulocytes over the preceding 2–4 days, was positively associated with Hb in contrast to ferritin, and more strongly correlated with Hb than TSAT [88]. Unlike ferritin, reticulocyte Hb equivalent is not an acute phase reactant, but is measured by flow cytometry, which limits its availability in clinical practice [88].

Iron Supplementation

Iron may be supplemented enterally or IV. While enteral iron supplementation (dosing range 3–6 mg/kg/day of elemental iron) is relatively inexpensive, highly available, generally safe, and efficacious in many children with CKD, those with more advanced disease or especially those on hemodialysis often benefit from iron preparations administered IV due to poor enteral tolerance or absorption. Table 64.7 summarizes recommendations for iron supplementation in children with CKD. Currently available IV forms of iron supplementation include iron dextran, sodium ferric gluconate, and iron sucrose. There are currently no adequately powered trials comparing IV agents

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 64.7 Evidence-based recommendations for iron supplements in CKD

Intervention	Systematic review	Evidence rating[a]	Comment on rating	Recommendation[b]	Comment on recommendation
Initiation of iron supplements		Very low (KDIGO)	Limited studies assessing association of achievement of iron targets with clinical outcomes	For anemic children not on iron or ESA, give oral iron (or IV in HD patients) when TSAT is ≤20% and ferritin is ≤100 ng/ml (KDIGO)	
Definition of iron replete status		Very low (KDIGO) Ungraded (RA)	Limited studies assessing association of achievement of iron targets with clinical outcomes	In children on ESA, give oral iron (or IV in HD patients) to maintain TSAT >20% and ferritin >100 ng/ml (KDIGO) Define iron repletion as % hypochromic red blood cells <6%, reticulocyte Hgb count >29 pg, ferritin >100 ng/ml, TSAT >20% (RA)	Patients should be iron replete to maintain target Hb whether on ESA or not (RA)
			KDOQI: IV vs. PO iron		
IV iron dextran vs. oral iron[c]	Three RCTs: 2 HD patiens, 1 ND patient (two RCTs included placebo arm, one RCT included PD)	Moderately high to high for HD patients	Some inconsistencies for studies which examined ND-CKD patients	The preferred route of iron administration is IV in patients with HD-CKD	Final mean Hb ranged higher 0.9–4.5 g/dl (90–450 g/dl) in IV arms vs. PO for HD patients
IV iron sucrose vs. oral iron[c]	Three RCTs, ND patients	Moderately high for ND and PD patients	Studies in HD patients were reasonably consistent No RCTs with PD patients only	The route of iron administration may be either IV or PO for ND-CKD and PD-CKD patients	Mean final ESA dose was lower in IV arms in studies with HD patients
IV iron sodium gluconate vs. oral iron[d]	One RCT, HD patients				No significant difference in ESA dosing was found in nondialysis patients on IV vs. PO iron

[a] Evidence rating based on study design, study quality, consistency, and directness of results.
[b] Recommendation based on assessment of risks and benefits, quality of evidence, translation of evidence into practice.
[c] Oral iron = ferrous sulfate or iron polysaccharide.
[d] Nondialysis (ND), hemodialysis (HD), peritoneal dialysis (PD).

for adults or children [24]. Several studies comparing IV versus oral iron in adult HD and CKD patients demonstrated superior efficacy of IV forms of iron in repleting iron stores and minimizing ESA dosing [81, 89, 90]. RCT evidence comparing IV versus oral iron in adult CKD, including nondialysis, HD, and peritoneal dialysis patients, is presented in Table 64.7. In 2005, Gillespie and Wolf published a meta-analysis that combined clinical data on IV iron use in children on HD [91]. They included nine studies that included eight cohort studies and one prospective trial with historical controls, and they showed increased Hb, ferritin, and transferrin saturation levels and reduced use of ESAs with IV iron use. In 2004, Warady et al. performed an RCT to examine the preferential route of iron administration for children. The authors prospectively randomized 35 iron-replete children <20 years old with ESRD on HD to receive either IV iron dextran with each dialysis session ($n = 18$) or oral iron daily ($n = 17$) for up to 16 weeks. In both groups the Hb was stable, but the IV iron group experienced a significant increase in serum ferritin and the oral iron group did not. There was no statistically significant difference in ESA dosing detected between the two groups [92].

Concerns about potential adverse effects of IV iron supplementation include increased oxidative stress, iron overload, adverse reactions including anaphylaxis, and increased risk when administered in the context of active infections. There have been no pediatric studies focused on the long-term effects of IV iron supplementation in patients on chronic dialysis. The DRIVE trial, conducted in adults on dialysis, demonstrated that IV ferric gluconate was effective at raising Hb and decreasing ESA dose requirements in patients with ferritin levels 500–1200 ng/ml and TSATs ≤25%, dispelling the widely held belief that patients with ferritin levels in this range were unlikely to benefit from IV iron [93]. However, further study is needed to determine whether IV iron supplementation is effective and safe in children with higher ferritin levels. KDIGO recommends avoidance of IV iron in patients with active systemic infections [20]. Ishida et al. showed, using observational data, that adults on HD who received IV iron within 14 days of hospitalization for a bacterial infection had no increased risk for 30-day or 1-year mortality or readmission or death within 30 days, but no comparable studies have been conducted in children [94]. Goldstein et al. conducted a RCT in 145 children with CKD to compare the safety and efficacy of varying doses of iron sucrose. They showed that a 0.5 mg/kg dose was noninferior to higher dosing regimens (1 and 2 mg/kg) in terms of reaching a composite endpoint of Hb in range of 10.5–14 g/dl, TSAT 20–50%, and a stable ESA dose, supporting the practice of utilizing the lowest effective dose of IV iron in children [95].

There are novel, ESA-independent CKD-related anemia therapies in varying stages of development. Small-molecule hypoxia-inducible factor (HIF) stabilizers/prolyl hydroxylase domain inhibitors modulate HIF-controlled gene products and are capable of inducing endogenous erythropoietin production even in the setting of decreased renal oxygen consumption and have been shown in adult trials to increase Hb and decrease hepcidin, but trials have not been conducted in children [96–98]. Human antihepcidin antibodies have been successfully developed and applied in animal models, but await large-scale trials in humans [99]. Additional iron agents are also under investigation. Ferric pyrophosphate citrate is a novel water-soluble complex iron salt that can be administered via dialysate. It was approved by the FDA in 2015 and has shown good efficacy and safety in adults on hemodialysis, providing smaller amounts of iron over hours which may serve to decrease oxidative stress [100]. Ferric citrate is a novel oral phosphate binder that also supplies elemental iron and has been approved for use in adults [101]. Neither of these novel iron agents have had their safety and efficacy systematically assessed in children as yet.

Conclusions

In summary, anemia is a prevalent and serious problem among children with CKD. At all stages of CKD, low Hb has been associated with increased risk of hospitalization and death, and other comorbidities including decreased QoL. Guidelines for clinical management of anemia in children with CKD are primarily based on adult data. Although the majority of existing pediatric studies do support the current adult guidelines, more pediatric-based research in the form of multicentered RCTs is needed to establish valid pediatric-specific treatment goals. At this time, for children with CKD the treatment goal for anemia management should be a target Hb of ≥11 g/dl and <12 g/dl, using ESAs and iron as necessary adjuncts to achieve this target. Table 64.8 provides a summary of the current treatment guidelines and the certainty and strength of the current evidence.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 64.8 Treatments for anemia in children with CKD

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Erythropoetic-stimulating agents (short acting) (epoetin alfa, epoetin beta)	Initiation is recommended when Hb ≤10 mg/dl and iron deficiency has been corrected. SC administration is recommended for nondialysis and peritoneal dialysis patients. IV administration is recommended for HD patients. Hb target of 10–12 mg/dl is recommended. Short-acting ESAs are typically given multiple times per week [20].	Moderate	Strong
Erythropoetic-stimulating agents (long acting) (darbepoetin alfa)	Recommendations are the same as for short-acting ESAs, although darbepoietin can be given once every 2 weeks or once monthly [72].	Moderate	Strong
Erythropoetic-stimulating agents (EPO receptor activator – CERA, long acting)	Patients on stable doses of epoetin alfa/beta or darbepoietin may be safely converted to once monthly doses of CERA with no changes to the known safety profile [75]	Moderate	Moderate
rHuEPO vs. darbepoetin	Darbepoietin is considered more patient-friendly than rHuEPO given its less frequent dosing and similar effectiveness [74]	Moderate	Strong
rHuEPO vs. CERA	CERA may be equivalent to rHuEPO in terms of effectiveness and safety profile [75]	Moderate	Moderate
Use of Iron	For anemic children not on iron or ESA, give oral iron (or IV in HD patients) when TSAT is ≤20% and ferritin is ≤100 ng/ml [20]	Low	Strong
Route of iron (use of IV iron vs. PO iron)	PO or IV iron may be used for ND-CKD and PD-CKD patients The preferred route of iron administration is IV for HD-CKD patients [20]	Moderate	Strong

GRADE assessment of the certainty of the evidence(9): High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Peritoneal Dialysis in Children

Nathan T. Beins and Bradley A Warady

Division of Pediatric Nephrology University of Missouri-Kansas City School of Medicine; Children's Mercy Hospital Kansas City, Missouri, USA

Introduction

Peritoneal dialysis (PD) is the most popular chronic dialysis modality in children worldwide. In young children, PD is particularly beneficial because it is fairly simple to perform, it permits home-based therapy, and there is a lower fluid restriction with a more liberal diet than typically occurs with hemodialysis (HD). Despite these apparent benefits, there is no evidence to suggest that PD improves long-term outcomes such as mortality, cardiovascular disease, or metabolic bone disease when compared to HD. Transplantation is the preferred treatment for end-stage renal disease (ESRD) in children, a practice that limits the overall exposure time on dialysis. This lack of exposure time has resulted in a paucity of long-term studies on the outcome of chronic dialysis in children.

A search for available evidence was conducted through The Cochrane Renal Group for Systematic Reviews, the Cochrane Central Register of Controlled Trials, MEDLINE, and EMbase for randomized controlled trials (RCTs) on the management of PD in children(Table 65.1). Recent guidelines on the management of PD in children were also critically reviewed. Data on mortality and comorbidities were obtained directly from annual registry reports and published analyses of these registry data. Studies published before 2000 were predominantly excluded from analysis, unless more recent studies examining a specific topic were not available. Studies examining medications, dietary modifications, and the outcome of predominantly adult patients were excluded from analysis as these topics are covered in other chapters.

PD in Acute Kidney Injury

Acute kidney injury (AKI) is a common complication among hospitalized children and in severe cases renal replacement therapy may be instituted. Despite the common nature of AKI, there are no prospective RCTs comparing the type of renal replacement modality for the treatment of AKI in pediatric patients. Continuous renal replacement therapy (CRRT) is the predominant modality used for children with severe AKI in Europe and the United States, except in young infants [35]; however, PD is still frequently utilized depending upon local center resources and preferences. Retrospective studies with patient selection bias have demonstrated evidence of poorer survival among children treated with PD and CRRT versus HD for the treatment of AKI, but no difference was observed between PD and CRRT [2, 36]. These studies are limited in their significance because older children with a lower severity of illness were predominantly dialyzed using HD in comparison to patients who were dialyzed using PD and CRRT. Current guidelines supporting the use of PD for the treatment of AKI in children have been published, with recommendations largely based on observational studies and expert opinion (Table 65.2) [37, 38].

Numerous retrospective studies and a meta-analysis published in 2018 [39] have demonstrated poor outcomes in hospitalized children with AKI complicated by marked fluid overload. Due to these findings, there has been a growing interest in avoiding a fluid overloaded status through the timely institution of dialysis in patients with AKI. This has been best studied in patients undergoing repair of congenital heart disease. The empiric use of PD following congenital heart surgery has predominantly been studied via

Table 65.1 Peritoneal dialysis in children.

	Recommendation	Certainty of evidence	Strength of recommendation
Use in AKI	We suggest that PD is an appropriate therapy for management of AKI and fluid overload in pediatric patients. Impact on hard outcomes (mortality, hospital length of stay) is unclear.	Low	Weak [1–5]
Choice of PD modality	We recommend the choice of modality be based upon available resources and physician/family preference. No pediatric-specific studies exist examining hard outcomes and PD modalities. Tidal PD may result in improved clearance, especially in high transporters.	Low	Weak [6, 7]
Dialysis adequacy	We recommend utilizing adult adequacy guidelines as a minimum standard for pediatric patients and making further treatment decisions based on overall patient "wellness." We recommend use of the pediatric modified peritoneal equilibration test to assess peritoneal transport characteristics.	Low	Weak [8–10]
Dialysate choice	We recommend use of neutral-pH, low GDP solutions for PD where available. Lactate and bicarbonate-buffered solutions both provide adequate clearance, with possibly improved membrane preservation with bicarbonate-buffered solutions.	Low	Weak [11–13]
PD catheter placement	We recommend double-cuff Tenckhoff catheters be placed with a lateral/downward tunnel in a paramedian location. The laparoscopic approach is appropriate for PD catheter placement. Omentectomy and fibrin glue application may reduce catheter complications.	Low	Weak [14–21]
Peritonitis diagnosis	We recommend following the current ISPD guidelines for the diagnosis of peritonitis. No pediatric trials exist examining the sensitivity/specificity of current recommended diagnostic criteria for peritonitis. One prospective analysis supports current diagnostic guidelines.	Low	Weak [22, 23]
Peritonitis prevention	We recommend implementation of standardized caregiver education and PD catheter follow-up care bundle to prevent peritonitis. Perioperative antibiotics at PD catheter placement and a "flush-before-fill" system of automated PD are also recommended. Conflicting evidence exists regarding peritonitis prevention with intranasal mupirocin for nasal *Staphylococcus aureus* colonization.	Low	Weak [24–29]
Peritonitis treatment	We recommend following the current ISPD guidelines for treatment of peritonitis. Few pediatric trials exist examining current treatment guidelines, although a prospective evaluation found empiric therapy successful in 93.7% of peritonitis.	Low	Weak [23, 30]
Use in ESRD vs HD	We suggest that PD is an appropriate therapy for management of ESRD. There is currently no strong evidence to support a specific dialysis modality, although there is some suggestion of improved preservation of residual renal function with PD therapy.	Low	Weak [6, 31–33]

AKI, acute kidney injury; ESRD, end-stage renal disease; HD, hemodialysis; ISPD, International Society of Peritoneal Dialysis; PD, peritoneal dialysis. GRADE assessment of the certainty of the evidence [34]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

retrospective analysis, but appears to be associated with less frequent development of hypervolemia, earlier extubation, and a shorter hospital length of stay [3–5]. There have also been two randomized clinical trials examining the use of PD post cardiac surgery. One demonstrated no difference in achievement of negative fluid balance, time to extubation, or hospital length of stay with PD versus diuretic therapy, but was conducted in a single center and had a very small intervention group that included only 10 patients [40]. The largest randomized trial to date compared PD to furosemide therapy in 73 patients (41 received PD) and demonstrated superior fluid management and shorter ventilator times with PD, but no difference in intensive care unit length of stay, overall hospital length of stay, or mortality [41].

Table 65.2 Summary of findings: peritoneal dialysis (PD) for acute kidney injury.

Outcome/intervention	No. of participants (no. of studies)	Absolute risk (95% CI)	Relative risk (95% CI)	Certainty of evidence	Conclusion
PD versus diuretics in postcardiac surgery					
Mortality	95 (2)	Assuming baseline risk: 6 per 100; with PD: 4 per 100 (0–9)	0.57 (0.10–3.24)	Low	No clear evidence that PD results in decreased risk of mortality
Negative fluid balance on postoperative day 1	73 (1)	Assuming baseline effect: 66 per 100; with PD: 70 per 100 (57–85)	1.08 (0.78–1.48)	Low	PD may increase the likelihood of achieving a rapid negative fluid balance
Significant fluid overload (10%)	73 (1)	Assuming baseline risk: 43 per 100; with PD: 15 per 100 (4–26)	0.33 (0.15–0.77)	Low	PD may decrease incidence of significant fluid overload
PD versus continuous renal replacement therapy (CRRT) for acute kidney injury					
Mortality	—	No studies	No studies	Absent	No randomized controlled trials comparing PD and CRRT

CI: confidence interval; corresponding risk is the absolute risk for those in the intervention arm or control group.
GRADE assessment of the certainty of the evidence [34]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

PD for ESRD

Modality of PD

Automated peritoneal dialysis (APD) is the predominant PD modality prescribed for children in nonresource limited countries due in part to the social advantages of nocturnal therapy over daytime PD that are characteristic of continuous ambulatory peritoneal dialysis (CAPD). No studies exist comparing the outcomes of CAPD and continuous cycling peritoneal dialysis (CCPD) in children. During their study of peritoneal membrane characteristics, Fischbach et al. noted that dialysis performed in the supine position, as is the case with CCPD, resulted in ~17% higher transport of creatinine, urea, and phosphate, along with a lower intraperitoneal pressure in comparison to PD conducted in the upright position [42]. There was no difference in net ultrafiltration between the two positions. Edefonti et al. retrospectively examined a group of seven children, all of whom were previously treated with nocturnal intermittent peritoneal dialysis (NIPD) and the absence of a daytime fill volume, and then transitioned to tidal PD, which is characterized by limited complete drains throughout the dialysis session. Increased creatinine and urea clearances were noted in patients undergoing tidal PD, most notably in patients with high peritoneal membrane transport capacity [43]. Holtta et al. compared clearance sequentially in a randomized, crossover trial of 17 patients who underwent both tidal PD and CCPD that demonstrated lower glucose concentration requirements among patients treated with tidal PD and no difference in ultrafiltration [7]. There was a significantly increased dialysate flow rate and creatinine clearance with tidal PD, but no overall difference in Kt/V urea. There was some suggestion of increased clearance in high transporters with tidal PD; however, the small patient population limited statistical evaluation of this difference.

Adequacy of Dialysis and Fill Volume

Determining the optimal dialysis adequacy in children on PD is difficult due to the general rarity of pediatric ESRD, the low incidence of pediatric mortality associated with dialysis treatment of ESRD, and the emphasis on early renal transplantation leading to a relatively short duration of dialysis therapy in most instances. Holtta et al. compared outcomes in an age-matched retrospective analysis of 10 PD patients treated from 1995 to 1999 to 27 patients treated from 1986 to 1995 [8]. In 1995, peritoneal equilibration testing (PET) was added to their treatment program and the target weekly urea Kt/V was increased from 1.7 to >2.0. The analysis demonstrated a significant improvement in anemia and phosphorus control associated with the increased clearance and possible reduction in the number of hospitalization days. Schaefer et al. prospectively examined a cohort of 51 children during an 18-month

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

period with a mean Kt/V urea of 2.3 and found that a high transporter state per PET was associated with a high creatinine clearance, but also with poor growth velocity and obesity [9]. At this time, there is no pediatric data to support or refute the current recommendations of a weekly Kt/V urea of >1.8 apart from the studies above, although the guidelines emphasize consideration of patient's overall wellbeing when making treatment decisions [10].

The PD fill volume should be prescribed based upon body surface area (BSA) due to the fact that the peritoneal membrane surface area is independent of age when expressed in terms of BSA. De Boer et al. demonstrated that the association between age and net ultrafiltration disappeared when fill volumes were prescribed as 1200 ml/m^2 BSA instead of 40 ml/kg body weight [44]. Fischbach et al. performed several observational studies that demonstrated no benefit and some decreased clearance with fill volumes over 1400 ml/m^2 BSA [42, 45, 46]. Current guidelines recommend a target fill volume of 1000–1200 ml/m^2 in patients older than 2 years and 600–800 ml/m^2 BSA for younger patients [6, 47]. A small, multicenter study performed by Warady et al. found that solute dialysate to plasma ratios varied with intraperitoneal fill volumes, demonstrating the need for a standardized approach to PET [48]. Warady et al. subsequently performed a multicenter cross-sectional study in which 95 patients underwent a standardized PET and pediatric reference data was generated [49]. This reference data demonstrated that pediatric solute dialysate to plasma ratios are similar to adult data with a standardized fill volume of 1100 ml/m^2; however, age-related changes are present for normalized mass transfer area coefficient (MTAC) with younger children having higher MTAC values.

Dialysate Composition

One of the consequences of long-term PD is the resultant morphological changes to the peritoneal membrane that can lead to decreased clearance and ultrafiltration failure over time. Traditional PD solutions containing glucose as the osmotic agent and lactate as the buffer generate glucose degradation products (GDPs), which result in local and systemic inflammation contributing to these morphological changes [50]. Adult studies have demonstrated mild benefits of "biocompatible" fluids (improved ultrafiltration/clearance) and a Cochrane review found low-quality evidence supporting the use of neutral, low GDP solutions for PD over standard lactate-based solutions [13]. A few trials comparing bicarbonate-buffered PD solutions to standard lactate-buffered solutions have been performed in children [11, 12, 51–53]. These studies have demonstrated improved metabolic acidosis correction, decreased glycation end products, possible improved mesothelial regeneration, and mildly decreased clearance with bicarbonate-based solutions. Schmitt et al. performed a multicenter randomized trial in 37 children on chronic PD comparing lactate-buffered and bicarbonate-buffered neutral-pH dialysate [11]. Following a 2-month run-in period, patients were randomized to either a lactate- or bicarbonate-buffered solution and were monitored via serial visits over the following 10 months. There were no statistical differences in creatinine clearance or Kt/V, but ultrafiltration per glucose exposure significantly increased in association with the use of bicarbonate-buffered solutions and decreased in lactate-buffered solutions. This moderate quality study suggests that use of a bicarbonate-buffered solution is associated with a similar clearance and possibly improved peritoneal membrane preservation when compared to a lactate-buffered PD solution. The study was, however, limited by the small study population, lack of hard outcomes regarding peritoneal preservation, and a short follow-up period.

Amino-acid-based dialysate solutions, which also avoid the risk of GDPs, have historically been proposed for management of protein-calorie malnutrition among children undergoing PD. Few studies have examined these solutions in children and all are complicated by small sample size and relatively short follow-up period [54–56]. No significant benefit was found with regards to anthropometric indices, although the solutions were well-tolerated and there was the suggestion of improved appetite in one study [55].

The use of icodextrin has been studied in several small pediatric studies with several limitations in methodological quality (small sample sizes, lack of randomization, short follow-up period) [57–59]. The largest study of icodextrin use in pediatrics was a retrospective analysis by Rousso et al. which found improved ultrafiltration with fill volumes >550 ml/m^2 (88% achieved any ultrafiltration vs. 44% with fill volumes <550 ml/m^2) [57]. Four patients with possible allergic reactions to icodextrin were reported, although other potential complications of icodextrin therapy were not examined or reported. A crossover study in eight children demonstrated improved clearance (weekly Kt/V increased from 1.99 to 2.54) and increased loss of amino acids with use of icodextrin [58]. Similarly, a crossover trial in 11 children demonstrated equivalent ultrafiltration comparing the use of icodextrin and 3.86% glucose-based solutions [59].

PD Catheter Placement/Usage

In 2012, the International Society of Peritoneal Dialysis (ISPD) published guidelines on PD catheter placement, management, and treatment of peritonitis in children [22]. The majority of these guidelines are supported only by

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

expert opinion, with weak evidence. A brief summary of these guidelines is presented in Table 65.3. A double-cuff Tenckhoff catheter with a downward/lateral subcutaneous tunnel is recommended due to decreased rates of infection compared to other catheter characteristics in registry data [14]. However, conflicting results from other registry studies show increased risk of infection with downward tunnels [16, 60]. Para-median catheter placement has been associated with decreased leakage compared to midline placement in one registry study [15]. Catheter tip type (straight vs. curled) has also shown conflicting results with either no significant impact on infection risk [61, 62] or possibly an increased risk for infection/access revision with used of a curled, intraperitoneal segment [63, 64]. Although the potential for a comparative evaluation of double versus single cuff catheters is limited due to the

Table 65.3 ISPD guidelines on initiation of peritoneal dialysis and prevention/treatment of peritonitis in children [22].

PD catheter insertion and care

- Double-cuff Tenckhoff catheter with downward or lateral subcutaneous tunnel
- Perioperative antibiotic prophylaxis
- Weekly sterile dressing changes and catheter immobilization until well-healed
- Use of double-bag and Y-set disconnect systems with "flush before fill"
- Luer-lock connections instead of manual "spiking" of dialysate bags
- Exit-site care with sterile antiseptic solution and topical antibiotic application with dressing changes

Diagnosis of infection

- Peritonitis: cloudy effluent, effluent white blood cells >100/mm^3, >50% polymorphonuclear leukocytes, with or without positive effluent culture
- Exit-site/tunnel Infection: use of exit-site scoring system to assess for swelling, redness, tenderness, or drainage at PD catheter site with or without pathogenic organism isolated by exit-site culture

Treatment of peritonitis

- Intraperitoneal route for empiric initiation of antibiotics when peritonitis is suspected
- Empiric cefepime monotherapy, if indicated and available; otherwise, use first-generation cephalosporin with ceftazidime or aminoglycoside
- If center-specific rates of methicillin resistance are >10%, recommend use of glycopeptide
- Use susceptibility data in guidance of antibiotic selection following culture results
- Duration of intraperitoneal therapy 2–3 weeks depending on microbial species

  Gram-positive organism

  Discontinuation of ceftazidime/aminoglycoside

  If delayed response to therapy (>72 h), recommend addition of rifampin in patients with *Staphylococcus* species

  Gram-negative organism

  Discontinuation of glycopeptide therapy

  Recommend discontinuation of aminoglycoside if possible, once susceptibility data is available

  Suggest administration of second antimicrobial with *Pseudomonas* species

  Culture negative peritonitis

  Empiric antibiotic therapy (other than aminoglycosides) to be continued for 2 weeks

  Recommend discontinuation of aminoglycoside therapy if culture negative with clinical improvement at 72 h

  Fungal

  Recommend catheter removal and treatment with antifungal agent for 2 weeks after catheter removal and resolution of clinical symptoms
- Catheter removal for refractory peritonitis, fungal peritonitis, combined exit-site/tunnel infection and peritonitis with same organism, and refractory tunnel/exit-site infection
- Consider dialysis prescription modification with prolonged dwell time until effluent clears

Treatment of exit-site/tunnel infections

- Oral antibiotic therapy initiated on receipt of culture results unless there is a history of *Staphylococcus aureus* or *Pseudomonas aeruginosa* or signs of severe infection, in which cases empiric therapy is recommended
- Treat for minimum of 2 weeks and at least 7 days after resolution of symptoms except in case of *S. aureus* or *P. aeruginosa* where therapy should be at least 3 weeks

ISPD, International Society of Peritoneal Dialysis; PD, peritoneal dialysis.

current standard practice of double-cuff catheters in most children (but not all infants), the International Pediatric Peritonitis Registry (IPPR) did find an increased risk of infection with single-cuff catheters [16].

Several retrospective analyses have examined PD catheter complications in children. Rinaldi et al. reported on both 10- and 15-year long-term outcomes from an Italian registry of chronic pediatric PD and found a total 451 catheter complications resulting in an incidence of approximately one catheter complication every 20 months of chronic PD [15, 65]. The most common complications were infection, leakage, catheter dislocation, and catheter obstruction. They found an association between leakage and midline catheter location versus para-median catheter location, although this difference did not reach statistical significance. Catheter complications and catheter removal were more common in young children (<2 years), although this improved in the more recent analysis [15]. An analysis of the International Pediatric Peritoneal Dialysis Network (IPPN) registry found an increased risk of catheter revision/complications in children <1 year of age, those with an ostomy, in countries with higher national GDP, with diagnosis of congenital anomaly of the kidney/urinary tract, and with use of a catheter with a swan-neck tunnel and a curled intraperitoneal portion [63]. Reported indications for catheter revision in the IPPN registry were most commonly mechanical dysfunction/leakage (66%), with peritonitis (16%) and exit/tunnel infection (12%) being less common indications. Similar associations with young age [18, 21, 66–68], ostomy presence [18], and early use [66, 69] have been reported by others.

Due to the risk of leak or necessity for a catheter revision with early catheter use, several studies have reported on the use of fibrin glue to prevent the leakage of dialysate [17, 70, 71]. Sojo et al. performed the only randomized, controlled prospective trial on the utilization of fibrin glue at the time of catheter implantation in 45 children (52 catheter placements) and found a significantly lower rate of leakage (9% catheter leakage in fibrin group, 57% catheter leakage in control group, $P < 0.05$) without any concomitant increase in infection in association with the use of fibrin glue [17]. Laparoscopic placement of PD catheters has become an accepted practice, although no large pediatric trials exist. Several small retrospective studies have found equivalent long-term performance between laparoscopic and open catheter placement in children [18, 19, 21, 72, 73]. Omentectomy at the time of PD catheter placement in children remains somewhat controversial. No large randomized trials examining omentectomy exist and available studies are typically small, single-center, and retrospective in nature. Omentectomy has been found to be associated with less early catheter failure in several small studies [18, 20, 21, 74–76]; however, Radtke et al. found no benefit of omentectomy and found catheter survival dependent more on catheter and surgeon characteristics [68].

PD-associated Infections

Peritonitis and catheter-related infections are the primary cause of catheter removal/revision, morbidity, and treatment failure in children who receive chronic PD. Long-term damage to the peritoneal membrane from infections may lead to peritoneal adhesions/fibrosis and result in the inability to utilize the peritoneal membrane as a dialyzing membrane in the future. Rates of peritonitis, exit-site, and tunnel infections vary depending on the reporting population. Recent publications from registries and collaboratives report a peritonitis frequency of 0.46–0.64 episodes per patient year [14, 62, 77], although rates as low as 0.17 episodes per patient year have been reported [61].

There are no pediatric-specific studies examining the sensitivity or specificity of the diagnostic criteria for peritonitis recommended by the current guidelines (see Table 65.3). A prospective evaluation of the ISPD 2000 guidelines performed by the IPPR found that 3.8% of patients had clear effluent at diagnosis, 2.8% had effluent cell counts <100 cells/μl, and 8.5% of cases had a differential with <50% polymorphonuclear cells [23]. This evaluation included 491 episodes of peritonitis (44% gram-positive, 25% gram-negative, and 31% culture-negative).

Prevention

Preventive strategies for peritonitis and catheter-related infections have been a priority in pediatric studies due to the higher rates of these infections in pediatric (especially young) patients (Table 65.4). The catheter-related preventive strategies discussed above currently do not contradict the current recommendations for a double-cuffed Tenckhoff catheter with a lateral/downward facing tunnel. There have not been any RCTs in pediatrics comparing rates of peritonitis among different PD modalities. Warady et al. completed a prospective randomized multicenter trial of 121 patients which demonstrated that a "flush before fill" APD system was not associated with any impact on overall rates of peritonitis [24]. Nevertheless, gender stratification found significantly lower rates of peritonitis associated with flush before fill in females (one infection every 44.7 months vs. 12.4 months). Due to the lack of an obvious physiological mechanism for a gender difference and the small sample size, further studies are required to confirm this finding. Plastic PD catheter adapters have also been found to be associated with peritonitis in comparison

Table 65.4 Summary of findings: infection prevention.

Intervention	No. of participants (no. of studies)	Absolute effect (95% CI)	Relative risk (95% CI)	Certainty of evidence	Conclusion
Peritonitis prevention					
Tenckhoff catheter	—	No RCTs	No RCTs	—	No randomized controlled trials comparing Tenckhoff and other catheter types. Registry studies suggest decreased rates of infection.
Downward/lateral subcutaneous tunnel	—	No RCTs	No RCTs	—	No randomized controlled trials comparing catheter placement locations. Registry studies suggest decreased rates of infection.
"Flush before fill"	121 (1)	Assuming baseline risk: 53 per 100; with PD: 40 per 100 (31–50)	0.77 (0.57–1.04)	Very Low	No pediatric evidence that a flush before fill system decreases rates of peritonitis.
SCOPE follow-up bundle	857 (1)[a]	No RCTs	0.49 (0.3–0.8)[b]	Low	Compliance with the SCOPE follow-up bundle likely reduces the subsequent risk of peritonitis.
Exit-site mupirocin	— (1)[c]	—	0.59 (0.46–0.76)	Low	Exit-site mupirocin likely reduces the risk of peritonitis.
Exit-site infection prevention					
10% clorhexidine vs. povidone iodine	150 (1)	Assuming baseline risk: 28 per 100; with chlorhexidine: 5 per 100 (0–10)	0.19 (0.07–0.53)	Low	10% chlorhexidine may be associated with a lower risk of exit-site infections compared to povidone-iodine.
Exit-site mupirocin	—(1)[c]	—	0.43 (0.34–0.54)	Low	Exit-site mupirocin likely reduces the risk of exit-site infection.

CI, confidence interval; RCTs, randomized controlled trials; SCOPE, Standardizing Care to Improve Outcomes in Pediatric ESRD.
GRADE assessment of the certainty of the evidence [34]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

with titanium adapters in univariate analysis, but the finding did not remain statistically significant in multivariable analysis [62].

Survey and registry data have suggested that increased provider/caregiver education and training are associated with lower peritonitis rates [25, 61]. The Children's Hospital Association's Standardizing Care to Improve Outcomes in Pediatric ESRD (SCOPE) Collaborative is a multicenter quality improvement effort designed to improve and standardize practices in pediatric dialysis care [78]. The SCOPE PD catheter care bundles address catheter insertion, patient/caregiver training, and follow-up management and were instituted with a goal of reducing dialysis-related infection. Subsequent analyses of this collaborative have demonstrated that compliance with the follow-up bundle was independently associated with a lower risk of peritonitis, as evidenced by a relative risk (RR) 0.49 (95% confidence interval 0.3–0.8) [62]. Mean monthly peritonitis rates declined from 0.63 episodes per patient year at initiation to 0.42 episodes per patient year at 36 months following implementation of the SCOPE initiative [26]. An analysis of peritonitis rates among patients who received a PD catheter at age <1 year in the SCOPE collaborative found increased rates of peritonitis among patients undergoing nephrectomy at or prior to PD catheter placement (odds ratio [OR] 5.93, 95% confidence interval [CI] 1.51–23.27) and in patients having a gastrostomy placed after PD catheter placement (OR 2.81, 95% CI 1.31–6.01) [64].

Perioperative antibiotics are recommended for prevention of post-catheter placement infectious complications. This

recommendation is supported by only a single retrospective analysis in pediatric patients that demonstrated a peritonitis rate of 44% in untreated patients versus 10% in those receiving prophylactic antibiotics [79]. A systematic review performed by Van Pierre et al. found that exit-site mupirocin was effective at reducing exit-site infections (RR 0.43, 95% CI 0.34–0.54) and peritonitis (RR 0.59, 95% CI 0.46–0.76) predominantly caused by *Staphylococcus aureus* [27]. No other pediatric studies have been published regarding other topical exit-site antibiotics and adult studies have demonstrated conflicting results [80]. Topical honey has been reported in one pediatric case series of eight patients as being effective in the management of poorly appearing exit-sites, in combination with other treatments [81]. The use of intranasal mupirocin has been associated with conflicting results with some reports of improved prevention of infection [28] versus no impact [29], which is consistent with adult data [80]. This variability may be due to the lack of impact of the therapy on gram-negative infections and the potential development of mupirocin resistance. An RCT of 150 pediatric PD patients demonstrated lower rates of exit site infections (four infections versus 21 infections) with 10% chlorhexidine daily exit-site care compared to povidone-iodine [82].

Treatment

Few trials exist examining treatment of peritonitis in the pediatric population. Available guidelines are based on extrapolated data from adult studies and expert opinion. All experts agree that empiric therapy should consist of broad (gram-positive and gram-negative organisms) coverage, with subsequent therapy to be tailored to the specific organism cultured and the associated antibiotic susceptibilities. Schaefer et al. examined intermittent glycopeptide (every 7 days) and daily ceftazidime versus continuous glycopeptide/ceftazidime intraperitoneal therapy in a prospective randomized trial of pediatric patients [30]. A total of 195 episodes of peritonitis in 90 patients were studied and while no significant difference in treatment outcomes were found, intermittent therapy appeared less successful in the treatment of gram negative peritonitis by clinical judgment, but not by disease severity scores.

The prospective evaluation of the previous pediatric ISPD guidelines (2000) by the IPPR found that there was regional variation in peritonitis and causative organisms, but empiric antibiotics adequately covered 69–97% of bacterial susceptibilities, depending on empiric antibiotic choice [23]. Empiric treatment failure was identified in 6.3% of peritonitis episodes and was associated with gram-negative infections, PD prescription with a "dry" daytime schedule, intermittent ceftazidime administration (gram negative only), and exit-site scores >2 in gram-positive infections.

PD-associated Comorbidities

The presence of comorbidities may have a significant influence on patient outcome, but the evaluation of comorbidities in pediatric PD patients suffers from many limitations. The majority of information regarding comorbidities in pediatric PD comes from registry studies, which are limited by retrospective data, missing/incomplete data, and the voluntary nature of registries. The largest study specifically examining comorbidities in pediatric PD was published in 2012 by the IPPN [83]. They reported on 1830 pediatric PD patients of whom 32.9% had a comorbidity, with cognitive/neurological comorbidities being the most common (15.5% of patients). Motor abnormalities (12.6%), ophthalmologic disease (11.6%), and cardiac disease (9.1%) were the next most common observed comorbidities. These comorbidities were voluntarily reported by treating centers, raising the possibility of incomplete and/or inconsistent data. Other studies have demonstrated high rates of growth retardation, cardiovascular disease, metabolic bone disease, and cognitive impairment in pediatric PD patients [84–87].

PD-associated Patient Survival and Causes of Death

Studies examining pediatric patient survival in association with chronic PD are uncommon due to renal transplantation serving as the definitive treatment for pediatric ESRD. Available evidence is primarily obtained from national and international registries, which invariably results in numerous limitations, including retrospective/incomplete data, inclusion of transplant/HD patients, and lack of data on patients not pursuing therapy for ESRD. Mortality rates among children with ESRD remain significantly increased over the healthy population; however, these rates have been decreasing over time. Registry reports document a mortality rate of 1.5–8.9 per 100 patient years [32, 33, 86, 88–91] or a 5-year survival of 70–91.5% [87, 91–96] over the past two decades for children who receive chronic dialysis. Recent studies typically report a 5-year survival of approximately 90% for children <19 years of age and on PD [97].

Analyses that have focused specifically on the outcomes of neonates and infants initiating renal replacement therapy have demonstrated that significant progress has been made in the survival of the youngest dialysis patients [98–101]. Whereas one study demonstrated no increased risk of death in neonates compared to older infants [98], mortality among infants remains elevated compared to older children [102]. Currently reported 5-year survival among patients who initiated dialysis as neonates ranges from 76.4% to 83.9% [98, 99, 101].

Determination of the cause of death in children with ESRD is fraught with difficulty. Many registries and studies do not report on the cause of death and the methodology utilized to confirm cause of death is often unclear, with substantial missing data. With recognition of those limitations, most studies have found cardiovascular disease and infection to be the most common causes of death among PD-treated children [14, 31, 33, 88, 92, 93, 98, 101]. Other reported etiologies include malignancy, social (dialysis withdrawal, substance abuse/suicide), and cerebrovascular events [33, 93, 101].

Risk factors and their association with mortality in children on PD are commonly reported, but all studies suffer from the lack of inclusion of children not pursuing renal replacement therapy, transitioning between dialysis modalities, and a short duration of dialysis therapy prior to renal transplantation. Virtually all reports acknowledge young age at onset of dialysis as a primary risk factor for death [32, 33, 86–91, 93–96, 100, 101, 103–105]. With the documented improvement in survival among neonates starting dialysis therapy, there has been an increased frequency of chronic dialysis conducted in relatively sick infants with a variety of comorbidities that also likely impact patient outcome.

PD versus HD

Comparison of outcomes between chronic dialysis modalities is fraught with difficulties due to varying sources of selection bias (e.g. preference for PD in young children, numerous PD modalities). With recognition of those limitations, several registry studies have demonstrated higher mortality rates with PD in comparison to HD [32, 33, 88, 94]. Given the strong association between young age and increased mortality, the association between PD and mortality often fails to persist with multivariate analysis due to the common preference for PD in young children. No RCTs exist comparing risk of death between PD and HD in children. Available registry and cohort studies demonstrate conflicting results. The Dutch National Cohort study demonstrated increased mortality among patients on HD; however, the study suffers from selection bias with more complicated patients receiving HD therapy [87]. An analysis of the European Society of Pediatric Nephrology-European Renal Association (ESPN-ERA)/European Dialysis and Transplant Association (EDTA) registry demonstrated a 6.6-fold increased risk of death with dialysis therapy versus preemptive transplantation, while finding no difference in survival when comparing PD and HD [31].

Residual renal function (RRF) has been found to be an important prognostic indicator for outcomes in adult dialysis patients [106]. While comparable studies associating RRF and definite end-points such as mortality are not available for children, there has been interest in preserving RRF in pediatric patients. Improved linear growth has been associated with the presence of RRF in children receiving PD [107]. Feber et al. demonstrated improved RRF preservation in a retrospective analysis of pediatric PD patients [108]; this finding was also observed in a similar retrospective study was completed by Fissbach et al. in France [109]. An analysis conducted by the IPPN demonstrated evidence of increased risk of RRF loss in PD patients that had either prolonged PD therapy or glomerulonephritis as an underlying etiology of ESRD [110].

Conclusions

PD is a common modality for chronic renal replacement in children. Despite its common use, well-constructed RCTs providing evidence regarding benefits and harms of this therapy are not available. The development of large registries, as well as national and international collaboratives, have greatly improved our understanding of the risks, outcomes, and treatment practices regarding PD in children. Further research with randomized controlled trials based on the observational data that has been generated in pediatric PD should be encouraged.

Introduction

Since the 1960s, when hemodialysis (HD) was first described in children [1], there have been significant technological advances and improvements in the clinical management of children with end-stage kidney disease (ESKD). The availability of portable home hemodialysis (HHD) machines, machines to dialyze premature infants, the encouraging outcomes of using hemodiafiltration (HDF) in children, and extended dialysis programs are some of the medical achievements that have improved the quality of care in the pediatric population with ESKD [2]. Despite these advances, the mortality of children on dialysis remains unacceptably high, and there is no evidence to suggest that HD improves long-term outcomes such as survival, quality of life, cardiovascular disease, or metabolic bone disease when compared to peritoneal dialysis (PD). There are few high-quality randomized studies to provide an evidence base for practice in children on HD. In this chapter, we present the available studies and discuss current clinical recommendations for HD in children.

Literature Search

We searched MEDLINE and EMbase for randomized controlled trials (RCTs), as well as the Cochrane Renal Group for Systematic Reviews, and the Cochrane Central Register of Controlled Trials on the management and outcomes of HD in children. Given that there few RCTs in this field, we performed a wider review of the literature and include prospective observational studies in children (irrespective of the number of patients or duration of study) as well as retrospective studies in children (if >20 children included) and data from international registries describing outcomes in children on chronic dialysis. Studies examining medications, dietary modifications, and the outcome of predominantly adult patients were excluded from analysis as these topics are covered in other chapters.

After critically reviewing the evidence we have followed the Grading of Recommendation, Assessment, Development, and Evaluation (GRADE) [3] method for assessing the certainty of evidence and formulating the strength of recommendations.

Technique of HD, HDF, and Home Dialysis in Children

Conventional HD is characterized by three main principles: diffusion, convention, and ultrafiltration (UF). All forms of extracorporeal dialysis use a semipermeable membrane, which allows only small-to-medium molecular weight (MW) particles to go through, leaving behind larger solutes. Randomized trials in adults suggest that high-flux membranes (with high convection volumes) may be associated with better survival and reduced cardiovascular mortality [4–7]. The main principles and key features of each modality are presented in Table 66.1.

HDF: Potential Advantages Over Conventional HD

Outcomes on dialysis cannot be further improved by increasing the flux or efficiency of HD [8]. HDF utilizes a combination of diffusive and convective solute transport through a highly permeable membrane [9–12], thereby achieving clearance of middle molecular weight solutes unlike conventional HD. In HD circulating uremic toxins

Table 66.1 Techniques of dialysis.

Technique	Principle	Key features
Hemodialysis	Diffusive small-solute transport that involves the movement of molecules from an area of high concentration to an area of low concentration across a semipermeable membrane	• The dialysis fluid flow and the dialyzer surface area (which determines the mass transfer area coefficient [K_oA] and consequently the solute permeability of the membrane) determine the quality of HD provided
Hemodiafiltration	Combination of diffusion and convection Optimizes the removal of middle (up to 300–500 kDa MW) and larger molecules (>15–50 kDa MW)	• There is no osmotic disequilibrium while arriving at a maximum of the urea clearance (as the continuous iso-osmotic substitution fluid inflow maintains an osmotic stability throughout the whole dialysis session) • The effectiveness of a membrane to ultrafiltrate fluid is described by the UF coefficient (K_{UF}), which is Q_{UF}/delta$P$ (volume of UF per unit time, divided by the pressure gradient across the membrane, the TMP gradient • The FF is the fraction of plasma that is removed from the blood during hemofiltration and the relationship between the TMP and the oncotic pressure determines the FF • In HDF, a high sieving coefficient is required for middle molecule removal
Hemofiltration	Convective transport of small and medium-sized molecules	• It is mainly used in the acute setting in intensive care units, e.g. for rapid fluid removal

FF, filtration fraction; HD, hemodialysis; HDF, hemodiafiltration; MW, molecular weight; TMP, transmembrane pressure gradient UF, ultrafiltration.

such as β2-microglobulin (β2M), retinol-binding protein, adiponectin, leptin, ghrelin, cholecystokinin, cystatin C, and others accumulate and are responsible for systemic inflammation, endothelial dysfunction, and oxidative stress [13, 14]. HDF has been shown to clear significantly more β2M compared to HD [15, 16] and increase removal of inflammatory cytokines with reduction in inflammation and oxidative stress [17]. An observational study in children has shown significant reduction in β2M, inflammatory markers, and measures of oxidative stress and endothelial dysfunction when children were switched from conventional high-flux HD to high volume HDF, keeping all other measures (dialysis time, blood flow speed, filter size, water quality) constant [18].

In adults on dialysis, a recent RCT, the Estudio de Supervivencia de Hemodiafiltración Online (ESHOL) study, has shown a survival benefit of HDF compared to high-flux HD (30% lower risk of all-cause mortality, 33% lower risk of cardiovascular mortality and 55% lower risk of infection-related mortality) [5]. ESHOL, as well as pooled data [7] from the Convective Transport study (CONTRAST) [19], Turkish Online Hemodiafiltration [6] studies, and the French Convective versus Hemodialysis in Elderly (FRENCHIE) study [20] have indicated a critical dose–response relationship between the magnitude of the convection volume and survival. Although a number of biologically plausible explanations have been suggested for improved outcomes with HDF, observational studies, registries, and RCTs provide conflicting results, which to some extent can be explained by differences in the convection volume [7], with patients achieving the highest convection volumes benefiting most. Improved survival and reduced cardiovascular mortality were demonstrated when higher convection volumes (>17.4 and 23 l per session) were used. HDF has been associated with improved cardiovascular outcomes in adults [21], partly explained by improved hemodynamic stability, leading to less intradialytic hypotension and faster recovery time after dialysis [22, 23]. ESHOL, FRENCHIE, and several observational studies have shown that HDF improves intradialytic hemodynamic stability compared to HD [5, 20, 24]. Post hoc analysis of the CONTRAST study, an RCT in adults, showed that HDF helps improve phosphate control (more than 30%) when compared to HD [25]. In addition, patients on HDF compared to HD may have a lower erythropoietin resistance index, possibly associated with reduced inflammation, better biocompatibility, and reduced removal of erythropoietin-inhibiting factors [26].

The International Pediatric Hemodialysis Network (IPHN) has recently performed a multicenter observational study to test the hypothesis that HDF improves the cardiovascular risk profile, growth and nutritional status, and health-related quality of life outcomes in children compared to conventional HD. The HDF, Hearts and Height (3H Study) [27], the largest pediatric dialysis study to date, suggests an association between HDF modality and lack of progression in vascular measures, increase in height, and self-reported improvement in patient-related outcomes compared to HD. Children on HDF had improved blood pressure and hemodynamic stability, reduced inflammatory markers and lower β2-microglobulin compared to children on HD. The annualized change in vascular measures correlated with improved blood pressure (BP) control and clearances on HDF. 3H is not a randomized trial, so confirmation of results through randomized trials is required.

Smaller pediatric cohorts have previously studied the effects of HDF on nutrition and growth [28], inflammation [18, 29], left ventricular hypertrophy (LVH) [30], anemia control [30], and post-dialysis recovery time [28] but these are single-center and often retrospective case reports. It is postulated that HDF might have a possible anabolic effect associated with the greater removal of uraemic toxins, including hormones that regulate appetite and growth [28]. A small single-center study also suggests that switching children from nocturnal in-center HD to nocturnal in-center HDF has shown significant improvement in BP, phosphate and parathyroid hormone (PTH) control [31]. All potential advantages of HDF over HD are summarized in Table 66.1.

Home Hemodialysis

Literature on pediatric HHD is scarce. The main advantage for children while being on home HD are growth, improved cardiovascular control, and improved quality of life [32]. Improved growth without growth hormone therapy was demonstrated in patients on intensive HD three times a week for approximatively 5 hours per treatment with a single pool Kt/V of 2.0 and a caloric intake at 150% of the recommended daily allowance for age [33].

Simonsen described four children aged 10–19 years who were treated with slow nocturnal HD for 7–8 hours, six nights weekly, for a period of 5–55 months. The children achieved a weekly Kt/V of 7.2–13.6, had no dietary or fluid restriction, and achieved catch-up growth [34].

Hothi et al. studied four children aged between 12 and 16 years on nocturnal HHD with a follow-up period of 6–20 months. All children showed a decrease in their $Ca \times PO_4$ product below 4.4 $mmol^2/l^2$ with a concomitant significant decrease in PTH levels [35]. Review articles from this group suggest that children can be successfully managed with HHD and show many advantages compared to in-center HD, particularly improved appetite, growth, energy levels, increased flexibility with dialysis times, and opportunities to attend school or have a more normal social life [32, 34].

Goldstein et al. have demonstrated improvements in BP control in four patients receiving six-times weekly HHD, with an average of 2.5 hours per treatment for 16 weeks. The dialysis prescription was adjusted to deliver a single-pool Kt/V (spKt/V) ≥2.1. All patients demonstrated progressive reductions in predialysis BP mean values, with progressive discontinuation of antihypertensive medications in two patients [36]. A further case report also suggests that children on home HD can develop regression of LVH and reduced need for antihypertensive treatment [37].

Vascular Access in Children

To optimize dialysis adequacy reliable vascular access is essential. Current HD access options for children include central venous catheters (CVC), arteriovenous fistulas (AVF), and arteriovenous grafts (AVG). The evidence for the benefit of AVFs over CVCs in adult dialysis programs has been known for some time and pediatric studies suggest similar outcomes: better quality dialysis, fewer infections, fewer access changes, and less hospitalization [38–42]. However, AVFs may not be suitable in the very young or those with an anticipated short dialysis course before transplantation, so the "fistula first" policy may not be applicable for all children. Although the international consensus guidelines recommend AVF as the access of choice in children above 20 kg and adolescents who are unlikely to receive a kidney transplant within a year [43–45], most pediatric patients are still dialyzed via a CVC [44–46]. AVGs are used in <2% of children on HD, and usually as a last resort when other options have been exhausted; we have not addressed this further in this chapter [46]. Table 66.2 describes the major outcomes of infections and access patency with CVCs and AVFs.

Central Venous Catheters: Site of Placement

The type and size of catheter, the catheter site, and the technique for insertion need to be considered in order to choose the right catheter for each patient. CVCs in the femoral vein are associated with a higher risk of infections and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 66.2 Summary of evidence for the use of arteriovenous fistula versus central venous catheters in children on hemodialysis.

Outcome	No. of participants (no. of studies)	Summary results from published studies	Certainty of evidence (GRADE)	Conclusion
Infection	198 children (3) [40, 47, 48]	Rate of infection with CVC compared to AVF (0.25 per 100 pm vs. 3.2 per 100 pm) Proportion with infection (1.9% with AVF vs. 16.5% with CVC) Risk relative reduction (34% in AVF group)	Low	Use of AVF for hemodialysis in children may lead to less infection
Access survival and patency	299 children (7) [39, 40, 48–52]	Rate of primary access survival in AVF compared to CVC (1 per 78.8 pm vs. 1 per 15.5 pm) Annualized hospitalization rate of those admitted for access malfunction with AVF compared to CVC (0.44% in AVF vs. 3.1% CVCs) Median survival of AVF compared to CVC (3.14 years [95%CI 1.22–5.06] for AVF, and 0.6 years [95% CI 0.20–1.00] for CVC)	Low	Use of AVF for hemodialysis in children may lead to improved access survival

AVF, arteriovenous fistula; CI, confidence interval; CVC, central venous catheter; pm, patient-months.

thrombosis [53] so should be avoided except in emergency situations or where all other access has failed. Although subclavian catheters are associated with less infectious complications [54], they are clearly associated with a high risk of postoperative stenosis [55], which affects dialysis adequacy and damages the central vasculature, limiting options for future vascular access. A study of 100 patients dialyzed either by a subclavian or internal jugular catheter (50 in each group) showed that 42% of the subclavian group had a stenosis of the subclavian/brachiocephalic vein, compared to 10% of the internal jugular group [56]. Left-sided subclavian and internal jugular catheters provide flows that are more erratic and up to 100 ml/min lower than elsewhere because their tip may abut the vein walls. Although there are no comparative studies in children, a fluoroscopic or ultrasound-guided technique for CVC insertion may be considered to increase the success rate of insertion while decreasing the mechanical complications rate [57, 58]. Recently, the IPHN showed that vascular access dysfunction was more common when the CVC was placed in the femoral (56%) or subclavian vein (35%) as compared to the internal jugular vein (21%, $P = 0.002$) [53].

Arteriovenous Fistulas: Access, Maturation, and Needling

The IPHN registry data suggests that AVFs have better event-free survival probability and thereafter higher primary and secondary patency rates after 1, 2, 3, and 4 years compared to CVCs ($P < 0.0001$ for all time points) [53]. Having a CVC increases the need for new access at a different site by twofold and moreover may compromise fistula formation in the future by causing stenosis and superior vena cava syndrome [45]. In addition, AVFs have been shown to have lower rates of access-related sepsis, reduced frequency of hospitalizations [40], and allow activities that are important to children, such as bathing and swimming (Table 66.2).

However, not every child is a suitable candidate for AVF formation. Using microvascular surgical techniques AVFs can be achieved in small children weighing less than 10 kg [59], but K/DOQI guidelines suggest that an AVF should be given in those weighing more than 20 kg and expected to be listed for >1 year on the kidney transplant list. Given the well-documented benefits of AVF, a recent guideline from the European Society for Pediatric Nephrology (ESPN) dialysis working group suggests AVF formation even for children who are deemed to receive a transplant between 6 months and 1 year [53]. However, for "crash-landers," children being prepared for PD, or children in whom a living donor kidney transplant is planned earlier than 6 months, a CVC might be the appropriate option [53].

Fistulas are needled by the rope ladder or button-hole technique. An AVF in the nondominant arm allows for self-needling of the AVF, easy use of the dominant arm during dialysis, and limits any potential neurovascular complications of surgery to the affected arm. There are no randomized studies comparing different sites of AVF formation in adults or children but pediatric retrospective studies have showed that radiocephalic AVFs have excellent primary and secondary patency rates reaching levels of 78–85% and 94%, respectively [49, 60].

Outcomes of CVCs versus AVFs in Children

Comparison of AVF versus CVCs in terms of the risk of infection are presented in Table 66.2. The recent clinical practice recommendation for vascular access in children produced by the ESPN presents a comprehensive and up-to-date literature review on the subject [45].

Multiple retrospective studies in children have shown that CVCs present a significant higher infection rate compared to AVFs (Table 66.2). The recent IPHN guidelines reported an overall incidence rate of 1 per 26 catheter months (0.8/1000 catheter days) concerning CVCs, with predominant pathogens thought to be gram-positive (63%), while 17% of blood or exit-site cultures remained negative [53]. Interestingly, De Sousa et al. studied 61 children retrospectively and found that thrombosis is possible and frequent in the pediatric population with AVF, but other studies have shown that choosing the right site for placing an AVF and the use of primary thrombophylaxis decrease the incidence of thrombosis.

In addition to the above, not only were the annual hospitalization rates due to dysfunction were higher for CVCs compared to AVFs, but also the access survival rates were higher for AVFs and a positive overall impact on dialysis adequacy and less anemia episodes was noted with patients dialyzed with AVFs (Table 66.2). Altogether, the higher infection and dysfunction rates of CVCs and the higher survival patency rates with AVFs, places AVF as a better vascular access choice wherever it is possible to perform it.

HD Adequacy

Since the publication of the National Cooperative Dialysis Study in adults in 1981 [61], the efficiency of urea removal has been correlated with patient's morbidity and mortality. Consideration of urea kinetics led to the subsequent mathematical model of Gotch and Sargent, where they propose using Kt/V_{urea} to measure the adequacy of dialysis [62]. Kt/V_{urea} is an estimate of the clearance of urea from the blood during a dialysis session-standardized by total body water (TBW), which reflects the urea distribution volume. Over the years, Kt/V_{urea} has become accepted as the standard measure of delivered dialysis dose used to assess the dialysis adequacy; although the optimum Kt/V for children is not known, it is generally accepted that the delivered dose aimed for in adults should be a minimum in the pediatric population [63].

Although "adequate" dialysis seems to be the target, the pediatric nephrologist is aiming for "optimal" dialysis which includes optimizing nutrition, growth, less need for hospitalization as well as improvement in school attendance and quality of life [64]. When aiming for "optimal dialysis" maximum effort in preservation of the renal residual function (RRF) is critical. RRF can clear uremic toxins that are not removed by conventional dialysis and in adults, even 1 ml/min/1.73 m^2 renal urea clearance is more beneficial than increasing Kt/V by dialysis and is associated with an almost 50% decrease in mortality in adults [65, 66].

Although small solute clearance (represented by urea) is only one part of the effectiveness of dialysis, it is an important and well standardized outcome. We describe the techniques most frequently used to assess adequacy in HD patients:

Urea kinetic model: Urea kinetic modeling is measured by mathematical equations such as the double-pool Kt/V equation, which uses the plasma urea 60 minutes after dialysis in adults, and the single-pool Kt/V (spKt/V), which despite overestimating urea removal is shown to predict mortality in adult studies [67–71]. Goldstein extrapolated and validated an equation in children on HD using the estimated equilibrated blood urea nitrogen (estBUN, from which eKt/V is calculated using a logarithmic extrapolation of the BUN increase from 30 seconds to 15 minutes post dialysis) [72]. Further studies by Mammen et al. demonstrated that a standard Kt/V (stdKt/V) ≥ 2.0 for three-weekly pediatric HD achieves a spKt/V ≥ 1.2 [73]. European guidelines [66] recommend a minimum Kt/V level of 1.2–1.4 and in a more recent study Fischbach et al. suggest a spKt/V > 1.4 in anuric patients [74] to achieve "optimal" dialysis. For simplified Kt/V equations, see to Table 66.3.

The main advantage of kinetically modeled methods for estimating Kt/V_{urea} is that they also provide an estimate of the urea generation rate, from which the normalized protein catabolic rate (nPCR, an estimate of dietary protein intake in the clinically stable patient) can be estimated. However, two of the main drawbacks in this

Table 66.3 *Kt/V* simplified equations.

General formula	$Kt/V = -\log n(R - 0.008t) + (4 - 3.5R)\mathrm{UF}/\mathrm{BW}$
Arteriovenous access	$\mathrm{e}Kt/V = \mathrm{sp}Kt/V - (0.6 \times \mathrm{sp}Kt/V/T) + 0.03$
Venovenous access	$\mathrm{e}Kt/V = \mathrm{sp}Kt/V - (0.47 \times \mathrm{sp}Kt/V/T) + 0.02$

eKt/V, equilibrated Kt/V; R, predialysis urea/postdialysis urea; spKt/V, single-pool Kt/V; UF, weight loss (in kg); t, dialysis time (in hours); V, anthropometric urea distribution volume (in liters).

model are the possible inaccuracy of the urea clearance (blood recirculation, reduction in the efficacy of dialyzer due to clotting, temporary stop of treatment due to kinked lines/hypotensive patient/other) and the fact that determining the urea distribution volume (V) may be imprecise, especially in children.

1) *Urea reduction ratio*: The urea reduction ratio (URR) has been proposed as another measurement of urea removal during HD. The URR is calculated easily using the percentage of reduction in plasma urea during the dialysis session ($\text{URR} = (1 - \text{urea}_{\text{post}}/\text{urea}_{\text{pre}} \times 100)$). A URR of less than 0.6 has been associated with increased risk of death (odds ratio 1.28 for URRs of 0.55–0.59 and 1.39 for ratios below 0.55) [72]. URR is not recommended as the primary measurement of dialysis adequacy as significant variations of Kt/V may be obtained with each URR value (especially when URR is greater than 0.65) and increasing UF underestimates urea removal. However, it might be a useful assessment in patients with dialysis disequilibrium symptoms.
2) *Measurement of normalized protein catabolic rate (nPCR)*: nPCR is an indirect estimate of protein daily intake ($\text{nPCR} = 5.43 \times G/V + 0.17$), where the urea generation rate (G) is calculated as follows: G (mg/min) = (predialysis BUN × predialysis V) – (postdialysis BUN × postdialysis V)/T, where V is the TBW estimated from 0.58 × body weight and T is time in minutes from the end of the dialysis treatment to the beginning of the next dialysis treatment. Goldstein et al. validated its clinical value [75] by demonstrating that its substantial increase was associated with improvement in nutritional status in pediatric patients with intradialytic parenteral nutrition. However, other studies showed a significant variation in calculated nPCR and underline the underestimation of the prescribed protein intake in that formula [76].

The current guidelines concerning HD adequacy are presented in Table 66.4.

Choice of Anticoagulation in HD/HDF

Prevention of Thrombosis

To prevent circuits clotting with consequent blood loss and reduced dialysis efficacy, anticoagulation of the extracorporeal circuit is almost always required in patients on chronic HD [53]. In the pediatric population, unfractionated heparin (UFH) is primarily used. Concerning UFH, a loading dose of 15–20 units/kg is recommended followed by a continuous infusion of 20–30 units/kg/h and monitoring should include activated partial thromboplastin time (APTT), activated clotting time (ACT), and platelet count on a regular basis. Low-molecular-weight heparin (LMWH) is also used in some centers and is given in divided doses of 0.5–1 mg/kg as the loading dose followed by a half dose in the middle of the dialysis session if the session duration is more than 4 hours in total. Anti-Xa levels should be monitored [77]. Irrespective of which anticoagulant is chosen, the clinician should balance the risk of bleeding versus the risk of clotting. It must be kept in mind that the risk of clotting is inversely related to the dialysis blood flow rate and is higher in less biocompatible dialyzers (e.g. Cuprophane). Whereas LMWH has unpredictable kinetics in ESKD patients, prolonged half-life without any antidote, and an insignificant clearance by HD/HDF as it is impermeable across dialysis membranes, its main benefit is that it consists of a single bolus at the start of dialysis. Comparing the safety and efficacy of LMWH with UFH, meta-analyses show that LMWH seems to be as safe as UFH in terms of bleeding complications and as effective as UFH in preventing extracorporeal circuit thrombosis [78, 79]. A recent Cochrane review showed that tissue plasminogen activator (t-Pa) is the best catheter locking solution in adults on dialysis to prevent catheter thrombosis, reduce risk of bacteremia, and decrease catheter malfunction rates [80]. In maintaining the patency of AVFs or AVGs, a Cochrane review recommends an antiplatelet agent (aspirin, ticlodipine,

Table 66.4 HD adequacy guidelines and recommendations in children.

Guideline	Recommendations	Comments
KDOQI 2015	• sp$Kt/V > 1.4$ • URR > 0.65 (aim at least for 0.70) • Importance of nutritional status (nPCR) and optimize UF	Need for a validated formula to calculate V in children Data extrapolated from adults

or clopidogrel) to be administered for the lifetime of the AVF/AVG [45].

Citrate has the advantage of a regional anticoagulation effect without systemic anticoagulation, but due to the challenges with monitoring and adjusting levels, and the paucity of pediatric experience, it cannot be advised for routine use in chronic HD patients [81] despite its growing application in pediatric plasmapheresis and continuous renal replacement therapy (RRT). In patients with high risk of bleeding, alternative approaches include saline hemodialyzer boluses 60–90 ml/h, optimizing the blood flow depending on the filter, and if the patient is on HDF trying the predilution HDF technique [77].

To prevent CVC malfunction and bacteremia, the only RCT in adults includes 225 patients undergoing HD. The use of heparin three times a week increased the incidence of catheter malfunction (hazard ratio [HR] 1.91, 95% confidence interval [CI] 1.13–3.22, I = 0.02) and catheter-related bacteremia (HR 3.30, 95%CI 1.18–9.22, $P = 0.02$) compared to recombinant tissue plasminogen activator (rt-PA) [82]. In the pediatric population, Gittins et al. conducted a double-blind multiperiod crossover randomized study comparing heparin to alteplase lock in nine children [83] and the main outcome was a 2.4-fold higher risk of clotting when heparin lock is used. In a recent Cochrane review, a combination of antimicrobial and antithrombotic lock solutions did not make any difference to thrombosis compared to the use of standard locking solutions alone [84].

Treatment of Thrombosis

Thrombosis includes both late-onset CVL malfunction (more than 7 days after catheter insertion) and/or fibrin sheath formation (with or without infection). A Cochrane review suggests that thrombolysis with t-Pa should be tried for restoring the CVC patency as it is a safe and effective treatment [85, 86]. Studies in adults suggest that interventional radiology techniques are equal to pharmacological treatment [87] whereas catheter exchange appears to be a superior choice in sheath disruption [88].

Dry Weight and UF Management

At the time of prescribing dialysis, it is important to have assessed the fluid status of the patient, their dry weight, and the desired fluid removal. Prescribing UF allows for the balance of the fluid input and the removal of excessive fluid over time, which serves to make room to maximize nutrition and provide solute clearance by a convective mechanism. Dry weight is the postdialysis session weight at which the patient is considered to be euvolemic and under which the patient will become symptomatically hypotensive. Hypotension is related not only to UF but also to the plasma refilling rate [89]. Incorrect dry weight estimation, with an underestimation of dry weight, can lead to hemodynamic instability, manifesting as hypovolemia-related symptoms or intradialytic hypotension. Defining the dry weight of a child can be very challenging; the physician must account for appropriate growth and changes in body composition, promoting adequate food intake and keeping in mind the largely liquid diet of infants.

Currently, there is no optimal method for assessing the dry weight of a child. Clinical evaluation is the most frequently used method to assess a patient's hydration status. Physical examination for edema, BP measurement, and laboratory parameters such as hemoglobin/hematocrit and serum albumin levels have routinely been used to assess the fluid status of patients on dialysis. Other commonly used techniques include clinical assessment (orthostatic vital signs, jugular venous distention), biochemical markers (e.g. atrial natriuretic peptide [ANP], n-terminal pro brain natriuretic peptide [NTproBNP]), inferior vena cava diameter, bioelectric impedance spectroscopy (BIS), and noninvasive blood volume monitoring markers (Table 66.5). The most commonly used method in children on dialysis is the BIS technique, which estimates the TBW, lean and adipose tissue mass, and overhydration, though scarce data are available on the accuracy of BIS in estimating fluid overload in children on dialysis [93, 103, 104]. In a prospective, observational study in children on dialysis (PD and HD), it was suggested that BIS can serve as an objective method for the assessment of hydration status [90]. In this study, there was a poor correlation between clinical assessment of "dry weight" and BIS-determined weight, with the BIS-determined weight showing a strong correlation with peripheral pulse pressure, higher NTproBNP, and left ventricular end-diastolic diameter. The study also noted a marked discrepancy between BP and hydration status, suggesting that factors other than volume overload may contribute to high BP in some children on dialysis [90]. A further study has shown an improvement in left ventricular mass index (LVMI) and pulmonary edema when BIS was used to guide target weight [94].

Complications of Dialysis

The most serious complications of conventional HD are severe intradialytic hypotension, dialysis disequilibrium syndrome, air embolism, hemolysis during dialysis, and bacteremia/septicemia. Intradialytic hypotension is the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

commonest complication and may be due to multiple patient- and dialysis-related factors, such as difficulty in assessing the dry weight of a patient and targeting higher than required or very rapid UF during the short period of dialysis treatment. Many adult studies have associated intradialytic hypotension episodes with high cardiovascular and all-cause mortality [105]. There are no large studies in children, but a small single-center study has shown that pediatric nocturnal HDF improves the patients' hemodynamic stability [31].

The most common complications in HD patients, and although mild can be extremely distressing for children, are cramps, headaches, nausea, and dialysis-related hypertension. The 3H study reported improved health-related quality of life perceived by children on HDF, but, since the study is not blinded, results must be interpreted with caution [30].

Table 66.5 Summary of findings: dry weight assessment in children.

Method	References	Conclusions	Level of evidence (GRADE)
Biochemical markers	Eng et al. [90] (30 children, longitudinal study, comparison with 13 age-matched healthy controls)	NT-proBNP was significantly elevated when bioimpedance analysis showed overhydration. However, no correlation was seen between NT-proBNP levels and clinical estimation of fluid overload.	Low
Inferior vena cava diameter	Krause et al. [91] (15 children, prospective observational study) Sonmez et al. [92] (12 children, matched-case control study)	Following hemodialysis mean IVCD (average of expiration and inspiration) decreased from 1.12 ± 0.38 to $0.75 \pm 0.26\,cm/m^2$ ($P < 0.0001$). Changes in IVCD were significantly correlated with alterations in body weight following dialysis ($P < 0.0001$). The collapse index (percentage change in IVCD in expiration vs. inspiration) increased significantly after dialysis ($P = 0.035$). IVCD clearly reflected alterations in fluid status. It did not vary significantly with changes in dry weight in a given patient. Increased diameter of the inferior vena cava and plasma ANP concentrations and decreased collapsibility due to overhydration was found. Echography of inferior vena cava may be a promising noninvasive tool to estimate the dry weight in hemodialysis children	Low
Bioelectric impedance study	Eng et al. [90] (30 children, longitudinal study, comparison with 13 age-matched healthy controls) Zaloroszyc et al. [93] (23 children, 1-year retrospective study) Paglialonga F et al. [94] (13 patients on HD 2007 compared to 18 patients on HD 2011, retrospective comparison using the BIS) Brooks et al. [95] (seven children, randomized single-blinded treatment with repeated measurement) Dietel et al. [96] (28 children, prospective study)	BIS provides an accurate assessment of the hydration status and correlates with established biomarkers like NT-proBNP and cardiovascular measures (BP, PWV). Hypertension is not always related to overhydration. Therefore, BIS should restrict the practice of "probing dry weight" in hypertensive children. Moreover, sodium dialytic balance needs to be considered to improve BP management. BIS may be useful in assessing dry weight in pediatric patients on HD. When applying the BIS on patients in 2011, they experienced no pulmonary edema (3/13 patients on 2007 presented four PE episodes). Moreover, when using the BIS patients experienced significantly less LVH and had lower LVMI. Subsequently, by using this tool we can improve patients' cardiovascular status. The use of BIS during HD may aid in the prediction of cardiovascular instability before the development of symptoms because intravascular hypovolemia and hypotension can result from excessive UF below the critical dry weight. In addition, BIA explains, in part, the variability of SBP, DBP, and HR during HD. We suggest that our data also demonstrate the delay in mobilization of fluid from the interstitial space for plasma refill, as evidenced by the delayed change in |Z| over HD. Bioelectric impedance is useful for explaining changes in volemic status and, in part, the variability of SBP, DBP, and HR during HD. Strong correlations of both resistance and IVCD with age, height, weight, and, in particular, body surface area was found. Applying age-related reference intervals to pediatric dialysis patients resulted in overestimation of overhydration.	Low

Table 66.5 (Continued)

Method	References	Conclusions	Level of evidence (GRADE)
Noninvasive blood volume monitoring (e.g. "Crash" Hct[a])	Michael et al. [97] (nine children, prospective study) Fadel et al. [98] (15 children, prospective study) Patel et al. [99] (20 children, prospective) Candan et al. [100] (nine children, observational study)	Routine determination of target dry weight using NIBVM and aiming for 100% UF helps to achieve the target dry weight, reduces both the risk of chronic fluid overload and the need for antihypertensive medication, and does not lead to increased intra- or interdialytic symptomatology in pediatric patients treated with chronic HD. NIVM can serve as an objective method for determining dry weight as well as predicting and preventing intradialytic morbid events in the pediatric population on maintenance HD. Adoption of a standardized NIBVM-guided algorithm led to (i) improved ABPM profiles, (ii) decreased antihypertensive medication burden, and (iii) decreased UF-associated symptoms. Wider use of NIBVM-guided UF may decrease cardiovascular morbidity in pediatric HD patients. Short-term BVM-guided UF may be a useful tool to diagnose volume overload and to adjust dry weight and, consequently, to achieve a better control of BP in pediatric HD patients.	Low
Lung USS	Allinovi M et al. [101] (23 children, prospective observational study)	Lung ultrasound is a practical and sensitive method of quantifying subclinical fluid overload in infants and children on dialysis.	Low
Air displacement plethysmopgraphy	Wong Vega and Srivaths [102] (15 pediatric and young adult patients, prospective study)	This is the first pediatric dialysis study using ADP to assess body composition. Estimation of FM in pediatric HD patients via ADP and BI has significant error rates in two populations: (i) males with Tanner stage ≥4 (BI underestimates FM) and (ii) weight extremes (BI underestimates FM for obese and overestimates FM for malnourished). BI should be used with caution in these populations when estimating fluid content and leads to false estimates of dry weight.	Low

ABPM, ambulatory blood pressure monitoring; ADP, air displacement plethysmopgraphy; ANP, atrial natriuretic peptide; BI, bioelectrical impedance; BIS, bioelectric impedance study; BP, blood pressure; BVM, blood volume monitoring; DBP, diastolic blood pressure; FM, fat mass; HD, hemodialysis; HR, heart rate; IVCD, inferior vena cava diameter; LVH, left ventricular hypertrophy; LVMI, left ventricular mass index; NIBVM, noninvasive blood volume monitoring; NIVM, noninvasive hematocrit monitoring; NT-proBNP, N-terminal pro-brain natriuretic peptide; PE, pulmonary embolism; PWV, pulse wave velocity; SBP, systolic blood pressure; UF, ultrafiltration. USS, ultrasound scan.
[a] "Crash" Hct is the level of Hct at which the patient has lost more than 10% of his blood volume in 3 hours.

The 3H study showed that patient-related outcome measures that are primarily associated with fluid status, such as the postdialysis recovery time, headaches, dizziness, and cramps, were less frequent and less severe in HDF compared to HD patients. A lower interdialytic weight gain on HDF, implying lower UF rates per session and greater hemodynamic stability, was strongly associated with fewer symptoms. This is supported by the FRENCHIE study, in which fewer symptomatic intradialytic hypotensive episodes and muscle cramps were reported in a vulnerable population of elderly dialysis patients [6]. Similarly, ESHOL reported a lower risk of stroke attributed to improved intradialytic hemodynamic stability in HDF [5, 106]. The Standardized Outcomes in Nephrology – Hemodialysis (SONG-HD) workgroup has identified fatigue as one of the most highly prioritized outcomes for dialysis patients and clinicians [107], and we suggest that it is included in future studies in adults or children on dialysis.

HD in Young Children <10 kg

Neonates and children below 10 kg are very challenging to dialyze for many reasons; vascular access is one of the main issues, as the size of the CVC required may be disproportionally large for the size of the vessels of the neonate/toddler to achieve an adequate blood flow (Poiseuille's law) and usually only single-lumen catheters can be used. The relatively large circuit volume (≥60 ml) implies blood priming to avoid dilution with crystalloid use and anemia in case of circuit loss. For these reasons, PD is usually the modality of choice for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. RRT in infants, but can be fraught with difficulties such as unpredictable UF and less efficient clearance [108]. Currently, the CARPEDIEM device has become available with a miniaturized extracorporeal circuit (27 ml) for babies as small as 2.5 kg and its fluid pump imprecision is ±7.5% [109]. Coulthard et al. have developed the NIDUS machine, which has a circuit volume of 13 ml and can be used in babies weighing as little as 800 g and 3.4 kg, using a single-lumen access line, and without the need for blood priming [110, 111]. The NIDUS generates higher urea, creatinine, and phosphate dialysis clearances than PD, and delivers more precise UF control than either PD or conventional HD [108]. These new machines may allow more precise and safer conventional HD in small children, but more data are needed.

General suggestions based on our experience and the existing literature are:

- **Access in very small children**: Single lumen access may be more appropriate as the lumen of the catheter will be larger and therefore the flow that can be obtained through it is relatively greater. To obtain bidirectional blood flows with a single lumen line, the dialysis circuit has to be modified. This can be achieved by the double-pump method, using two blood pumps which pump alternately, or by using a single pump which pumps intermittently, using gravity to let blood flow back into the child. Disadvantages of the single lumen catheter are that an expansion chamber is necessary in the circuit to allow for the pressure changes and this increases the volume of the blood circuit; dialysis adequacy and clearances are also compromised by a greater degree of recirculation.
- **Anticoagulation**: Tighter control of the degree of anticoagulation can be achieved with lower ACT target ranges, as the increased likelihood of clotting has to be weighed against the detrimental effects of bleeding.
- **HD prescription**: Normally four to five sessions per week are needed in such small children to promote optimal nutrition without restricting the feed volume. Blood priming of the extracorporeal circuit is likely to be needed, and careful attention should be paid to the volume of fluid used for extracorporeal blood replacement at the end of the session.

Urinary Tract Infections in Children

Nicholas G. Larkins[1,2] *and Jonathan C. Craig*[3]

[1] *Department of Nephrology, Perth Children's Hospital, Nedlands, Western Australia, Australia*

[3] *College of Medicine and Public Health Flinders University, Adelaide, Australia*

Introduction

Urinary tract infections (UTIs) are a common and potentially serious infection among children. While most infections are readily treated and do not lead to long-term sequalae, some children go on to develop recurrent infections and/or kidney damage. This chapter reviews the epidemiology of UTIs among children, presentation and treatment of acute infection, risk factors and approaches to managing recurrent infection, the role of diagnostic imaging, and long-term outcomes. Table 67.1 presents recommendations for practice based on the available evidence, which is summarized by topic in Summary of Findings tables throughout the chapter.

Epidemiology

The cumulative incidence of UTIs is around 8% among girls and 2% among boys prior to 7 years of age [2]. The highest risk period for febrile UTIs is the first year of life, when infection is slightly more common among boys, thereafter nonfebrile UTIs among girls predominate [3]. Among boys, circumcision is associated with a substantially lower risk of UTI [4, 5]. *Escherichia coli* (*E. coli*) is the causative organism in about 90% of infections [6, 7]. While there is some fluctuation across time and place, other common causative organisms include *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, and *Enterococcus* species. Infections caused by organisms other than *E. coli* are more common among children with urinary tract abnormalities [8, 9]. Antibiotic resistance is an increasing problem, and more likely among children who have recently received antibiotics [10]. This is reflected globally by a higher prevalence of resistant organisms in countries with a higher rate of antibiotic use among the community, for example where antibiotics are available over the counter [11].

Among children with febrile UTIs, approximately 60% will have renal parenchymal involvement (pyelonephritis), 25% of whom (15% overall) will have residual kidney damage on a follow-up dimercaptosuccinic acid scan (DMSA; otherwise referred to as renal scarring) [12, 13]. The risk of kidney damage is predicted by the severity of initial pyelonephritis as measured by inflammatory markers (neutrophil count, c-reactive protein [CRP]) and temperature, the presence of structural abnormalities on ultrasound, infection with an organism other than *E. coli*, and vesicoureteric reflux (VUR) [13]. Individual patient meta-analysis of 1280 children following a first UTI found that the inclusion of more invasive measures (inflammatory markers, voiding cystourethrogram [VCUG]) added little the predictive ability of a model comprising of only temperature (≥39 °C), ultrasound findings (normal/abnormal), and a causative organism other than *E. coli* [13]. Lower urinary tract dysfunction predicts future kidney damage among children with UTI, probably by increasing the likelihood and frequency of recurrent infections [14].

Between 10% and 20% of children will develop a second UTI in the year following their index infection, with this risk being greatest in the first 3–6 months [15, 16]. A number of risk factors predict recurrence, including the presence of VUR, lower urinary tract dysfunction, and an abnormal renal tract or parenchyma at baseline, with isolated VUR being the least strong predictor, but more important when concurrent with lower urinary tract dysfunction or at higher grades [17].

Table 67.1 Treatment of urinary tract infection in children.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Route of antibiotic delivery	Oral antibiotics are as effective as IV antibiotics in children >1-month old with pyelonephritis. For those too unwell or unable to tolerate oral antibiotics initially, 2–4 days of initial IV therapy is equivalent to 7–14 days.	Moderate (time to resolution of fever, microbiologic cure, recurrence, kidney damage)	Strong
Length of treatment for pyelonephritis	The total length of treatment should be 7–14 days.	Low (microbiologic cure, recurrence)	Weak
Length of treatment for cystitis	A 3- to 7-day course can be used in children with uncomplicated cystitis.	Low (microbiologic cure, recurrence)	Weak
Prophylaxis for recurrent infections	Antibiotic prophylaxis results in small risk reduction for children following an initial UTI (NNT ~ 15 patient-years of antibiotics to prevent one recurrence), but does not reduce kidney damage.	Moderate (recurrence) Low (kidney damage)	Strong
Surgery for vesicoureteric reflux	Given the natural history to improvement with time and negative trial results to date, a watchful waiting approach is appropriate for most patients initially.	Moderate (recurrence, kidney damage)	Strong

CI, confidence interval; IV, intravenous; NNT, number needed to treat.
GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Pathophysiology

Most infections are caused by ascending coliform bacteria, with both host and pathogenic factors contributing to the development and sequalae of UTI. At the pathogen level, the predominance of *E. coli* amongst causative organisms is partly due to the presence of fimbria on most uropathogenic strains [18]. These allow the bacteria to adhere to the uroepithelium in the presence of normal urinary flow, which under normal circumstances acts to displace bacteria within the urinary tract [19]. The host's immune response to infection has been implicated in the pathogenesis of UTI, and several genetic loci linked to innate immunity have been associated with recurrent infection, although heterogeneity among published studies makes it difficult to be certain about the relative importance of individual genes [20]. Another host factor facilitating infection is VUR, which is the retrograde passage of urine from the bladder into the ureter, resulting from an incompetent vesicoureteric valve. As a result, bacteria from the bladder are more easily transferred to the upper urinary tract, potentially leading to pyelonephritis. The vesicoureteric valve is formed at the vesicoureteric junction by the oblique passage of the ureter through the detrusor muscle. VUR is graded from 1–5 according to VCUG findings [21]. Grades 3–5 are associated with progressive dilation of the renal pelvis and calyces, and are often referred to as high-grade, or dilating, reflux. VUR tends to improve with age, as detrusor muscle structure and function matures. Hereditability among families with VUR is well described, but efforts to elucidate the genetic etiology suggest the cause is polygenic and/or the result of complex effect modifiers [22]. Host factors are also important in the development of kidney damage following pyelonephritis. Consistent with its role as one of the key genes regulating fibrosis, transforming growth factor-β1 has been identified as a susceptibility locus [23]. Angiotensin converting enzyme inhibitor polymorphisms may also be important [23]. While both genes are biologically plausible candidates, study quality and heterogeneity limit the certainty of this evidence.

Nonbacterial UTIs can occur (such as fungal, viral), but are uncommon in the immunocompetent host. One notable exception is adenovirus, which may cause a self-limited hemorrhagic cystitis in otherwise well children [24].

Diagnosis

Presentation

Older children with UTIs present in a similar fashion to adult patients. Where infection is limited to the bladder and urethra (cystitis), symptoms may include malodorous

and/or cloudy urine, dysuria, frequency, urgency, lower abdominal pain, and fever. Infection extending to the kidneys (pyelonephritis) may produce flank pain, and children tend to be more systemically unwell, with vomiting, lethargy, and a high fever.

Young children and infants often have difficulty localizing symptoms. Thus, vague abdominal pain or fever without focus may be the only presenting feature. In combination with the relative frequency of UTIs among children, this makes testing for UTIs mandatory in young children presenting for fever without focus.

Sample Collection

The diagnosis of UTI first requires the collection of an uncontaminated urine sample. In toilet-trained children midstream collection is used, but this is not usually possible for younger children. Bag urine samples are frequently contaminated and are useful in ruling out infection only [25, 26]. Clean catch samples, in–out urethral catherization, and a supra-pubic aspirate are all reliable options [27], although the latter two are more appropriate in children clinically evaluated to be systemically unwell, requiring prompt antibiotic administration. The collection of a clean catch sample may be aided by techniques to encourage voiding. One randomized controlled trial (344 infants) found rubbing cold soaked gauze over the suprapubic region to be effective, resulting in 31% versus 12% of controls voiding within 5 minutes (difference in proportions 19%, 95% confidence interval [CI] 11–28) [28]. Successful supra-pubic aspiration may be aided by bladder scan prior to confirm an adequate quantity of urine in the bladder to readily aspirate. There is widespread practice variation, and the exact approach will also depend on local resources and expertise.

Rapid Diagnostic Testing

The most common rapid diagnostic test is urine dipstick testing for leukocyte esterase and nitrites. Applying an either/or rule for leukocyte esterase (≤ trace) and nitrites, correctly identifies 88% of children with UTI (sensitivity 0.88, 95% CI 0.82–0.91) and conversely a dual negative result makes UTI unlikely. A dual positive result for leukocyte esterase and nitrites is uncommon in children without UTI (specificity 0.98, 95% CI 0.96–0.99). While urine microscopy for white cells is still routinely performed at most centers, leukocyte esterase testing is at least as accurate [29]. Where available, microscopy for bacteria, including gram staining, is the single most accurate test (sensitivity 0.91, 95% CI 0.80–0.96; specificity 0.96, 95% CI 0.92–0.98). However, there is substantial heterogeneity among study results, partly because the relative accuracy of tests varies according to the population sampled (outpatient, inpatient, concurrent bacteremia) and reference standard used (method of collection, culture criteria) [29, 30]. Among some populations, for example where there is a high pretest probability of infection, a clinically relevant number of inaccurate results will be obtained if using rapid diagnostic testing alone.

Microbiologic Criteria

Confirmation of UTI requires the growth of a potentially causative organism from an uncontaminated sample. Both clean-catch and catheter samples may be contaminated during collection, and low-level growth or mixed growth is usually considered to represent contamination. Given urine culture is the current reference standard, it is difficult to establish the accuracy of different culture thresholds and recommendations vary. One approach, based on a review of the literature and expert opinion, is presented in Table 67.2. None of these criteria are absolute, and UTIs have been described at lower thresholds. As with rapid diagnostic testing, interpretation must also depend on the clinical scenario.

While urine culture is the current reference standard, asymptomatic bacteriuria is well described. Cross-sectional screening of 89% of the population of 5–12-year schoolgirls in Cardiff (United Kingdom, 13 369 children) demonstrated a covert bacteriuria prevalence of 1.7% [31]. Furthermore, random allocation of those with bacteriuria to treatment or not had no impact on long-term outcomes. Even among infants, bacteriuria is not uncommon and may have a similar prevalence again [32].

Role of Inflammatory Markers to Identify Pyelonephritis

The utility of CRP, procalcitonin, and the erythrocyte sedimentation (ESR) rate in identifying pyelonephritis among children with febrile UTI has been examined in a Cochrane review (six studies with procalcitonin, 434 children; 13 studies with CRP, 1638 children; six studies with ESR, 1737 children) [33]. This found that a low CRP (<20 mg/l) was the best test to rule out pyelonephritis, reducing the post-test probability to <20%, assuming a pretest probability of 60%. Procalcitonin was the most specific test (summary estimate 0.74, 95% CI 0.55–0.87), and so may be more suited to ruling in infection. While the risk of bias among included studies was low, the certainty around these estimates for specific populations was limited by heterogeneity among included studies.

[b] Based on consensus opinion of three senior staff specialists in infectious disease, general medicine and nephrology (Children's Hospital at Westmead).

Prognosis

Prospective data suggest that clinically meaningful complications following UTI in children (such as chronic kidney disease or hypertension) without kidney damage at baseline are rare [34]. While new kidney damage on DMSA is often used as a surrogate outcome, this would indicate it is an overly sensitive measure, possibly because most scars involve a relatively small amount of the renal parenchyma and children with previously normal kidneys have adequate renal reserve to compensate for a small reduction in nephron mass.

Historically, kidney damage due to UTI in childhood was thought to be an important cause of end-stage kidney disease (ESKD), and when associated with VUR was labeled reflux nephropathy. However, ESKD due to reflux nephropathy is rare, and many cross-sectional studies likely misclassified cases of renal dysplasia as reflux nephropathy, given testing at a single timepoint cannot reliably differentiate the two [35–37]. That VUR and dysplasia commonly coexist should not be surprising given normal ureteric budding is necessary to induce normal renal development in the developing fetus. The term congenital abnormalities of the kidney and urinary tract (CAKUT) encompasses patients with renal dysplasia and/or concurrent VUR, and better reflects our current understanding of the association between the two [35]. This concept is reflected in registry data, which in recent years, despite a trend to less aggressive management of UTI and VUR, have reported a falling prevalence of ESKD attributed to reflux nephropathy [38, 39]. In contrast, during 1971–1998, when extensive investigation and surgical management of VUR were more common, there was no change in the prevalence of ESKD due to reflux nephropathy [37]. Further to these trends, the low frequency of ESKD due to reflux nephropathy (incidence ~5 per million per year) has never been consistent with clinically relevant kidney disease being common following childhood UTI (prevalence ~5% or 50 000 per million) [37]. In retrospect, a failure to recognize this substantial discrepancy, and a focus on radiologic findings, led to a large number of children being subjected to invasive and unnecessary procedures [40].

Without intervention, the natural history of VUR is resolution with time. Among children enrolled in the Randomized Intervention for Children with Vesicoureteric Reflux (RIVUR) trial, which included 607, <6-year-old children with proven VUR (47% grade 3 or 4), VUR resolved in 51% and was downgraded in a further 23% during 2 years of follow-up [41]. These data are similar to those from other randomized trials for children enrolled in nonoperative intervention or placebo arms [42].

Treatment and Imaging

Acute Infection

Increasingly, the treatment of febrile UTI and pyelonephritis in children is informed by trial-level evidence, with the current Cochrane review including 4452 children from 27 randomized trials [43]. The first set of trials to be performed demonstrated that among children receiving intravenous antibiotics initially there was no difference between a short duration (3–4 days prior to transition to oral antibiotics) and a long duration (7–14 days) of intravenous therapy. This applies equally to symptoms (most commonly measured as time to resolution of fever), proportion of children free of bacteriuria following treatment, and the prevalence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. persistent renal defects on a 3- to 6-month DMSA scan (Table 67.3) [43]. The next series of trials for pyelonephritis in children investigated whether it was possible to forgo the intravenous component altogether and use only oral antibiotics. These again demonstrated no difference in outcomes between treatment arms (Table 67.4) [43]. Among children receiving intravenous antibiotics initially, the time to resolution of fever was on average 2.05 hours longer (95% CI 0.84 shorter to 4.94 longer) and the relative risk of renal parenchymal defects after 6–12 months 0.82 (95% CI 0.59–1.12). There is still substantial uncertainty around the estimates for kidney damage and in some subgroups of children, such as those with high-grade VUR. The quality of evidence for most findings is moderate, with loss to follow-up (attrition bias) and unclear allocation concealment common among reported trials. Regardless, there are sufficient data on which to make evidence-based suggestions about clinical care (Table 67.1).

There are insufficient head-to-head data to recommend a specific choice of antibiotics, which will be influenced by regional variation in antimicrobial resistance and access to specific agents. The combination of an aminoglycoside to cover gram-negative organisms including *E. coli* and a penicillin to cover *Enterococcus* species, is common. Once-daily aminoglycoside dosing appears as effective and safe as 8-hourly dosing, and although the quality of evidence is low, it seems likely that the large evidence base for once-daily dosing in adults can be translated to children [43].

There are few data to guide the total duration of therapy in children with pyelonephritis, and 7–14 days therapy remains standard practice. However, among children with uncomplicated, lower UTI, it appears the duration of therapy can be safely shortened to 3–5 days (Table 67.5) [44]. The certainty around these estimates for children is low, but the findings are consistent with the large, high-quality evidence base among adults. The current Cochrane review includes four studies (328 children) in the comparison between 3–7 and 7–10 days of antibiotics (Table 67.5) [44]. Another systemic review performed in 2001, with broader inclusion criteria, that included 22 studies (1279 children) found 3 days of therapy equivalent to longer courses [45]. Small studies have considered the efficacy of single-dose therapy, and although the sample sizes are reflected by low precision, persistent bacteriuria was significantly more common (six studies, 228 children, relative risk [RR] 2.01, 95% CI 1.06–3.8). For adults, the extent which antibiotic use in the treatment of cystitis can be minimized has been investigated by randomized trials comparing symptomatic-first and antibiotic-first approaches. These have shown that while it is possible to avoid antibiotics in some patients, around half of those treated symptomatically go on to require treatment. Different authors have interpreted these data differently, either as indicating a failure of symptomatic-first treatment or that symptomatic-first treatment is appropriate for some patients in conjunction with appropriate counseling and a shared decision-making approach [46, 47]. At this point in time there is no evidence to support this strategy in children.

Most trials investigating UTI exclude children less than 1 month of age. One reason for this is a higher rate of bacteremia among young infants, with approximately 10% of

Table 67.3 Summary of findings: short- versus long-course intravenous antibiotics for febrile urinary tract infection.

Outcomes	No. of participants (no. of studies)	Absolute effect (95% CI)	Relative risk (95% CI)	Certainty of evidence (GRADE)	Conclusion
Persistent bacteriuria	305 (4)	Assuming baseline risk 5 per 1000, corresponding risk 4 per 1000 (1–13)	0.78 (0.24–2.55)	Low	Unclear whether longer treatment improves frequency of microbiologic cure
Recurrent infection within 6 months	993 (5)	Assuming baseline risk 59 per 1000, corresponding risk 57 per 1000 (34–95)	0.97 (0.58–1.62)	Moderate	No reduction in recurrent UTI in 6 months following treatment
Persistent kidney damage at 3–6 months	726 (4)	Assuming baseline risk 246 per 1000, corresponding risk 249 per 1000 (197–318)	1.01 (0.8–1.29)	Moderate	No reduction in risk of kidney damage

CI, confidence interval; IV, intravenous.
Corresponding risk is the absolute risk for those in the intervention arm.
GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. children less than 2 months of age having bacteremia at presentation [48]. Hence, it is common practice to initiate treatment with 2–3 days of intravenous antibiotics for young infants with febrile UTI before transitioning to oral antibiotics, provided the child is systemically well and blood cultures are negative. There is variation in the exact threshold applied, but most centers apply a cutoff between 1 and 3 months of age.

Imaging Following Pyelonephritis in Children

The evidence base to guide imaging following pyelonephritis is mostly limited to low-quality, diagnostic test accuracy studies using VUR on VCUG, or kidney damage on DMSA, as the reference standard [49]. Uncertainty about how clinically important either finding is limits the applicability of such studies. A randomized trial of imaging pathways has been performed, but details are limited to the publication

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. of one abstract. The trial included 172 2- to 10-year-old children following a first UTI, randomized to routine ultrasound and VCUG, or a selective approach based on recurrent UTI or concerns [49, 50]. There was no difference in UTI recurrence or kidney damage between the arms after 2 years of follow-up, despite 100% of children in the routine arm and 21% of children in the selective arm receiving imaging at some point.

Ultrasound is commonly performed following UTI in children younger than 2–3 years of age. It is a relatively inexpensive, noninvasive procedure that can detect important structural abnormalities, such as posterior urethral valves or severe ureteropelvic junction obstruction, that require surgical intervention [51]. In isolation, ultrasound is not an accurate test for VUR or predictor of subsequent kidney damage [49]. However, the test performance of ultrasound improves substantially when combined with other noninvasive tests [13]. As antenatal ultrasound technology improves, it may be that most children with severe structural urinary tract abnormalities are identified on routine antenatal screening. This would reduce the benefit to performing ultrasound in all children following a first UTI, facilitating a more selective approach to imaging [52].

Nuclear medicine scans are another commonly used imaging modality in childhood UTI. Reduced radioisotope uptake during acute infection signifies pyelonephritis, but rarely changes management [52]. A persistent, new, parenchymal defect following UTI is the reference standard for acquired kidney damage. DMSA provides better cortical resolution than MAG-3, and thus is preferred for this purpose unless obstruction is a specific diagnostic consideration. As discussed previously, most scars detected will not result in clinical sequalae, limiting the clinical utility of routinely performing delayed DMSA. One reason cited for performing delayed DMSA scans in children following UTI is that a normal result makes high-grade VUR highly unlikely [52, 53]. However, a poor specificity (0.44, 95% CI 0.33–0.56) in combination with a low pretest probability of high-grade VUR among most populations will result in a large number of false-positive results, which would require progression to VCUG if detecting high-grade VUR is the primary purpose of the investigation [54]. Assuming a pretest probability of 13%, among 1000 children screened by DMSA for high-grade VUR there will be 487 false-positive results. The relevant Cochrane review includes 10 studies (2499 children), five of which were assessed to be at high risk of bias or reduced applicability, mostly because of patient selection concerns [54]. This was reflected in heterogenous results, leading to low certainty about the findings. However, the results were unchanged when considering only studies at low risk of bias, and no study had a specificity approaching 90%, making it unlikely that the true specificity will be adequate in a population where the pretest probability is low.

VCUG is the reference standard to detect VUR. The test should be delayed until acute infection has resolved, and despite limited evidence many suggest a brief period of antibiotic prophylaxis to prevent procedure-induced infection [55]. It is no longer standard practice to routinely perform VCUG following a first UTI in children. The main reason for this is the low likelihood that a diagnosis of VUR will confer a meaningful change in management, given current evidence suggests that available interventions are highly unlikely to result in a clinically meaningful risk reduction (further discussed in next section). Another reason is that high-grade VUR is uncommon among children presenting with a first UTI, being identified in only 3–4% of cases [7, 13]. The prevalence of high-grade VUR is lower (≤1%) in children with uncomplicated, *E. coli* infections, even among those <3 months old [7]. VCUG is an invasive test, requiring the placement of a urinary catheter and a small ionizing radiation dose [56]. Indirect cystography using a radioisotope such as MAG-3 is appealing as a less invasive method, but the negative predictive value is low and thus utility in reducing formal VCUG limited [49]. VCUG remains an important test in selected cases, for example to detect posterior urethral valves when ultrasound findings indicate obstruction.

Management of Children with Recurrent Infections

There are three main approaches to managing a child with recurrent UTIs: watchful waiting, continuous antibiotic prophylaxis, and surgical correction of VUR when present. Multiple, well-designed, randomized trials have been conducted comparing antibiotic prophylaxis to placebo for the prevention of recurrent UTI. While antibiotics are effective at reducing the incidence of recurrent infections, the effect size is modest (number needed to treat [NNT] is ~15 patient-years of antibiotics to prevent one recurrence) [16, 41]. This must be balanced against an increased proportion of antibiotic-resistant UTI among children on prophylaxis, which may limit the ongoing efficacy of treatment. Since the results of the Cochrane review summarized in Table 67.6, the RIVUR trial has been published [41, 57]. RIVUR demonstrated a similar effect size to previous trials, but among a study population with confirmed VUR (47% grade 3 or 4). The effect size appears constant across sex, age, VUR grade (≤4), and children with a first or second infection. While no individual study has been adequately powered for kidney damage as the primary outcome, a recent systematic review and meta-analysis (seven trials, 1427 children) found no evidence of benefit among the

[a] Studies with adequate allocation concealment.
[b] Small number of patients with recurrent infection, but both well-designed and reported trials, supported by subsequent trial and observational evidence.

cumulative published data (risk ratio 0.83, 95% CI 0.55–1.26) [58]. There is a lack of evidence to guide treatment of children in higher risk subgroups, such as those with a history of frequent UTI or severe hydronephrosis. If the relative effect size among these patients is at least equal to the lower risk populations enrolled in trials to date, then they might derive a substantial risk reduction (absolute effect size) with treatment.

Given high-grade VUR is a predictor of recurrence and parenchymal damage among children presenting with UTI, operative interventions designed to correct VUR have been proposed as a method to improve outcomes among this group of patients. There are two broad categories of intervention, surgical re-implantation of the ureter into the bladder and the endoscopic injection of bulking agents. While intuitively appealing, and previously commonly practiced, it is not clear that operative intervention improves outcomes. One factor favoring the null hypothesis (no effect to intervention) is that the natural history of VUR is improvement over time. Another is that VUR is one of many factors predicting outcomes among children with UTI, and it may be that other factors are relatively more important in determining a patient's clinical course. Compared to no antibiotic prophylaxis alone, endoscopic correction is more likely to result in resolution of VUR after 1–2 years (two studies, 164 children, risk ratio 2.69, 95% CI 1.57–4.63) [59]. In the European arm of the International Reflux Study, surgical correction did not significantly impact VUR status, which is unsurprising given VUR resolved in 299 of 310 ureters among children in the antibiotics-only arm (risk ratio 0.97, 95% CI 0.93–1.00) [59, 60]. Multiple trials have been conducted, but variable methodology and a lack of blinding (bias toward a greater effect size) means there is low certainty about the impact of surgical or endoscopic correction on specific clinical outcomes (Table 67.7) [59]. The available evidence suggests that surgical correction results in a small reduction in febrile UTI by 5 years (equivalent to an NNT of 15), but does not alter the outcomes of symptomatic UTI or kidney damage. Overall, while the certainty about the impact of operative intervention on individual outcomes is low, results consistently indicate that any effect size is small and unlikely to be clinically important. Operative intervention is not without risk, and while some studies report no cases of obstruction, surgical correction resulted in obstruction in 10 of 149 children who received surgery in the European arm of the International Reflux Study [60, 61].

Another important component of treatment that does not usually require pharmacologic or surgical intervention, is the management of lower urinary tract dysfunction, which as discussed is a strong predictor of recurrent infections and kidney damage. Validated questionnaires are available and may improve detection of lower urinary tract dysfunction in clinical settings [62]. Standard therapy for lower urinary tract dysfunction focuses on improving fluid intake and voiding habits. Additional therapies may include bladder training, pelvic floor exercises, biofeedback, and pharmacotherapy aimed at stabilizing detrusor

Table 67.7 Summary of findings: surgery or endoscopic correction for vesicoureteric reflux versus antibiotic prophylaxis (1–24 months).

Outcomes	No. of participants (no. of studies)	Absolute effect (95% CI)	Relative risk (95% CI)	Certainty of evidence (GRADE)	Conclusion
Symptomatic UTI by 1–2 years (endoscopic correction)	179 (2)	Assuming baseline risk 220 per 1000, corresponding risk 194 per 1000 (57–660)	0.88 (0.26–3.01)	Low	Lack of precision does not rule out benefit to endoscopic correction
Symptomatic UTI by 4–5 years (surgical correction)	393 (1)	Assuming baseline risk 250 per 1000, corresponding risk 238 per 1000 (168–338)	0.95 (0.67–1.35)	Low	Single trial result suggests no reduction in symptomatic UTI with surgical correction
Febrile UTI by 1–2 years (endoscopic correction)	179 (2)	Assuming baseline risk 180 per 1000, corresponding risk 131 per 1000 (27–648)	0.73 (0.15–3.60)	Low	Lack of precision does not rule out benefit to endoscopic correction
Febrile UTI by 5 years (surgical correction)	429 (2)[a]	Assuming baseline risk 200 per 1000, corresponding risk 86 per 1000 (64–140)	0.43 (0.27–0.70)	Low	Surgical correction may reduce febrile UTI by 5 years
New or progressive renal parenchymal defects at 4–5 years (surgical correction)	468 (3)	Assuming baseline risk 422 per 1000, corresponding risk 443 per 1000 (359–544)	1.05 (0.85–1.29)	Low	Available evidence does not support preservation of parenchyma by surgical correction
End-stage kidney disease[b]	154 (2)	Assuming baseline risk 40 per 1000, corresponding risk 40 per 1000 (9–202)	1.07 (0.23–5.04)	Very low	Insufficient evidence to draw conclusion
Hypertension	154 (2)	Assuming baseline risk 60 per 1000, corresponding risk 56 (15–205)	0.93 (0.25–3.42)	Very low	Insufficient evidence to draw conclusion

CI, confidence interval; UTI, urinary tract infection.
Renal parenchymal defects and scars were measure by intravenous pyelogram. Corresponding risk is the absolute risk for those in the intervention arm.
GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*
[a] The two studies are the European and United States arms of the International Reflux Study, which were considered separately.
[b] Studies included patients with existing parenchymal defects at presentation, possibly due to renal dysplasia.

activity. One randomized trial among 6- to 12-year-old children attempted to determine the additive value of oxybutynin (compared to placebo) and bladder training among 97 children with urge incontinence, and pelvic floor training among 105 children with dysfunctional voiding. None of the interventions tested significantly improved the cure rate compared to standard therapy, which was 39% among children with urge incontinence and 52% among children with dysfunctional voiding [63]. Standard therapy in this trial included three visits with a urotherapist, printed summaries of treatment for families, and the use of 72-hour voiding diaries. Another treatment modality sometimes employed for lower urinary tract dysfunction is biofeedback, designed to encourage pelvic floor relaxation during voiding. A recent systematic review found no evidence of benefit to biofeedback, including on the incidence of UTI (four studies, 163 children, odds ratio 1.3, 95% CI 0.65–2.58) [64]. Pharmacologic therapy is sometimes used, including anticholinergic agents and alpha-blockade. Small, heterogenous trials, mostly among children whose primary problem is incontinence, means that there is very low certainty about the efficacy of pharmacotherapy in reducing UTI [65]. Anticholinergic agents, such as oxybutynin and tolterodine, are commonly used. One randomized trial of 62 4- to 12-year-old children with VUR and lower urinary tract dysfunction found that prazosin significantly improved urodynamic parameters and the number of children with improvement in VUR at 12 months compared to placebo (60% versus 17%, risk ratio 0.49, 95% CI 0.32–0.75) [66].

As discussed, observational data indicate that circumcision is associated with a substantially reduced incidence of UTI in boys [4]. One randomized trial has been conducted among 70 boys presenting with UTI and a normal renal ultrasound, comparing early circumcision (after 3 days) with delay by 6 months (mean age 29 months in early group and 33 months in delayed group) [67]. While circumcision reduced the frequency of bacteriuria in routinely collected samples, there was no significant difference in the number of children with symptomatic UTI, although a low event rate resulted in the trial being underpowered for this outcome (zero versus three infections, risk ratio 0.15, 95% CI 0.01–2.89). There are no randomized data to support routine neonatal circumcision for the primary prevention of UTI [68].

Cranberries and probiotics have been proposed to be effective in preventing and treating UTI, and both treatments have undergone systematic review by Cochrane. Despite promising results among early trials, the cumulative evidence does not support the routine use of cranberries [69]. Among children with recurrent infections, the pooled effect size was greater than other subgroups (two studies, 309 children, risk ratio 0.48, 95% CI 0.19–1.22), but remained nonsignificant. While suggestive of a subgroup effect, it may also simply reflect the smaller sample sizes among studies in children, with smaller studies being prone to inflated estimates of effect [70]. There are fewer data identified regarding the effect of probiotics. For adults and children with recurrent UTI combined, the pooled risk ratio was 0.74 (275 people, four studies, 95% CI 0.54–1.01), but certainty about this estimate is low [71].

Conclusion

UTI is a common childhood infection. While recurrence and kidney damage on DMSA are well described, the best available evidence suggests that with prolonged follow-up, clinically evident kidney disease among children with normal urinary tracts is rare. For most children with pyelonephritis, intravenous antibiotics are unnecessary. The optimal length of treatment for pyelonephritis in children remains unclear, but some data suggest that a shortened course (3–7 days) is adequate for uncomplicated cystitis. Antibiotic prophylaxis reduces the frequency of recurrent infections, but the effect size is modest for children following an initial, or infrequent, UTI. Fewer trials of operative interventions to correct VUR have been conducted, but overall point to a clinically relevant effect size being unlikely, and prospective studies indicate that most children with VUR do well without intervention. The evidence outlined in this chapter is beginning to translate into practice, with fewer admissions for intravenous antibiotics and VCUG being performed [72, 73]. The current evidence base lacks certainty about treatment effects in specific subgroups, and further trials to identify children that might benefit from more aggressive management are in progress.

Introduction

Henoch–Schonlein purpura (HSP) nephritis and IgA nephropathy are the two most common glomerular diseases occurring in children characterized by predominant glomerular IgA deposits. While IgA nephropathy is a renally limited glomerular disorder, HSP nephritis is associated with extrarenal involvement including the typical rash, arthralgia, arthritis, and gastrointestinal involvement. The understanding of the pathophysiology of IgA nephropathy and HSP nephritis, as of now, is identical, with the difference being that IgA nephropathy tends to have an insidious onset, while HSP nephritis occurs and progresses more acutely. Other differences between the two conditions include the peak age of presentation, with HSP nephritis presenting in childhood and IgA nephropathy commonly presenting between the ages of 15 and 30 years [1]. A nephrotic and nephritic presentation also occurs more commonly in HSP nephritis and more endocapillary and extracapillary inflammation is noted on biopsy compared to children with IgA nephropathy [1]. IgA nephropathy more commonly presents with isolated microscopic hematuria or non-nephrotic range proteinuria associated with hematuria [2] and tends to be a slowly progressive disease that occurs sporadically in its most common form, and rarely as a familial disease.

In HSP nephritis, less common manifestations include genitourinary involvement in the form of testicular inflammation, as well as pulmonary and central nervous system involvement. The occurrence of kidney disease is estimated to be as low as 20% in some studies and up to 50% in other studies [3–6]. The renal disease in HSP is quite variable, with the majority of patients demonstrating spontaneous resolution of the nephritis and treatment strategies are based on the risk of progressive disease [4–7]. HSP is a very common disorder in pediatric patients and is less common in adults. However, as described below the development of renal disease associated with HSP is more common and more severe in adolescent and adult patients with HSP compared to the younger patient with HSP [8–14]. Treatment strategies in HSP are based on very few controlled trials with prednisone to prevent the development of renal disease and virtually no controlled trials for therapy of severe renal disease associated with HSP. While there are no controlled trials of therapy for HSP nephritis, there are multiple case series and anecdotal reports of successful immunosuppressive therapy for severe HSP nephritis. Treatment in IgA nephropathy in children is primarily based on adult literature, with a few randomized control trials in children. HSP nephritis and IgA will be discussed in separate sections in this chapter.

HSP Nephritis

Etiology

While the clinical manifestations of HSP are well known, the specific pathogen(s) that triggers the clinical features of HSP is unknown. Associations with group A beta hemolytic strep infections, viral infections including hepatitis B, herpes simplex, human parvovirus B, influenza, and other infections including Toxocara and mycoplasma have been reported by many investigators [15]. HSP has also been associated with a number of drugs, some immunizations, and other agents [15]. The large majority of the reports associating specific infectious agents, drug, or immunizations with

HSP are anecdotal reports and despite extensive investigation there is no clear pathogen that is accepted as a trigger for the clinical manifestations of HSP. As described below, recent studies suggest genetic susceptibility to the development of HSP and it is also likely that genetic and environmental factors each play a role in the development of HSP and HSP nephritis.

HSP is a leukocytoclastic vasculitis that affects small vessels and the pathology demonstrates white blood cell (WBC) infiltration, small vessels inflammation, and deposition of IgA in vessels obtained from skin biopsies and in the kidney biopsies [16]. IgA containing immune complexes from extrarenal sources result in renal inflammation [16]. In patients who have received a kidney transplant due to end-stage renal disease (ESRD) from HSP nephritis, IgA deposition can reoccur in the transplanted kidney, but this does not typically result in graft failure with the exception of lower graft survival in adults presenting with crescentic nephritis at the time of presentation of HSP [17, 18]. Studies show that abnormalities in the O-linked glycosylation of IgA1 result in abnormal IgA in HSP and in IgA nephropathy [15]. The abnormally glycosylated IgA forms immune complexes with IgG antibodies that are specific to the galactose-deficient abnormal IgA1, which in turn prevents the IgA from being internalized and degraded by liver cells [19, 20]. The abnormal IgA associated immune complexes are deposited in the renal mesangium and trigger the mesangial cells to produce chemokines such as transforming growth factor beta or tumor necrosis factor alpha, which in turn can cause further renal damage [21].

There is no specific test to confirm the diagnosis of HSP and the diagnosis is typically made using the history, physical examination with typical rash, and other clinical manifestations of HSP as described above. In any clinical presentation that is not typical and in severe cases of HSP and HSP nephritis, it is important to rule out other vasculitic diseases such as lupus and ANCA-positive vasculitis with appropriate serologic studies.

Epidemiology of HSP Nephritis

While HSP and HSP nephritis have been described in all age ranges, HSP is most common in children. Age has a major influence on the development of HSP nephritis; multiple studies have demonstrated that the incidence of renal disease in HSP and the severity of the renal disease increases at older ages [22]. A large majority of children with HSP in the first decade of life do not develop serious renal involvement, but the incidence of serious renal disease in the adolescent is increased in comparison to younger children and adults with HSP [9–14].

The incidence of HSP has been reported in several population studies and ranges from 10.45 to 20.4 per 100 000 [23–25]. The incidence of HSP is higher in autumn and winter, and there is a peak amongst children between age of 4 and 6 years of age, with the incidence being as high as 70 cases per 100 000 [4, 23–25]. The incidence of renal involvement in children with HSP is estimated to be around 30–50% [4, 26]. Significant renal involvement manifesting as a nephritic or nephrotic picture is noted in an even smaller percentage of patients and found in about 10–30% of children with renal involvement [4, 26].

In a study of 150 Italian children, the male to female ratio was 1.8 : 1, the mean age was 6.1 years, and renal involvement occurred in 54% with 7% of the children demonstrating severe nephritis and 2% acute renal failure [26].

Several interesting studies have demonstrated that genetic polymorphisms may play a role in the development of HSP and/or in the evolution to HSP nephritis. In a study of 57 patients with HSP, there was no significant difference in the allele or genotype frequencies for two vascular endothelial cell growth factor (VEGF) polymorphisms between patients with HSP and control patients but the high VEGF producer allele was increased in patients with HSP nephritis compared to healthy controls [27]. Polymorphisms of the interleukin-1 beta gene were not different in the patients with HSP compared to controls, but each of the five patients who developed severe nephropathy carried the rare T allele compared with 16 of the remaining 44 patients [28]. The authors suggested that carriage of the interleukin-1 beta T allele influences the severity of renal involvement. Other interesting studies demonstrated that the tubuloglomerular feedback (TGF)-beta C-509T polymorphism of the TGF-beta gene was significantly more common in children with HSP compared to control children [29]. Polymorphisms of the renin-angiotensin system have also been associated with the development of HSP and the possibly the development of renal disease [30]. Patients with familial Mediterranean fever (FMF) have a higher incidence of HSP, with approximately 5% of patients with FMF developing HSP [31]. Similarly, polymorphisms in thrombophilia genes, including methylenetetrahydrofolate reductase, prothrombin, and factor V genes, did not differ in patients with HSP and controls [32]. While more studies clearly need to be performed, it is clear from the existing studies that the development of HSP and the evolution to severe HSP nephritis may be related to genetic susceptibility.

Natural History of HSP Nephritis

HSP nephritis is diagnosed when the patient with HSP develops hematuria with or without proteinuria, nephrotic syndrome, hypertension, and/or decreased renal function

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. with elevation of serum creatinine or blood urea nitrogen (BUN). The majority of children with HSP demonstrate mild to no renal disease and when renal disease occurs it usually resolves spontaneously without the need for therapy [3–7].

The majority of patients with HSP who are destined to develop renal involvement will demonstrate renal disease within a few months of the onset of HSP, but unusual cases of the occurrence of HSP nephritis several years after the onset of HSP were reported in the literature [33]. A systematic review has shown that 34.2% of patients who did not have renal involvement at diagnosis subsequently developed renal involvement, and in 85% of cases renal disease developed within 4 weeks, 91% within 6 weeks, and 97% within 6 months [34]. The most common manifestation is hematuria alone, which generally resolves spontaneously and therapy is not required. Some patients also develop proteinuria in addition to hematuria and in the majority of such patients the nephritis will also resolve spontaneously. Proteinuria that is increasing in quantity and/or has evolved into nephrotic syndrome, and/or clinical signs of rapidly progressive glomerulonephritis are highly suggestive of more severe pathology and a worse long-term prognosis. While there are many notable exceptions to this, in general the severity of the clinical presentation and laboratory values correlates with the severity of the pathologic findings [7, 35–38]. Of children who did not have renal disease at presentation, permanent renal impairment did not occur in any child with a normal urinalysis. However, permanent renal damage did occur in 1.6% of children who developed minor urine abnormalities, and 19.5% of those who developed nephritic or nephrotic syndrome developed renal impairment [34].

Evidence for the Efficacy of Therapies in HSPS

Development of Nephritis

Steroids have been used to treat the abdominal symptoms and joint pain of HSP and it has been suggested that steroids may prevent the development of nephritis. Five interventional trials and other retrospective observational studies address this issue [39–43] (Table 68.3). Dudley et al. [94] conducted a randomized, double-blind, placebo-controlled trial to determine if steroids reduce the incidence and severity of nephropathy in HSP. Children <18 years of age (352 participants) were randomized to receive prednisolone 2 mg/kg for 7 days followed by 1 mg/kg for 7 days or placebo for 14 days. The primary outcomes were the presence of proteinuria at 12 months (urine protein to creatinine ratio >20 mg/mmol) and the need for additional treatment (defined by hypertension requiring treatment or renal biopsy abnormalities or the need for treatment of renal disease) during a 12-month follow-up period. No difference was found between those who were randomized to prednisolone compared to the placebo group (adjusted odds ratio for primary outcome 1.29, 95% CI 0.58–2.82, $n = 247$). Another randomized double-blind placebo-controlled trial of 40 children with HSP seen in an emergency room were randomized to receive placebo ($n = 19$) or oral prednisone 2 mg/kg/day for 1 week with weaning of the prednisone over the next week ($n = 21$). At 1 year, there was no difference in the incidence of renal involvement or gastrointestinal complications between the two groups [39]. In a larger study of 171 children with HSP, 84 children were treated with 1 mg/kg/day prednisone for 2 weeks with a tapering dose of prednisone over the next 2 weeks while 87 children received placebo in a

Table 68.1 Treatments for Henoch–Schonlein purpura in children.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
ACE inhibitors	We suggest that ACE inhibitors be used in children with proteinuria and acute/chronic nephritis for nephroprotection as long as it does not cause significant rise in serum creatinine or potassium	Very low	Weak
Corticosteroids	We suggest the use of corticosteroids either as an IV pulse or oral course as part of the initial treatment in patients with mesangial proliferation, endocapillary proliferation, and/or crescents on kidney biopsy	Low	Weak
Immunosuppression	We recommend the use of additional immune-suppression for 6 months in children with mesangial proliferation, endocapillary proliferation, and/or crescents on kidney biopsy	Very low	Weak
Heparin, warfarin, aspirin or dipyridamole	We do not recommend the use of heparin, warfarin, aspirin or dipyridamole in affected children	Very low	Weak

double-blind, randomized placebo-controlled trial [40]. In total, 74 patients had renal symptoms (38 in the prednisone group and 36 in the control group) during the 6 months of follow-up. Four patients in the prednisone group and three in the placebo group developed severe nephritis requiring biopsy. Renal symptoms resolved in 61% of prednisone patients after treatment, compared with 34% of the placebo patients ($P = 0.02$). Prednisone did decrease the intensity of abdominal pain and joint pain [40].

Retrospective studies of children with HSP without renal disease at the time of diagnosis demonstrated that prednisone therapy did not decrease the risk of nephritis [42, 48]. However, these studies suggest that prednisone is effective for the joint and gastrointestinal manifestations of HSP but does not prevent the development of renal disease. In contrast, a prospective study of early administration of prednisone (1 mg/kg/day for 2 weeks) in children with HSP and no signs of renal involvement demonstrated that none of the 84 children who received prednisone and 10 of 84 children who did not receive prednisone developed nephropathy within 2–6 weeks after the acute episode of HSP [41].

Altering Course of Established Nephritis

Summary of current recommendations for the treatment of HSP nephritis are listed in Table 68.1. There are very few trials of therapy for established HSP nephritis (Table 68.2). In the study described above by Ronkainen et al., the investigators found that in those who developed renal disease and were treated with prednisone, renal symptoms resolved significantly more rapidly in the prednisone-treated group compared to those in the placebo group [40]. Prednisone therapy was most effective in treating renal disease in patients over the age of 6 who had developed renal symptoms during the first month after the diagnosis of HSP [40].

Table 68.2 Randomized controlled trials in children with HSPN and IgA nephropathy.

Study	Therapy	Number of patients and characteristics	Outcome
Tarshish [44], prospective randomized trial (HSPN)	Supportive therapy with or without 90 mg/m^2/day cyclophosmide	56 children; 28 treated, 28 control	No difference in renal outcome
Ronkainen [40], randomized placebo-controlled (HSPN)	1 mg/kg/day prednisone for 2 weeks and weaning dose for 2 more weeks	84 treated patients and 87 placebo children aged 1.7 to 15.6 years	61% of prednisone-treated renal symptoms resolved 34% of placebo-treated renal symptoms resolved
Yoshikawa [45], randomized controlled (IgA)	Prednisolone[a], azathioprine[b], heparin-warfarin and dipyridamole for 2 years (group 1) vs. heparin-warfarin and dipyridamole only for 2 years (group2)	40 patients in group 1 and 34 patients in group 2 at the time of completion of the trial All patients had diffuse mesangial proliferation on biopsy	Patients in group 1 had less glomerular sclerosis and had less immunological renal injury manifesting as a decrease in mesangial IgA deposits
Yoshikawa [46], randomized controlled trial (IgA)	Prednisone[a], azathioprine[b], heparin-warfarin and dipyridamole for 2 years compared to prednisone alone for 2 years	39 patients received combination therapy and 39 patients received prednisone alone All patients had diffuse mesangial sclerosis	Primary end point: proteinuria <0.1 g/m^2 per day 92.3% of patients in the combination group achieved the primary end point compared to 74.4% in the group receiving prednisone alone Possible increase in sclerotic glomeruli in the group treated with prednisone alone
Hogg [47], double-blind, randomized, placebo-controlled trial	Cellcept vs. placebo after 3-month treatment with lisinopril/losartan and highly purified omega-3 fatty acid	Patients aged 7–70 years with Pr/Cr > 0.6 for males and 0.8 for females and estimated GFR ≥ 50 ml/min/1.73 m^2 or ≥ 40 ml/min/1.73 m^2 if on lisinopril/losartan	No difference in outcomes was noted between the two groups The trial was terminated early at the recommendation of the Data Monitoring Committee due to the absence of any benefit

[a] Prednisone given at 2 mg/kg/day (max. 80 mg/day) for 4 weeks, followed by 2 mg/kg every other day for 4 weeks, 1.5 mg/kg/day every other day for 4 weeks, 1 mg/kg every other day for 21 months.
[b] Azathioprine at a dose of 2mg/kg/day.

Table 68.3 Evidence for therapy to prevent HSP nephritis

Study	Therapy	Number of patients and patient characteristics	Outcome
Mollica [41], randomized controlled study	1 mg/kg/day prednisone for 2 weeks	84 patients treated with prednisone 84 patients not treated with prednisone (age not reported)	No treated patient developed nephritis 10 (11.9%) control patients developed nephritis
Saulsbury [43], retrospective study	Any prednisone therapy	50 children without nephritis	20% of patients who received predisone and 20% who did not receive prednisone developed nephritis
Islek [42], randomized controlled trial	1 mg/kg/day for 10 days and weaning dose for 1 week	70 patients treated with prednisone and 50 not treated with prednisone aged 9.2 ± 2.7 years	21% (15/70) of treated patients and 36% (18/50) control patients developed nephritis
Huber [39], randomized, placebo-controlled, double-blind trial	2 mg/kg/day prednisone for 1 week and weaning dose for 1 week	21 treated patients and 19 placebo patients aged 2–15 years	No difference in rate of renal involvement 3/21 treated and 2/19 placebo developed nephritis
Ronkainen [40], randomized, placebo-controlled, double-blind trial	1 mg/kg/day prednisone for 2 weeks and weaning for two weeks and weaning dose for 2 more weeks	84 treated patients and 87 placebo children aged 1.7 to 15.6 years	No difference in rate of renal symptoms 38/84 treated and 36/87 control patients had renal symptoms
Bayrakci [48], retrospective study	Prednisone 1 mg/kg PO for 1–2 weeks	157 patients without HSP nephritis	No difference in rate of renal symptoms 17/61 treated patients developed nephritis 18/96 untreated patients developed nephritis
Dudley 2013, randomized, placebo-controlled, double-blind trial	Prednisone 2 mg/kg for 7 days followed by 1 mg/kg for 7 days	352 children randomized	No difference in treated and untreated children

Fifty-six patients participated in a randomized trial of cyclophosphamide and supportive therapy compared to supportive therapy alone (control group); 28 children received supportive therapy and 28 received supportive therapy and cyclophosphamide 90 mg/m^2/day for 42 days [44]. The clinical status at last follow-up (mean follow-up time of 6.93 years) demonstrated that there was no difference in outcome between the two groups. Fourteen of the treated patients and 13 of the control patients were classified as recovered, while 10 of the treated patients and 12 of the control patients were classified as have mild, moderate, or several residual renal abnormalities. Four treated patients and three control patients had reached ESRD. The investigators concluded that therapy with cyclophosphamide was not effective for HSP nephritis. A 12-month, multicenter, prospective, and open-label trial in adults in 2010 compared steroid therapy with steroid and cyclophosphamide cotreatment, with the primary end point being complete remission, and found no benefit of cyclophosphamide [49].

In a study published in abstract form, 19 patients with severe HSP nephritis were treated with cyclosporine A or pulse intravenous methylprednisolone. Ten of 10 (100%) cyclosporine A treated patients compared with five of nine (56%) pulse intravenous methylprednisolone patients achieved remission in 3 months, suggesting that cyclosporine A may be more effective than pulse methylprednisolone in severe HSP. However, this study is quite small and did not have long-term follow-up [50]. Similarly, Jauhola et al. compared cyclosporine treatment for 12 months at a dose of 5 mg/kg with three intravenous methylprednisolone pulses of 30 mg/kg each followed by 4 months of oral prednisone for the treatment of severe HSP nephritis, in a randomized open-label trial [50]. A total of 24 children were in the study. Seven were randomized to receive cyclosporine and eight to receive intravenous methylprednisolone. Four patients were treated with cyclosporine and five with intravenous methylprednisolone without randomization. All 11 patients treated with cyclosporine A had complete remission of nephrotic range proteinuria by 3 months. Six out of 13 children in the intravenous methylprednisolone group did not respond and required additional immune suppressive treatment. However, 2-year biopsies were similar in both groups and both had similar long-term outcomes [50].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. While there is a dearth of evidence-based studies to demonstrate effectiveness of therapy in HSP nephritis, there are numerous retrospective case studies of therapy for HSP nephritis [38, 51–60], but the sum of these is prone to publication bias. In a retrospective study of 12 children with severe HSP nephritis, therapy with pulse intravenous methylprednisolone, oral cyclophosphamide, oral dipyridamole, and oral prednisone resulted in complete remission in seven children, partial remission in four children, and residual nephrotic range proteinuria in one child [51]. In eight children with severe HSP who were treated with pulse intravenous methylprednisolone followed by alternate day prednisone and oral cyclophosphamide daily, seven of the eight patients had a complete remission [52]. In another series, therapy with pulse intravenous methylprednisolone followed by oral prednisone in 38 children resulted in 27 children who recovered normally, seven children had residual renal abnormalities and four children had reached ESRD [53]. In this study, sequential renal biopsies showed a significant decrease of active disease and with a decrease or disappearance of IgA deposits [53]. Among 21 children treated with pulse intravenous methylprednisolone followed by oral prednisone and azathioprine, 19 showed an excellent response to therapy with a decline in hematuria, improvement of renal function, and a marked decrease in proteinuria from 8.8 ± 7.5 g/24 h before therapy to 0.47 ± 0.39 g/24 h after therapy. The remaining two children progressed to ESRD [38]. Of 14 children who were treated with prednisone, cyclophosphamide, heparin/warfarin, and dipyridamole, and were followed for 7.5 ± 0.9 years, nine children demonstrated a complete recovery, four had minor urinary abnormalities and one had residual heavy proteinuria [55]. In this study, histological improvement was also noted in biopsies obtained after the completion of therapy.

When 17 children with severe HSP nephritis who were treated with prednisone 1–2 mg/kg/day and azathioprine 1–2 mg/kg/day were compared to historical controls, significantly more patients in the study group (15 of 17 [88%]) had a favorable outcome compared to the historical control group (17 of 32 [54%]) [54]. At least two retrospective case studies have demonstrated that therapy with cyclosporine A is beneficial in patients with severe HSP [56, 57]. Other therapies including intravenous immunoglobulin therapy, plasmapheresis, and tonsillectomy have been reported in patients resistant to immunosuppressive therapy [58–61].

The paucity of controlled studies of therapy in severe HSP considerably hinders evidence-based recommendations for therapy.

Given the well-described poor outcome of severe HSP nephritis, randomized controlled trials (RCT) comparing placebo to therapy are unlikely to be performed. There is, however, a need to compare different treatment strategies for effectiveness in altering the course of nephritis using low risk of bias study designs. Until such studies are performed, evidence-based treatment recommendations cannot be formulated. Treatment with oral prednisone or intravenous methylprednisolone followed by oral prednisone depending on the severity of nephritis is a reasonable course of action. Since HSP nephritis is a variable disease, individual risk factors for progressive renal disease need to be taken into consideration when formulating therapy for patients with HSP.

IgA Nephropathy

Pathogenesis

IgA nephropathy comprises mesangial deposition of IgA within the glomerulus. Patients with IgA nephropathy overproduce an aberrant form of IgA1. In the aberrant IgA1, there is undergalactosylation of O-glycans at the hinge region along with production of glycan-specific IgG and IgA antibodies against the under galactosylated IgA1 [19]. The level of these serum antibodies in affected individuals has been found to correlate with the degree of proteinuria [19]. The underglycosylated IgA1 molecules can also self-aggregate and form antibody complexes with IgG [19]. In addition, IgG and IgA antibodies that are specific to the hinge region of the abnormal IgA molecule result in the formation of IgA1 immune complexes [62]. IgA deposits are primarily in the mesangium, with limited deposition in the podocytes or tubular epithelial cells. Interactions between cells/molecules in the glomerular region with those in the tubular region may play a role in the tubulointerstitial injury found in patients with IgA nephropathy [63].

There are emerging data demonstrating that the gut–kidney axis, determined by genetics, gut microbes, diet, and the environment, plays a role in the development of IgA nephropathy [64]. In a genome-wide association study, an association between the presence of IgA nephropathy and genes playing a role in immunity against gut pathogens was found [65]. Gene loci involving ITGAM-ITGAX, AVA3, and CARD9 along with two independent signals at HLA-DQB1 and DEFA have been associated with IgA nephropathy and inflammatory bowel disease, maintenance of the intestinal epithelial barrier, and response to mucosal pathogens [65]. Gut microbial diversity also appears to be a factor influencing the development of IgA nephropathy [66]. Compared to patients with IgA nephropathy, healthy controls had the greatest gut microbial diversity. *Enterococcus*, *Lactobacillus*, and

Clostridium species were found in the highest levels in healthy controls [66]. In contrast, low levels of *Bifidobacterium* species and higher levels of *Streptococceae* were found in patients with IgA nephropathy [66].

There are case reports of celiac disease in patients with IgA nephropathy. Mice that are fed a gluten-rich diet have higher renal IgA deposits compared to mice on a gluten-free diet [67]. In mouse models of IgA nephropathy where the mice are expressing human IgA1 and CD89 (a soluble form of IgA receptor), animals were fed a gluten-free diet for three generations, after which gluten was introduced into their diet for 30 days [68]. After gluten exposure, the mice developed intestinal injury, IgA1 mesangial deposition, increased IgA1-sCD89 complexes, and IgA1-antigliadin antibodies [68]. Proteinuria also increased in the mice [68]. Few studies examining the effect of gluten and IgA nephropathy exist in human subjects exist and they are limited by a small number of patients and a short follow-up. Inferences about the effect of a gluten-free diet in human subjects with IgA nephropathy therefore remain uncertain.

The light microscopy findings on renal biopsy in patients with IgA nephropathy can range from near-normal appearing glomeruli to a rapidly progressing glomerulonephritis picture with cellular crescents. Focal sclerosis without evidence of acute inflammation can also be seen. Mirroring the findings on renal biopsy, patients can present in several different ways, such as with microscopic hematuria alone to rapidly progressing glomerulonephritis or with a nephritic/nephrotic presentation. On immunofluorescence staining for IgA, glomerular deposits of abnormally glycosylated IgA1 are often found diffusely present in the glomerulus [69]. Some patients may also have IgA1 deposits along the capillary walls [69]. Capillary wall deposition of IgA1 has been associated with increased mesangial and endocapillary cellularity and/or advanced fibrosis lending a poorer outcome [70, 71].

Epidemiology and Natural History

The peak age of presentation of IgA nephropathy is between 15 and 30 years [1].

Children do not present before the age of 3 and after that cases are fairly evenly distributed throughout childhood [72, 73]. IgA nephropathy is a slowly progressive condition in most settings and spans the spectrum of childhood into adulthood. Initially it was believed to be a benign condition in children. In long-term studies it appears that in children with hypertension and proteinuria, 10-year renal survival is similar to those of adults and is around 24% [74]. In a retrospective study by Shima et al. among 96 patients having IgA nephropathy with minor glomerular abnormalities that were not treated, 57 patients achieved spontaneous remission by 5 years [75]. However, if all children, even those without hypertension and proteinuria, are included the 10-year survival is significantly better at 87–95% [74, 76]. In children, proteinuria both at presentation and during follow-up is a risk factor for disease progression [77]. Similarly, reduction/resolution of proteinuria during the disease course is a favorable prognostic indicator [78]. Spontaneous remission in children presenting with IgA nephropathy has been observed, while at the other end of the spectrum development of heavy proteinuria can occur in patients who had minimal proteinuria at the time of presentation [75, 79]. Therefore, predicting the course of IgA nephropathy for a single patient based on clinical and biopsy criteria is challenging.

Classification

In 2009 the Oxford Classification for IgA nephropathy was introduced with the goal of providing a common pathological and clinical classification, accepted by the international community, as this would allow for better clinical prognostication and prediction of disease progression in adults and children [80]. Three main pathological lesions were identified to be predictive of renal outcomes: mesangial hypercellularity, segmental sclerosis, and interstitial fibrosis/tubular atrophy [80]. Endocapillary hypercellularity was included as part of the classification because patients with endocapillary proliferation who received immunosuppressive treatment had a significantly lower rate of decline in renal function compared to those who did not, making a case for treatment with immune suppressive medication in patients with such lesions [80]. In the group of patients studied, a 50% reduction in estimated glomerular filtration rate (GFR) as well as rate of renal function decline was associated with increased mesangial hypercellularity, the presence of segmental glomerular sclerosis, and tubular atrophy/interstitial fibrosis [80]. Patients with the greatest degree of tubular atrophy/interstitial fibrosis had the fastest rate of decline in renal function and those with mesangial hypercellularity had the lowest rates of progression [80]. Validation studies in children show that mesangial hypercellularity, endocapillary hypercellularity, and tubular atrophy/interstitial fibrosis are predictors of renal outcome when performing univariate analysis [81, 82]. A large study (161 participants) from China showed that only tubular atrophy/interstitial fibrosis was associated with worse outcomes, while another study from Japan demonstrated mesangial hypercellularity, crescents, and interstitial fibrosis/tubular atrophy to be important variables determining renal outcomes in children [81, 83]. These studies highlight the need to prospectively study a large and diverse pediatric patient cohort.

A limiting factor in the initial Oxford classification study was that crescents were not included in the classification. This was because a very small number of patients in the study had crescents secondary to exclusion of patients with estimated GFR less than 30 ml/min/1.73 m^2 at the time of biopsy [80]. The 2016 update from the IgA Nephropathy Classification Working Group was published recommending the inclusion of crescents in the classification based on evidence from newer studies showing crescents to be predictive of a worse renal prognosis [84, 85].

Recommendations for Therapy of IgA Nephropathy in Children

Data from several adult studies demonstrates that prednisone therapy slows the progression toward ESRD and also lowers urinary protein excretion [86, 87]. The addition of an angiotensin converting enzyme inhibitor (ACEi) to treatment with corticosteroids improves renal survival [88].

In a RCT of Japanese children, the use of a combination of prednisone, azathioprine, heparin-warfarin, and dipyridamole for 2 years given early in the course of IgA nephropathy decreased the extent of renal injury compared to a 2-year treatment course of just heparin-warfarin and dipyridamole [45]. Kidney injury was confirmed by renal biopsy: the patient had to have an acute presentation with findings of diffuse mesangial proliferation on biopsy. A subsequent analysis assessing the long-term outcomes in this study group after 10 years revealed that based on both univariate and multivariate analysis the 10-year renal survival was better in the children treated with combination therapy that included prednisone and azathioprine [89]. Two out of 40 patients who received combination therapy (5%) developed end-stage kidney disease compared to five of 34 (14.7%) of children who received only heparin-warfarin and dipyridamole. A subsequent randomized trial among Japanese children studied the use of prednisone as a single agent compared to combination therapy (prednisone, azathioprine, heparin-warfarin, and dipyridamole) over 2 years [46]. This study showed that in children with diffuse mesangial proliferation on biopsy the combination therapy was more effective in preventing progressive glomerular sclerosis over the course of 2 years [46]. A recent RCT in 2018 also conducted among Japanese children through the Japanese Pediatric IgA Nephropathy Treatment Study Group compared the effectiveness of prednisone in combination with mizoribine instead of azathioprine (group 1) to a combination of prednisone, mizoribine, warfarin, and dipyridamole (group 2) [90]. The study showed similar rates of remission (give the numbers here for both group for the rates of remission or proportion with remission) in proteinuria between the two groups at the 2-year mark, suggesting that the use of pyridamole and warfarin is unlikely to be of benefit in children [90]. Thirty of 34 patients in group 1 (88.2%) and 27/36 (75%) in group 2 showed normalization of urine protein to creatinine ratio during the 2-year treatment period. According to their study, the disappearance of proteinuria was higher in group 1 compared to group 2 (the group with warfarin and dipyridamole), log-rank $P = 0.04$.

In the adult literature, there are conflicting results from large randomized trials assessing the benefit of the use of mycophenolate mofetil (MMF) in patients with IgA nephropathy with some showing no benefit and others demonstrating improvement in renal function. A recent multicenter, double-blind, RCT of MMF in children and adolescents evaluated the outcomes in children and adults treated with MMF [47]. Patients were initially treated for 3 months with ACEi and purified omega-3 fatty acids and only those patients with persistent proteinuria at the 3-month mark went on to be randomized into the MMF arm or placebo. This trial was terminated early due to lack of benefit as it found no difference between the two groups at the 6-month mark [47]. Another recent trial in adults comparing MMF with low-dose prednisone compared to prednisone alone in patients with active proliferative renal lesions found no difference in renal outcomes between the two groups, but did find less steroid side effects in the group receiving MMF with lower dose prednisone [91]. In a prospective study of eight patients, Roccatello et al. describe significant improvement in patients with acute inflammatory histological lesions and associated significant proteinuria and acute renal insufficiency that were treated with three pulses of intravenous methylprednisolone followed by an oral taper for 4 months along with MMF for 6 months [92]. The authors in this paper speculate that it is patients with acute inflammatory lesions that may benefit the most from treatment with MMF. In 2015, Kang et al. evaluated treatment with MMF in 58 children with nephrotic syndrome associated with IgA nephropathy [93]. Patients were initially treated with prednisone 2 mg/kg/day for 8 weeks. There were 48 children who were steroid resistant, and 33 of these children were then given MMF with a tapering prednisone dose over 4 months. After this 4-month treatment, 21 patients showed complete remission, six patients had partial remission, and six patients did not show any response [93]. Complete remission was defined as urine protein to creatinine ratio of <0.3 g/g and partial remission was defined as >50% reduction in proteinuria from baseline [93]. There were significant differences in renal morphology on biopsy between the steroid-sensitive and steroid-resistant groups, with the steroid-sensitive group having very low MEST (M = mesangial cellularity, E = endocapillary hypercellularity; S = segmental sclerosis, T = tubular

atrophy) interstitial fibrosis scores as determined by the Oxford Classification. When comparing the group of children demonstrating complete, partial, or no responsiveness to MMF plus prednisone, the children with no response to therapy had a lower GFR at presentation and a higher T score (interstitial fibrosis) [93].

Conclusion

Limited evidence-based recommendations can be made for the treatment of IgA nephropathy and HSP nephritis in children due to overall lack of controlled low risk of bias studies in this population. Nonetheless, based on the studies summarized in this chapter we can conclude that in children with acute and more severe disease with mesangial proliferation and/or nephrotic syndrome, immunosuppression with either oral or intravenous corticosteroids is beneficial. The addition of an ACEi when possible also provides additional benefit for prevention of chronic kidney disease progression. Children with higher MEST scores and mesangial proliferation may benefit from additional treatment with immunosuppressive agents such as azathioprine or MMF for 4–6 months.

Hereditary Nephritis in Children

Judy Savige

Department of Medicine (Melbourne Health) and Northern Health, The University of Melbourne, Australia

Introduction

Hereditary nephritis usually refers to Alport syndrome and thin basement membrane nephropathy, but could also include membranoproliferative glomerulonephritis (dense deposit disease), atypical hemolytic uremic syndrome, and some cases of focal and segmental glomerulosclerosis (FSGS), IgA glomerulonephritis, and systemic lupus erythematosus. All these conditions are associated with hematuria except for FSGS, where proteinuria predominates.

Hematuria occurs in about 6% of the pediatric population [1] and is mainly transient and nonglomerular, from, for example, cystitis or familial hypercalciuria. The most common cause of persistent glomerular hematuria is thin basement membrane nephropathy, and Alport syndrome is much less frequent [1].

Alport Syndrome

Definition

Alport syndrome is an inherited disease characterized by hematuria, progressive kidney failure, hearing loss, and ocular abnormalities [2]. It is suspected when there is hematuria together with a family history of hematuria, kidney failure or Alport syndrome, hearing loss, lamellated glomerular basement membrane (GBM), lenticonus, or a fleck retinopathy [3].

The diagnosis of Alport syndrome is confirmed most accurately with the demonstration of a pathogenic variant in the *COL4A5* gene (with X-linked inheritance) or two variants in the *COL4A3* or *COL4A4* genes (recessive disease) [4–6]. Inheritance is X-linked in 85% of cases and recessive in 15% [7]. The use of "autosomal dominant" inheritance for heterozygous *COL4A3* or *COL4A4* variants remains controversial because the typical Alport features of kidney failure, lamellated GBM, hearing loss, and ocular abnormalities do not occur with single copies of these mutations [6].

Massively parallel sequencing has greatly increased our ability to detect likely causative mutations in Alport syndrome, and identifies the underlying pathogenic variants in nearly 90% of individuals with suspected disease [6]. Whole-exome sequencing has also identified novel combinations of Alport variants, in say *COL4A3* and *COL4A4*, that result in milder features than are typically seen in recessive disease. Conversely, up to 30% of some FSGS cohorts have mutations in the Alport genes and a diagnosis of Alport syndrome [8]. Thus, recent guidelines recommend that genetic testing is used to confirm the diagnosis of Alport syndrome, and that the Alport genes are also included in the panels for FSGS [6, 8].

Epidemiology

In children, Alport syndrome is one of the commonest causes of end-stage kidney failure after FSGS and structural renal disease. In adults, Alport syndrome is second only to polycystic kidney disease as a cause of inherited kidney failure [9].

Reports of the prevalence of Alport syndrome vary from one in 5000 in a well-studied population in Utah [10] to one in 17000 in Southern Sweden [11] and one in 50000 in Finland [12]. However, the abundance of likely pathogenic variants in normal DNA variant databases suggests that Alport syndrome is even more common than one in 5000. Many individuals with X-linked Alport syndrome are undiagnosed, especially boys, men with mild or late onset disease, and girls and women. Indeed, it is only boys and men with the characteristic Alport phenotype who are readily recognized.

Interestingly, because X-linked inheritance is at least five times more common than recessive disease, overall Alport syndrome occurs nearly twice as often in females as in males, but is usually milder with many fewer women developing kidney failure [13].

Genetics

X-linked Alport syndrome is caused by mutations in the *COL4A5* gene and autosomal recessive disease by two *COL4A3* or *COL4A4* mutations. Features are similar in boys with X-linked disease, and boys and girls with recessive inheritance. Thin basement membrane nephropathy occurs with a heterozygous *COL4A3* or *COL4A4* mutation and represents the carrier state for recessive disease [14–16].

In X-linked Alport syndrome, the pathogenic mutations are different in nearly every family and more than 2500 have been reported to date [17, 18]. Fifteen percent of these variants have arisen de novo. Forty percent are missense changes, 10% are nonsense, 40% are complicated mutations, often resulting in downstream nonsense changes, and 10% affect a splice site. In general, nonsense mutations are associated with more severe clinical features than missense variants, with an earlier age at kidney failure [19, 20] and an increased likelihood of lenticonus and fleck retinopathy. Most of the missense mutations are glycine (Gly) substitutions, since Gly is the smallest amino acid and fits easily within the triple helix. Its replacement with any other amino acid in a collagenous sequence disrupts this structure. Substitutions of Gly are nearly always pathogenic, and substitutions with a glutamic acid, aspartic acid or arginine are typically associated with more severe disease [21, 22]. These genotype-phenotype correlations mean that it is possible to use the type of mutation to predict the approximate age at kidney failure onset.

Disease-causing variants in autosomal recessive Alport syndrome are compound heterozygous changes in the *COL4A3* or *COL4A4* genes, or homozygous variants where the parents are often consanguineous [6]. Many fewer pathogenic variants have been identified in *COL4A3* or *COL4A4* than *COL4A5*, but again the same variant types indicate the likelihood of severe disease (large rearrangements, insertions, deletions, nonsense mutations, splicing variants, certain Gly substitutions) and a younger age at kidney failure onset. Thus, in autosomal recessive Alport syndrome, two nonsense mutations result in earlier onset kidney failure than one nonsense and one missense mutation, which in turn are associated with an earlier onset than two missense mutations [18, 23].

Pathogenesis

The GBM is abnormal in both X-linked and autosomal recessive Alport syndrome, with thinning, and later thickening, lamellation, subepithelial frilling, and intramembranous deposits [24, 25].

The GBM lies between the epithelial and endothelial cells of the glomerular capillary loop and comprises mainly type IV collagen, a triple helix of three of the six α chains [26]. These chains are encoded by the *COL4A1–COL4A6* genes, which are found in pairs (*COL4A1-2*, *COL4A3-4, COL4A5–6*) head-to-head on chromosomes 13, 2, and X, respectively. In infancy, the GBM collagen IV consists of mainly the α1α1α2 heterotrimer, but it is replaced at about 2 years of age with the α3α4α5 network. In adults, the α3α4α5 network is found in the basement membranes of the glomerulus, distal tubule, cochlea, lens capsule, cornea, and retina, and the collagen IV α1α1α2 network persists in the vascular membranes. The collagen IV α5α5α6 heterotrimer is found in Bowman's capsule and the dermis epithelium.

Mutations in *COL4A5* in a male result in loss of the α5 chain from the collagen IV triple helix and of the other chains that form the α3α4α5 heterotrimer. Initially the GBM is thinned but over time there is a compensatory increase in collagen IV α1α1α2. This network is more susceptible to proteolysis, which contributes to successive episodes of thinning, repair, and eventual lamellation and scarring [24, 27]. In a female with X-linked Alport syndrome, lyonization means that each cell produces either a normal collagen IV α3α4α5 heterotrimer or none in the cells where the mutation is expressed. In autosomal recessive Alport syndrome, the two *COL4A3* or *COL4A4* mutations result in the loss of both copies of the corresponding α3 or α4 chain, and subsequently the whole α3α4α5 network. There are similar changes in the other tissues affected by Alport syndrome.

Heterozygous mutations in the *COL4A3* or *COL4A4* gene result in the loss of about half the collagen IV α3α4α5 network from the GBM, producing thinning. This thinning does not change over time, in contrast to the appearance in boys, girls, and women with X-linked Alport syndrome, where lamellation develops.

The mechanisms by which mutations in the Alport genes result in disease have not been well studied in humans but are probably the same as for other collagen diseases. Thus, with missense mutations there is likely to be a build-up of misfolded protein in the endoplasmic reticulum (ER) leading to ER stress and autophagy. Nonsense mutations may result not in truncated proteins but rather in "nonsense-mediated decay" with the destruction of the corresponding mRNA [28, 29].

Clinical features

The typical clinical features of Alport syndrome are hematuria, progressive impairment, anterior lenticonus, and a fleck retinopathy (Tables 69.1 and 69.2, and Figure 69.1) [2, 19, 20, 32, 33]. Most of these features may be present in children.

X-linked disease in males. Hematuria in boys with X-linked Alport syndrome is present from infancy. Transient episodes of macroscopic hematuria may occur with coincidental respiratory tract infections. Proteinuria develops at a variable age from childhood to adolescence or later. Kidney failure occurs as young as 7 years, with 40% of men having renal failure by 30 years and 90% by the age of 40 [17, 19, 20].

The hearing loss is first noted from about the age of 6 and is a bilateral, high-tone sensorineural defect. Speech discrimination is well-preserved but hearing aids are generally helpful.

Table 69.1 Clinical features in X-linked Alport syndrome in boys and girls, other causes, and management.

Characteristic of Alport syndrome (OMIM 301050)	Clinical features in boys and girls with X-linked Alport syndrome	Other causes	Management
Hematuria	Persistent microscopic hematuria occurs in all affected boys and girls from infancy, together with episodes of macroscopic hematuria with coincidental respiratory tract infections	Thin basement membrane nephropathy; IgA disease; atypical hemolytic uremic syndrome; post-streptococcal glomerulonephritis; causes of nonglomerular hematuria such as polycystic kidney disease	Confirm the diagnosis and mode of inheritance of Alport syndrome with genetic testing; cascade testing of other at-risk family members; provide genetic counseling to family members
Proteinuria	Persistent, from childhood or adolescence in boys and typically later onset in women	Focal and segmental glomerulosclerosis	Minimize any proteinuria with ACE inhibitors etc.; control BP adequately; provide kidney failure support
Kidney function impairment; end-stage kidney failure	Age at end-stage kidney failure is determined by underlying mutations, but also by coincidental nephrotoxic medications, hypotension, sepsis	Glomerulonephritis, nephrotoxic medications, hypotension, sepsis	Preemptive kidney transplantation; confirm that the kidney donor is not affected using genetic testing if necessary
Hearing loss	High tone sensorineural hearing loss, first noted at about the age of 6 years in boys and in middle age in women	Hearing loss also occurs with many other inherited kidney diseases, e.g. mitochondrial diseases, branchio-oto-renal syndrome, and with dialysis treatment	Be vigilant to prevent learning issues; screen all affected individuals with audiometry at presentation; provide hearing aids early to maximize hearing retention
Lenticonus	Not present until third decade in males and not present in girls or women	No other cause known Lenticonus is pathognomonic for Alport syndrome Difficulty with visual focusing; needs frequent changes to prescription glasses	Lens replacement when necessary
Fleck retinopathy	Present in more than half the boys with X-linked Alport syndrome, especially by end-stage kidney failure onset; may occur in adolescent girls but often later	No other cause known Fleck retinopathy is pathognomonic for Alport syndrome	Fleck retinopathy does not affect vision nor need treatment
Anti-GBM disease post transplant	<2% of affected boys but not affected girls	Must be differentiated from acute rejection	Difficult to predict, but appears to depend on the underlying mutation; diagnosed on transplant biopsy; cannot be detected with conventional anti GBM assays; recurs with subsequent grafts

Table 69.1 (Continued)

Characteristic of Alport syndrome (OMIM 301050)	Clinical features in boys and girls with X-linked Alport syndrome	Other causes	Management
Additional features			
Leiomyomatosis (ATS-DL, OMIM 308940)	Rare (<1% of all patients with Alport syndrome), only occurs with contiguous gene deletion extending from *COL4A5* into *COL4A6;* a common presentation is difficulty with swallowing from late adolescence; present in all affected boys and girls with these mutations	No other cause known for familial hematuria and leiomyomatosis	The diagnosis is confirmed histologically and with genetic testing
Intellectual disability (Alport syndrome, mental retardation, midface hypoplasia, elliptocytosis) (ATS-MR, OMIM 300194)	Very rare, associated with midface hypoplasia, elliptocytosis and intellectual disability; another contiguous gene deletion; only described in boys	No other cause known for this syndrome	Diagnosis is confirmed with genetic testing
Vascular aneurysms (aortic, intracranial)	Very rare; noted incidentally or at the time of rupture; may rupture in adolescence [30]	Other causes of end-stage kidney failure and aneurysms include polycystic kidney disease, Ehlers–Danlos syndrome, Marfan syndrome [31]	Diagnosis is confirmed with genetic testing; blood pressure control is critical

Table 69.2 Clinical features in young people and adults with X-linked or autosomal recessive Alport syndrome.

	Boys and adolescent males with X-linked Alport syndrome	Adult males with X-linked Alport syndrome	Girls and women with X-linked Alport syndrome	Males and females with autosomal recessive Alport syndrome
Hematuria	From early infancy in all boys	Hematuria in all	Hematuria in 95%	In all, from early infancy
Proteinuria	Often by adolescence	Almost all	30% of women in middle age	Often by adolescence
Kidney failure	May occur in children, but average age at onset is 21 years with severe mutations	90% have end-stage kidney failure by the age of 40	20–30% have end-stage kidney failure by the age of 60	Often before 20 years of age
Hearing loss	Starts from the age of 6, present in many adolescents	50–80% have a clinical hearing loss and 85–100% on audiometry	Very common by 40 years of age	Almost all
Lenticonus	Not reported in childhood	30%	Not reported	Very common, at least 40%
Fleck retinopathy	Earliest at age 8 years, up to 60% by end of adolescence	80%	Uncommon in girls, but 70% of women	Very common, 70%

Lenticonus does not occur in children or adolescents [33]. Only men with X-linked disease and men and women with autosomal recessive Alport syndrome have lenticonus. The lens can be replaced and lenticonus does not recur after surgery. A fleck retinopathy has been reported from the age of 8, but is more common in adolescence. It does not affect vision nor require treatment. Other ocular complications are rare.

X-linked disease in females. Girls and adolescents have hematuria from childhood, some develop proteinuria as adults, and 20–30% have end-stage kidney failure by the age of 60 [13, 32]. It is unclear why some women develop kidney failure, but it is often only one woman in a family. Kidney failure in such cases may be better explained by poorly controlled hypertension, diabetes or renovascular disease than by the mutations.

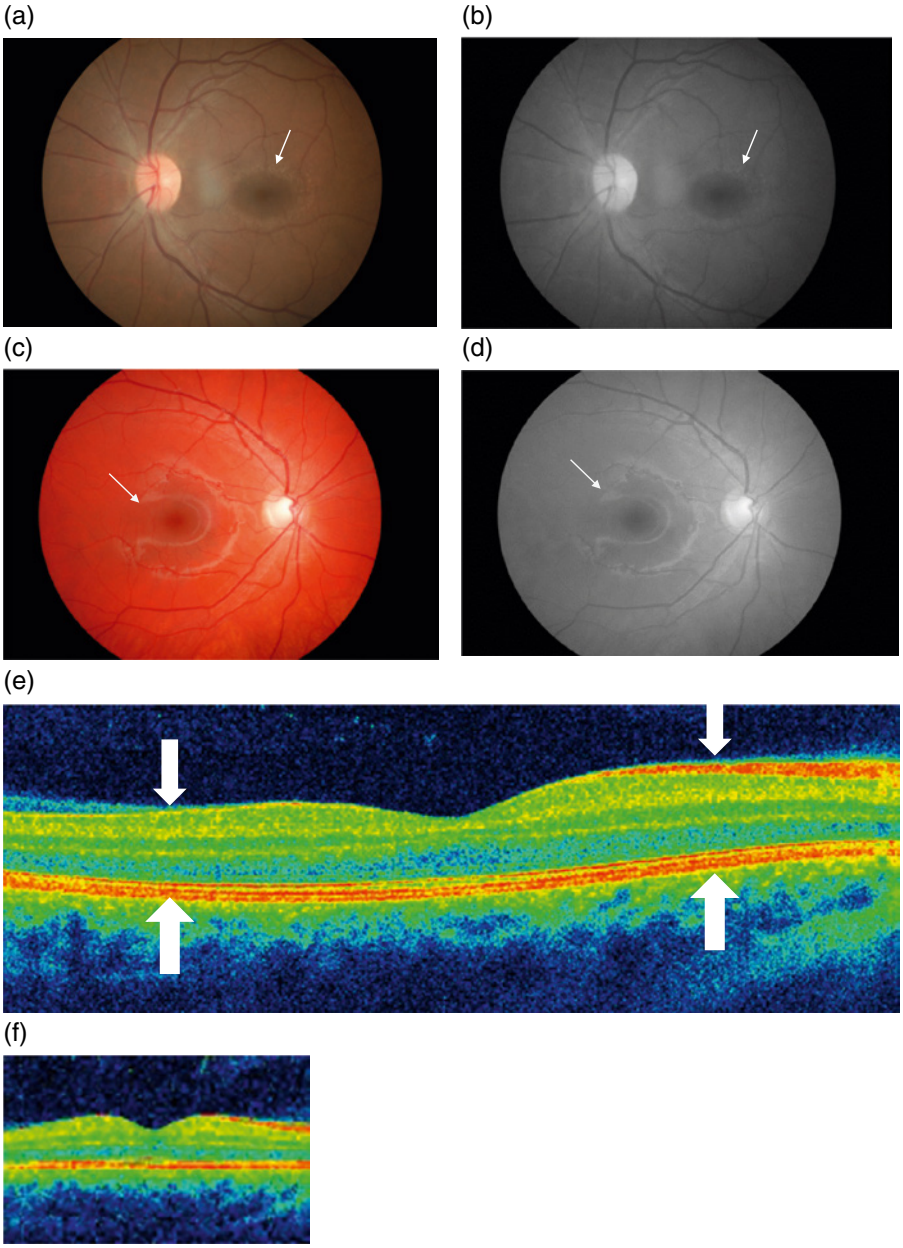

Figure 69.1 (a) Color retinal photograph of a 12-year-old boy with X-linked Alport syndrome demonstrating the typical perimacular fleck retinopathy (arrow) that spares the fovea. (b) Black and white view demonstrating more clearly the perimacular fleck retinopathy (arrow). (c) Color retinal photograph of a 14-year-old boy with thin basement membrane nephropathy demonstrating the normal retinal sheen (arrow) which is simply the light reflection seen in young people. The fleck retinopathy has to be distinguished from this normal appearance. (d) Black and white view illustrating the normal retinal sheen (arrow). (e) Optical coherence tomographic (OCT) appearance of the retina demonstrating that the temporal retinal thickness is much less than the nasal retinal thickness (arrows). (f) Normal OCT appearance where both nasal and temporal retinal thickness are similar.

Many affected middle-aged women have a hearing loss. Women with X-linked disease do not develop lenticonus, and the central fleck retinopathy is less common than in men. However, 70% have a peripheral fleck retinopathy.

Autosomal recessive Alport syndrome. Autosomal recessive Alport syndrome is much less common than X-linked disease but is often confused with this condition. The clinical features in boys and girls with autosomal recessive Alport syndrome are indistinguishable from those in boys with X-linked disease and severe mutations. Affected boys and girls with recessive disease caused by two severe mutations have hematuria from infancy and develop proteinuria, renal failure, hearing loss, and central fleck retinopathy in their teens, at an earlier age than those with only one severe mutation or none [23].

A number of features suggest autosomal recessive inheritance [3]:

- The age at onset is often younger than for X-linked disease. Thus, children may develop end-stage kidney failure by 10 years of age with hearing loss and retinopathy.
- Disease occurs in only a single generation, sporadically or in siblings.
- Boys and girls are affected equally often and equally severely. Girls have features more typically seen in boys with X-linked disease, with renal failure, hearing loss, and retinopathy.
- The family may be consanguineous or have originated from the same relatively isolated geographic region. The family may be unaware of the consanguinity from previous generations.

Testing a boy or girl with autosomal recessive Alport syndrome for proteinuria, renal impairment, hearing loss, and fleck retinopathy is likely to yield one of these features by the age of 15 years. Both parents will have a heterozygous *COL4A3* or *COL4A4* mutation and thin membrane nephropathy, and the mother and possibly the father will have hematuria, but no proteinuria, normal renal function, and no other features of Alport syndrome.

Diagnosis of X-Linked or Autosomal Recessive Alport Syndrome

The diagnosis of Alport syndrome is suspected where the typical clinical features are present, especially if there is a family history of the disease, hematuria or kidney failure, hearing loss, lenticonus, or fleck retinopathy. The diagnosis is confirmed most accurately with genetic testing, usually with whole exome sequencing [3].

Another frequently used diagnostic method is the demonstration of a lamellated GBM on electron microscopy of a renal biopsy [3]. However, the GBM may be thinned without lamellation in a boy or girl, or their mother with X-linked disease, and there may be no distinctive features in an end-stage kidney. Some laboratories use GBM immunohistochemistry where GBM typically lacking the collagen IV α5 chain confirms the diagnosis of Alport syndrome [34], but this technique is not widely available and staining is more difficult to interpret in girls and women.

Genetic testing has the advantage of not only confirming the diagnosis but also identifying the mode of inheritance [6]. The distinction between the X-linked and autosomal recessive forms of Alport syndrome can be difficult to interpret even from a three-generation pedigree, where families are small and include only women or children, or uncharacterized relatives. However, the mode of inheritance is critical because of the implications for other family members. Thus, for a man with X-linked disease, none of his sons but all his daughters inherit the mutation. For a woman with X-linked disease, half her sons and half her daughters have the mutation, and all her affected sons develop kidney failure. This contrasts with autosomal recessive Alport syndrome, where the offspring of an affected person all have only one copy of the mutation and none develops Alport syndrome or kidney failure.

Clinicians often want further evidence suggesting Alport syndrome before proceeding with genetic testing. Examining the affected individual carefully, as well as the parents and siblings, is often very helpful.

For a boy with hematuria:

- Finding that he has proteinuria, renal impairment, hearing loss or a fleck retinopathy is consistent with X-linked or autosomal recessive Alport syndrome. The presence of proteinuria or kidney function impairment suggests X-linked Alport syndrome more than thin basement membrane nephropathy.
- Finding that he has hearing loss. This is consistent with both X-linked and autosomal recessive Alport syndrome but also with many other inherited renal diseases and coincidental middle ear infections.
- Finding that he has fleck retinopathy. This is consistent with both X-linked and autosomal recessive Alport syndrome.
- Finding that his mother has no hematuria suggests that a mutation has developed de novo or that this is not X-linked Alport syndrome or thin membrane nephropathy.
- Finding that his mother has hematuria but no other features of Alport syndrome is consistent with the boy having thin membrane nephropathy and X-linked or autosomal recessive Alport syndrome.
- Finding that his mother has proteinuria, renal impairment, hearing loss or a fleck retinopathy suggests X-linked Alport syndrome.
- Finding that his father has hematuria is consistent with the boy having thin basement membrane nephropathy or autosomal recessive Alport syndrome, but not X-linked Alport syndrome.

For a girl with hematuria:

- Hearing loss and a fleck retinopathy are not usually present if she has X-linked Alport syndrome. However, where present, proteinuria, hearing loss or fleck retinopathy suggest X-linked or autosomal recessive Alport syndrome.

- Finding that her mother has hematuria is consistent with thin basement membrane nephropathy, or X-linked or autosomal recessive Alport syndrome. Where her mother does not have hematuria, the mutation may be inherited from her father or has arisen de novo.
- Finding that her mother has a hearing loss or fleck retinopathy increases the likelihood of X-linked Alport syndrome or of autosomal recessive Alport syndrome.
- Finding that her father has hematuria is consistent also with thin basement membrane nephropathy, X-linked or autosomal recessive Alport syndrome.

Treatment

To date, very few randomized controlled treatment trials have been undertaken in Alport syndrome. It has been necessary for international experts to collaboratively produce guidelines for the management of these conditions [3, 6, 13, 35], largely based on the following studies. While limited data is available from case series and animal models, large multicenter interventional studies addressing new agents and protocols are underway (Table 69.3).

Angiotensin Converting Enzyme Inhibitor

There is no cure for Alport syndrome, but a retrospective analysis of the European Alport Registry of 174 treated and 109 untreated individuals demonstrated that early use of angiotensin converting enzyme (ACE) inhibitors delayed end-stage renal failure in boys with X-linked disease by up to 13 years [36]. The subjects included 33 boys with hematuria or microalbuminuria, 115 with proteinuria, and 26 with renal impairment, who were followed for a mean duration more than 20 years. With treatment, no boy with hematuria or microalbuminuria developed end-stage kidney failure, but those with renal impairment developed end-stage kidney failure at a median of 25 years and those with proteinuria at a median of 40 years. This contrasted with their untreated relatives, who developed end-stage kidney failure at a median of 22 years. Commencing ACE inhibitors at an earlier age resulted in a progressive delay in the age at end-stage kidney failure onset through both reducing proteinuria and interstitial fibrosis, the latter through opposing transforming growth factor β (TGFβ) (Table 69.3). Hypertension control is less important because it often occurs late in Alport syndrome. Side effects

Table 69.3 Recommendations for the treatment of Alport syndrome.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
ACE inhibitors	We suggest the use of ACE inhibitors in X-linked Alport syndrome: in boys, starting use as soon as possible, and in girls, from the onset of proteinuria	Moderate (retrospective registry data) strongly suggests that ACE inhibition delays kidney failure and increases life expectancy in both boys and girls. This recommendation is also based on the compelling observational evidence of renoprotective effects of ACE inhibitors.	Moderate [36]
	We suggest the use of ACE inhibitors in autosomal recessive Alport syndrome: in boys and girls, as early as possible	Moderate (retrospective registry data) strongly suggests that ACE inhibition delays renal failure and increases life expectancy in both boys and girls	Moderate [36]
Angiotensin receptor blockers (ARB)	We suggest the use of ARB to reduce proteinuria in Alport syndrome	Strong evidence for reducing proteinuria	Moderate [37]
Combination of ACE inhibitors and ARB	We suggest the combination of ACE inhibition and an ARB reduces proteinuria more than a single agent in Alport syndrome (subject to satisfactory K level)	Strong evidence for reducing proteinuria more than ACE inhibitor or ARB alone; the combination is also more effective in other kidney diseases associated with proteinuria	Moderate [38]
Aldosterone blockade in addition to ACE inhibition and ARB	We suggest that the addition of aldosterone antagonist to ACE inhibitor or ACE inhibitor in combination with ARB may have a further beneficial effect in reducing proteinuria in children with Alport syndrome (subject to satisfactory K level)	Strong evidence for further reducing proteinuria compared with the combination of ACE and ARB inhibition; also effective in other renal diseases associated with proteinuria	Moderate for proteinuria, but very low for likelihood of delaying renal failure onset [39]

ACE, angiotensin converting enzyme.

such as cough were rare, occurring in only 5% of treated individuals. This study's major limitation was that it was a registry review and not a randomized controlled trial regarding the efficacy of ACE inhibition to delay end-stage kidney failure. However, the effects of ACE inhibitors in Alport syndrome are similar to those seen in other forms of glomerulonephritis and in several studies of diabetic nephropathy and the results have recently been confirmed in a randomized control trial [40].

The results of ACE inhibitor treatment of 205 heterozygous carriers of X-linked Alport syndrome and 29 carriers of recessive Alport syndrome with thin basement membrane nephropathy were similar to those described in individuals with Alport syndrome, where renin-angiotensin-aldosterone system (RAAS) inhibition significantly delayed the onset of end-stage renal failure [41]. One hundred and eleven patients (47%) of the cohort received nephroprotective treatment at a mean age of 28 years at start of therapy. Of these, 53 (47%) had proteinuria, 27 (24%) had renal impairment, and 17 (15%) had microalbuminuria. One hundred and nine were treated with ACE inhibitors, 34 with angiotensin receptor blockers (ARBs) and 21 with both, for an average of 5.8 years (range 1–21 years). Six (5%) reached end-stage kidney failure. One hundred and twenty-four patients received no nephroprotective therapy. They had milder disease, with 20 having proteinuria (18%) and 7 (5%) renal impairment. Twenty-eight reached end-stage kidney failure (25%). Thus, the likelihood of end-stage kidney failure was less in treated patients and end-stage kidney failure occurred later in treated than untreated disease ($P < 0.0001$). Both these cohorts included children and adolescents. The authors concluded that RAAS blockade delayed the onset of end-stage renal failure in Alport carriers with proteinuria who received therapy before the onset of end-stage kidney failure. They emphasized that there was no selection bias in the treatment group, indeed the treatment group had more proteinuria and renal impairment. However, this was again a registry review with known limitations of observational studies. There were also too few carriers of autosomal recessive Alport syndrome for them to be examined separately.

In general, the ACE inhibitor, ramipril, is recommended as the agent of choice for treating children because of its safety profile [35], but a beneficial effect has been demonstrated only in small case series and in animal models.

Combination Therapy

The age at end-stage renal failure may be further delayed with the addition of ARB and aldosterone antagonists to ACE inhibitors (subject to satisfactory K levels) (Tables 69.3 and 69.2). In one study, 306 children aged 1–17 years with proteinuria completed a randomized double-blind 12-week trial of losartan versus amlodipine or placebo. Losartan treatment significantly reduced proteinuria compared with amlodipine or placebo: -35.8% (95% CI -27.6% to −43.1%) versus amlodipine/placebo 1.4% (95% CI–10.3% to 14.5%), $P \leq 0.001$. Adverse events were few and comparable in all groups. In a further subgroup analysis, the authors randomized 27 of these subjects to losartan ($n = 15$) or enalapril ($n = 12$), and their proteinuria and renal function followed. Losartan maintained the reduction in proteinuria, but enalapril produced a further reduction over the 3 years of study. There were no serious drug-related adverse effects with either agent [37]. However, this study had limitations. It was underpowered, Alport syndrome was diagnosed clinically, patients could be given further medications at their clinicians' discretion, and there was no placebo arm.

The combination of ACE inhibitor and an ARB is even more effective [38]. Ten children with proteinuria and a mean age of 12 years ± 4.1 years were randomized to treatment with an ACE inhibitor or ARB for 3 months and then combination therapy for a further 3 months. The investigators demonstrated that the combination of agents reduced proteinuria by –80.21% ± −10.75 at the end of the 6-month trial. This was a significant reduction compared with no treatment. Left ventricular hypertrophy also was reduced.

Finally, the effect of aldosterone blockade has been examined in five patients, aged 11 – 19 years of age, three with X-linked and two with so-called autosomal dominant Alport syndrome, all with a lamellated GBM and persistent proteinuria >0.2 g/g urinary protein creatinine (UPC) [39]. Treatment with an ACE inhibitor ($n = 1$) or ACE inhibitor/ARB combination ($n = 4$) and spironolactone 25 mg daily resulted in a reduction in UPC ratio to 0.13 ± 0.06 g/g at 18 months but no change in eGFR. However, one patient developed a serum $K > 5$ meq/l, and another developed renal failure.

Newer agents undergoing evaluation for the treatment of Alport syndrome include some that target the interstitial fibrosis that correlates best with renal impairment, and bardoxolone with its effects on antioxidant and anti-inflammatory activity. The aim of current treatments is to further delay renal failure rather than to effect a cure. Although there is currently no specific treatment for missense and nonsense mutations, future therapies are likely to directly target the mechanisms by which mutation types cause disease, namely ER stress and nonsense-mediated decay, respectively [42]. Correction of a genetic defect in stem cells is still too difficult and carries too much risk to be clinically useful when compared with the low risk and the efficacy of renal transplantation.

Renal Transplantation

Children with X-linked or autosomal recessive Alport syndrome typically undergo pre-emptive renal transplantation. In X-linked disease, it is important that the donor is not an affected family member, which in most cases excludes the mother [3, 13], because her inherent risk of renal failure is amplified by the additional load on her residual kidney after donation [3].

Many renal physicians also discourage donation from the parent of a child with autosomal recessive Alport syndrome since they are themselves likely to be heterozygotes and already have an increased risk of renal impairment.

Individuals with Alport syndrome who undergo renal transplantation have a better outcome than others with end-stage kidney disease [43]. There is a very small risk of post-transplantation antiGBM disease [44], but antiGBM antibodies are directed against different epitopes from antiGBM disease and cannot be detected with routine assays [44].

Thin Basement Membrane Nephropathy

Introduction

Definition

Thin basement membrane nephropathy, previously known as benign familial hematuria or benign persistent hematuria, is characterized by hematuria, minimal proteinuria, normal blood pressure and kidney function, and a benign course [1]. The GBM is thinned without the lamellation seen in Alport syndrome [30]. Thin membrane nephropathy is caused by heterozygous mutations in the *COL4A3* or *COL4A4* genes [14, 16, 45] and represents the carrier state for autosomal recessive Alport syndrome [15, 16].

Epidemiology

Thin basement membrane nephropathy affects at least 1% of the population [9] but, like Alport syndrome, is often unrecognized.

Inheritance of thin membrane nephropathy is autosomal dominant, and boys and girls are equally likely to have a heterozygous *COL4A3* or *COL4A4* mutation. There are two peaks in the age at presentation [1]. Children first come to attention by the age of 7, when they are often detected because of infection-associated macroscopic hematuria or through screening programs on starting school.

The second peak in presentations is in young or middle-aged women whose hematuria is noted incidentally on testing for insurance or employment purposes, or at postnatal visits [1]. Interestingly, in later life men appear to be affected less often than women because they are less likely to have hematuria. This is probably because their GBM is normally thicker and the mutation-associated thinning is not sufficient to allow the transient GBM breaks through which red blood cell escape [46].

Most, but not all, children with thin membrane nephropathy also have another affected family member with hematuria [1]. A child with hematuria is more likely to have a mother with hematuria than a father. Even if a child has inherited the mutation from their father, he may not have hematuria, so the familial nature is not apparent.

Pathophysiology

The demonstration of a single heterozygous *COL4A3* or *COL4A4* pathogenic variant is consistent with thin basement membrane nephropathy being the carrier from of autosomal recessive Alport syndrome [14–16].

Relatively few mutations have been reported in thin membrane nephropathy, but the mutation types are likely to be the same as for autosomal recessive Alport syndrome, that is, 10% nonsense variants, 30% complex variants, 10% splice site changes, and 40% missense variants. Most reported missense variants are Gly substitutions, but it may simply be that Gly substitutions are easier to identify as pathogenic.

There are no data on genotype-phenotype correlations for *COL4A3* and *COL4A4* heterozygous variants in thin membrane nephropathy [47]. In particular, too few variants have been described in individuals with proteinuria, hypertension or renal impairment to determine genetic risk factors. In addition, coincidental causes, such as superimposed IgA disease [48] or additional mutations in other podocyte genes [49], are rarely sought routinely.

Glomerular podocytes produce the collagen IV α3α4α5 heterotrimer, and a mutation in the *COL4A3* or *COL4A4* gene results in about half the amount of the corresponding collagen IV α3 or α4 chain and of the α3α4α5 network, resulting in GBM thinning, transient breaks, and hematuria. It is unclear why proteinuria is not more prominent in thin membrane nephropathy when GBM gaps are observed, but one explanation is that proteinuria is normally reabsorbed by the tubules and any that persists reflects secondary FSGS. Alternatively, sometimes proteinuria or renal impairment in thin membrane nephropathy occur because of mutations in other podocyte genes [49].

Diagnosis

The diagnosis of thin basement membrane nephropathy is suspected clinically where there is persistent glomerular hematuria, but minimal proteinuria and normal blood

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pressure and renal function [1]. In many cases, especially in children, a renal biopsy is not undertaken where thin membrane nephropathy is suspected. Sometimes a mother or grandmother will have already undergone biopsy, in which case, the GBM is thinned but not lamellated, often with increased mesangial expansion and cellularity, and sometimes with secondary FSGS.

Current recommendations are that a boy or a girl with thin basement membrane nephropathy does not necessarily need to have their diagnosis confirmed with genetic testing.

However, genetic testing is warranted if X-linked or autosomal recessive Alport syndrome cannot be excluded. Thus, any child with hematuria but also proteinuria, hypertension, renal impairment, or hearing loss, or with a family history suggesting Alport syndrome or renal failure, should have genetic testing rather than a renal biopsy [6]. Genetic testing not only confirms the diagnosis of thin basement membrane nephropathy, but also of X-linked or autosomal recessive Alport syndrome.

Where a child with hematuria is identified, both the parents and any at-risk family members should be screened for hematuria and reviewed for the clinical features of Alport syndrome. Risk factors that indicate genetic testing is warranted include a family history of Alport syndrome or renal impairment, proteinuria, a lamellated GBM in a family member, hearing loss, lenticonus, or fleck retinopathy.

These recommendations may mean that some children, especially girls with X-linked Alport syndrome, will be misdiagnosed with thin membrane nephropathy. This occurs especially where the family comprises only females or young boys, or where late-onset Alport syndrome occurs.

Where a child is demonstrated to have thin membrane nephropathy, other family members are also likely to be affected. One of the child's parents usually has the mutation but not necessarily hematuria. In general, half the siblings of a child with thin basement membrane nephropathy will also have the mutation and half the child's future offspring have the mutation too.

Prognosis

Complications from thin basement membrane nephropathy are rare in early life but children should be reviewed at least annually to ensure they do not develop complications of thin membrane nephropathy or features of Alport syndrome. The child's affected parent will also need to be reviewed regularly by their family doctor.

The prognosis of thin membrane nephropathy for children is excellent. However it remains difficult to differentiate clinically thin membrane nephropathy from X-linked Alport syndrome in girls and in boys with mutations associated with mild or late-onset disease.

There is a biased reporting of individuals with thin basement membrane nephropathy from hospital clinics rather than from primary care practitioners, which means that that they are more likely to have complications such as proteinuria and impaired kidney function. It remains unclear how often thin membrane nephropathy-associated mutations are associated with proteinuria and end-stage kidney failure.

Treatment

In general, thin membrane nephropathy does not require treatment. However, proteinuria and hypertension are best treated with ACE inhibitors and, if necessary, ARBs and aldosterone antagonists.

Conclusions

Thin basement membrane nephropathy is the commonest cause of inherited kidney disease, but usually has a benign course. Its genetic basis is known but the risk factors for proteinuria and renal impairment are still not completely understood.

Shigatoxin-related Hemolytic-uremic Syndrome

Silviu Grisaru

Alberta Children's Hospital and University of Calgary, Calgary, Alberta, Canada

Introduction

Hemolytic-uremic syndrome (HUS) is a common cause of acute kidney injury and an important etiology of acquired chronic kidney disease (CKD) in children [2]. Traditionally, childhood HUS was classified as typical or diarrhea-associated (D+HUS) and atypical (aHUS) or diarrhea-negative (D-HUS). More recently, classification within the larger family of thrombotic microangiopathies has been based on etiology and pathophysiology: infectious, genetic/hereditary, autoimmune, or metabolic [3]. In children, 90% of HUS cases are preceded by infections with Shiga toxin-producing *Escherichia coli* (STEC-HUS) heralded by a prodrome of diarrhea [4]. Most children with STEC infections suffer only from a self-limited severe infectious enterocolitis associated with hematochezia but 10–15% progress to develop HUS with potentially devastating acute and chronic complications [5]. Despite increasing understanding of the pathophysiology and highly effective drugs recently made available for other forms of HUS, management of STEC-HUS continues to be based mostly on supportive measures [6].

This chapter examines the evidence for management of STEC infections to STEC-HUS continuum.

Definition

HUS is defined as a fast drop in hematocrit to ≤30%, platelet count to $\leq 150 \times 10^3/\mu l$, and a rise in serum creatinine concentration to above the upper limit of normal for age [5]. Schistocytes on blood smear are characteristic of the underlying thrombotic microangiopathy (TMA) but are not pathognomonic of HUS. Diagnosis of STEC-HUS is confirmed by detection of STEC strains or Shigatoxin (STX) in stool samples but may be presumed if HUS was preceded by an enterocolitis with diarrhea and hematochezia or based on epidemiological confirmation of an infection source causing an outbreak.

Epidemiology

HUS is a rare disease with an incidence ranging from 0.7 to 8 cases/100 000 population per year with significant geographical and seasonal variability. The highest incidence of D+HUS is reported among children younger than 6 years who typically present in the late summer and autumn months [7]. Prevalence of STEC-HUS is closely related to the incidence of STEC infections and the main reservoir for such pathogens is the gastrointestinal tract of healthy cattle [8, 9]. Higher incidence of STEC-HUS has been reported in rural areas at northern latitudes with a developed cattle industry [10]. The highest incidence of STEC-HUS in the world was reported in Argentina, while in Canada it has been observed in the province of Alberta; in both geographic regions beef production is a major component of local agriculture and economy [7, 11–13]. Large outbreaks originating in contaminated food have been extensively publicized; one of the best-known outbreaks in the United States was caused by contaminated ground beef hamburgers served in a fast-food restaurant chain, hence the popular name for STEC-HUS: "hamburger disease" [14–16]. However, contrary to popular belief, most cases of STEC-HUS are sporadic or occur in small clusters and are not related to poorly cooked contaminated ground beef. The majority of sporadic cases, as well as small and large outbreaks, are caused by other contaminated foods and beverages, such as vegetables, cider, or milk, and transmission from person to person has also been reported [17, 18]. Moreover, not all outbreaks of STEC-HUS are associated with STEC infections; other pathogens may be responsible, the most common of which is Shigella dysenteriae type 1 (SD1) [19].

Pathophysiology

Gasser et al. were the first to describe the triad of symptoms and coin the term "hemolytic-uremic syndrome" in 1955, but only in 1983 were Karmali et al. able to identify the toxin produced by STEC as a causative factor [20, 21]. Notwithstanding Karmali et al.'s important discovery, HUS was reported to be associated with SD1 infectious diarrhea as early as 1975 [22]. The toxin isolated from stools of patients with STEC infections causing HUS was first named "verotoxin" due to its extremely toxic effect on Vero cells, an epithelial cell line isolated from the kidneys of African green monkey [21, 23]. Subsequently, two toxins were identified and reclassified as "Shiga-like toxins" (STX1 and STX2) due to their close similarity to the Shiga toxin produced by SD1 [24]. The Shiga toxins are produced by pathogens in the gut and are absorbed into the blood circulation, which delivers them to various organs, including the kidneys. Progression from STEC infection to STEC-HUS has been documented to be associated almost exclusively with pathogens sectoring STX2 alone or in combination with STX1 [25]. In fact, co-expression of STX1 in the presence of STX2, has recently been showed to be protective [26].

Shiga toxins are composed of five β-subunits that bind with high affinity to the globotriaosylceramide receptor (Gb3) and an α-subunit, which, after being internalized by cells, interferes with the ribosomal apparatus, effectively blocking protein synthesis and leading to cell death [27]. The currently accepted mechanism leading to HUS is a TMA triggered by endothelial cell death, exposure of the subendothelial space, and activation of the thrombotic cascade. Extensive microangiopathic intravascular thrombosis is responsible for hemolysis of red cells by fragmentation, platelet consumption, and decreased glomerular perfusion leading to kidney injury. However, in addition to a prothrombotic effect, the presence of STX in microvasculature has been shown to be vasoconstrictive, proadhesive, and proinflammatory. Recent scientific evidence suggests that the extent of endothelial cell injury observed in STX-related HUS exceeds expectations from interference with protein synthesis alone [27]. in vitro experiments demonstrated that bacterial lipopolysaccharide (endotoxin) acts synergistically with SD1 and STEC toxins to enhance endothelial damage and the coagulative microangiopathy. [28] One of the additional emerging mechanisms for cell injury in STX-related HUS involves activation of the complement system. In fact, evidence demonstrating activation of the complement system in STEC-HUS forms the basis for the hypothesis on the existence of a common pathogenetic mechanism unifying all forms of TMA, including aHUS and thrombotic thrombocytopenic purpura (TTP) [29].

In North America and Europe, *E. coli* O157:H7 producing both forms of STX is the most common serotype isolated from stools of STEC-HUS patients, but many other serotypes have been reported to trigger STEC-HUS: O11:H8, Ol03-H2, O123, O26, and more [30]. The mega-outbreak that occurred in Germany in 2011 was caused by *E. coli* 0104:H4, which was previously not known to cause outbreaks on such a scale [27, 31].

Diagnosis

Early effective supportive intervention depends on a high level of suspicion of STEC infection in all children presenting with acute enterocolitis associated with hematochezia followed by diligent close monitoring for emerging HUS diagnostic markers. Failure to obtain a stool sample at presentation may seriously impact the likelihood of STEC isolation or STX detection [32]. Culture of stool samples requires time and special conditions, and has limited rates of success, but new methods of screening stool samples for STX by enzyme-linked immunosorbent assay and polymerase chain reaction have greatly improved the likelihood and speed of detection [33]. More recently, multiplex molecular panels for diagnosis of gastrointestinal infections, based on protein-to-creatinine ratio (PCR) technology, promise to allow accurate point-of-care detection of STX and producing pathogens [34].

Diagnosis of evolving HUS requires sequential blood testing for monitoring hematological and biochemical markers of TMA and ultimately HUS: hematocrit/hemoglobin, platelet count, and serum creatinine. Increasing serum lactate dehydrogenase (LDH) and declining haptoglobin levels can further confirm hemolysis while detection of schistocytes on blood smear highly supports mechanical red cell damage such as occurs in TMA/HUS.

Prognosis

Infectious STEC enterocolitis as well as evolving TMA underlying STEC-HUS are self-limited; a majority of patients with STEC-HUS, including children with very severe acute disease courses, experience full recovery based on clinical and laboratory assessments [5, 6, 35]. Nevertheless, a significant percentage are affected by long-term, mostly renal, sequelae, and mortality rates continue to be reported at 2–4% [36–38]. Prior to availability of acute RRT, mortality rates in children reached more than 30%. Unlike mortality rates, risk for long-term renal sequelae has not significantly changed over the years, remaining around 30%, with 3–5% of children affected by STEC-HUS developing stage 5

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. CKD [37, 39]. Children with identifiable sequelae such as hypertension, proteinuria, or impaired renal function should be treated according to best practices for nonspecific CKD management. Most such patients are likely to benefit from long-term nephrology follow-up. However, children that seem to have made a full recovery may also benefit from long-term monitoring, as the extent of nephron loss during the acute phase cannot be accurately assessed [39].

While the kidneys are always affected by STEC-HUS, the acute phase may be complicated by extrarenal pathology, the most serious of which involves the central nervous system (CNS) and accounts for most observed mortality. Seizure, coma, and stroke are among the most frequent CNS complications, which overall affect up to 25% of STEC-HUS patients [40]. The gastrointestinal tract is also frequently affected by STEC-HUS beyond injury caused by the prodromal enterocolitis. Bowel or intestinal perforation and stricture, pancreatitis with evolving diabetes mellitus, as well as injury to all other components of the gastrointestinal system have been reported [41]. Involvement of other systems such as respiratory, musculoskeletal, and cardiovascular are rare, but have been documented [41].

Treatment

Antibiotic Treatment

Antibiotic treatment of STEC infections before and after development of D+HUS has been a subject of great interest for researchers (Table 70.1). However, most available data were obtained from retrospective and some prospective cohort studies demonstrating conflicting results [42–50]. Prospective, blinded, and randomized studies have not been conducted, and observational studies have been affected by bias toward use of antibiotics in initially "sicker" patients. A number of meta-analyses and systematic reviews have attempted to summarize the results of available studies, reaching inconclusive results and stating that more prospective, appropriately powered studies are needed [51–53]. However, a more recent meta-analysis that excluded reports with high risk for bias concluded that use of antibiotics for treatment of STEC infections was associated with an increased risk of developing HUS [54]. Most studies found no difference or favored a negative

Table 70.1 Treatment for STEC HUS.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Antimicrobial therapy	We suggest avoiding antimicrobial treatment of STEC infections or STEC related HUS with antimicrobials due to the reported association with increased risk for worse outcomes	Moderate to low (a number of meta – analyses and systematic reviews demonstrate a negative effect of antibiotics on outcomes)	Weak as the evidence is contradictory and randomized prospective studies are missing
Erythropoietin	We suggest that erythropoietin may be considered for treatment of STEC-HUS related hemolytic anemia to minimize exposure to red blood cell transfusions	Very low	Weak as the evidence is based on a very small sample size
Intravenous fluid volume expansion	We suggest that volume expansion with an isotonic intravenous fluid solution in children with STEC infection or STEC-HUS, having adequate urine output with no to mild fluid overload, may be associated with better outcomes	Low (a meta-analysis based on observational data, prospective randomized studies are lacking)	Weak
Renal replacement therapy	We suggest avoiding delays in initiation of RRT for treatment of STEC-HUS related AKI, according to universally accepted indications and using the safest and most readily available modality	Low no studies available except descriptive reports	Weak
Terminal complement inhibitors	We suggest that the use of terminal complement inhibitors in STEC-HUS is not routinely indicated but it should be considered in patients suspected of atypical HUS	Very low (Case reports and series with contradicting conclusions)	Weak

GRADE assessment of the certainty of the evidence [1]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making.*

impact of antibiotics on risk for STEC-HUS and outcome [51, 52]. Only one retrospective cohort analysis of a large outbreak that occurred in Japan demonstrated benefit for using the antibiotic fosfomycin within the first 2–3 days from beginning of STEC infection symptoms. Among 130 children aged 6–11 years, the odds ratio (OR) for developing HUS was less than 1.0 if fosfomycin was given within 3 days from start of infection symptoms compared to no antibiotics [44]. The reduction in odds ratio was statistically significant when the antibiotic was started even earlier, within the first 2 days of illness (adjusted OR 0.09, 95% confidence interval [CI] 0.01–0.79) [44]. The negative impact of antibiotic use on risk and outcomes of HUS is not well understood. in vitro exposure of bacteria to antibiotics induces lysis with release of toxin, which, in the gut, could potentially be more likely to be absorbed [55, 56]. However, a toxin binder designed to diminish toxin absorption was not proven effective in a prospective randomized controlled trial [57]. Antibiotics have not been shown to directly influence interaction between toxins and their Gb3 receptor, suggesting that the antibiotic influence on risk and outcome of HUS is mediated by modulation of toxin bioavailability [58–60]. Recently, further evidence for a possibly beneficial role of early use of antibiotics in patients with D+HUS was provided by the retrospective analysis of antibiotic use during the 2011 German mega-outbreak [31]. Nevertheless, based on best available evidence, the current recommendations are to avoid use of antibiotics in treatment of STEC infections [54].

Shiga Toxin Binding and Blocking Agents

STX1 and STX2 are highly potent toxins in very small concentrations. Blocking STX access into the bloodstream or inactivation of blood-borne STX are major areas of interest in the search for D+HUS treatment options. SYNSORB Pk (Synsorb Biotech Inc., Calgary, AB, Canada) is a synthetic potent STX binder that was designed to bind STX in the gut, thus blocking absorption of STX; unfortunately, a large phase III trial with this agent failed to demonstrate any benefit [57].

Blocking the effect of blood-borne STX with inactivating antibodies has also been attempted, but currently the results of a trial with monoclonal anti-STX1 and anti-STX2 antibodies have not been reported [6, 61]. The main challenge with STX binding and blocking agents has been timing of administration, which needs to occur before the STX effect is further amplified by a cascade of events involving the thrombotic, inflammatory, and complement systems [6, 57].

Fluid Management in D+HUS

The benefits of early intravenous fluid expansion for management of STEC infections are supported by a growing body of evidence. Retrospective analysis by Oakes et al., Balestracci et al., Ojeda et al. and others have shown that dehydration at presentation is associated with increased risk for HUS complications such as oligoanuria, need for renal replacement therapy (RRT), neurological complications, and death [62–64]. On the contrary, early proactive intravenous fluid expansion with isotonic solutions was shown in retrospective and prospective studies by Ake et al., Hickey et al., and Ardissino et al. to reduce risk for HUS complications [65–67]. A meta-analysis that pooled these data demonstrated that dehydration at presentation with HUS was associated with increased risk for oligoanuria (OR 2.38, 95% CI 1.30–4.35), RRT (OR 1.90, 95% CI 1.25–2.90), and death (OR 5.13, 95% CI 1.50–17.57), while intravenous fluid administration up to the day of HUS diagnosis was associated with a decreased risk of RRT (OR 0.26, 95% CI 0.11–0.60) [68]. However, once STEC-HUS develops and oligoanuria is identified, careful fluid management, including restriction, should be considered to avoid fluid overload. Fluid overload that is present at the time of initiation of urgent RRT in critically ill children with multisystem involvement has been shown to be a bad prognostic factor [69, 70]. Among other benefits, close monitoring during the STEC infection is important to facilitate early detection of evolving HUS and allow timely necessary adjustments to fluid management. As HUS and acute kidney injury evolve, hypertension frequently develops along with fluid and salt retention. In this situation, general principles for management of acute kidney injury in children should be applied [71, 72]. Careful attention should be given to the type of fluids administered, aiming to minimize salt load, while total administered volume should not exceed the total of all losses such as urine output, insensible losses, ongoing diarrhea, etc. The volume required for adequate nutrition should be given priority and be included in the total fluid balance. Judicious use of loop diuretics can help manage hypertension as well as maintain adequate urine output, which can facilitate fluid management and nutrition, and improve outcomes [73]. Additional use of antihypertensive agents may be needed to control hypertension.

Renal Replacement Therapy

RRT is required in 50–70% of cases in the acute phase of HUS [7, 37]. There are no specific indications or benefit for early initiation of acute dialysis in D+HUS [6]. General indications for acute RRT in the management of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

acute kidney injury should be applied. Oligoanuria, severe azotemia, electrolyte abnormalities, acidosis, and need for nutritional support are among the common indications for acute dialysis [74]. There is no clear benefit for a specific type of RRT, but peritoneal dialysis has been extensively and successfully used in children with D+HUS [75, 76]. Insertion of a peritoneal dialysis catheter can usually be safely performed in thrombocytopenic patients without the need for platelet transfusion, and trained staff can safely perform peritoneal dialysis on general pediatric wards [6, 76, 77]. Complications and technical failure are rare despite the severe intestinal injury caused by the STEC infection, which is not a contraindication for peritoneal dialysis and does not interfere with the effectiveness of this modality [75]. Hemodialysis or continuous veno-venous hemodiafiltration are also very efficient, but require appropriate venous access and admission to an intensive care unit. Nevertheless, in patients with aHUS or in whom aHUS is suspected, hemodialysis or veno-venous hemodiafiltration may be preferred modalities since the venous access can also be used for administration of plasma exchange, which is generally indicated in these patients. Finally, despite the fact that there is no proven benefit for early RRT, efforts should be made to start dialysis before development of fluid overload, which may be associated with a worse prognosis in a critically ill child [70, 78].

Erythropoietin and Transfusions

Platelet consumption and hemolysis are integral consequences of the TMA in HUS. Thrombocytopenia in these cases can be extreme, yet platelet transfusions are not indicated unless there is evidence of active bleeding. Transfused platelets may enhance the thrombotic events occurring in various microvasculature beds of affected patients [79]. Severe anemia secondary to hemolysis, on the other hand, can further destabilize patients by negative effects on the cardiovascular and respiratory systems. Erythrocyte transfusions are considered an important component of the supportive therapy in HUS, and have been reported to be required in up to 92.6% of patients [80]. Use of erythropoietin (EPO) early in the course of HUS has been proposed as a possible measure toward reducing the need for erythrocyte transfusions [81]. A small prospective study that randomized 10 children with HUS to early EPO vs. placebo found that EPO significantly reduced the required number of red blood cell (RBC) transfusions (0.2 vs. 1.4, $P < 0.04$, *t*-test) [81]. However, a more recent retrospective study did not support these results, therefore further studies are needed to evaluate the routine use of EPO in patients with STEC-HUS [82].

Complement Inhibitors

Currently, the single commercially available complement inhibitor is eculizumab, a recombinant, humanized monoclonal antibody against complement component C5. This antibody effectively blocks cleavage of complement factor C5 and the formation of the complement membrane attack complex C5b-9 [83]. Clinical trials and postmarketing prospective observational studies have demonstrated that eculizumab is very effective and superior to plasma therapy for prevention and treatment of aHUS episodes caused by dysregulations of the complement system [84]. A role for eculizumab in management of STEC-HUS is not established. [85] However, in view of evidence demonstrating complement activation associated with STEC infection and HUS, exploratory use of eculizumab in patients with STEC-HUS has been attempted. A letter to the editor published in the *New England Journal of Medicine* in 2011 described prompt recovery after administration of eculizumab in three children with severe STEC-HUS, associated with RRT and severe CNS complications [86]. However, in the same year, widespread use of eculizumab during the mega outbreak of HUS in Germany led to a high-quality retrospective review which did not demonstrate an outcome benefit for 67 out of 298 patients who were treated with this agent, compared to matched patients who did not receive eculizumab [31].

A recent narrative review published in 2018 included 11 reports and reached the conclusion that current evidence cannot support or disprove a role for eculizumab in the management of STEC-HUS and a clinical trial is desperately needed [87].

Conclusions

Most cases of childhood HUS evolve as a devastating complication of an infectious STEC colitis in otherwise healthy children. There is currently no specific treatment for STEC colitis or HUS that is supported by high-quality evidence, but timely and appropriate supportive care has been associated with good outcomes in the majority of patients. Low-quality evidence supports some measures that appear to be associated with better outcomes: intravenous volume expansion in children with STEC colitis at risk for or with imminent HUS and avoidance of antibiotics for treatment of the STEC colitis or HUS. Erythropoietin may limit the number of blood transfusions and early intervention with RRT may lower the risk associated with fluid overload, but the evidence for these interventions is of very low quality. Routine use of terminal complement inhibitors such as eculizumab is not supported by currently available

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. evidence, but in view of physiological plausibility and positive case reports further investigation in this matter is justified. Moreover, there is currently no evidence supporting an intervention that may decrease the risk of progression from STEC-infectious colitis to HUS. However, preliminary indications that early intravenous volume expansion with isotonic fluids may be effective should be investigated in a randomized prospective trial.

Introduction

The chronic kidney disease (CKD) journey, from diagnosis to end-of-life care, includes many complicated treatment decisions that require patients and physicians to consider the risks and potential benefits of life-extending treatments and therapies. The impact of treatment decisions on a patient's life vary significantly from minor changes in their daily routine (e.g. having to begin daily medication to control blood pressure or limiting salt intake in their diet) to life-altering changes that accompany life-prolonging therapies (such as thrice weekly hemodialysis).

The trade-off made between the burdens and benefits of any given treatment will differ for each patient depending on their values and preferences. Many patients rely on their clinicians for guidance on treatment decisions that are not only in their best prognostic interests, but also align with their values and preferences. Over the last few decades, the clinician's role in treatment decision-making has shifted from paternalism to partnership, and it is now recognized that clinicians should engage in shared decision-making (SDM) to determine the most appropriate course of treatment for each patient.

Nephrology clinicians frequently face situations such as in the example in Box 71.1 in which they inform and guide patients to make treatment decisions about their kidney disease and how to manage accompanying setbacks. In addition to dialysis modalities and transplantation, comprehensive conservative care (CCC) is an elected treatment path that emphasizes quality of life and symptom management. For older patients, especially those with advanced conditions, dialysis may not offer meaningful longevity or quality of life [1–5]. Patients managed without dialysis are more likely to have their symptoms alleviated, spend survived time out of the hospital, and receive dedicated end-of-life care with services such as hospice [6, 7]. Yet, patients are less likely to understand these prognostic trajectories or the options available to have treatment without dialysis and choose CCC [8].

SDM in nephrology care is an essential component to ensuring patients make informed decisions that reflect their priorities. In SDM, clinicians and patients work together to make decisions that balance the potential risks and expected benefits with patient preferences and values. This chapter provides a summary of the evidence for SDM in nephrology care, particularly for older patients with advanced comorbidities facing difficult decisions about treatment of advanced kidney disease and preferences for end-of-life care. The chapter includes a definition of SDM, communication strategies to facilitate clinicians in engaging in SDM, and patient decision aids aimed to prepare patients to consider their values and preferences with the treatment decision.

Definition

SDM has been defined as the meeting of two experts – the patient and clinician – with the goal of working together to make the best healthcare decision for the patient. The concept of SDM is countered by traditional models, including paternalistic and informed models [9] (Figure 71.1). Within the paternalistic model, the clinician is viewed as the expert

Box 71.1 Case Example

Ms. K is a 75-year-old wheelchair-bound woman with progressive stage 4 kidney disease due to heart failure and diabetes who is seen in nephrology clinic for management of advanced kidney disease. She requires assistance for bathing and dressing, and recently moved into a personal care home. The nephrology clinician has cared for Ms. K over 3 years and notes a progressive decline in function and health. Reflecting on the treatment decisions that she and Ms. K will address, the clinician asks herself:

- How do I help Ms. K make the right decision to manage her advanced kidney disease?
- How do I prepare Ms. K to make the right decisions to manage her future end-of-life care?

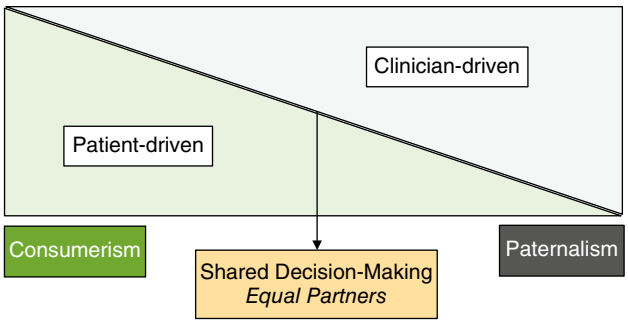

Figure 71.1 Continuum of patient–clinician decision-making models.

and so uses their skills to determine the best treatments based on the patient's medical condition and circumstances. The paternalistic model assumes that the clinician knows what is in the patient's best interest and hence the flow of information and deliberation is unidirectional with minimal input from the patient. A major limitation of this model is the assumption that the clinician and patient espouse similar values and views of what qualifies as benefit.

The countering model on the other end of the decision-making spectrum is the informative model. Sometimes referred to as the consumer model, the informative model shifts the role of decision-making to the patient. Within this model, the clinician provides the necessary information about the disease process, possible treatments, and expected risks and benefits with the expectation that the patient decides what is best [9]. This model lacks essential elements of the clinician–patient relationship, including helping patients to deliberate and recommending treatment decisions based on their values and preferences.

SDM responds to the limitations of these traditional models and addresses real-world challenges to decision-making within healthcare. In the case in Box 71.1, the right choice for how Ms. K manages her kidney disease and future end of life is not straightforward and depends on her individual values and priorities.

Charles and authors define SDM as requiring four necessary elements to address these preference-sensitive decisions in which no best answer exists [10]:

1) First, at a minimum, the treatment decision-making process must involve the clinician and patient.
2) Second, the process is bidirectional, meaning both the clinician and patient share information with each other.
3) Third, both the clinician and patient actively participate in the decision-making process by sharing treatment preferences.
4) Fourth, the final treatment decision is made and agreed on by both the clinician and the patient.

Shared Decision-making in Nephrology

Frameworks and Processes

The Renal Physicians Association (RPA) and the Choosing Wisely Campaign recommend nephrology clinicians engage in SDM to address complex treatment decisions such as dialysis initiation versus CCC and preferences for end-of-life care [11, 12]. Yet patients describe insufficient preparation and involvement in treatment decisions. In one qualitative study of US dialysis patients over the age of 65, no patient felt they made the choice to initiate dialysis [13]. Rather these decisions were either influenced by the perception of imminent death without dialysis or by the clinician. Among 197 dialysis patients in Canada with an average age of 53 years, 48% reported that treatment decisions were made by their clinician, with only 25% reporting shared responsibility [14].

A fundamental component of SDM in advanced kidney disease involves providing patient-specific prognostic information. Patients report rare prognosis discussions which influence how decisions for end-of-life care are made. In an interview study, incident hemodialysis patients who reported an overly optimistic prognosis were more likely to elect life-prolonging treatments if they were seriously ill, even if this meant suffering or discomfort [15]. Although there are emerging efforts to develop and validate various risk predictions models into usable forms for clinicians, such as online calculators or calculators integrated within the electronic health record, these most often focus on mortality risk and do not provide individualized information about other outcomes important to patients [16]. This omission of relevant prognostic information may in part explain why dialysis

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

patients are more likely to receive intensive therapies at end of life and less likely to receive quality end-of-life care such as hospice services [7, 17].

Another component of the SDM process is for the patient and clinician together to understand the patient's values and priorities (Tables 71.1–71.5) [18]. In a survey study conducted in Australia and Canada, hemodialysis patients and their caregivers prioritized important outcomes in hemodialysis patients. They defined survival in terms of living well, with mortality ranking only 14th in terms of importance [19]. These findings reinforce that clinician focus on treatment decision-making discussions must address more than just survival alone [20].

Table 71.1 Priorities identified as important to patients with advanced kidney disease [18].

Maintain independence	Physical appearance
Flexibility in daily schedule	Social relationships (family and friends)
Privacy	Burden on others
Comfort of environment	Safety related to treatments
Reliability of treatment timing and schedule	Work or school

Source: Based on Dahlerus et al. [18].

SHARE Approach to Shared Decision-making

Multiple SDM models exist. All models reinforce the importance of prognostic information and the elicitation of patient values and priorities to guide treatment decisions [10, 21–23].

The SHARE Approach is a five-step process for SDM endorsed by the Agency of Healthcare Research and Quality [23]. The steps are (i) seek the patient's participation, (ii) help the patient explore and compare treatment options, (iii) assess the patient's values and preferences, (iv) reach a decision with the patient, and (v) evaluate the patient's decision. These steps are best accomplished through patient-centered communication strategies. The communication framework Ask-Tell-Ask supports a two-way conversation in which the clinician elicits information

Table 71.2 Characteristics of included studies.

Study ID	*n*	Study design	Setting	Participants	Topic
Dahlerus et al. [18]	180	Semistructured interviews	United States	18 years or older, eGFR <25 ml/min/1.73 m^3 or on dialysis for >3 months	Perspectives on modality choice
Davison et al. [51]	24	Ethnographic study with interviews	Canada	Purposive sample: 44–88 years (mean 64), 50% women, $n = 1$ first nations Aboriginal, $n = 23$ white	Perspectives of salient features of effective facilitated advance care planning
Fortnum et al. [44]	NA	Development of decision aid	Australia and New Zealand	NA	Shared decision-making: dialysis vs. conservative care
Harwood et al. [60]	410	Qualitative synthesis	Six databases	>18 years with chronic kidney disease	Dialysis modality decision-making
Holley et al. [61]	614	Observational survey: two time points	United States	Nephrologists	Changing clinician attitudes and practices of end-of-life decision-making
Hussain et al. [49]	270	Qualitative synthesis	Four databases	Patients aged 26–93 years, health professionals aged 26–61 years	Factors affecting patient or health professional decisions to commence or withdraw from dialysis
Joly et al. [3]	146	Cohort study	France	Consecutive pre-ESRD octogenarians referred to nephrology unit	Factors affecting clinician and patient choice of dialysis or conservative care in octogenarians, and impact on survival
Moattari et al. [62]	48	Randomized controlled trial	Iran	Patients on hemodialysis	Effect of empowerment on self-efficacy and quality of life (including decision-making)
Morton et al. [54]	462	Qualitative synthesis	Six databases	Patients with chronic kidney disease and caregivers	Decision-making and choice for dialysis, transplantation or palliative care

eGFR, estimated glomerular filtration rate; NA, not applicable.

Table 71.3 Impact on patient-centered care and outcomes.

Study ID	Impact on patient-centered care and outcomes
Dahlerus et al. [18]	More informed/engaged patients who were active in decision-making chose options that better fit their priorities. Important outcomes that impact decision-making were quality of life, convenience of at home therapy, ability to work, risk of infection, and medical expertise.
Davison et al. [51]	Most patients believed healthcare providers wanted to know their preferences for advance care planning and believed this would influence outcomes of treatment. Patients based their decisions on the impact of the care plan on their personal lives and wanted to know how interventions could help achieve personal goals, e.g. avoiding hospitalization.
Holley et al. [61]	Significantly more nephrologists in 2005 were willing to stop dialysis in a severely demented patient (53% vs. 32%, $P<0.00001$) and to withhold dialysis from a permanently unconscious patient (90% vs. 83%, $P<0.001$). Most nephrologists in both surveys would respect the request of a competent patient to stop dialysis. When asked whom they would consult to assist in decision-making for each of these hypothetical cases, <98% would consult the patient's family in each scenario in both 1990 and 2005. In 2005, compared with 1990, nephrologists are more likely to honor a dialysis patient's wish for DNR status.
Hussain et al. [49]	For many patients the effects of treatment on their quality of life was more important than medical effectiveness – quality of life was prioritized over longevity/survival. As life on dialysis deteriorated, patients questioned its worth and considered withdrawal. Knowing they had this option gave them control. Health professionals depended on biomedical criteria to guide decision-making rather than patient preference, delaying withdrawal until medically necessary.
Joly et al. [3]	Aside from patient refusal, late referral, social isolation, low functional capacity, and diabetes may have oriented the medical decision to withhold dialysis.
Moattari et al. [62]	A significant change was observed between the groups in terms of stress reduction (adjusted mean difference −3.6 [−4.4 to −1.57], $P<0.02$) as well as the decision-making dimension (adjusted mean difference −3.21 [−4.39 to −2.03], $P<0.001$) and overall self-efficacy scores (adjusted mean difference −12.02 [−18.41 to −5.53], $P<0.001$). Also, a significant difference was found in the overall mean score of quality of life and in all dimensions of the quality of life between the groups (adjusted mean difference −2.93 [−4.39 to −1.47], $P<0.001$).
Morton et al. [54]	Medical outcomes of treatment were considered less important than the effect of treatment on patient's lifestyle. Longevity was viewed as less important than quality of life.

Table 71.4 Communication.

Study ID	Prognosis, preferences
Davison et al. [51]	Patients wanted more information earlier in the disease process – this promoted self-reliance, alleviated fear/uncertainties, helped prepare them for future, and gave them the knowledge to make decisions that were compatible with their values and beliefs. Patients wanted clear honest discussions in lay language. They explained that jargon caused confusion and misunderstanding. They believed physicians were responsible for initiating discussions around end-of-life care.
Hussain et al. [49]	More information about their future was considered better than none by patients, despite fears/uncertainty this may raise. It was important to patients that information was delivered by a trusted person.
Morton et al. [54]	Framing of treatment/interventions by physicians impacted patient decisions, e.g. Transplant framed as a 6-h operation with risk of death was seen as not worth it by some patients, despite increased rate of survival.

from the patient (Ask) before giving relevant information (Tell) and then assesses how the information impacted the patient's understanding (Ask).

Seek the patient's participation (Step 1): The first step of the SHARE Approach is to invite the patient's participation in SDM. This can involve establishing rapport, reinforcing patient's autonomy, and the patient's preferences for decision-making. Both clinician and patient are expected to collaborate proactively in this decision-making process by exchanging information about the illness, diagnosis, and treatment from their areas of expertise, outlining explicit values and preferences in the context of care pathways and/or lifestyle, reasoning together to determine the best option for the patient, and agreeing and implementing the choice that aligns best with clinical evidence and patient preference. Establishing rapport and trust is an important aspect of seeking patient participation. This involves gaining an understanding of the patient's experience and culture

Table 71.5 Barriers to SDM.

Study ID	Barriers to SDM
Dahlerus et al. [18]	Medical crisis/need was prioritized over patient choice. Physician control over decision limited patient involvement in decision-making.
Davison et al. [51]	Patients less likely to actively engage in decision-making process if they did not perceive any benefit (e.g. aligned priorities). The use of medical jargon was confusing for patients and discouraged them from participating in decision-making. A lack of family support also prevented patients from participating in shared decision-making.
Hussain et al. [49]	The perceived power and dominance of the healthcare team hindered patient involvement in medical decision-making. The healthcare team were considered to "own" the knowledge and they decided what the patient should know. Lack of time for acutely unwell patients meant decisions were made without including them. Inconsistent and "accidental" delivery of information left patients unable to participate in shared decision-making as they did not understand their treatment options and the respective consequences of each.
Morton et al. [54]	Lack of information about all available treatment options limited patients' involvement in their treatment decisions. Physiological contraindications (e.g. no vascular access) eliminated treatment options in the eyes of physicians in favor of biomedical outcomes. Limited healthcare resources (e.g. availability of chair/kidneys) meant patients' options were also limited. Problematic timing of presenting information to patients by physicians meant they were sometimes too sick or did not have enough time to absorb information.

which may involve traditions, beliefs, and values based on cultural norms [24, 25]. In addition, seeking participation also involves determining the patient's desired level of involvement in the decision-making process. Some patients may prefer a passive role, deferring decision-making to a loved one, or may elect a clinician-centered approach that is more directive [26]. This preference to limit their involvement or defer the final decision to the clinician can be respected and the SHARE Approach can be adapted to support these decision-making preferences and needs.

The first *Ask* of the *Ask-Tell-Ask* framework starts with gaining the patient and/or family's input rather than reflectively disclosing information. Open-ended questions such as "What have the doctors told you about your kidney disease?" allow the clinician to explore what the patient understands about their condition. These exploratory questions also allow the clinician to learn decision-making preferences, cultural experience, and belief system (Box 71.2).

Box 71.2 Seek Patient's Participation (Step 1)

The clinician caring for Ms. K wants to learn about her experience with her disease and learn how much involvement Ms. K wants in her treatment decisions and who, if any, are the other people that will be involved in the decision-making process. To determine these important aspects, the clinician asks Ms. K:

- Can you tell me about the impact your treatment has had on your life so far?
- As your clinician, what would be helpful for me to know about you and your life?
- How much involvement have you had in other medical decisions? Has this worked for you? Why/why not? Do you want to do this differently?
- Who would we include in these discussions and decisions?

Help the patient explore and compare treatment options (Step 2): This step involves detailed explanations and discussions of the potential treatment options available to the patient, including the expected benefits and risks associated with each one. This step addresses the *Tell* of the *Ask-Tell*-Ask framework. This *Tell* should include information about treatment options, including prognostic information, and should be given in a way that is clear without medical jargon.

Discussions about prognosis are often avoided until forced, either in the setting of decline or after prompted by the patient. This may be due to the inherent uncertainties regarding prognosis. While prognostic tools exist to help predict how a patient might respond to a given treatment, significant uncertainty remains for how a patient will actually do [27–29]. This uncertainty challenges the clinician's skills in guiding treatment decision-making and helping prepare patients for living with a life-prolonging treatment. Yet, many patients do want information about what to expect in the future, and prefer that this information be given voluntarily by the clinician [30].

Understanding what prognostic information the patient desires can influence the kinds of information the clinician should provide [31]. Prognostic information should include both survival and quality of life to ensure the patient receives information that addresses their personal concerns. During discussions of treatment options, it is helpful

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to describe the different treatment paths in terms of the expected benefits or potential risks ("Choosing to start dialysis may extend your life, but it may also mean that you spend more time in hospital and depend on others for help") (Box 71.3).

Assess the patient's values and preferences (Step 3): After sharing prognostic information and relevant treatment options, the conversation should shift from giving information (*Tell*) toward eliciting goals and values (*Ask*). This process ensures the decision is guided by what matters most to the patient, such as quality of life, level of independence, and preferences for care at the end of life. This also may be integrated throughout the therapeutic relationship between patient and clinician over time. In a small study of 99 dialysis patients reflecting on their recent experience with selecting a treatment option for advanced kidney disease, 20% reported that their doctor asked about their values and preferences [8]. In a recent study of 271 patients with stage 4 or 5 nondialysis-dependent CKD from one center, patients most commonly identified maintaining independence as their top priority (49%). However, when the clinician was asked about the top priority of the patient only 31% (95% CI 26% to 37%) were in agreement [20]. There continues to be significant opportunity to increase the activities in clinical care in support of eliciting and understanding values and preferences.

Learning what matters most to patients involves learning patient goals and values. These "big picture" goals and values are best elicited with open-ended questions that explore hopes for, as well as worries about, the future [32–34]. By asking about hopes for the future, the patient can consider the values and priorities that are most important and whether these values and priorities support a treatment focused on quantity or quality of life. In addition to understanding what the patient hopes for in the future, it is as important to explore what the patient hopes to avoid. These concerns may be related to physical suffering, psychological distress, and being a burden to loved ones. Asking the patient about their worries provides insight into the conditions or health states that a patient hopes to avoid. For patients whose goals are focused on comfort, worries may include going back to the hospital, being away from the family or living in dependent condition (Box 71.4).

Reach a decision with the patient (Step 4): The fourth step involves offering a treatment recommendation that incorporates the prognostic data and the patient goals. For patients with older age and advanced comorbidities, the relevant treatment options are trial of dialysis (hemodialysis or peritoneal dialysis) versus CCC. Many patients desire a recommendation from the clinician while a minority of patients do not. Therefore, it is helpful to *ask permission* to provide a recommendation. If the patient agrees, the clinician can proceed with a recommendation that is grounded in the patient's own goals and values (Box 71.5).

Evaluate the patient's decision (Step 5): After the treatment path is elected, the SDM process continues and includes opportunities to reassess and revisit the care plan. First, it is difficult to prepare a patient for exactly what to expect living with dialysis or CCC. Words often fall short compared to the lived experience. Second, uncertainty makes it difficult to adequately prepare patients for what to expect even with prognostic guidance. Third, many patients may choose dialysis as a better alternative compared to

Box 71.3 Help Explore and Compare Treatment Options (Step 2)

Ms. K's nephrology clinician considers the relevant treatment options available and tailors the prognostic information based on Ms. K's clinical condition to include both survival and quality of life:

Option 1 Trial of dialysis: "For patients who are older with other advanced conditions, dialysis may add little additional time and survived time will likely include setbacks such as loss of function and more hospitalizations."

Option 2 CCC: "For patients similar to you, choosing conservative care may lead to shorter time, but time lived is focused on managing your symptoms and quality of life, without life prolonging treatments such as dialysis."

Box 71.4 Assess the Patient's Values and Preferences (Step 3)

After giving Ms. K all the relevant treatment information it is now time to elicit her priorities for treatment:

- Given this news, what is most important to you?
- As you think about the future, what concerns you the most?
- What do you want to avoid in the future?

It may be helpful to give an example comparing the two treatment options with specific potential consequences:

"Some people want to live as long as possible and choose dialysis even at the risk of frequent hospitalizations and less independence. Other people wish to focus on the quality of their lives and prefer treatments that are focused on their symptoms without dialysis even if this meant life could be shorter. Do you have a sense of how you feel about this?"

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

death. Therefore patients, especially those who elect dialysis, benefit from evaluation of the decision and anticipatory guidance for future end of life needs [35] (Box 71.6). A recent study noted that it is equally important not to continually question a decision once it has been made, as this may be perceived as badgering and threaten the trust previously developed in the clinician–patient relationship [36]. Determining the intervals of re-evaluation of the treatment decision should be a part of the collaborative plan.

Evaluating the decision also involves preparation for future setbacks and end of life. Advance care planning (ACP) is a continuous process through which providers engage in discussions with patients and their families to learn their goals and preferences toward future medical treatments [37]. ACP conversations allow patients to reflect on their care preferences to inform decision-making in future declining health states. Patients who had have an ACP are more likely to receive care that is consistent with their care goals, including end-of-life care such as hospice [38]. Dialysis patients are less likely to have engaged in ACP conversations. Thus, end of life is often experienced in the hospital following life-sustaining treatments with less opportunity for quality hospice care [7]. In US nursing home patients with dementia on dialysis, those who engaged in early ACP by completing an advance directive and naming a surrogate decision-maker had fewer hospitalizations, less intensive care, and fewer invasive procedures compared to those who lacked both [39].

The SHARE Approach is generally supported by efforts to increase clinician communication skills and self-efficacy in the provision of SDM. Educational materials in kidney disease can be used in Step 2 when delivering information about treatment options, however decision tools specific to the SDM process that aim to deliver prognosis information aligned with values (Step 3) are helpful to reach a collaborative treatment decision (Step 4).

Box 71.5 Reach a Decision (Step 4)

The nephrology clinician asks Ms. K's permission prior to offering a suggested treatment plan based on what she has shared with you:

From our discussion I have a sense of what things are most important to you. Would it be ok if I offer my suggestion about a plan moving forward?

Ms. K agrees, and the clinician offers a recommendation that is supported by Ms. K's goals and priorities:

"Based on your goals to spend as much time with your family and away from the hospital even if this means shorter time, I would recommend *we pursue conservative care with a focus on your quality of life and we will not do dialysis as this would not achieve your goals. How does that sound to you?"*

Box 71.6 Evaluate the Decision (Step 5)

Patients who elect trial of dialysis especially benefit from evaluation of the decision to assess whether the treatment is meeting the patient's goals without causing unwanted burdens:

- It's been two months since we started dialysis, what has been your experience?
- When we started dialysis, we hoped that it would help you get stronger and back home. Have you been able to accomplish this goal?
- What concerns do you have with continuing dialysis?

Decision Tools

Decision aids are informational documents that present educational and prognostic information about the health condition. Information then is presented about the treatment options, and when available information about outcomes including side effects (Figure 71.2). Decision aids do not make recommendations about a specific treatment and they do not replace evaluation and counseling from a clinician. Optimized decision aids have the capability to customize the information presented to the patient using the decision aid. The International Patient Decision Aid Standards (IPDAS) Collaboration has developed criteria to assess the quality of patient decision aids using a checklist with 28 different criteria [41].

Although there has been a growing interest in the development and provision of decision aids in nephrology, few have been tested in trials to determine their impact on outcomes. The most common outcomes influenced by decision aids include addressing decisional uncertainty, knowledge and understanding, and congruence between the decision and patient values [42]. A recent review of decision aids for renal replacement therapy described 10 decision aids and another four that were more specific to conservative care [43]. Most decision aids had yet to be rigorously tested for efficacy on either decisional or clinical outcomes. The reports available support that the various decision aids are generally accepted by patients (Table 71.6). One small study examined the online self-directed decision aid http://Chooosingdialysis.org, which provides information about all treatment options but focuses on dialysis modality decisions (in-center hemodialysis or peritoneal dialysis). It was tested in 63 people (average age 59 years) and demonstrated increased kidney knowledge and less

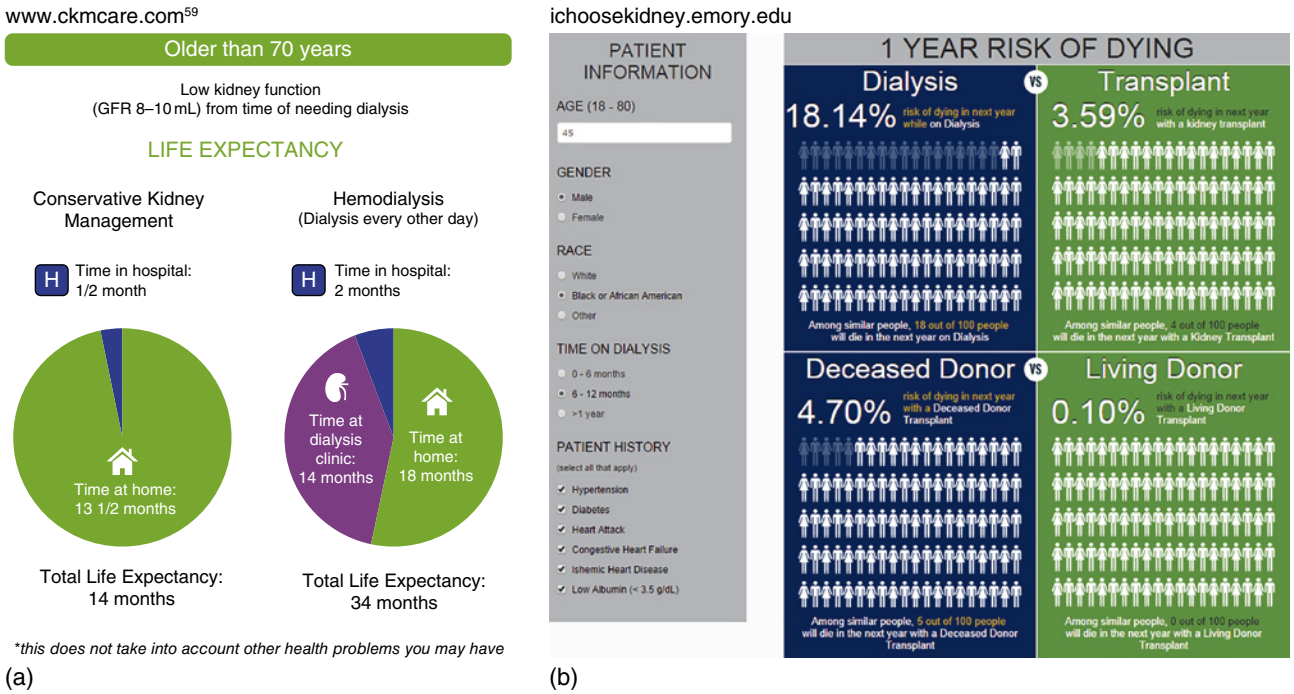

Figure 71.2 Examples of kidney decision aid content: (a) www.ckmcare.com [40] and (b) http://ichoosekidney.emory.edu.

decisional conflict after its use [48]. There was no change in decisional self-efficacy score. The largest studies reported are in the context of increasing the use of kidney transplantation as a therapy option and have shown variable results. None of the studies describe the process of using a decision aid during the clinical encounter compared to self-directed use. There are substantial gaps in knowledge regarding the use of decision aids to facilitate SDM in kidney disease care and importantly critical gaps in understanding their influence on decisional, behavioral, and health outcomes in diverse patient populations.

Barriers and Opportunities

A review of the evidence reveals potential barriers to SDM, many of which can be attributed to poor communication strategies, highlighting opportunities to address these barriers in future.

Perceived power imbalance with emphasis on lack of information: A systematic review of qualitative studies found that patients believed that the healthcare team were considered to "own" the knowledge and it was up to them to decide what patients should know [49]. A study that included interviews of 35 nephrologists from nine US states found that they generally attributed failed discussions to factors related to the patient rather than self-reflection of their own skills [50]. Participants in an interview study identified the use of medical jargon by health professionals as confusing [51]. This perception may be amplified when the patient has low health literacy which is associated with lower perceived knowledge ($r_s = 0.19$, $P < 0.0001$) among patients with advanced CKD [52] and patients with higher perceived knowledge express greater satisfaction with their clinician's communication (adjusted odds ratio 2.13 [1.59, 2.86], $P < 0.0001$). Training to improve clinicians' communication skills may directly address these potential barriers, and this may become a priority as nephrologist communication metrics have been incorporated into value-based payment systems in the United States [53].

Patients identified a lack of information about all available treatment options as a barrier to actively participating in their treatment decisions [54]. Delivery of information was labeled as "inconsistent" and "accidental," leaving patients feeling that they did not have all the information they needed to participate in SDM [49]. Complete and systematic delivery of information, using effective communication strategies, early in the diagnosis may help to address these issues. A recommended communication strategy to ensure that Step 2 is effective and that patients understand the content of the information is to perform a teach-back whereby as an example the clinician asks the patient to share how they would explain the concept or skills to their family member. This method has effectively improved self-care in kidney disease hypothesized to be due to better patient knowledge, self-efficacy, and practical skills [55].

Medical crisis: In some cases patients believed that there was no time or opportunity to engage in SDM when there is a need for urgent treatment or because of a physiological contraindication (e.g. no vascular access) [18, 49, 54]. While urgent treatment decisions may be necessary in a small proportion of patients, for most there is time to present the treatment options to the patient and determine their preferences before proceeding. Also identified as a barrier was the timing of when the information was presented – some explained that it was left too late and they were too unwell or did not have enough time to absorb the information in order to make a decision [54]. The SHARE approach is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

flexible to patient needs and desire for engagement, and it allows opportunities to process the informational content while performing Step 4 to collaboratively reach a treatment decision.

A transitional care unit (TCU) program is a novel healthcare system delivery approach to address the concern regarding those who have advanced to end-stage kidney disease, who have not yet developed a treatment decisional plan, but now their medical status precludes them from fully participating in SDM [56]. This program emphasizes stabilization of medical status paired with a comprehensive educational curriculum that purposefully employed SDM techniques and decision aids. While the programs efficacy is yet to be evaluated it demonstrates that with leadership buy-in SDM can be core to the mission of integrated kidney care.

Lack of treatment options: Clinicians may perceive dialysis to be the only relevant treatment option and may therefore guide the discussion with dialysis as a default decision. In a study of Veterans Administration clinician documentation from the electronic health record, clinicians were more likely to push dialysis even when patients strongly verbalized a wish to forego dialysis [57]. Three themes that emerged described (i) dialysis as a norm in which clinicians felt obligated to repeat or reexamine the patient's decision to forego dialysis, (ii) when clinicians decided dialysis was not a viable option, this decision was justified based on biomedical factors rather than patient goals and values, and (iii) when it was determined dialysis would not be pursued, clinicians felt they had little to offer patients beyond dialysis and so often signed off from their care. Increasing education and comfort in providing CCC are strategies to overcome this "all or nothing" view of dialysis [58].

Other barriers identified were no perceived benefit of participating in SDM, lack of time during typical clinical visits, a lack of family support, and limited healthcare resources (e.g. availability of dialysis chairs) [51, 54]. Opportunities for SDM are emerging within the context of kidney transplantation organ allocation. One study found that 63% of patients wished to participate in decisions about quality of the organ [59]. This may become even more relevant as other biomarkers, including genetic information, are used for estimating risks related to graft survival.

Conclusions

SDM is a patient-centered approach to ensure patient values and priorities inform treatment decisions. SDM is especially relevant for treatment decisions for advanced kidney disease as well as end-of-life care. The SHARE Approach provides a framework for supporting SDM that ensures treatment decisions reflect relevant prognostic information and what is most important to the patient. Decision tools can help patients consider the treatment options in terms of their values and priorities. Barriers to SDM can be overcome through two-way communication, avoidance of medical jargon, and providing patients with the necessary decision tools to guide the process.

Introduction

Among patients with chronic kidney disease (CKD), fatigue is associated with cardiovascular disease and depressive symptoms [1]. Patients experience a limitation in freedom, a loss of sense of self, and social isolation [2–4]. In hemodialysis, fatigue has been identified by patients, caregivers, and health professionals as the most important patient-reported outcome to report in trials [5, 6]. In this population, it has also been marked as a predictor for cardiovascular events and mortality, independent of potential confounding risk factors such as age, diabetes, body mass index, and history of cardiovascular disease [1, 7–9]. Despite the high prevalence and importance of this symptom, fatigue remains under-recognized and undertreated.

The prevalence of fatigue in early stages of CKD (CKD stages 1–2) is unclear. This may be because CKD is often asymptomatic in earlier stages [10–12]. In CKD stages 3–5, including those on kidney replacement therapy, 54–97% of patients report fatigue [1, 13, 14]. Fatigue can be a debilitating symptom that causes emotional and physical interference in patients' lives [1, 4, 7, 10]. For patients on dialysis, 60–97% of adult patients on hemodialysis report fatigue [8] and 55–89% on peritoneal dialysis report fatigue, with increasing prevalence of fatigue over time [4, 15, 16]. Although less is known about the prevalence of fatigue in kidney transplantation, kidney recipients continue to experience severe and disabling fatigue compared to the general population [17, 18].

Although the exact cause of fatigue is unknown, it is likely to be multifactorial and different combinations of factors may contribute to fatigue as CKD progresses. Physiological factors such as anemia, uremia, comorbidities, and inflammation have shown to be correlated with fatigue [1, 11, 19, 20]. Psychosocial factors such as mood disorders and social support are also associated with fatigue [1, 11, 19, 20]. Sleep quality (including sleep apnea) may also contribute to fatigue [1, 8, 21]. It is unclear how these factors affect the frequency and severity of fatigue, but the these are potentially modifiable aspects of a patient's care that may help improve the management of fatigue.

Most of the research on fatigue in CKD has been in the hemodialysis population [21] as patients on hemodialysis experience a high symptom burden, and the fatigue experienced in this population is believed to be unique and particularly debilitating due to the nature of their treatment. However, despite the increasing number of studies of interventions to manage fatigue in the hemodialysis population, the evidence remains uncertain. The current evidence is also limited by the plethora of measures being used to assess fatigue with measures that have not been well-validated. There is also a need for more research examining onset and associated factors of fatigue in the early stages of CKD and kidney transplantation as it may contribute to identifying treatment to reduce its prevalence and severity. This chapter examines the available evidence for associated factors and interventions for fatigue across the spectrum of CKD.

Definition

Fatigue is the subjective perception of extreme and persistent tiredness, weakness, and lack of energy [22]. Traditionally,

frameworks have conceptualized fatigue as having a dual nature: central vs. peripheral, brain vs. muscle, mental vs. physical [8, 23]. Central or mental fatigue is expressed by the inability to initiate and/or sustain concentration, motivation, and alertness. It prevents patients from participating in activities that require these functions of the brain. Peripheral or physical fatigue refers to the inability to exert or sustain muscle force. Fatigue has also been conceptualized as being on a spectrum of exhaustion and tiredness on one end, and energy and vitality on the opposite end [24]. Increasingly, multidimensional frameworks of fatigue encompassing affective, cognitive, and physical aspects are being accepted as the most suitable paradigm [10, 25]. Aspects of this complex symptom and the framework that are relevant in clinical practice and research are dictated by patient priorities and clinical importance.

Fatigue, as experienced by patients on hemodialysis, can be largely divided into two types: postdialysis fatigue and general fatigue. Postdialysis fatigue is defined as the overwhelming sense of being "washed out" immediately after dialysis [26]. General fatigue is a persistent and relentless feeling of tiredness, weakness, and lacking energy [27].

Assessment

There is a wide range of measures used to assess fatigue in patients across the spectrum of CKD. They vary considerably in terms of characteristics such as recall period, content, length, cost, and the population for which they were designed. Validation data to support the appropriateness and psychometric robustness of these measures in CKD are sparse. For example, 43 different measures were used to assess fatigue in hemodialysis without comprehensive validation data, 17 (40%) of which were developed primarily for a different patient population [28]. Validation of measures in the population of interest is necessary to ensure the accurate assessment of the outcome as psychometric properties such as content validity, reliability, and responsiveness are not always transferrable beyond the population for which it was designed and tested [29, 30].

The vitality subscale embedded in the 36-Item Short Form Health Survey (SF-36) is widely used as a measure of fatigue in CKD and other chronic health conditions [8]. While it is frequently used because it is a short, four-item scale assessing fatigue relating to the lack of energy and vitality, it is not a specific measure of fatigue. It has been criticized as a measure of fatigue because it does not capture the multidimensional nature of this symptom such as lack of motivation and weakness [8]. Vitality is also conceptualized as a different construct to fatigue, which would suggest that this measure may not adequately capture the complete patient experience of fatigue [11]. The vitality subscale has not been validated in CKD as a standalone fatigue measure. For the purposes of assessing one aspect of fatigue, the Visual Analogue Scale (VAS) may be useful for a quick assessment as it consists of one question that is easy to complete. However, explicit instructions to disaggregate sleepiness and fatigue may be needed as previous failure to differentiate between the two symptoms has been documented [21]. For a more comprehensive assessment of fatigue, the Functional Assessment of Chronic Illness Therapy-Fatigue (FACIT-F) [31, 32] may be considered. This 13-item questionnaire demonstrated stronger associations with important clinical outcomes such as serum albumin and creatinine in patients on hemodialysis [33], compared with other measures of fatigue such as Fatigue Severity Scale and vitality subscale. However, FACIT-F is yet to be validated in the CKD population. The Chalder Fatigue Scale (CFS) has been examined in patients on hemodialysis, demonstrating good internal consistency, construct validity, and reasonable discriminant validity [33].

For assessment of postdialysis fatigue, ecological momentary assessment has been suggested as a potential method that may be able to capture the fluctuations related to dialysis more accurately while avoiding recall bias associated with patient-reported outcome measures [8, 34]. Using ecological momentary assessment to assess postdialysis fatigue involves the patients' real-time documentation of their symptom before and after dialysis. With appropriate and valid questions to assess the level of fatigue, ecological momentary assessment may be a useful tool in monitoring and improving aspects of fatigue that are treatment specific. Furthermore, a single question about the time taken to recover from a dialysis session has been used as another approach to assess the severity of postdialysis fatigue. It has demonstrated strong correlations with fatigue and vitality (SF-36 subscale), and sensitivity to change [35].

Pathophysiology

Although the exact cause of fatigue in CKD and ESRD is unknown, it is likely to be multifactorial as many variables have been suggested to contribute to the severity and prevalence of this symptom (Figure 72.1). As the disease progresses, contributors of fatigue may change. While the cause–effect relationship is unclear, various psychosocial, physiological, and treatment-related factors as well as individual characteristics have demonstrated significant

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Figure 72.1 Factors affecting fatigue. *Source:* From Jhamb et al. [8].

associations with fatigue. However, these relationships are not always consistent across the literature, which limits the state of current knowledge regarding factors contributing to fatigue.

Physiological contributors have long been examined in patients on hemodialysis but a range of variables have been linked to fatigue only in the last couple of decades. Anemia is frequently cited as a speculated cause of fatigue across all stages of CKD [11] as increased levels of fatigue can be experienced as anemia develops [36]. The reduced erythropoietin (EPO) production is believed to be culpable [11]. Comorbidities such as hypertension, diabetes, heart failure, cancer, and conditions causing frailty may exacerbate fatigue [14, 20, 37]. As patients progress to CKD stage 5 and beyond, the elevated levels of inflammatory cytokines such as interleukin-6 (IL-6) may also contribute to fatigue [1, 19, 21, 38]. Such association can be seen in other chronic conditions such as multiple sclerosis, cancer, and chronic fatigue syndrome, where cytokines have been identified as contributors and even mediators of fatigue [39–42]. Some studies have found lower levels of creatinine demonstrate an association with increase in fatigue [19, 33, 43]. In advanced stages of CKD, uremia may also contribute to fatigue as it causes energy, protein, and creatinine deficiency. Dialysis adequacy is thought to have a significant role in causing uremic symptoms, including fatigue [1, 20]. Nutrient loss during hemodialysis has led to the hypothesis that malnutrition as marked by serum albumin is associated with fatigue, but more research is warranted to strengthen the inconsistent evidence [16, 19]. Fluid shifts that occur after hemodialysis are believed to cause postdialysis fatigue [11]. Furthermore, large interdialytic weight gain for patients on hemodialysis has also shown a significant relationship with lack of energy, a comparable construct to physical fatigue [44, 45].

Psychosocial factors associated with fatigue have not been well-studied in CKD. Symptoms of depression such as tiredness, lack of energy, and motivation are closely related to fatigue [46]. Thus, unsurprisingly, Depression has shown significant associations with severity of fatigue, as well as physical and mental fatigue [1, 19, 20]. Scores of fatigue were significantly higher for those who were depressed compared to those who were not. In patients on hemodialysis, postdialysis fatigue is also highly associated with depression [26]. Although it is not extensively documented in patients with CKD and end-stage renal disease (ESRD), coping mechanisms and perception of one's condition are believed to help the severity of fatigue experienced [47, 48]. Similarly, there is evidence for the role of social support as a buffer for fatigue in patients with rheumatoid arthritis [49], but this is yet to be studied in the CKD and ESRD population. However, since social support has been documented to alleviate symptoms of depression for patients on hemodialysis, it may also have a similar effect on fatigue [50].

Sleep disorders, poor sleep quality, and sleep-related breathing disorders are common in CKD and ESRD, especially in the hemodialysis population [51]. Sleep problems

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

may be one of the contributors of fatigue as intuitively it is plausible to hypothesize that a lack of good sleep may result in daytime sleepiness. Sleep problems may contribute to fatigue also by increasing the release of cytokines [1] as this increase has been associated with sleep disturbances and fatigue in the general population [52]. In patients on hemodialysis, sleep disorders have been shown to be associated with reduced vitality [11, 25].

Postdialysis fatigue is a type of fatigue unique to hemodialysis patients [26, 53]. It is a fatigue associated, temporally, with the dialysis therapy session itself, and can vary in duration from minutes to several hours in length. Cross-sectional studies suggest that almost 50% of patients maintained on hemodialysis experience postdialysis fatigue lasting more than a few hours, with almost a quarter experiencing fatigue until shortly before their next treatment. Contributing factors include depression, excessive or rapid ultrafiltration, rapid and dramatic changes in osmolar, and electrolyte levels as well as possibly myocardial ischemia or stunning [53, 54].

Treatment

Due to the lack of clarity in determining the causes of fatigue, an effective treatment for this debilitating symptom also remains uncertain and difficult. Although the past decade has seen a growing number of trials assessing interventions for fatigue, evidence remains sparse and uncertain. This uncertainty can be attributed to the wide range of measures used to assess fatigue across different trials, small sample sizes, and lack of consistency in findings. Given the plethora of factors associated with fatigue, clinicians may need to take a multidisciplinary approach to manage this symptom in practice.

Pharmacological Interventions

Pharmacological interventions such as erythropoiesis-stimulating agents (ESA) and human growth hormone (HGH) have demonstrated small yet positive effects on fatigue. These interventions are summarized in Table 72.1.

Table 72.1 Pharmacological treatment for fatigue.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
ESAs	There is not enough evidence to recommend the use of ESAs in predialysis CKD patients, peritoneal dialysis, and kidney transplant recipients for the symptom of fatigue when present alone. If used for the management of fatigue in the setting of anemia, the evidence is insufficient to recommend an altered optimal target hemoglobin.	*Very low or absent* in CKD 1–5, PD, Tx *Low in HD* (data from one-placebo-controlled trial suggest ESAs may reduce fatigue; several trials and cohort studies suggest improvement in fatigue scores using different measures)	No recommendation: patients with CKD 1–5, PD, Tx Weak: patients on HD
Growth hormone	We suggest that the certainty of the evidence for growth hormone replacement to manage fatigue is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low or absent* in CKD 1–5, PD, Tx *Very low or absent in HD* (data from small trials suggest growth hormone may improve health-related quality of life, including symptoms of fatigue)	No recommendation
L-carnitine	We suggest that the certainty of the evidence for L-carnitine to manage fatigue is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low or absent in CKD 1–5, PD, Tx* *Very low in HD* (data from two small trials suggest L-carnitine may improve fatigue)	No recommendation
Antidepressants	We suggest that the certainty of the evidence for antidepressants to fatigue is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low or absent* (evidence from a single trial was not robust to data missingness to suggest change in fatigue with sertraline therapy)	No recommendation

ESA - erythropoietin-stimulating agents; CKD - chronic kidney disease; PD - peritoneal dialysis; Tx - transplant; HD - haemodialysis.
GRADE assessment of the certainty of the evidence: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Erythropoiesis-stimulating Agents

ESAs, such as epoetin alpha or darbepoetin, are typically prescribed for anemia management in CKD. Treatment of anemia has demonstrated an improvement in symptoms contributing to health-related quality of life, including fatigue. In patients with CKD and with diabetes, a reduction in fatigue was seen in patients who received darbepoetin [55]. Only one randomized controlled trial (RCT) has compared those receiving ESAs to a placebo group with relation to fatigue. In this study patients treated with ESA to a low Hb target (range 9.5–11.0 g/dl) and a high Hb target (range 11.5–13.0 g/dl) had higher improvement in fatigue scores compared to those in the placebo group (22%, 26%, and 2%, respectively) [56]. One study comparing subcutaneous and intravenous ESA in patients naïve to ESAs found moderate to large improvements in fatigue for both (11%, effect size = 0.36; 19%, effect size = 0.57, respectively). Another study with ESA-naïve patients demonstrated substantial reduction in fatigue of 23% and 25% after reaching a hematocrit of 30% [57, 58]. Studies involving patients already receiving ESA treatment showed less pronounced but improvements in fatigue nevertheless [59]. A study comparing EPO and DAR (darbepoetin alfa) showed that vitality scores increased significantly after switching to DAR from EPO in patients with an Hb increase of 1 g/dl and those with Hb > 10.0 g/dl at follow-up [60]. Overall, greater improvement in fatigue scores were shown for patients with a lower baseline Hb level. However, because the use of ESAs is also associated with a substantially increased risk of stroke, the use of ESA purely for fatigue management is not recommended [61].

Growth Hormone

In the general population, treatment with HGH has been reported to improve physical functioning and vitality [62]. In CKD, however, there is only limited evidence. Early proof-of-concept studies suggested reduced protein catabolism may result in nutritional improvements, but larger studies have had more modest results. In one small study comparing controls and patients treated with HGH, the authors found higher lean body mass and serum albumin levels after 6 months of treatment. Interpretation is limited, however, by the high loss to follow-up rate (>50%) [63]. In a larger study of 712 patients randomized to placebo or HGH, neither objective measures of lean body mass or serum albumin levels, nor subjective measures such as health-related quality of life (HRQOL) and exercise capacity improved over the 20-week follow-up period, with recruitment challenges leading to early study termination [64].

l-Carnitine

Although the effects of intravenous L-carnitine have been examined in the hemodialysis population in many studies [19], direct effects on fatigue are not well-studied. Two RCTs have demonstrated that L-carnitine significantly improves fatigue compared to the placebo group in patients on hemodialysis [65]. However, these RCTs were small and thus the resulting evidence is considered weak.

Antidepressants

Antidepressants have been postulated as treatments for those with chronic fatigue because of their effect on lowering inflammatory mediators such as IL-6, and because of the close relationship between fatigue and depression. One study found selective serotonin reuptake inhibitor (SSRI) treatment was associated with reduced levels of IL-6 in patients on hemodialysis [66]. Direct evidence of the effect on fatigue scores was not measured. In a second study, sertraline was not clearly associated with a change in the energy/vitality subscale of Short Form 36 Health Survey.

Methylphenidate

A number of studies in the cancer population have reported improved fatigue in patients prescribed low-dose short-acting methylphendidate [67]. No trials in the CKD population have been done and therefore the effectiveness remains unknown. Disadvantages of methylphenidate, of importance to the CKD population, include reduced appetite and sleep quality.

Nonpharmacological Treatments

Studies examining nonpharmacological interventions such as exercise and acupoint stimulation have shown some promising results. These interventions are summarized in Table 72.2.

Frequent Dialysis

More frequent hemodialysis sessions (six times per week) have shown to improve HRQOL and time to recovery compared to the conventional (three times per week) regimen [69]. On average, patients who received more frequent dialysis recovered an hour earlier than those who received usual care.

Physical Activity

Physical activity may help improve fatigue through various mechanisms. Regular exercise may improve fatigue through

Table 72.2 Nonpharmacological treatments for fatigue.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Frequent nocturnal dialysis	There is not enough strong evidence to make recommendations. However, for those for whom this treatment is relevant and feasible, patients may reasonably choose to or not to receive more frequent, nocturnal dialysis.	*N/A in CKD 1–5, Tx*	Weak: patients on HD No recommendation: patients with CKD 1–5, PD and Tx
Exercise (aerobic, resistance training)	There is not enough evidence to recommend exercise in predialysis CKD patients and kidney transplant recipients to improve fatigue. We suggest that patients on hemodialysis may reasonably choose to or not to do light to moderate aerobic or resistance training exercise based on the limited evidence that it is associated with reduced fatigue scores. For patients on peritoneal dialysis, current evidence does not support exercise for fatigue, but they may experience an improvement in overall quality of life.	*Very low or absent in CKD 1–5, Tx* (data from systematic review suggest that exercise may improve fatigue across the spectrum of CKD, but outcome was limited to muscular strength and overall quality of life) *Very low in HD* (data from small trials suggest that intradialytic, low-intensity ergometric cycling, and resistance training may improve fatigue) *Very low* in PD (data from systematic review suggest possible increase in quality of life, but not necessarily for fatigue)	Weak: patients on HD No recommendation: patients with CKD 1–5, PD and Tx
Relaxation and stretching (yoga, progressive muscle relaxation, simple stretching)	We suggest that the certainty of the evidence for relaxation and stretching activities such as yoga, progressive muscle relaxation, and simple stretching to manage fatigue is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low or absent in CKD 1–5, Tx* Very low in HD, PD (data from small trials using different fatigue measures suggest relaxation and stretching activities may improve fatigue)	No recommendation
Reflexology, stimulation of acupoints (acupressure, acupuncture)	We suggest that the certainty of the evidence for reflexology massages, acupressure or acupuncture to manage fatigue is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low or absent* in CKD 1–5, PD, Tx *Very low in HD* (data from small trials using different fatigue measures suggest that acupuncture, acupressure, and reflexology may improve fatigue)	No recommendation
Cognitive behavioral therapy	We suggest that the certainty of the evidence for cognitive behavioral therapy to manage fatigue is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low or absent* in CKD 1–5, HD, Tx *Very low* in PD (data from one trial suggests improvement in fatigue)	No recommendation

CKD - chronic kidney disease; Tx - transplant; HD - harm-dialysis; PD - peritoneal dialysis.
GRADE assessment of the certainty of the evidence [68]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

its anti-inflammatory effects [70]. Aerobic exercises such as cycling and walking have been shown to improve fatigue in both the peritoneal dialysis and hemodialysis populations [71–73]. Low to moderate intensity strength training and flexibility exercises have also demonstrated improvement in fatigue [74–76]. Strength training may increase muscle strength and physical function [8]. In a study comparing aerobic and strength training exercises, both exercise types improved quality of life but only aerobic exercises (low intensity ergometric bicycle) decreased fatigue in patients on hemodialysis [77]. In a systematic review of physical activity in peritoneal dialysis, traditional

aerobic exercises such as cycling, walking and running, tai-chi, and resistance training demonstrated inconsistent benefits on fatigue [78]. A few trials in predialysis and kidney transplant populations also showed that exercise led to improvement in factors related to fatigue such as HRQOL, physical capacity, and muscle strength [79–82]. One study found a significant slower disease progression that may prevent onset or severity of fatigue. While the effects of exercise – regardless of type – seem promising for aspects of quality of life, if not specifically fatigue regardless of stage of CKD, many of the studies are confounded by high drop-out rates, interventions, and short follow-up periods [83]. Few, however, demonstrate harm arising from incorrect prescription of exercise, excessive muscular fatigue or cardiac stress, and thus a recommendation for a modest increase in exercise is likely advisable despite the weak evidence.

Acupoint Stimulation

Reflexology and stimulation of acupoints have been studied as methods of fatigue management in patients on hemodialysis. Reflexology has shown to decrease fatigue [84]. It is a safe and feasible method to use in patients on hemodialysis [44]. Acupuncture, acupressure, and transcutaneous electrical acupoint stimulation have all demonstrated relief of fatigue compared to the control group [44, 85–87]. Larger RCTs are needed to verify the seemingly beneficial effects through more rigorous methods.

Relaxation

In hemodialysis, variations of stretching and relaxation methods such as yoga and progressive muscle relaxation have demonstrated positive results for fatigue and overall quality of life [74, 87–90].

Education and Cognitive Behavioral Therapy

One RCT reported lower fatigue following an educational intervention increasing illness knowledge in the hemodialysis population [91]. In patients on peritoneal dialysis, cognitive behavioral therapy has been found to decrease fatigue and cytokine levels [92]. The widespread uptake of educational and cognitive behavioral interventions is limited by a need for specialist trained staff to administer the intervention(s), the time commitment required from the patient for both the intervention and the homework, and the need for relatively high levels of language fluency and comprehension.

There is limited evidence for interventions to improve fatigue in any stage of CKD. For the dialysis population, there needs to be more rigorous RCTs to confirm the promising effects that have been demonstrated in smaller, shorter studies. More research involving predialysis patients and kidney transplant recipients is required to prevent fatigue in patients in earlier stages of CKD and help manage patients' lives after transplant. Treatment for patients experiencing fatigue should be a multidisciplinary approach. Before suggesting treatment, clinicians should take time to monitor levels of fatigue and assess the different factors that may be contributing to their patients' experience of fatigue, as it may differ from patient to patient.

Patient Experience of Fatigue

When considering strategies to manage fatigue, it is important to understand patient experiences, preferences, and perspectives. Fatigue is a critically important symptom for patients across all stages of CKD who identify fatigue as one of the most intrusive symptoms. Patients with CKD stages 2–4 have described their fatigue as "sudden moments without having any energy and without being able to do anything" [3]. The experience of fatigue for patients in different stages of the disease may differ, but it is clear that patients are burdened with this symptom on a day-to-day basis. Physical fatigue is common to all patients, but patients on hemodialysis seem to describe a persistent and severe physical and mental fatigue that manifest in all aspects of their lives [27]. Postdialysis leaves patients feeling like they will "collapse" and that they are "worn out" momentarily after treatment. However, patients have reported the limitations and frustrations caused by the constant need to rest due to the general fatigue they experience throughout the week. Simple, everyday activities such as walking to a taxi, getting groceries out of the car, remembering names of people, and seeing family members become difficult [20, 93]. Prioritizing aspects of fatigue that are important to patients may help to identify effective interventions.

Furthermore, patients with CKD have previously expressed their desire for treatment and strategies to manage their condition through lifestyle changes such as diet and exercise, rather than pharmacological options [94]. Similarly, exploring nonpharmacological interventions may be more aligned with patient preferences and needs regarding fatigue.

Conclusions

Fatigue is an intrusive and debilitating symptom for patients with CKD. It is associated with low quality of life, cardiovascular disease, and mortality. RCT evidence to provide evidence of high certainty to support a specific method of treatment to manage fatigue remains lacking. Current treatment for fatigue should be based on known and perceived benefits for overall wellbeing, patient preferences, and safety.

Introduction

Major depressive disorder (MDD) is defined as a clinical syndrome that lasts for at least 2 weeks whereby the individual experiences depressed mood or anhedonia, and at least five symptoms from the criteria listed in the Diagnostic and Statistical Manual Criteria, Fifth Edition (DSM-5) [1]. MDD is common among patients with chronic kidney disease (CKD) and end-stage kidney disease (ESKD), more so than in other chronic conditions, and is associated with a range of adverse clinical outcomes [2–4]. Depression contributes to functional impairment, decreased quality of life (QoL), and poor adherence among patients with ESKD [5–7]. It is therefore imperative to identify and treat depression in this population. However, as will be discussed further in this chapter, depression is underdiagnosed and undertreated in this population, as only a small proportion of patients receive adequate treatment for it [8]. For example, a prospective observational study of 98 patients receiving hemodialysis found that 26% of the sample met the DSM-5 criteria for depression, however only 23% of these cases identified to experience depression were provided with interventions to treat their depressed symptoms [4]. In the majority of patients, depressed symptoms do not spontaneously improve over time without treatment, and in a large proportion of patients they worsen [9–11]. There are added difficulties in the assessment of depression in these populations due to the overlap in physical symptoms between depression and uremia [12]. There have been very few clinical trials conducted in this population to determine the safety and efficacy of pharmacological and non-pharmacological treatments [13].

It is not known whether depression in patients with CKD is different from depression that is seen in individuals without a comorbid chronic medical condition, and in particular whether depressive symptom severity and the efficacy of treatment is modified by decrements in kidney function. It is also not currently known whether the treatment of depression in CKD requires any modifications to the types of treatments used to treat depression in the general population. Across the trajectory of ESKD, treatment and disease-related factors may trigger depression, and this population experience some burdens that are different to other chronic conditions. In the early stages of CKD, the realization and acceptance of the diagnosis of CKD, changes to lifestyle and identity, fear and uncertainty regarding treatment options and their prognosis, and difficulties navigating the healthcare system may cause significant distress [14]. Kidney transplantation, which is associated with the best clinical outcomes for patients with ESKD, comes with significant burdens, including life-long immunosuppression therapy, associated side effects, and ongoing medical evaluation and monitoring [15, 16]. Kidney transplant recipients experience fear relating to the longevity of their transplant, and for those who experience graft failure, the commencement or return to dialysis can be devastating [15, 16]. Due to shortages in the availability of organs for transplantation, most patients with ESKD, with access to renal replacement therapy, receive hemodialysis [17]. Dialysis is associated with a time-consuming, painful, and often uncomfortable treatment regime that is associated with significant lifestyle disruption, and physical and neurocognitive symptoms including changes to cognition and appetite, anemia, nausea, vomiting, fatigue,

and shortness of breath [18]. Patients on dialysis are also required to manage a complex diet and fluid regimen. Dialysis can also impact on self-esteem, social functioning, identity, and a decreased sense of self-worth [14, 19].

The following sections will discuss the definition of depression, the prevalence of depression among patients with CKD and ESKD (dialysis and transplant), risk factors and correlates, the diagnosis of depression, evidence regarding the impact of depression on clinical outcomes, evidence-based treatments for depression in this population, and finally patient and family caregiver perspectives on the impact of depression among patients with CKD and ESKD.

Definition

The DSM-5 and the International Classification of Diseases (ICD) ICD-10 are the most widely used diagnostic criteria in both clinical practice and research. While the criteria are similar, most epidemiological studies have used the DSM-5 framework. A diagnosis of MDD, according to the DSM-5, requires at least five of nine depressive symptoms to be present during the same 2-week period and represent a change from previous functioning [1]. The symptoms include (i) depressed mood most of the day, nearly every day, (ii) loss of interest or pleasure in almost all activities, (iii) significant weight loss, weight gain or change in appetite nearly every day, (iv) insomnia or hypersomnia nearly every day, (v) psychomotor agitation or retardation nearly every day, (vi) fatigue or loss of energy nearly every day, (vii) feelings of worthlessness or excessive or inappropriate guilt nearly every day, (viii) poor concentration or indecisiveness nearly every day, and (ix) recurrent thoughts of death, suicidal ideation, intent or suicide attempts. At least one of the five symptoms must include depressed mood or loss of interest or pleasure. To meet criteria for a depressive episode the symptoms must cause significant distress or impairment in social, occupational or other areas of functioning. The diagnosis is excluded if the symptoms are attributable to the use of a substance or another medical condition or psychiatric diagnosis. Persistent depressive disorder (PDD) is defined as a more pervasive but less severe depression that is present for at least 2 years [1]. To meet criteria for PDD, individuals have depressed mood for most days for at least 2 years, and the presence of two or more of the following symptoms while depressed: (i) poor appetite or overeating, (ii) insomnia or hypersomnia, (iii) low energy or fatigue, (iv) low self-esteem, (v) poor concentration or difficulty making decisions or (vi) feelings of hopelessness. An individual must not have been without these symptoms for a period of longer than 2 months.

The ICD-10 criteria for a diagnosis of a depressive episode requires four or more of 10 symptoms, present for at least 2 weeks [20]. The 10 symptoms listed include depressed mood, loss of interest and enjoyment, reduced energy leading to increased fatigability and diminished activity, reduced concentration and attention, reduced self-esteem and self-confidence, ideas of guilt and unworthiness, bleak and pessimistic views of the future, ideas or acts of self-harm/suicide, disturbed sleep, and diminished appetite. Symptoms must include two or more of depressed mood, anhedonia or energy loss. A mild episode must include four of the 10 symptoms and at least one of depressed mood, anhedonia or energy loss. A moderate episode requires six or seven of the 10 symptoms, whereas a severe depressive episode is defined by the presence of at least eight symptoms. The ICD-10 also includes a definition of a melancholic subtype of depression, called somatic syndrome. A formal diagnosis of somatic syndrome in the ICD-10 requires four or more of the following eight symptoms: marked loss of interest or pleasure, loss of emotional reactivity, waking early in the morning, 2 hours before the usual time, feeling more depressed in the morning, evident psychomotor retardation or agitation, marked loss of appetite, significant weight loss (5% or more in the past month), and loss of libido.

Epidemiology

It is estimated that the 12-month prevalence of MDD is about 7% in the general population and 10% for any mood disorder [2]. The prevalence has been shown to be 1.5–4 times higher among patients with major chronic illnesses than the general population, and even higher among patients with ESKD compared to other chronic conditions [21]. This may be due to disease-related factors including the progressive nature of CKD and the unpredictable course of the illness. Other proposed reasons include treatment-related factors such as the high medication burden among patients with CKD, the impact of dialysis on QoL, and difficulties in accessing transplantation. Risk factors for depression among patients with CKD are discussed in the following section.

Studies of patients with CKD and ESKD have identified vastly different estimates of the prevalence of depression. The difficulty determining the prevalence of depression among this population may be due to the great heterogeneity in the characteristics and treatments of the populations included in these studies, as well as the use of different screening and assessment tools to diagnose depression or assess the severity of depressive symptoms. Only a minority of patients with CKD have reached ESKD, and those with CKD have a range of different kidney diseases [12]. The

severity of the disease and symptom burden that patients experience varies greatly depending on the cause of their disease and their associated comorbidities [18]. Most of the studies that have assessed the prevalence of depression are limited to patients receiving dialysis treatment.

The assessment of depression among patients with CKD can also be challenging due to the overlap between somatic symptoms of depression and many of the symptoms of uremia which occur with severely reduced kidney function [12]. For example, sleep disturbance, loss of appetite, fatigue, and gastrointestinal disorders are symptoms of both uremia and depression. The use of self-report tools for the assessment of depression may therefore lead to inflated estimates of the rates of depression. The diagnosis of depression using clinician interview is therefore the gold standard and will be discussed below in a section on Diagnosis. The prevalence of depression among CKD populations has primarily been studied using self-report assessment tools. Various tools have been used, thereby utilizing a range of different definitions of depression and cut-off points [22]. Moreover, many studies have used tools that have not been validated in the study population of interest.

Prerenal Replacement CKD Populations

The majority of patients with kidney disease are diagnosed with CKD, rather than ESKD. The patients with CKD stages 1–5 are extremely heterogeneous, with varying causes of kidney disease and differences in their residual kidney function. Very little is known about depression in general in this population [12]. The prevalence of MDD in patients with CKD who are not yet on renal replacement is not known but is likely to vary substantially within this group. The prevalence rates that have been reported using self-report questionnaires range from 7% to 47% [23, 24].

Hemodialysis Populations

The Dialysis Outcomes and Practice Patterns Study (DOPPS) assessed depression using both a clinician-rated and a self-report tool in an international, multicenter study of 9382 hemodialysis patients from 12 countries [8]. This study determined an overall prevalence rate of 14% for clinician-diagnosed depression, while the prevalence of depression determined by self-report measures was 43%. This study identified a wide range in depression rates across countries, ranging from 2% in Japan to 22% in the United States, using the clinician-rated assessment [8]. However, there were no differences compared to the whole sample using the Center for Epidemiological Studies Depression Scale (CESD) self-report assessment, leading the authors to conclude that cultural attitudes and practices in the diagnosis of depression may explain these differences among countries. These findings may also reflect differences in what patients feel is appropriate to report to an assessor in various countries. Single-center studies using structured clinical interviews report consistent estimates of the prevalence of depression as 25–30% among hemodialysis patients in the United States [25–27].

Peritoneal Dialysis Populations

Compared to studies assessing depression among hemodialysis populations, there are limited studies among individuals receiving peritoneal dialysis and the available studies involve relatively small samples of patients. A study of 66 adult peritoneal dialysis patients from three units in the United States found that a third of their sample had depressive symptoms [28]. A study of 124 patients on peritoneal dialysis from a single center in Turkey found that the prevalence of depression was 25.8% in their sample using the Beck Depression Inventory (BDI) [29].

Kidney Transplant Populations

The studies assessing the prevalence of depression among kidney transplant populations are predominately small single-center samples. Depression has primarily been measured by symptom levels rather than diagnosable depressive disorders among kidney recipients. A recent meta-analysis found that the pooled estimate of clinically significant depressive symptoms was 27% [30]. Recipients of a kidney transplant risk of an interview-based diagnosis of depression has been shown to be lower compared to patients with ESKD, although it remains higher than the prevalence in the general population [30]. Arapaslan et al. assessed a range of psychological disorders among 40 kidney transplant recipients during their routine follow-up appointments, held on average 5 years post-transplantation [31]. Using a structured clinical interview, 22% of the randomly selected sample were found to have MDD, and anxiety disorders were identified in 15% of the sample [31]. In a large cross-sectional study, symptoms of depression were reported by 22% of the 850 transplant recipients [32]. Dobbels et al. assessed the insurance claims through Medicare of 48 000 kidney transplant recipients between 1995 and 2003, and found that the cumulative incidence of depression increased from 6.74% to 12.9% over the first 3 years after transplantation [33]. However, another study found that self-reported symptoms of depression decreased in the first 5 years after transplantation [32]. More research is needed to understand the trajectory of depression after transplantation, including number and duration of episodes and risk for relapse [34].

Pediatric Populations

Few studies have explored the prevalence of depression in pediatric populations with CKD. Using the Child Depression Inventory, a study of 28 children and adolescents with CKD found that these participants had a higher frequency of depressive symptoms compared to healthy controls [35]. In a study of 23 adolescent transplant recipients, depressive symptoms, assessed using the BDI, were found to occur in 17.4% of participants [36].

Risk Factors for Depression in CKD Populations

The risk factors and correlates for depression in patients with CKD can be divided into biological (inflammation), demographic (e.g. age, gender), psychosocial (e.g. social support), and cognitive factors (e.g. control expectancies and illness representation). Risk factors that have been associated with depression in patients with ESKD include younger age, female gender, white race, longer duration of dialysis, and comorbid conditions such as diabetes, coronary artery disease, cerebrovascular disease, and peripheral vascular disease [29, 37]. For patients with CKD, the risk factors are slightly varied, including younger age, female gender, minority ethnicity, lower education, lower family income, unemployment, hypertension, smoking status, diabetes, and coronary artery disease [4, 7, 23, 31, 38, 39]. However, lower socioeconomic status (SES) and comorbid conditions have been associated with higher prevalence of depression in the general population and therefore some risk factors may not be specific to CKD [15, 40, 41]. The shared risk factors for CKD and depression are depicted in Figure 73.1.

Biological risk factors associated with depression in the CKD population include the immune system, inflammatory pathways, disturbances of the hypothalamic pituitary axis and changes in the parasympathetic and sympathetic nervous systems [1, 43, 44]. Inflammation is particularly relevant to CKD and depression though studies have considerable heterogeneity [21, 34]. Pro-inflammatory cytokines have been found in higher concentrations in those with depressive symptoms and there is evidence to suggest they play a role in pathophysiological metabolism, neuroendocrine function, synaptic plasticity, and behavior [43]. CKD is often considered a pro-inflammatory state with increased concentration of markers and oxidative stress which may relate to the higher than expected rates of cardiovascular disease and other causes of increased mortality [45–48]. It is possible that this inflammatory connection could also partly explain the high rates of depression in the CKD population [5]. Additionally, in a recent cross-sectional survey of 533 individuals, Jhee et al. concluded that vitamin D deficiency was an independent confounding factor in CKD patients with depression [49]. Vitamin D is a distinctive neurosteroid hormone present in many areas of the brain which have been implicated in the pathophysiology of depression [40]. This may also partly explain the high prevalence in patients with CKD as it is well known that the blood level of vitamin D is low in this population [49].

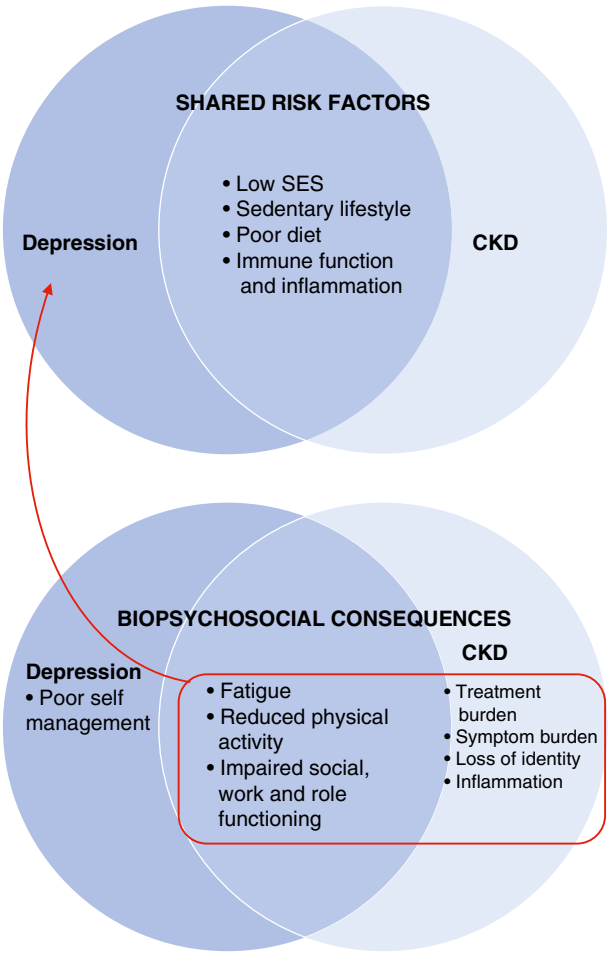

Figure 73.1 Shared risk factors and biopsychosocial consequences of CKD and depression. *Source:* Adapted from Bautovich et al. [42].

Psychosocial factors including social support, personality attributes, cognitive appraisals, and perceived stress may be associated with depression [10]. Personality attributes and cognitive appraisals have shown to have a particularly large effect [10]. Beck's cognitive triad theory describes a cognitive model of vulnerability to developing depression when faced with a stressful event, such as diagnosis of a chronic illness, which is characterized by negative views of the self, world, and future [50]. A negative view of the self leads one to view loss as personal, leading to self-loathing, self-criticism, and feelings of inadequacy and worthlessness. Negative views of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the world lead one to view loss to be pervasive, and the world as unfair, harsh, and hostile. Others are viewed as being uncaring, unable to help, and superior. Depression is also characterized by a negative view of the future, where loss is seen as permanent, the future is predicted to be bleak, pointless, and there is a sense of hopelessness that their circumstances will change or improve. Relating to the perception of loss, cognitive factors such as health locus of control, illness representation, negative illness schemas, and illness intrusiveness have also been associated with increased risk for depression in CKD [11, 13, 17–19, 24]. One study found that patients with ESKD who perceived greater consequences as a result of their health status and less personal control over their illness were more likely to endorse symptoms of depression [11]. Moreover, research suggests that negative illness schemas are associated with increased depression in ESKD and that positive illness schemas mediate the relationship between social support and depression in this population [24]. Schemas represent the cognitive generalizations that guide the processing and interpretation of information that is relevant to the self [51]. Studies by Chan et al. [45, 52] in dialysis patients identified a relationship between cognitive factors, depression, and QoL. Such cognitive factors included the perceived burden of kidney disease, a sense of loss related to kidney disease, and self-efficacy.

Studies examining the role of coping styles in depression in this population have had inconsistent findings. One study found that coping styles associated with seeking information in order to manage health problems was associated with reduced risk for experiencing ongoing or increasing depression symptoms after kidney transplantation [53]. However, other studies have not found a significant association between either maladaptive coping strategies or adaptive coping strategies and depression [54, 55]. Given the small number of studies assessing the impact of coping styles, it remains unclear whether this is a risk factor for depression.

Actual and perceived lack of social support have also been identified as risk factors for depression across chronic health conditions, including patients with ESKD. In a study of 109 dialysis patients from the United States, risk factors for depression were explored, including participants' perceptions of their illness, disease severity, and level of social support [51]. In this study, negative illness perceptions were associated with depression, whereas positive perceptions were negatively associated with depression. Similarly, access to social support was associated with a positive illness schema, and lower levels of social support were shown to be associated with higher levels of depression. Social support was significantly related to depression, independent of positive illness schemas, suggesting that a low level of social support is a risk factor for depression. In studies of kidney transplant recipients, poor social support has been found to increase depression risk, with both the lack of available support persons and poorer perceived quality of the emotional and tangible support having been shown to be important factors [32, 37, 46, 56]. Researchers have suggested that perceived social support in patients may encourage positive psychological adjustments to life with CKD and associated losses in wellness, lifestyle, independence, autonomy, and identity [5, 9, 57, 58].

Low SES is a risk factor for depression [59]. Low SES is also a risk factor for diabetes and cardiovascular disease, adverse health behaviors, and poor management of health conditions [41]. Therefore, low SES is a shared risk factor for both depression and CKD [60]. In kidney transplant recipients, unemployment and personal financial stress post-transplant have consistently been found to increase depression risk [32, 37, 61].

Among patients with ESKD and the general population, the strongest risk factors for a future episode of depression are a family history of depression and a past history of depression symptomatology [62, 63]. For example, across all types of organ transplant recipients, a pre-transplant history of mental health disorders, including depression and anxiety, is the strongest risk factor for development of such disorders post-transplant [57]. Thus, screening for psychological and family history could provide important information, among other risk factors, to encourage screening of depression symptoms.

Anxiety is often comorbid with depression in the general population [43, 64]. Anxiety is an important consideration because it may contribute to the onset of depression and may also exacerbate symptoms of depression [37]. Anxiety has an estimated prevalence rate of 38% (12–52%) among dialysis patients, however there is even less research on anxiety in this population compared to that of depression [65]. A cross-sectional study of 119 renal transplant recipients in Panama found that the prevalence of anxiety was 15.1% [37]. This study also found that the presence of an anxiety disorder was significantly and independently associated with depression symptoms, as was increasing age and a lower educational attainment [37]. One study found that patients with ESKD who were receiving renal replacement therapy present with a higher level of anxiety compared to healthy controls and a lower level compared to patients diagnosed with breast cancer [66]. They found that the severity of anxiety did not differ by end-stage renal disease (ESRD) treatment type. This study also found that patients with a high level of trait anxiety (a relatively stable tendency toward anxiety in response to the anticipation of a threat) had a more severe anxiety-induced state (which depends on external factors) when faced with advanced somatic disease [66]. Anxiety may also be difficult to detect due to similar difficulties distinguishing symptoms of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

anxiety from symptoms of CKD. Common symptoms of anxiety include dizziness or lightheadedness, racing heart, shakiness/unsteadiness, indigestion, numbness/tingling, nervousness, avoidance, hand trembling, difficulty breathing, hot/cold sweats, muscle tension, a fear of losing control, and a fear of death [65].

The Impact of Depression on CKD Outcomes

Clinical depression and depressive symptoms bring many disadvantages, including poor psychosocial and medical outcomes in patients with CKD and ESKD. Patients are at increased risk for adverse clinical outcomes including mortality, hospitalization, poor adherence to treatment, and decreased QoL [8, 38, 49, 56, 60, 67].

Mortality and Morbidity

A strong and statistically significant association exists between depression status and risk of all-cause mortality in patients with all stages of CKD, regardless of sex or age [49, 62]. A study by Tsai et al. found that those with a higher depressive symptom burden at baseline (BDI, score > 11) are more likely to reach the endpoint of ESKD or death by 25.2 months (±11.9 months) as compared to those with a lower BDI score [7]. Similarly, those with more depressive symptoms also had a faster decline in their estimated glomerular filtration rate (eGFR), more hospitalization, and were more likely to start dialysis at a higher eGFR [7]. These findings of individual studies have been confirmed by a meta-analysis conducted by the Cochrane Renal and Transplant Group, which shows a strong association between depression and all-cause mortality at a relative risk of 1.59 with moderate levels of heterogeneity in the studies [67]. While the meta-analysis adjusted for stage of CKD, length of dialysis, method used to diagnose depression, and point in time when depression was assessed, the association was weaker when studies controlling for cardiovascular disease were taken into consideration [67]. One suggested mechanism for the increased risk of death among CKD patients with depression is the presence of cardiovascular disease [22]. However, this meta-analysis found that depression consistently increased the risk of all-cause mortality, but was less certain for cardiovascular mortality specifically. The increased risk of mortality among adults with CKD was shown to be higher than for other populations, including patients with cancer, diabetes, and cardiovascular disease [67].

In a systematic review by Farrokhi et al., the authors found that the mortality risk in patients on dialysis was 1.5 times higher in the presence of depressive symptoms, independent of other confounding factors [58]. They also found that this relationship was dose dependent (the more severe the depression, the higher the risk of mortality) [58]. A meta-analysis of 27 studies across heart, liver, kidney lung, pancreas, and mixed transplants found that depression increased the relative risk of mortality by 65% and the level of risk was not affected by the type of transplant [6]. Depression also increased the risk of graft loss (censored for death), whereas anxiety was not found to significantly increase the mortality or morbidity risk [6]. Among kidney transplant recipients specifically, an association has been found between depression and adverse outcomes, with comorbid depression associated with worse graft function, graft failure, increased risk for chronic allograft nephropathy, return to dialysis or death [2, 20, 60, 65].

Suicide and Treatment Withdrawal

Another reason that patients with depression may have an increased mortality rate is due to a higher risk of suicide and withdrawal from treatment [68]. As described in the section on the definition of depression, suicidal ideation is a common symptom of depression. An early study reported very high rates of suicide among ESKD patients compared to the general population and other chronic disease populations [69]. This study appeared to have selected a sample that was high in risk factors for suicide and this sample was utilizing less efficient and adequate dialysis technology compared to those available currently [69]. More recent studies have identified much more moderate rates of suicide. In a recent study, suicide rates were found to be higher among dialysis patients compared to the general population [70]. In this study, the crude suicide rate between 1995 and 2001 was 24.2 deaths from suicide per 100 000 patient years [70].

There is also confusion regarding the distinction between treatment withdrawal and intended death by suicide [47]. Patients with suicidal ideation may attempt suicide through nonadherence to their dialysis, diet, fluid or medication prescription or by altering their vascular access [48]. Alcohol and drug dependence and recent hospitalization for mental illness were found to be strong risk factors for patient death by suicide [70]. This same study found that the populations who withdraw from treatment are different from those who die by suicide. The risk of death by suicide was highest in the first 3 months after the initiation of dialysis, whereas the likelihood of withdrawal from dialysis was highest for the first year of dialysis therapy [70]. Older age and recent hospitalization were stronger predictors of treatment withdrawal than death by suicide [70].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Medical complications, diabetes, cerebrovascular disease, and dementia have been associated with the decision to withdraw from treatment [47, 71].

It has been estimated in these studies that approximately 20% of patients on dialysis choose to discontinue treatment [47, 71]. Withdrawal from dialysis is the second most common cause of death among dialysis patients after cardiovascular disease [38]. There is considerable cultural variation in the rates of treatment withdrawal such that higher rates have been identified among Caucasian patients compared to Asian and African American patients in the United States [72]. A large international study by Lopes et al. found that patients receiving hemodialysis who met criteria for depression or depressed symptoms were shown to have a higher rate of treatment withdrawal [73]. However, this study relied on medical records and nonstandardized assessment tools to determine participants' depression diagnosis or frequency of depressive symptoms. Subsequently, a study by McDade-Montez et al. estimated that the risk of withdrawing from dialysis was 43% higher for participants who scored one standard deviation above the mean on the BDI compared to patients who had average scores on this depression measure [74]. It is therefore recommended that patients' end-of-life treatment decisions include assessment and treatment for depression [18].

Hospitalization

Depression has been associated with increased healthcare costs, including primary, pharmacy, inpatient medical, inpatient psychiatric, and outpatient mental healthcare [35]. DOPPS was a large study with 5256 hemodialysis patients that found depression was associated with an increased risk for first hospitalization even after adjusting for time on dialysis, age, race, SES, comorbid indicators, and country [56]. Depression has also been significantly associated with other adverse medical outcomes including emergency department visits, cumulative hospital days, cardiovascular events, peritonitis, withdrawal from dialysis, and suicide [8, 29, 54, 71, 75]. Multiple other studies have investigated the association between depression and a variety of negative health outcomes in renal disease, including dialysis initiation, hospitalization rates, length of stay, and death [26, 29, 30]. Each study has noted an association between depression and hospitalization.

Adherence

Treatment nonadherence is another potential pathway through which depression may affect mortality and morbidity in patients with CKD. Treatment adherence can be quite complex for patients with CKD, requiring adherence to a weekly dialysis schedule, maintenance of peritoneal exchanges for peritoneal dialysis, dietary restrictions, physical activity, and complex polypharmacy. Depression has been identified as the most important predictor of adherence to medication prescriptions among patients on hemodialysis [75, 76]. While adherence in ESKD is challenging to quantify [12], most studies have indicated a relationship between depressive effect and laboratory and behavioral markers of poor compliance in the dialysis patient [3, 36, 53, 55]. Depressive symptoms of low motivation, hopelessness, and suicidal ideation can significantly interfere with adherence to dialysis schedule and prescribed medication as well as dietary regimens [3, 36, 55, 59]. Decreased behavioral adherence, such as skipping dialysis sessions, shortened dialysis time, and nonadherence to the prescribed diet, can have a significant effect as it has been associated with impaired nutrition, higher risk of withdrawal from treatment, and ultimately decreased survival [3, 50, 53, 59]. In a 2002 DOPPS report, a diagnosis of depression was associated with a 1.6 times increased likelihood of skipping or shortening hemodialysis sessions when controlling for other risk factors [75].

Infection

Compared to patients without depression, patients on peritoneal dialysis who endorse symptoms of depression are twice as likely to develop peritonitis [39]. Troidle and Wanick's study included 162 patients and showed that a BDI score of 11 or greater was associated with the development of peritonitis. Juergensen et al. studied a large sample of patients on chronic peritoneal dialysis and found that more than one past experience of peritonitis was associated with higher anxiety and depression scores than in patients with one or no episodes of peritonitis, although the increased depression was not statistically significant [77].

Quality of Life

Health-related quality of life (HRQOL) provides an assessment of the patient's perception of the physical and psychosocial impacts of their condition and treatment. HRQOL is significantly compromised in patients with ESKD and has been associated with increased morbidity and mortality [69]. Depression has been found to have a profound negative impact on QoL among patients on renal replacement therapy and is possibly more strongly associated to QoL than clinical and sociodemographic variables [51, 72, 74]. This is likely because patients with comorbid CKD and depression are more likely to perceive

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and rate their QoL lower due to the impact of low mood on their subjective appraisals of their functioning. Patients with depression have been found to have two- to threefold more medical symptoms compared with controls without depression, including more fatigue, cognitive difficulties, pain, sleep disturbances, sexual dysfunction, and interpersonal difficulties [35, 69]. Depression is also associated with reduced social and occupational functioning, which can cause financial difficulties and thus further impact wellbeing [25, 52].

Diagnosis

As with most chronic disease populations, depression is often underdiagnosed among individuals with CKD. This may be due to the limited resources available for clinicians to assess mental health symptoms, and complaints about somatic symptoms may not be recognized as being associated with depression due to also being associated with kidney disease. Given this overlap, it is generally recommended that the diagnosis of depression among CKD populations relies more heavily on psychological symptoms such as anhedonia, guilt, hopelessness, and suicidal ideation [44].

Clinical Examination

The clinical diagnosis of depression is based on clinical interviews including specific criteria or various self-reported questionnaires [67]. The DSM-5 is the current standard set of criteria used to diagnose mental disorders and is often used in prevalence studies of depression in CKD and ESKD [4, 62]. The DSM-5 criteria are useful for studies that use a broad definition of depression encompassing several different depressive disorders, including MDD, PDD, and depressive disorder not otherwise specified [4].

The gold standard to diagnose depression in the research setting is the clinical interview, including the Structured Clinical Interview for DSM-5 (SCID-5) [70], the Composite International Diagnostic Interview (CIDI) [76], and the Mini-International Neuropsychiatric Interview (MINI) [66]. In clinical practice, lengthy clinical diagnostic interviews might be used, but these are not currently standard practice. Self-reported questionnaires are often used in clinical and research settings for screening of depressive symptoms. The most commonly used depression screening questionnaires that have been validated for use in patients with CKD and ESKD are the Patient Health Questionnaire-9 (PHQ-9) [73], the Patient Health Questionnaire-2 (PHQ-2) [78], the BDI [27, 73], the Hospital Anxiety and Depression Scale (HADS) [64], CESD [27], and the Quick Inventory of Depressive Symptomatology Self-Report (QIDS-SR) [32]. The PHQ-9 items are shown in Table 73.1 as an example of a screening questionnaire.

Several studies have validated depression-screening questionnaires against the SCID in patients with ESKD, while only one study has validated questionnaires against SCID to screen for depression in patients with CKD [14, 16, 27, 32, 73]. However, some overlap between the somatic symptoms of depression and the symptoms related to ESKD exist (including fatigue, difficulty concentrating, difficulty sleeping, and poor appetite), therefore patients with uremic symptoms may screen positive for depression with a self-reported questionnaire [14, 16, 27, 32, 73]. Many investigators have suggested that nonsomatic or psychological symptoms of depression (e.g. dysphoric mood, guilt, etc.) distinguish depressed from nondepressed ESKD patients better than somatic symptoms [13, 16, 61]. Researchers have also proposed that focusing on more subjective indicators such as social withdrawal may better capture depression in chronic illness populations [68].

In one study that screened patients with CKD and ESKD for depression using the BDI, the authors found that the optimal cut-off scores for patients with ESKD are 14–17, whereas for patients with CKD they were the same as the general population (i.e. cut-off score of 11 or greater) [6, 27, 28, 64]. However, the inclusion of patients with CKD stages 2 and 3, who are less likely to experience symptoms related

Table 73.1 Patient health questionnaire-9 (PHQ-9).

Over the last 2 weeks, how often have you been bothered by any of the following problems (not at all, several days, more than half the days, and nearly every day?):
1) Little interest or pleasure in doing things
2) Feeling down, depressed or hopeless
3) Trouble falling or staying asleep, or sleeping too much
4) Feeling tired or having little energy
5) Poor appetite or overeating
6) Feeling about yourself – or that you are a failure or have let yourself or your family down
7) Trouble concentrating on things, such as reading the newspaper or watching television
8) Moving or speaking so slowly that other people could have noticed? Or the opposite – being so fidgety or restless that you have been moving around a lot more than usual
9) Thoughts that you would be better off dead or of hurting yourself in some way.
If you checked off any problems, how difficult have these problems made it for you to do your work, take care of things at home, or get along with other people? (not difficult at all, somewhat difficult, very difficult, extremely difficult)

to kidney disease, could have influenced the results. The clinical interview remains the gold standard for diagnosing depression in patients with ESKD to distinguish overlapping symptoms. Future validation studies are needed for patients with advanced CKD and depressive disorders [67].

Screening Strategies

There are two screening strategies in patients with CKD and ESKD that are generally used: a conservative approach and an aggressive approach [14, 33]. The conservative approach is only implemented when patients display signs of depression such as social isolation, changes in mood or physical functions and/or increasing physical complaints (sleep disturbances, decreased self-care, etc.). The aggressive approach is to periodically screen all new CKD or ESKD patients for depression at key points of transition (initial evaluation, dialysis initiation, etc.) with screening questionnaires [33, 67, 78, 80]. These questionnaires can be completed during regular visits for dialysis or while waiting for appointments. However, it has also been recommended that the benefits and harms of psychiatric intervention in this population need to be evaluated before implementing screening programs [22].

Depression screening should be carried out by specific healthcare providers, such as a nurse, social worker or physician, who should be trained on a protocol for administering depression screening questionnaires [67]. Questionnaires, particularly items evaluating suicidal ideation, should be reviewed prior to patients leaving the clinic or dialysis center [67]. Patients who screen positive for depression should be referred to a qualified professional to confirm the diagnosis with a clinical interview [67]. Patients who require immediate referral to a mental health professional or emergency psychiatric services include those with suicidal ideation, plan, or intent and those with depression complicated by psychosis or mania (bipolar) [33]. A proposed pathway for assessing and managing depression in patients with CKD and ESKD is summarized in Figure 73.2.

Treatment

Despite reports of the high prevalence of depression among patients with CKD and ESKD, and the significant impact of depression on a range of important clinical outcomes, psychological conditions are undertreated in this population [44, 81]. Effective treatment of depression is likely to improve a range of outcomes for patients, as well as lead to reduced costs for the healthcare system. Systematic efforts to screen, diagnose, and treat depression need to be effectively integrated across the care pathway for patients with CKD. Psychotherapy, particularly cognitive behavioral therapy (CBT), pharmacotherapy, or a combined treatment, are the recommended first-line treatment for depression [82, 83]. However, in current practice very few patients with CKD/ESKD are assessed or treated for depression. Depression treatment has also received little attention in CKD research, with few randomized controlled trials available to inform evidence-based treatment and safety [42]. There is therefore a lack of data to inform the treatment of depression in this setting, or to suggest that treatment can improve depression or other impacted clinical outcomes [81], thus no recommendations are made based on research evidence. However, in clinical practice it is generally accepted that these strategies can be utilized safely. Given that antidepressants have been shown to work in other populations, it is generally accepted that they would work for kidney patients, as long as they can be used safely. Proposed clinical guidelines for the assessment and treatment of depression in CKD are described in Table 73.2.

Pharmacological Treatment of Depression

The main classes of antidepressants including selective serotonin reuptake inhibitors (SSRIs), serotonin and norepinephrine reuptake inhibitors (SNRIs), monoamine oxidase inhibitors (MAOIs), and tricyclic antidepressants (TCAs). Patients with more advanced CKD and those on dialysis or transplant have largely been excluded from large trials of antidepressant therapies among the general population and patients with cardiovascular disease [81, 84]. The clearance of antidepressant drugs or potentially toxic metabolites may be reduced in individuals with reduced kidney function and they may not be removed significantly by dialysis treatment as these medications are typically highly protein bound [83]. Drug–drug interactions are of particular concern in this population, given that patients with CKD and ESKD are typically prescribed a large number of medications, particularly individuals with complex comorbidities. Most immunosuppressive medications are metabolized by the enzyme CYP3A4 (e.g. tacrolimus, cyclosporine, sirolimus), therefore it is recommended that pharmacological treatments that interact strongly with 3A4 be avoided or used with caution among transplant recipients [85]. Drugs that inhibit or induce CYP3A4 can result in toxicity or inadequate immunosuppression and increase the risk of graft rejection. Several classes of antidepressants have cardiovascular side effects, which is problematic in this population due to the high prevalence of cardiovascular disease [44]. A range of other common adverse effects have been reported that would increase the symptom burden of CKD and ESKD [44]. Gastrointestinal side effects of immunosuppression can be

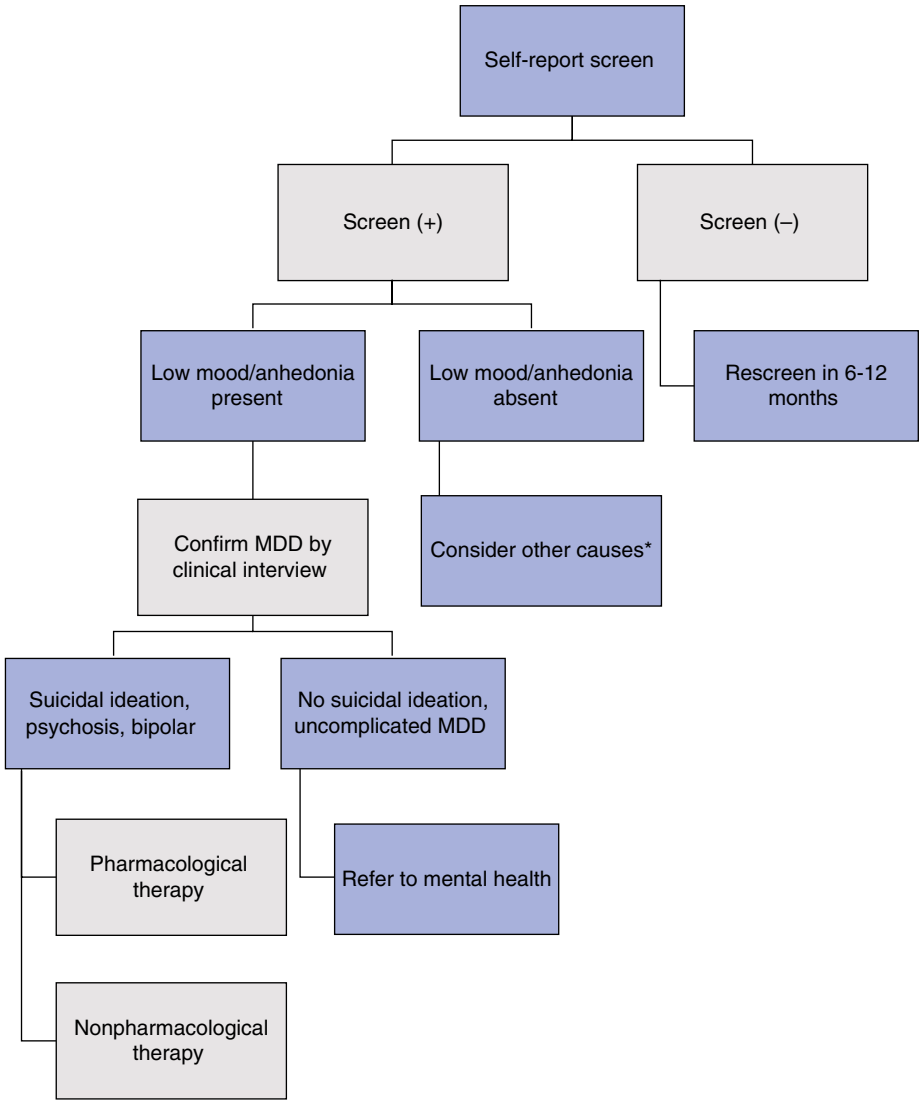

Figure 73.2 Hedayati's proposed algorithm for assessing and managing depression in patients with CKD and ESKD. *Other causes may include uremia, dialysis inadequacy, poor nutrition, cognitive dysfunction, comorbid illness, and inflammatory conditions. *Source:* Adapted from Hedayati et al. [44].

aggravated by using psychotropic medications with similar side effects, for example SSRIs and venlafaxine (a SNRI) [85]. Due to the lack of clinical trials in this population, the choice of antidepressant is based on what is known about the pharmacokinetics, drug–drug interaction effects, and the adverse event profiles of each antidepressant. Therefore greater caution is recommended in the prescription of antidepressants for patients with CKD compared to the general population [42].

While there are pharmacological trials of antidepressants with patients with CKD, these studies generally have small sample sizes, lack control groups, rarely use the gold standard assessments to diagnose depression, and the participants are not randomized to treatment [44, 81]. A recent metaanalysis conducted by the Cochrane Renal and Transplant Group included only four randomized controlled trials involving 170 patients on dialysis [13]. The metaanalysis compared SSRIs to placebo or psychological training, however the data were sparse and generally inconclusive regarding the benefits and harms of antidepressant medication [13]. This review concluded that there is not enough evidence to support the prescription of antidepressant medications in adults receiving dialysis, unless as participants in randomized controlled trials, due to the potential for increased harm. Although based on only three studies, this review also concluded that nausea may be caused by antidepressant treatment [13].

Since this review was published, the Chronic Kidney Disease Antidepressant Sertraline Trial (CAST), a randomized controlled trial involving 201 patients with stages

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 73.2 Clinical guidelines for depression assessment and treatment in chronic kidney disease.

- Assess for depression with face-to-face clinical interview in a private and confidential setting that encourages disclosure. Clinicians should focus on cognitive symptoms.
- Assessment of depression should be an iterative process, as patient moves between different stages of chronic kidney disease and treatment.
- Clinicians should actively monitor treatment adherence and suicide risk among depressed patients to reduce risk of poor clinical outcomes, suicide, and death, and monitor for voluntary withdrawal from treatment.
- Clinicians should seek to understand patient's preferences and attitudes toward depression treatment and seek to individualize treatment to their needs.
- Depression is best managed by a multidisciplinary support team.
- When considering pharmacotherapy for the treatment of depression, clinicians are advised to prescribe selective serotonin reuptake inhibitors, starting at low doses and frequently monitoring for side effects and adverse effects. Clinicians and patients should be aware that research regarding the efficacy and safety of antidepressant medication in this population is not sufficient to inform outcomes. Drug–drug interactions should also be monitored closely.

Source: Based on Christensen et al. [18].

3–5 nondialysis-dependent CKD, was completed to determine whether sertraline (an SSRI) improves depressive symptoms in patients with CKD and MDD [86]. After 12 weeks of sertraline treatment, the antidepressant therapy did not significantly improve depressive symptoms compared to placebo treatment [86]. These findings therefore do not support the use of sertraline to treat depression among patients with CKD not yet on renal replacement therapy. This study did find that nausea, vomiting, and diarrhea occurred more frequently in the sertraline group compared to the placebo group [86].

Given the lack of data available regarding the pharmacological treatment of depression in patients with CKD and ESKD, some nephrologists may be hesitant to prescribe their patients another medication. SSRIs are considered to be the most promising antidepressants for this patient population, based on established safety in patients with cardiovascular disease [44]. SSRIs are considered safer than MAOIs and TCAs for patients with kidney disease because they have fewer side effects and drug–drug interactions [42, 87, 88]. However, patients must make an informed decision to commence antidepressant therapy with awareness of the gaps in knowledge regarding the efficacy and safety for pharmacological treatments for depression for individuals with CKD/ESKD. Moreover, response to treatment, dose adjustment, possible drug–drug interactions, side effects, and adverse effects need to be monitored closely at each consultation. The use of antidepressant medication is supported by significant clinical expertise and experience. Despite the lack of data to guide decisions, it has been widely recommended that antidepressants be prescribed at the lowest effective doses, and that non-SSRIs be reduced by a third for kidney disease patients [87, 88]. Importantly, an increase in suicidal ideation and behavior after commencing antidepressant therapy has been shown in the first month after commencing antidepressants and must be monitored regularly [89].

Nonpharmacological Treatment of Depression

Nonpharmacological interventions, particularly CBT, are an important evidence-based treatment option for patients with depression in the general population that are requested and preferred by some patients over pharmacological interventions. In regards to the treatment of mild to moderate depression in the general population, nonpharmacological treatments have been shown to be as efficacious as pharmacological treatment and a useful adjunct to pharmacological treatment for more severe depression, with a particular benefit for the prevention of relapse [90]. Combined treatment of antidepressants and psychotherapy has not been studied in the CKD and ESKD populations. Some of the nonpharmacological interventions that have been studied in this population include adjusting the dialysis treatment regimen, exercise programs, psychotherapy (e.g. CBT), psychoeducation, music and art therapy, relaxation training, and meditation. However, nonpharmacological interventions for depression are often inaccessible to nephrologists and other healthcare providers in this setting due to limited resources [44].

Randomized controlled trials involving psychological treatments for depression in patients with CKD/ESKD have been scarce. A Cochrane Systematic Review published in 2005 was unable to identify any randomized controlled trials involving psychotherapeutic interventions for the treatment of depression among dialysis patients [91]. Psychological interventions that are adapted to the specific stressors and burdens experienced by patients with CKD and ESKD need to be evaluated. For example, dialysis-specific treatments may address fears around surgical procedures, loss of independence, changes in body image, uncertainty about health and the future, and the challenges of self-management. Some specific needs of dialysis patients that could be included in CBT could also include lifestyle disruption, feelings of loneliness and isolation due to their dialysis schedule, and the uncertainty of accessing transplantation [92]. For transplant recipients, a focus on a fear of graft failure and coping with immunotherapy would

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. be required [15]. CBT is the most widely investigated psychotherapy for depression (see different types of psychotherapy at https://www.div12.org/diagnosis/depression). CBT has a focus on the maladaptive beliefs, cognitive styles, and behavioral patterns that contribute to and maintain depressive symptoms. Specific techniques included in these interventions include problem solving, skills training to better cope with the impact of the disease, behavioral activation (increasing engagement in valued activities), and cognitive restructuring of dysfunctional thoughts [50]. Targeting unhelpful illness perceptions through CBT might be an effective approach for some patients [93].

There are only two small RCTs that have studied the efficacy of CBT for depression compared to usual care among patients receiving hemodialysis. A recent randomized crossover trial adapted a CBT intervention to provide chair-side depression treatment for dialysis patients from two centers during dialysis treatment, and focused specifically on the symptoms experienced by dialysis patients [94]. Compared to the waitlist group ($n = 23$), 33 participants in the treatment first group had significantly larger reductions in scores on the BDI and Hamilton Depression Rating Scale. Among participants with diagnosed depression at the start of the study, 89% of those in the treatment group did not meet criteria for depression at the end of the treatment compared to 38% in the waitlist group. The treatment group also experienced greater improvements in QoL and reductions in interdialytic weight gain. There may be issues regarding privacy and confidentiality when providing therapy chair-side while patients are undergoing dialysis in a public space among other patients. Duarte et al. conducted a trial of group CBT led by a trained psychologist over 3 months, whereby 41 hemodialysis patients attended 12 weekly sessions and were compared to 44 patients who received treatment as usual [95]. At 9 months follow-up, the intervention group had significant improvements in the BDI, MINI, and QoL compared to the control group. Their CBT intervention included 3 months of active treatment involving self-monitoring of symptoms, cognitive restructuring, behavioral activation, relaxation training, and relapse prevention. Participants received monthly maintenance sessions for 6 months. The treatment as usual group received emotional support and guidance on their treatment. This group intervention is considered a more cost-effective treatment option to individual sessions. A limitation of this study was that patients in both the active treatment and control groups were taking antidepressant medications during the study period.

More recent studies have explored adaptations to CBT to make it more acceptable and feasible in dialysis populations. A feasibility open trial was conducted with 22 patients on dialysis using an internet-delivered CBT program [96]. This single-group open trial found clinically significant improvements in depression, anxiety, and general distress which were maintained and further improved over a 3-month follow-up period. The patients who enrolled in the trial also reported improved QoL and perceived kidney disease-related loss. This study did not find any improvements in perceived disability or kidney disease burden. Importantly, this study was highly accepted by clinicians and patients. There is increasing evidence for the effectiveness of internet-delivered CBT in reducing depression and anxiety [97], including studies in patients with other chronic health conditions [98]. This would also likely be beneficial for rural renal patients.

There are also few studies of psychotherapy interventions for depression among individuals who have received a kidney transplant. In a randomized trial conducted with 82 kidney transplant recipients [99], patients were provided with 12 weeks of individual or group psychotherapy, which focused on adaptation to treatment. A control group was also constructed, although participants were not randomized into the control arm of the trial. This trial found that the kidney transplant recipients depression symptoms reduced when compared their pre-treatment scores to post-treatment scores for both intervention groups, compared to the control group where depression symptoms increased over time. This decline in depression symptoms was maintained 12 months after both interventions among the 55 patients who completed the follow-up assessment at 1 year post-transplant. Improvement in depression symptoms was significantly greater in the individual therapy group compared to group therapy.

A randomized controlled trial examined the effectiveness of an 8-week Mindfulness-Based Stress Reduction (MBSR) group intervention among kidney, lung or pancreas transplant recipients compared to health education [100]. The intervention targeted depression and anxiety symptoms and sleep disturbance. The intervention was shown to result in significantly reduced anxiety symptoms and sleep problems compared to the health education intervention, and these benefits were sustained at 12 months after treatment. The MBSR group also saw a reduction in depression symptoms that was sustained at 12 months, but this was not significantly greater than the health education intervention.

Exercise training programs may also be promising interventions that can possibly improve physical function, QoL, and depressive symptoms. In a trial of hemodialysis patients with reduced aerobic capacity, 19 patients were randomized to an intradialytic exercise training program over a 10-month period and 14 were randomized to a control group [101]. In the intervention group, participants had a 21% increase in VO_2 max and a 39% reduction in their BDI score, which was significantly different to the control group which experienced

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

no change in these measures. Levendoğlu et al. [102] evaluated the effects of a 12-week exercise program on functional capacity, mobility, walking capacity, QoL, and depression in patients on hemodialysis. This study found significant reductions in depression scores and improvements to physical and mental QoL in the intervention group. However, these studies were not conducted in patients with a diagnosis of depression. Exercise training programs may suffer from high patient dropout rates, particularly among hemodialysis patients compared to predialysis or post-transplant patients [103], possibly due to requiring frequent hospital appointments, and often suffering from fatigue and muscle weakness [104].

Given the other psychosocial risk factors for depression, it has been suggested that interventions targeting family discord, marital relationships, social support, and social participation may improve depressive symptoms [44]. Interventions directed toward caregivers or both patients and caregivers may be particularly important in home-based interventions [105, 106]. Financial support may also relieve emotional distress related to financial stressors for patients with ESKD [107].

Some research has suggested that increasing the dialysis prescription from three times weekly sessions to daily dialysis sessions improves depressive symptoms due to a reduction in physical symptoms through increased blood pressure control and improved renal clearance. An observational study showed that after a cohort of patients changed to six times weekly hemodialysis sessions, their BDI scores decreased and this was sustained at the 12-month follow-up assessment [108]. However, the efficacy of the intervention is uncertain due to the lack of a control group. The Frequent Hemodialysis Network (FHN) randomized controlled trial compared six sessions per week of in-center hemodialysis with participants undergoing the conventional three sessions per week hemodialysis [109]. This study found that patients in the frequent hemodialysis group had a significantly higher weekly standard Kt/V_{urea} compared to the conventional dialysis group, significant benefits in composite outcomes of death or change in left ventricular mass, death or change in physical health composite score, and improved hypertension and hyperphosphatemia control. However, they were more likely to require vascular access intervention and there were no significant effects on self-reported depressive symptoms. Both time on dialysis and vascular access interventions pose significant burdens and distress for patients [110–112].

Barriers to Depression Treatment

The treatment of depression in CKD and ESKD populations comes with some unique challenges and barriers. There may be reluctance among clinicians to treat depression in patients with CKD. A survey of renal clinicians from nine hemodialysis units in Pennsylvania, United States found that participants reported that they did not treat pain, sexual dysfunction, or depression in their patients. The reason for this was their belief that primary care providers were responsible for treating these symptoms [113]. Although this was a small study, this may be an important factor contributing to both the low rates of detecting and treating depression among the CKD/ESKD population and is not unique to CKD. Clinicians may also be hesitant due to the lack of data from large scale clinical trials [114].

Patient and family caregiver attitudes toward antidepressant therapy may also be an important barrier to treatment. A recent study examined the acceptance of antidepressant treatment by patients on chronic hemodialysis and their family caregivers [115]. This study suggests that patients may refuse recommendations for antidepressant therapy due to attributing their depression to an acute event, chronic illness or their dialysis therapy. Patient lack of interest in antidepressant medication was demonstrated by the high dropout rates in the study by Wuerth and colleagues, where only 45% of eligible patients agreed to receive the intervention after being assessed for depression [116]. Although the reasons for patient reluctance to accept pharmacological therapies were unclear, it is suspected this may be due to the already high medication burden among ESKD patients. A study by Johnson and Dwyer [117] reported that 50% of patients on dialysis who had elevated BDI scores were not aware of their depressed symptoms or did not believe that they needed help and believed they could improve without intervention or support. One study found that patients believed their depressed symptoms to be an inevitable part of their illness experience [25]. A sense of hopelessness is symptomatic of depression and could also prevent patients with depression from seeking help or seeing any benefit from psychological intervention.

Various studies provide insight into the relevance and importance of depression to patients and their family caregivers. A study published in 2014 conducted a national survey of Canadian adult patients who were on dialysis or about to commence dialysis, as well as their caregivers and health professionals [118]. As part of this study, a workshop was held to determine the top 10 research questions. This study identified depression as one of the top priorities among participants. Qualitative studies across all stages of kidney disease have identified psychosocial outcomes of living with kidney disease to be important and particularly relevant to the lived experience of patients with kidney disease and their family caregivers [14]. The standardized outcome in nephrology initiative (SONG) has been working to identify the most important outcomes across different

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

patient subgroups to develop a set of core outcomes to improve the relevance and consistency of outcomes reported in randomized controlled trials in nephrology [112]. Patients and caregivers contribute to this process. Psychosocial outcomes have not been ranked highly when compared to the medical outcomes, and outcomes like depression and anxiety have been ranked lower primarily because participants believe that these outcomes are easily treatable or within their personal control.

Many units do not have available resources, including psychologists, to provide time-intensive psychological interventions, which would need to be available to different cultures and patients of multiple languages. There is also difficulty in providing face-to-face CBT programs to patients around dialysis schedules, and patients are unwilling to travel to the hospital on nondialysis days given their already highly demanding and interfering treatment requirements [25, 119]. Recent studies have aimed at increasing accessibility of psychological interventions by providing chair-side treatment [94] or using e-health technology [96, 120].

A stepped-care model has also been proposed for the management of depression in the dialysis context [120]. Within this model, patients with mild-moderate symptoms (e.g. PHQ-9 scores between 5 and 19) would be referred for self-help interventions. Patients with suicidal ideation or moderate to severe depression and/or anxiety (i.e. PHQ-9 score of 20–27) would be referred to liaison psychiatry or a renal clinical psychologist, whereas those with severe depression and suicidal ideation (PHQ-9 score 20–27) would be referred more urgently for psychological interventions.

Conclusions

Depression appears to be common among patients with CKD and ESKD, and a range of biological, demographic, psychosocial, and cognitive factors increase the risk of depression. Depression has been associated with adverse outcomes including increased rates of mortality, suicide, treatment withdrawal, hospitalization, nonadherence, infection, and impaired QoL. Nevertheless, depression is underdetected and undertreated in this population. There is limited evidence for the treatment of depression in patients with CKD and ESKD, and there are patient, family caregiver, healthcare provider, and service delivery barriers to the assessment and treatment that need to be addressed. Most of the research on the epidemiology and treatment of comorbid depression in this population has been conducted in adults on hemodialysis. Large-scale randomized controlled trials are needed to inform treatment for all patients across the trajectory from CKD to ESKD, different treatment modalities, and age groups, including pediatric patients.

[2] *Departments of Nephrology and Palliative Care, St George Hospital, Sydney, Australia*

Introduction

Pain is a common and distressing symptom that affects patients with chronic kidney disease (CKD) throughout their illness. Pain is inadequately treated for many patients with advanced CKD [1, 2] and there is tremendous variability within and between countries in the management of pain, including the prescribing patterns of analgesics [3]. The International Association for the Study of Pain defines pain as "An unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage" [4]. This definition reflects the complex and multidimensional phenomenon of pain with physical, psychosocial, and spiritual components. The recognition of this complexity represents "a major advance over an exclusively sensory focus on pain" [5]. Its importance for clinicians, including nephrologists, is clear: that the assessment and management of pain requires a broad perspective.

This chapter reviews the epidemiology of pain reported worldwide for patients with CKD, including its impact on patient outcomes, and outlines strategies for the clinical assessment and management of acute and chronic pain. This will include both nonpharmacologic and pharmacologic interventions, and the role analgesics play in the overall approach to pain management.

Epidemiology

The high prevalence and severity of pain reported by dialysis patients has been well documented. Thirty-five studies examining the prevalence and severity of pain in 7832 hemodialysis patients from 20 countries have been published since 2000 [6–40]. Nineteen of these studies looked at overall pain: the pooled mean prevalence was 68.9% (95% confidence interval [CI] 67.7–70.2) and the prevalence of moderate or severe pain was 40.4% (95% CI 38.9–41.9) [9, 11, 16, 18–22, 24–27, 30, 31, 35–38, 40]. Fifteen of these studies focused on either bone/joint pain or muscle pain. These pains were also common, with mean prevalence rates of 46.4% (95% CI 43.5–49.2) and 59.4% (95% CI 57.6–61.7), respectively. When prevalence rates were restricted to those experiencing moderate or severe pain, 26.7% reported moderate or severe bone/joint pain and 31.3% reported moderate or severe muscle pain. Pain prevalence remained high in patients following withdrawal from dialysis (54.6%) [41, 42], even in the last 24 hours of life (36.0%) [41, 42].

Pain prevalence data for patients receiving peritoneal dialysis are much more limited. While seven studies from five different countries included data on peritoneal dialysis patients [6–8, 15, 16, 28, 38], only one reported their hemodialysis and peritoneal dialysis data separately [28]. For those 573 peritoneal dialysis patients, the prevalence of muscle pain was 64%.

Only five studies have explored pain in conservative kidney management (CKM), i.e. glomerular filtration rate (GFR) category five (G5) patients who had chosen conservative, nondialysis care [38, 43–46]. These were all small studies with a total of 271 patients from four countries: Republic of Guinea, United Kingdom, Australia, and China. Pain was experienced by 66.8% of patients at the time of initial assessment and increased to 73.4% in the last month of life. However, only 26.1% of these patients reported their pain as moderate or severe in intensity.

Data are limited for the prevalence of pain in patients with earlier stages of CKD, prior to the need for dialysis. Five studies from four countries have presented data on 2170 predialysis patients with various stages of CKD [6,

47–50]. The prevalence of overall chronic pain of 67.1% in G1-2 CKD patients appears similar to the 62.3% reported for G3-5 CKD patients. In one small study there were no statistically or clinically significant differences in mean pain severity scores between CKD stages, which ranged 4.8/10 to 5.7/10 for the entire population and 6.9–7.6/10 when calculated for those reporting pain [49].

There is great variation and often a lack of detail around the type and chronicity of pain in studies reporting on pain, which has tremendous implications on the impact of patient outcomes and the appropriate treatment strategies. While most studies attempt to describe chronic pain, the definitions of chronic pain included "pain experienced outside of dialysis sessions" and various durations of pain that included 7 days, 2 weeks, 4 weeks, 6 weeks, 3 months and "lasting weeks, months or even years." Studies rarely differentiated nociceptive from neuropathic pain. Despite these limitations, it is clear that the prevalence of pain is very high for patients with advanced CKD.

Clinical Relevance of Experiencing Pain

The impact of pain varies enormously between individuals, but those living with pain, specifically chronic pain, generally suffer from other physical and psychological consequences. A recent systematic review showed that people living with chronic pain experience depressive thoughts, disability, lower quality of life (QoL), conflicts in close relationships, and reduced participation in many social aspects of everyday life [51]. For patients with CKD, chronic pain has the same pervasive and detrimental effects on their lives and is associated with psychological distress, depressive disorders, limitations in work, family, and social life, and decreased life satisfaction and QoL [1, 16, 52–54]. For hemodialysis patients, severe pain has been shown to be independently associated with shortened or missed hemodialysis treatments (IRR 1.16, 95% CI 1.06–1.28) and increased health services utilization such as emergency departments visits (IRR 1.58, 95% CI 1.28–1.94) and hospitalizations (IRR 1.22, 95% CI 1.03–1.45) [36]. Chronic pain in the United States costs hundreds of billions of dollars annually [55]. When caring for people with chronic pain, it is essential that interventions and their evaluation take into consideration these far-reaching consequences.

Key Considerations in the Assessment of Pain

Routine screening for pain in patients with CKD is important for several reasons. First, pain is common in patients with CKD, as evidenced by the epidemiological data above. Second, a dance of silence may occur whereby patients do not volunteer they have pain and physicians do not enquire. Clinicians can only discern the pain experience of a patient by enquiring or, in the case of cognitive impairment, observing and asking carers. Third, it is important to treat acute pain in a timely fashion before it becomes chronic and, through pathological neuronal changes, a disease in its own right [56]. Moving from unawareness to awareness of the presence of pain hopefully triggers a response in management that may include a multidisciplinary approach including clinicians with pain expertise given that the evaluation of pain requires a comprehensive patient assessment and physical examination.

Four key aspects of the patient's assessment essential to determining a comprehensive approach to pain management include determining (i) pain intensity, (ii) chronicity and possible reversible causes for the pain, (iii) the type of pain (nociceptive, neuropathic or combined), and (iv) treatment goals.

Determining pain intensity helps establish the need for treatment. Pain is always subjective and unique to each individual. As such it can only be measured by that individual. Culture, ethnicity, mood, and the perceived meaning of the pain may influence how a patient experiences and reports pain. The concept of "total pain" refers to the physical, psychological, social, and spiritual influence on a patient's perception of pain. Listening to the patient validates the significance of their pain and their suffering, and is an important part of the therapeutic intervention. Pain that is perceived by the patient as mild, e.g. reported as a score of 1–3/10, does not usually require initiation of or a change in pain management. Pain perceived as moderate, e.g. reported as a score of 4–6/10, generally means therapy has to be initiated or changed as pain management is inadequate. Pain described as severe or rated as 7–10/10 typically requires immediate attention to treatment. Regularly enquiring about and recording the severity of pain is critical in following the progress of management. Clinicians should be aware that the assessment of pain in patients with cognitive impairment is focused on behavioral changes, such as crying out, facial grimacing, and protecting certain parts of the body.

Determining the chronicity of pain is important in understanding the potential long-term implications for the patient and in determining appropriate management strategies (Table 74.1). Acute pain is generally due to tissue injury: it is important to treat underlying causes to ensure long-term resolution. Although we still do not fully understand the development of chronic pain, lessons learned from patients undergoing surgery have taught us that good acute pain control reduces the likelihood of experiencing chronic pain. Chronic pain is much more

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 74.1 Defining the chronicity of pain.

Acute pain	
Pain characteristics	Typically persists for less than 3 months Associated with tissue damage Usually episodic with periods without pain
Clinical implications	• Tends to last a predictable period, have no progressive pattern, and subsides as healing occurs • Tends to respond well to pharmacologic therapy: titrating analgesics against pain intensity usually works well
Chronic pain	
Pain characteristics	• Often defined as any painful condition that persists for more than 3 months [4] • Usually initiated by tissue injury but is perpetuated by neurophysiological changes which take place within the peripheral and central nervous system leading to continuation of pain once healing has occurred • Severity is often out of proportion with the extent of the originating injury
Clinical implications	• More likely to result in functional impairment and disability, psychological distress, sleep deprivation, and poor quality of life than acute pain • The pain experience may be impacted substantially by mood, stress, and social circumstances • May not respond well to analgesics, including opioids, except early in the course of treatment.

likely to result in poor patient outcomes such as functional impairment, psychosocial distress, and poor QoL. As the disorder of chronic pain progresses, the original triggers become less important and the psychological mechanisms gain importance. As a result, patients with chronic pain often do not have a clear treatable underlying cause for their pain. Pharmacologic therapy alone is unlikely to be sufficient and nonpharmacologic assessment and support are essential.

Recurrent pain should be distinguished from chronic pain: it is pain from recurrent tissue injury, which may occur over long periods of time. Examples include pain from needling fistulas, intradialytic steal syndrome, and intradialytic headaches and cramps. The management of recurrent pain is more in keeping with acute pain: it focuses on strategies to minimize tissue injury and short-term pharmacologic management around the time of tissue injury if the cause cannot be avoided. Although recurrent pain typically has no progressive pattern and patients will be free from pain for long periods of time, it tends to be more intrusive on everyday life than acute pain.

Table 74.2 Distinguishing between nociceptive and neuropathic pain

Nociceptive pain	
Pain characteristics	Results from tissue damage in the skin, muscle, and other tissues, causing stimulation of sensory receptors May be described as sharp or like a knife and often felt at the site of damage With stimulation of visceral nociceptors, may be experienced as a dull, aching, and poorly localized
Clinical implications	Tends to respond to analgesics
Neuropathic pain	
Pain characteristics	Results from damage to the nervous system resulting in either dysfunction or pathological change May be felt at a site distant from its cause, e.g. in the distribution of a nerve Common descriptors include burning, shooting, and electrical May be associated with episodes of spontaneous pain, hyperalgesia, and allodynia; the presence of allodynia is pathognomonic
Clinical implications	Responds poorly to analgesics and typically requires adjuvant therapy

The choice of initial analgesic treatment is dependent upon whether the pain is neuropathic or nociceptive in nature (Table 74.2). Nociceptive pain is caused by damage to body tissue and responds well to nonopioid and opioid analgesics, at least in the short term. In contrast, neuropathic pain results from abnormal stimulation of sensory receptors due to nerve damage and is poorly responsive to nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids or requires doses for response that are associated with unacceptable toxicity. The initial treatment of neuropathic pain is an adjuvant drug, which is a drug that has a primary indication other than pain. Many pains experienced by patients with CKD will be of mixed type, e.g. pain associated with ischemia and calciphylaxis. It is important to target the neuropathic component first with adjuvant therapy to prevent inappropriate use of opioids.

Developing a treatment plan includes explaining the nature of the pain condition and setting appropriate treatment goals. Since relief of all pain is generally not possible, especially with chronic pain, the goal of therapy is to relive the pain to a tolerable level, allowing for acceptable function and QoL. For most patients this is a target of ≤3/10. The functional goals that patient sets, such as the ability to ambulate, sleep or interact socially, will need to be incorporated into the follow-up assessment of the patient.

Pain Assessment Instruments

In terms of pain assessment instruments, there are two broad approaches (Table 74.3):

1) Generic pain assessment instruments used across all conditions.
2) Validated kidney-specific symptom assessment instruments that include pain.

Each of the kidney-specific symptom instruments are global symptom assessment tools that include pain as one of many symptoms recorded. The most widely used are the Integrated Palliative care Outcome Scale I-POS (Renal) and the Edmonton System Assessment System – revised: Renal (ESAS-r:R). The I-POS (Renal) asks the patient to record the severity of pain in the past week on a 5-point Likert scale of severity that ranges from nil to overwhelming [57]. The ESAS-r:R asks the patient to record the severity of pain on visual analogue and numerical rating scales from 0 to 10 [52, 58]. The recall period can be current pain or pain in the past week.

Using the above tools to determine pain intensity alone is insufficient beyond initial screening. Elucidating the other core components of the pain assessment (chronicity and type of pain) can be done through the "PQRST" approach: **P**rovokes and Palliates, **Q**uality, **R**egion and **R**adiation, **S**everity, and **T**ime, as outlined in Table 74.4 [59]. Other core domains that should be assessed when managing pain include physical and psychosocial function, QoL, and adverse events. These are incorporated into the multidimensional pain assessment instruments as outlined in Table 74.3.

Table 74.3 Generic pain assessment instruments and kidney-specific global symptom assessment instruments that include the symptom of pain.

Generic pain assessment instruments

Severity scales

1) Visual analogue scale (VAS). Self-reported rating of pain from zero ("no pain") to 10 ("the worse pain imaginable") on a 10 cm line.
2) Categorical numerical scale. Ask patient to report pain severity from 0 to 10.
3) Categorical verbal rating scales. Rating pain as none, mild, moderate, or severe.

PEG scale: Assesses pain and its effect on the function and enjoyment of life of the patient.

Abbey scale: An instrument designed and validated for the assessment of pain in people with significant cognitive impairment.

Physical symptom distress scale (PSDS): Assesses 16 symptoms, including pain.

Brief Pain Inventory (BPI): Assesses location, type (nociceptive v neuropathic) and severity of pain.

Short Form McGill Pain Questionnaire (SF-MPQ): Self-reported pain severity. Does not assess the effect of pain on function or QoL

Kidney-specific symptom assessment instruments that include pain

I-POS (Renal): Combination of 17 symptoms, including pain, plus a series of psychosocial questions.

Palliative care Outcome Scale *POS-renal*: The precursor to the I-POS (Renal). Seventeen symptoms, including pain.

Dialysis Symptom Index (DSI): Assesses 30 symptoms, including pain. Validated for dialysis patients only.

ESAS-r: Renal: Eleven visual analogue scales with a superimposed 0–10 scale for 10 symptoms, including pain and wellbeing.

*Kidney Dialysis Quality of Life – Short Form/SF-36 (*KDQOL-SF*)*: Self-reported QoL measure for CKD patients.

*Choice Heath Experience Questionnaire (*CHEQ*) and SF-36*

Nonpharmacological Approach to Pain Management

A vital component of the management regimen of chronic pain is the use of nonpharmacological therapies. This aspect of comprehensive pain care has a prominent place in all evidence-based guidelines on pain management, especially chronic nonmalignant pain. A recent guideline promulgated by the United States Center for Disease Control recommends nonpharmacological treatment of chronic nonmalignant pain [61]. The recent Clinical Practice Guideline from the American College of Physicians recommends that nonpharmacological interventions should be the first-line management of chronic low back pain [62]. Indeed, in the modern era there is a strong focus on a multimodal and multidisciplinary approach to chronic pain management [63]. The evidence for these and other therapies is described below. Unfortunately, there is a significant dearth of nonpharmacological intervention studies on patients with CKD.

Physical Therapies

Exercise

A systematic review of guidelines for the physical management of osteoarthritis found the level of evidence for exercise ranged from low to high and the overall recommendation was strong [64]. Two subsequent authoritative guidelines reached the same conclusion [61, 63]. The effect of general exercise, aerobic exercise, and resistance training has been well studied, especially for osteoarthritis of the knees [65]. The findings of these studies were mostly positive, although some found no effect. The quality of these studies was low to moderate [65]. For chronic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 74.4 The PQRST approach to evaluating pain [59]

Components of the assessment	Questions to explore
P = Provokes and Palliates	What causes the pain? What makes the pain better or worse?
Q = Quality	What does the pain feel like? Is it sharp? Dull? Stabbing? Burning? Crushing?
R = Region and Radiation	Where is the pain located? Is it confined to one place? Does the pain radiate? If so, where to?
S = Severity	How severe is the pain?
T = Time (or Temporal)	When did the pain start? Is it present all the time? Are you pain-free at night or during the day? Are you pain-free on movement?

Adapted from Davison [60] with permission.

lower back pain, moderate quality evidence showed that exercise resulted in a small improvement in pain and function [66]. A recent meta-analysis found that both aerobic training and progressive resistance training reduced the severity of chronic low back pain significantly, with neither mode being superior to the other [67].

Weight Reduction

Weight reduction is strongly recommended across all guidelines for osteoarthritis pain of the knees [64, 65]. In studies that vary from very low to moderate quality, the effects of weight reduction varied from no effect to a positive effect [65].

Yoga

In one of the few intervention studies for pain in CKD patients, a yoga-based exercise program reduced pain in hemodialysis patients in a randomized controlled trial by 37% [68]. The American College of Physicians Guideline on chronic low back pain recommends yoga, albeit with low-quality evidence [62].

Acupuncture

A large individual patient meta-analysis showed good evidence for the efficacy of acupuncture in chronic musculoskeletal pain [69] and the systematic review of guidelines on the management of osteoarthritis recommended this treatment [64]. Similar results were found in meta-analyses of pain management in diabetic peripheral neuropathy and carpal tunnel syndrome, although in each case caution was expressed about the quality of the methodology in the randomized controlled trials (RCTs) examined [70]. Indeed, a recent Cochrane Review on the role of acupuncture in neuropathic pain concluded that there was insufficient evidence to support or refute its use [71].

Miscellaneous

There is low-quality evidence on the effect of thermal therapy, whole-body vibration, massage, and tai chi on chronic pain. Nevertheless, the systematic review of guidelines on the management of osteoarthritis recommended thermal therapy [64]. Given the increasing proportion of patients with CKD secondary to diabetic nephropathy, there are two physical treatments that should be noted. First, high-tone external muscle stimulation showed a statistically significant efficacy in a prospective pilot study in dialysis patients with symptomatic diabetic and uremic neuropathy [72]. Second, the role of mirror therapy for phantom limb pain following amputation was assessed in two recent systematic reviews and it was found that this intervention, while successful, was based on studies that were of low to moderate quality [73, 74].

Behavioral therapies

Education

Education and self-management are core recommendations in all major guidelines for chronic noncancer pain generally and for specific pain syndromes such as osteoarthritis [64]. Reviews of their role showed a spectrum from positive to no effects [65].

Psychological Intervention

Overall, reviews on the studies of the effect of cognitive-behavioral therapy (CBT), mindfulness-based interventions, and stress-management training on chronic pain have been positive [65]. The studies were of very low to moderate quality. In a systematic review of 42 RCTs for patients with chronic noncancer pain except headache, CBT was found to have a small to moderate effect on pain [75].

Interventional

The American Society of Interventional Pain Physicians, in their recent guidelines on chronic noncancer pain, stated that "multiple interventional techniques have been described in managing chronic pain with discordant opinions, often based on inappropriate evidence synthesis leading to inappropriate and often negative conclusions" [63]. They concluded that the level of evidence across numerous systematic reviews on interventional techniques was "at least moderate" [63]. They found

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

significant effectiveness for epidural injections for spinal pain, with a wider range of evidence for facet or zygapophysial joint injections [63].

Pharmacologic Approach to Pain Management

Analgesics play an important role in pain management. However, for patients with chronic pain, where the somatosensory component of the pain tends to be more important than the original tissue injury, pharmacologic treatment should only be used to augment the previously discussed nonpharmacologic therapies as required to meet patient-specific treatment goals. Unfortunately, data remain sparse even in the general population for the benefit of analgesics in managing chronic pain. While there is some moderate and low-quality evidence suggesting that long-term treatment with opioids can lead to significant improvements in functional outcomes and QoL in patients with chronic, nonmalignant pain, findings are not conclusive [76].

Current Analgesic Use in CKD

In recent years there has been an escalation in the prescribing and dose of opioids, resulting in an increase in opioid-related deaths, higher rates of addiction and social dysfunction, cognitive impairment, falls and orthopedic injuries in the elderly, and an increase in emergency department visits and in-patient hospitalizations [77, 78]. The rates of harm correlate directly with dose and continuous use. There is growing concern at regulatory, professional, and societal levels about opioid misuse, with the greatest focus being on high dosing and chronic use. Those most at risk for these adverse effects are adults aged 18–25 years, men, those with lower educational attainment, and people with psychiatric conditions or a history of substance or sexual abuse [77, 78].

The prevalence of overall analgesic and opioid use in CKD is highly variable within and between countries, and the differences cannot be accounted for by patient characteristics. A meta-analysis reported an estimated prevalence of overall analgesic use in patients with G4 and G5 CKD of 47% (95% CI 0.35–0.59), opioid prevalence 22% (95% CI 0.07–0.41), acetaminophen prevalence 26% (95% CI 0.16–0.36), and NSAID prevalence 16% (95% CI 0.11–0.21) [3]. The prevalence of opioid use is much higher in the United States compared to Europe, Canada, Australia, and New Zealand [3]. A large study across the United States showed that 64% of over 150 000 dialysis patients received opioids in 2010: 41% of patients had a short-term prescription while 23% received a chronic opioid prescription defined as ≥90 days [79]. Equally concerning was the choice of opioid used: 46% of these patients, representing 10.6% of entire hemodialysis cohort, received chronic prescriptions for opioids that are not recommended, while almost all other patients were prescribed hydrocodone, an opioid for which there is no evidence for its safety in patients with CKD. Only 1.9% of patients received a chronic prescription for an opioid that is recommended for use in the context of advanced CKD. The current high use of opioids for patients on hemodialysis in the United States is associated with a higher risk of altered mental status, falls, and fractures in a dose dependent manner [80].

Screening for High Risk of Opioid Misuse

Maintaining a balance between the legitimate needs of patients in pain and minimizing the risks of drug-aberrant behavior and addiction has proven challenging. First, it is important to distinguish tolerance and physical dependence, which are known effects of opioids, from compulsive opioid seeking and addiction (see Table 74.5). Recent comprehensive, evidence-based guidelines on the use of opioids in the management of chronic, nonmalignant pain [61, 63, 81] recommended several steps in this process:

1) First, determine carefully whether opioids are appropriate for the pain syndrome being addressed.
2) Second, if opioids are being considered, conduct an assessment of risk factors for substance use disorder. There is no single test or instrument that absolutely predicts this risk. Indeed, the United States Center for Disease Control and the American Society of Interventional Pain Physicians found the level of evidence for the reliability of these instruments to be "insufficient" and "limited" [61, 63]. Nevertheless, and conscious of these limitations, all bodies enumerated a series of risk factors to be considered by clinicians, which are shown in Table 74.6.
   The next steps are counsels of caution. They include the following when prescribing opioids:
   (a) Use, where available, a prescription monitoring program, which tracts in real time the history of prescriptions to detect a patient seeking multiple prescriptions from different physicians.
   (b) consider drawing up an opioid contract with the patient setting clear goals to the management, including the level of analgesia and restoration of function acceptable to the patient.
   (c) advise the patient to employ universal precautions, including a clear statement on the risks and benefits of opioid therapy, commencing with a trial of opioid therapy, regular reviewing, and emphasizing the security of medications at home.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(d) For patients deemed at high risk of substance use disorder, consider opioid therapy "only if they are able to implement more frequent and stringent monitoring parameters" and in consultation with a mental health or addiction specialists [81].

The Essential Principles

The essential principles of prescribing analgesics for pain management are summarized by five phrases that are described within the context of advanced CKD in Table 74.7.

Table 74.5 Defining drug tolerance, physical dependence, and addiction.

Tolerance

- Tolerance is defined as the need for increasing doses of a drug to achieve the same pharmacological action.
- It can occur to unwanted effects such as respiratory depression and nausea as well as to the desired pain relief.
- Although considered an expected response to chronic opioid use, the incidence is unclear. Studies of patients with malignant chronic pain show that after a period of dose titration patients may continue on the same dose of morphine for many months without needing to increase the dose and that the requirement for dose escalation is usually on account of progression of disease.

Physical dependence

- Physical dependence is characterized by withdrawal symptoms if treatment is stopped abruptly or if an antagonist is given. If pain is relieved by other means, e.g. abrupt pain reduction following a nerve block, the dose will need to be reduced to prevent respiratory depression, but low as needed doses may be required initially to treat withdrawal symptoms.

Addiction

- Addiction is a behavioral pattern characterized by loss of control over use, compulsion to use, craving, and continued use of a drug despite knowledge of harmful consequences.

Table 74.6 Risk factors for substance use disorder.

1) Current or past illicit drug or alcohol abuse.
2) Family history of alcohol or drug abuse.
3) History of sexual abuse, psychiatric disorder or post-traumatic stress disorder.

Source: Based on guidelines on opioid use in chronic nonmalignant pain published by the American Pain Society – American Academy of Pain Medicine (APS-AAPM), the Center for Disease Control (CDC), American Society for Interventional Pain Physicians (ASIPP), British Pain Society (BPS), Canadian National Opioid Use Guideline Group (NOUGG) and Australian and New Zealand College of Anaesthesiology (ANZCA).

The World Health Organization advocates a cautious stepwise approach to analgesic therapy for malignant and nonmalignant acute and chronic pain [83]. It involves the slow introduction and upward titration of analgesics, starting with nonopioids then progressing to weak then strong opioids as required for pain relief. There is preliminary evidence only to suggest that this approach may be appropriate and effective in hemodialysis patients with mild or moderate nociceptive and neuropathic pain [84]. Of particular importance is the careful selection of analgesics. Current recommendations are based on indirect pharmacologic evidence and clinical experience, i.e. "expert advice," rather than high-quality clinical studies: data remain scare. In view of the potential for toxicity and the narrow therapeutic window in patients with advanced CKD, short-acting rather than long-acting preparations should be used until stable pain relief has been achieved. There is also some evidence for increased mortality with long-acting opioids [82].

Adverse effects of strong opioids are sufficiently common to prevent effective analgesia, and patients should be warned of these and informed of the steps that can be taken to prevent or treat them at the time of opioid initiation. Constipation is nearly universal and persistent so patients should have a bowel routine, e.g. Polyethylene Glycol 3350 prescribed preemptively. Nausea and vomiting occur in about 50% of people, wearing off in most after 7–10 days. Central nervous system effects occur most frequently on initiating strong opioids and when increasing the dose, hence the need to "start low and titrate slow." Respiratory depression is unusual if oral, short-acting preparations are used and the dose is titrated slowly against pain and toxicity. When pain is stable, strong opioids can be used in long-acting preparations such as transdermal fentanyl or methadone. Hallucinations are a very distressing adverse effect of opioids and if they occur should be managed by dose reduction, switching to an alternative opioid, or with coadministration of haloperidol. The Center for Disease Control recommends that physicians mitigate risk of toxicity by offering naloxone when factors that increase risk for opioid overdose are present. These include a history of overdose, history of substance use disorder, higher opioid dosages (≥ 50 morphine milligram equivalents/day), or concurrent benzodiazepine use [61].

The Selection of Analgesics for Patients with Advanced CKD

Many analgesics and their metabolites are excreted by the kidneys. The analgesics that should be avoided in patients with advanced CKD and the evidence behind the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 74.7 The five principles of pain management within the context of advanced CKD.

Principle	Description	Specific considerations in advanced CKD
By mouth	Oral administration is safest and therefore usually preferred If ingestion or absorption is uncertain, analgesics need to be given by alternative routes such transdermal, rectal or subcutaneous	HD patients have easy intravenous access, but this is to be avoided as the route of administration for analgesics to optimize safety and minimize the risk of abuse and addiction
By the clock	For continuous or predictable pain, analgesics should be given regularly. Additional "breakthrough" or "rescue" medication should be available on an "as needed" basis in addition to the regular dose.	Some patients with mild-moderate pain may achieve adequate pain relief with analgesic dosing post-HD only. An example would be mild-moderate neuropathic pain dosed with gabapentin post-dialysis.
By the ladder	Pharmacologic management proceeds stepwise from nonopioids to low-dose opioids The drug should be used at its full tolerated dose before moving to the next level	Careful selection of analgesics based on severity of kidney failure with gradual titration is essential Sustained-release preparations are generally not recommended, at least until the individual patient's response to the medication has been observed, due to the narrow therapeutic window in patients with advanced CKD There is some evidence for increased mortality with long-acting opioids [82]
For the individual	The "correct" dose for strong opioids is the amount needed to relieve the pain without producing intolerable side effects. Evaluation of benefit and toxicity is essential. If an individual finds that a particular strong opioid causes unacceptable adverse effects, an alternative must be sought	Chronic pain is often experienced in the context of numerous other physical, psychosocial, and spiritual concerns, including end-of-life issues. Close attention to these other issues must not be forgotten if the pain management strategy is to be successful.
Attention to detail	Pain changes over time, therefore there is the need for ongoing reassessment Side effects of opioids should be explained and managed actively, e.g. constipation and nausea, with anticipatory prescribing of a bowel routine, e.g. PEG 3350 and antiemetic, e.g. Zofran 4–8 mg Offer naloxone when factors that increase risk for opioid overdose or concurrent benzodiazepine use are present	There are no studies on the long-term use of analgesics in patients with CKD. Careful attention must be paid to efficacy and safety. The impact on overall symptom burden, physical function, emotional state, cognition, and quality of life should be assessed routinely

CKD, chronic kidney disease; HD, hemodialysis. Adapted from Davison [60] with permission.

recommendations have been recently reviewed and are outlined in Table 74.8 [60].

Nonopioids for Patients with Advanced CKD

Acetaminophen

Acetaminophen is the initial analgesic of choice for patients with advanced CKD. Acetaminophen is an antipyretic analgesic with weak anti-inflammatory activity and is metabolized extensively in the liver. Only 2–5% of the dose is excreted unchanged in the urine and there are no clinically significant changes observed in patients with advanced CKD. Recent evidence suggests that lifetime cumulative doses of acetaminophen do not have an adverse effect on CKD progression [99]. The recommended maximum daily dose is 3000 mg given that liver injury can be seen with doses of <4000 mg.

Nonsteroidal Anti-Inflammatory Drugs

Geriatric and rheumatologic societies recommend that the chronic (>21 days) use of all oral NSAIDs, including high dose aspirin, be avoided, especially in the elderly (≥75 years) [85]. Clinicians should be particularly cautious about their use in patients with CKD due to increased risks of bleeding, cardiovascular events, psychiatric events, and kidney-related complications in those with residual kidney function (Table 74.8). NSAIDs are there-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 74.8 Analgesics to avoid in patients with advanced CKD.

NSAIDS (for chronic pain) [85]

- The major limitation is GI toxicity due to inhibition of cytoprotective mucus secretion and impaired platelet aggregation resulting in ulceration and bleeding. Risk increases in severity and frequency with increasing age: NSAID use increases the risk of GI bleeding in the elderly fourfold. Concomitant use of antiplatelet drugs such as aspirin, anticoagulants, and SSRIs further increases bleeding risk.
- Although the GI safety profile of COX-2 inhibitors is superior to nonselective NSAIDs, nephrotoxic and cardiovascular adverse effects (myocardial infarction, thrombotic events, and stroke) remain significant. It has been shown that the long-term use of all NSAIDs increases the risk of stroke by 64% at 2 years. COX-2 selectivity may not play a role in the increased cardiovascular risk of NSAIDs as Rofecoxib was the only drug in meta-analyses to demonstrate excessive harm and skewed the data of COX-2 selective NSAIDs [86]. There is insufficient evidence to confirm any NSAID to be safe in terms of cardiovascular risk.
- In patients with residual kidney function, NSAIDs may also cause a reduction in GFR that can be severe and irreversible if the patient has decreased effective circulating volume, sodium and water retention, which may aggravate hypertension, and hyperkalemia.
- The elderly may also be at increased risk for NSAID-associated psychiatric events such as agitation, depression, anxiety, paranoia, delirium, and hallucinations.

Codeine

- A weak opioid that is metabolized by the enzyme CYP2D6 in the liver to its active metabolite morphine, which provides the analgesic effect. Only about 5–10% of codeine is metabolized in this pathway, with most of the administered dose being converted to inactive metabolites.
- The percentage of codeine converted to morphine can be much higher in individuals who have three or more active copies of the *CYP2D6* gene (ultra-rapid metabolizers), resulting in life-threatening or fatal respiratory depression due to high plasma levels of morphine, even with trivial doses. Conversely, poor analgesic response will be seen in those who carry inactive copies of *CYP2D6* (poor metabolizers) due to low morphine levels after administration of standard doses [87].
- Up to 11% of codeine is also metabolized to hydrocodone (mechanism unknown).
- Both codeine and its metabolites are excreted by the kidneys and accumulate in patients with kidney failure.

Dextropropoxyphene

- A weak opioid that has been withdrawn from the market in the United Kingdom, Europe, New Zealand, and Canada due to its weak analgesic effect, addictiveness, and its association with deaths and possible arrhythmias. In the United States it has a Black Box warning and is on the High Risk Medications in the Elderly list.
- Decreased elimination of dextropropoxyphene and its major active metabolite, norpropoxyphene, occurs in patients with kidney failure [88].

Tramadol

- A weak synthetic opioid, related to codeine.
- Extensively metabolized in the liver with one main active metabolite, O-desmethyltramadol (M1). Both the parent drug and M1 contribute to the analgesic effect through u-opioid receptors and two nonopioid mechanisms, inhibition of serotonin, and norepinephrine reuptake [89]. M1 has a significantly higher affinity for opioid receptors than tramadol, while tramadol is a more potent inhibitor of serotonin and norepinephrine reuptake [90].
- The enzyme CYP2D6 catalyzes the production of M1 and other CYP enzymes (CYP2B6 and CYP3A4) catalyze the production of M2, an inactive metabolite (Figure 74.1).
- Unpredictable risk of serious overdosing or underdosing after administration of standard doses. The concentrations of tramadol may be 20% higher in "poor metabolizers" versus individuals who have multiple functional copies of the CYP2D6 gene ("ultrarapid metabolizers"), while M1 concentrations may be up to 40% lower. Factors such as the concurrent use of CYP2D6 inhibitors (Figure 74.2) could also result in increased tramadol concentration and decreased M1 concentration.
- Induction of CYP3A4 may pose an added risk of seizures, even when tramadol is administered in accepted doses. This is particularly problematic in the context of neuropathic pain where several of the adjuvants are CYP3A4 inducers (Figure 74.2).
- Serotonin syndrome is a potentially life-threatening syndrome that may occur with the use of tramadol, especially if other medications such as antidepressants or other drugs that impair the metabolism of tramadol (CYP2D6 and CYP3A4 inhibitors) are used concurrently. Symptoms include changes in mental status (e.g. agitation, hallucinations, coma), autonomic instability (e.g. tachycardia, labile blood pressure, hyperthermia), neuromuscular aberrations (e.g. hyperreflexia, incoordination), and/or GI symptoms (e.g. nausea, vomiting, diarrhea).

Table 74.8 (Continued)

Morphine

- Metabolized primarily to the active metabolites morphine-3-glucuronide (M3G) and small amounts (~10%) of morphine-6-glucuronide (M6G). M3G lacks analgesic effect but may have neuroexcitatory effects contributing to adverse effects such as allodynia, myoclonus, and seizures. M6G has potent analgesic effect, more so than morphine. Although M6G is dialyzed, it diffuses out of the central nervous system slowly so may not be completely removed during dialysis.
- M3G and M6G (more so than the parent drug morphine) accumulate in patients with advanced CKD.
- There is poor, inconsistent correlation between plasma levels of morphine, M3G, and M6G, and clinical efficacy or adverse effects [91]. The best correlation appears to be between higher levels of morphine and constipation and high levels of M3G and cognitive impairment [92]. There are many reports in the literature of profound toxicity in patients with advanced CKD.

Oxycodone

- A semisynthetic opioid metabolized primarily by CYP3A4 to the active metabolite noroxyodone with a small amount metabolized by CYP2D6 to the active metabolite oxymorphone, the clinical relevance of which is not clear. The potential for drug interaction and unpredictable pharmacodynamic response therefore is relatively high (Figure 74.1).
- Less than 10% is excreted unchanged in the urine. Despite this, both the parent drug and the active metabolites appear to accumulate in dialysis patients [93] with reports of toxicity [94]. The central opioid effects are governed by the parent drug.
- A recent systematic review of opioid use in cancer patients with some degree of kidney failure found two studies that evaluated oxycodone use: higher oxycodone levels were associated with increased fatigue but the metabolite noroxycodone was not associated with any of the evaluated adverse effects [92].
- A single study assessed the pharmacokinetics following a single 20 mg oral dose of an abuse-deterrent formulation of extended-release oxycodone in patients with mild ($n = 6$), moderate ($n = 5$) or severe ($n = 6$) kidney failure [95]. C_{max} and AUC continued to increase with increasing severity of kidney failure and patients with severe kidney failure had a C_{max} (31.6 ng/ml vs. 17.6 ng/ml) and AUC (493.5 ng.h/ml vs. 210.7 ng.h/ml) more than double that of those with normal kidney function. Adverse effects were experienced by 50% of patients with severe kidney failure vs. 14.3% in those with normal kidney function.
- In a case study of a single HD patient, oxycodone and its metabolites were reduced by dialysis, yet there was no loss of analgesia [96]. More recently, knowledge about the dialyzability of oxycodone comes from a study of 20 HD patients on stable doses of oxycodone CR [97]. Dialyzability of oxycodone and noroxycodone was possible but very limited. Not surprisingly therefore, there was no significant increase in postdialysis pain with no need for additional opioid dosing. This is not surprising as oxycodone has a relatively high volume of distribution (greater than hydromorphone), is nearly 50% protein bound, and is only moderately water soluble.

Hydrocodone

- A semisynthetic strong opioid synthesized from codeine: 99% of the world's supply is consumed in the United States, where it is the most commonly prescribed opioid, including for CKD patients.
- Primarily metabolized in the liver into several metabolites, including hydromorphone, via CYP2D6, therefore it might be expected to have a similar unpredictable risk of serious overdosing or underdosing after administration of standard doses, as seen with codeine and tramadol (Figure 74.1). In clinical practice this is less clear. The production of the active metabolite of hydrocodone (hydromorphone) is reduced in CYP2D6 "poor metabolizers" but there is little evidence of a difference in analgesic effect. Ultrarapid CYP2D6 metabolizers may have an increased response to hydrocodone with an increased risk of overdose.
- Approximately 26% is excreted in the urine either unchanged or as a metabolite, therefore kidney failure is hoped to have only a minimal effect on drug clearance. However, data are extremely limited as described below.
- There is only a single study that has assessed the extent to which varying degrees of kidney failure can affect the pharmacokinetics of hydrocodone and this involved a single 45 mg dose of extended-release formulation over 144 h [98]. All subjects received naloxone at 15 and 3 h before and 9 and 21 h postdose to minimize opioid-related adverse effects. There were eight patients with mild kidney failure (>50–80 ml/min), nine with moderate (30–50 ml/min), nine with severe (<30 ml/min), and nine on HD ≥6 mo. Systemic exposure was up to 70% greater in patients with moderate to severe kidney failure but appeared to be unchanged in patients on HD. There was no consistent trend toward an increase in maximum concentration of hydrocodone with increasing severity of kidney failure. However, the incidence of adverse effects in patients on dialysis was similar to that in those with normal kidney function despite the concurrent use of naltrexone.
- Without any data to support its use, and the high potential for unpredictable toxicity risk, it remains unclear the role that hydrocodone should or should not have in the pharmacologic management of pain for patients with advanced CKD.

fore best reserved for specific indications of inflammatory acute pain, limiting their use to the lowest effective dose and shortest duration [85]. Topical NSAIDs can provide effective pain relief without the systemic adverse events associated with oral NSAIDs when used for both acute and chronic pain [100, 101]. Where pain is present in joints or nonulcerated skin, this may be a useful alternative to oral administration.

Opioids for Patients with Advanced CKD

Opioid Metabolism and Advanced CKD

Opioid metabolism takes place primarily in the liver, with the metabolites, and to varying degrees the parent drug, excreted by the kidneys. Metabolism produces both active and inactive metabolites, some of which may be more potent than the parent compound. These will accumulate to various degrees in patients with advanced CKD, increasing the risk of opioid toxicity.

Careful selection of opioids is essential and understanding opioid metabolism is important in this determination. The risks of adverse effects, poor analgesic response, and drug interactions are determined largely by which enzyme system (s) metabolize the opioid and the patient's genetics factors and medical conditions, most notably kidney or liver failure.

Opioids are metabolized in the liver in one of two ways as outlined in Figure 74.1 [60]. Phase 1 metabolism involves oxidation or hydrolysis of the drug primarily via cytochrome P450 2D6 (CYP2DP) and/or cytochrome P450 3A4 (CYP3A4) enzymes. Phase 2 metabolism involves conjugation of the drug.

People's responses to drugs that are metabolized via the CYP2DP enzyme are highly variable due to the tremendous genetic polymorphism of the *CYP2D6* gene. Individuals who have three or more active copies of the *CYP2D6* gene are described as "ultra-rapid metabolizers" whereas those who carry inactive copies of *CYP2D6* are "poor metabolizers." This can result in poor analgesic response with standard doses or unpredictable toxicity with trivial doses [87]. Opioids that are metabolized by the CYP3A4 enzyme have a high risk of drug–drug interactions as this enzyme metabolizes more than 50% of drugs. Concomitant use of CYP3A4 substrates and inhibitors can increase the parent opioid concentration, thereby prolonging analgesic effect or toxicity. Examples can be seen in Figure 74.2 [60]. CYP3A4 inducers can reduce opioid levels and therefore reduce analgesic effect. The CYP2D6 enzyme metabolizes approximately 25% of drugs so is associated with a lower risk of drug–drug interactions. Drugs that are metabolized by phase 2 glucuronidation have minimal drug interaction potential. While genetic variability exists, these drugs do not appear to have the same risk for unpredictable toxicity as seen with CYP2D6-mediated metabolism.

Recommended Opioids for Pain Management in Patients with Advanced CKD

The current available pharmacokinetic and pharmacodynamic evidence for those opioids considered safer to use in patients with advanced CKD has recently been reviewed and is summarized in Table 74.9 [60]. Given the minimal changes in pharmacokinetics in kidney failure, hydromorphone, fentanyl, methadone, and buprenorphine may be useful analgesics. Hydromorphone has the advantage of undergoing no phase 1 metabolism therefore avoiding the

complications of unpredictable toxicity and drug–drug interactions seem with CYP2D6- and CYP34A-mediated metabolism. An additional consideration is the impact of the dialyzability of analgesics for those patients on dialysis. Opioids that are dialyzed will likely require supplemental dosing during or after dialysis and patients could be at higher risk for symptoms of opioid withdrawal after dialysis. Opioids that are not well dialyzed will have more stable analgesia. However, if there is accumulation of the parent drug and/or active metabolites, the risk for toxicity increases. Hydromorphone, fentanyl, methadone, and buprenorphine all appear to have a relatively stable analgesic effect during dialysis although their removal with dialysis varies, as seen in Table 74.9.

A Stepwise Approach to the Introduction and Titration of Analgesics

Figure 74.3 outlines the recommended stepwise approach to the pharmacologic management of pain for patients with advanced CKD [60]. Adjuvant therapy is the first step for people with a neuropathic component to their pain. In the general population, anticonvulsants and tricyclic antidepressants (TCAs) are the two classes of drugs for which there is the most evidence of efficacy [112, 113]. A small study showed improvement in pain and QoL scores for hemodialysis patients with diverse causes of neuropathic pain using gabapentin [114]. Gabapentin is almost exclusively cleared by the kidneys and substantial dose reduction is required as GFR declines to avoid toxicity. Adverse effects include somnolence, dizziness, peripheral edema, and gait disturbances. Gabapentin is cleared by hemodialysis and was recently found to be cleared slowly by continuous ambulatory peritoneal dialysis [115].

Evidence suggests carbamazepine may be as effective as gabapentin for treating neuropathic pain in the general population and, unlike gabapentin, requires no dose adjustment in CKD [115]. TCAs appear to be less well tolerated than the gabapentinoids in patients with CKD because of anticholinergic, histaminergic, and adrenergic side effects resulting in symptoms such as dry mouth, orthostatic hypotension, and somnolence. Although dose reduction of TCAs is not necessarily required in CKD, patients will often respond to lower doses. There are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 74.9 The pharmacokinetics of opioids recommended for use in patients with advanced CKD.

	Hydromorphone	Fentanyl	Methadone	Buprenorphine
Clinical description	A potent μ receptor agonist that is ~5–7 times more potent than morphine following oral administration and ~3 times more potent following intravenous administration. It may cause less pruritus, sedation, and nausea than morphine.	A potent synthetic opioid that is 50–100 times more potent than morphine. It causes less histamine release, has a lower incidence of constipation, and affords greater cardiovascular stability than morphine.	A potent synthetic opioid with activity mainly at the μ receptor. It also appears to function as an NMDA receptor antagonist and therefore may be more effective for neuropathic pain than other strong opioids, although evidence to support this remains limited.	A potent semisynthetic opioid. It is a partial μ receptor agonist and a κ receptor antagonist.
Oral bioavailability	Low-moderate	Low: usually administered intravenously or transdermally	High	Low: administered effectively sublingually or transdermally.
Route of clearance	Extensive first-pass hepatic metabolism with little unchanged drug found in the urine. It is metabolized principally to H3G, which has no analgesic activity but possibly causes neuro-excitation, agitation, confusion, and hallucinations. Unlike morphine, which has an active analgesic 6-glucuronide metabolite, H6G is present in trace amounts only. The pharmacokinetics of the active parent compound are not substantially altered by CKD due to the rapid conversion to H3G [102].	Hepatic metabolism with 10–20% excreted by the kidneys. Metabolites are inactive.	Hepatic metabolism into inactive metabolites with ~20% excreted unchanged in the urine. In anuric patients, methadone is exclusively excreted in feces with no significant accumulation in plasma [103].	Extensive first-pass hepatic metabolism with little unchanged drug found in the urine [104]. The two major metabolites, B3G and norbuprenorphine, are mostly excreted fecally with only 10–30% excreted in the urine [105]. B3G is inactive with no analgesic properties. Norbuprenorphine is a less potent analgesic at the μ receptor than buprenorphine; its clinical relevance is thought to be limited as it does not cross the blood–brain barrier readily. A study with 10 HD patients showed no elevated buprenorphine or norbuprenorphine plasma levels receiving transdermal buprenorphine (median dose 52.5 μg/h) for at least 1 week [106].
Plasma half-life	Hydromorphone: unchanged with CKD H3G: prolonged	Unchanged with CKD	Unchanged with CKD However, prolonged pharmacological action due to slow release from tissue reservoirs of up to 60 h [107].	Unchanged with CKD

Table 74.9 (Continued)

	Hydromorphone	Fentanyl	Methadone	Buprenorphine
Removal by HD	H3G accumulates between dialysis treatments but appears to be effectively removed during HD with no significant change in pain scores post-HD or a need for supplemental dosing [102, 108]	Not removed to any significant degree but there is the possibility of adsorption to CT190 dialysis membranes [109][a]	Parent drug and metabolites do not seem to be removed by HD: ~6.0 –14.9% reductions in plasma methadone [108, 110, 111]. No significant difference in pain scores post-HD and supplemental methadone is not required post-HD [108]. QT interval increased significantly: maximum 152 min after methadone intake. Remained <500 ms and was not linearly associated with serum methadone concentration, but may be exacerbated by HD reductions in serum potassium and/or magnesium [110].	HD does not appear to affect buprenorphine plasma levels, and analgesic effect is stable during HD [106]
Dosing recommendations	Start at 0.5 mg PO (or 0.2 mg subcutaneously) q4–6 h	Not recommended in opioid naïve patients. When converting from hydromorphone, 6-8 mg oral hydromorphone daily can be converted to 12 μg/h q72 h	Start 1–2 mg q12–24 h PO. Obtain a pre-treatment ECG and a follow-up ECG 2–4 weeks after initiation to monitor for prolonged QT interval.	Start at 5 μg/h q7 d

insufficient data or clinical experience with selective serotonin reuptake inhibitors and selective serotonin norepinephrine reuptake inhibitors for neuropathic pain in CKD to make a recommendation.

The anesthetic ketamine is an analgesic in subanesthetic doses. Ketamine is a potent N-methyl-D-aspartate (NMDA) receptor channel antagonist. Clinically, it is reserved for intractable chronic pain syndromes, especially those with a neuropathic component that are resistant to opioids and basic adjuvants. An example is the management of the pain of calciphylaxis (Specific Pain Syndromes in Patients with Advanced CKD). There is no need for dose adjustment in CKD [116]. Two reviews of ketamine for chronic noncancer pain (including neuropathic and ischemic pain) concluded that ketamine provides good analgesia but that adverse events such as psychotomimetic effects and tachycardia may limit its use [117, 118]. A systematic review of analgesia for phantom limb pain reached similar conclusions [119]. To eliminate or reduce the risk of psychotomimetic effects, the concurrent administration of haloperidol or midazolam is recommended [120].

Nonopioids should be used as initial pharmacologic management for nociceptive pain and for neuropathic pain if pain persists despite the maximal tolerated dose of an adjuvant. These drugs should be used to their full potential before moving on to a stronger analgesic. For patients with advanced CKD, there are no weak opioids considered suitable or safe for use so it is recommended to add a very low dose of a strong opioid. Weak opioids have the same dose-dependent adverse effects as strong opioids and there is no evidence that weak opioids are less risky than strong opioids if the strong opioid is used at its lowest effective dose [132]. A recent study of 140 899 adult hemodialysis patients in the United States showed the highest hazards for altered mental status, falls, and fractures were associated with codeine rather than the strong opioids [80]. There is also no evidence that at equivalent analgesic efficacy weak opioids carry a lower risk of addiction than low-dose strong opioids.

End-of-life Pain Management and Special Considerations

A critical aspect of the care of the dying patient with advanced CKD is vigilance about pain and its management. Near the end of life, swallowing becomes compromised and alternate routes for analgesic administration are required. Given that patients are often unconscious and not able to articulate the severity of their pain, physicians

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

should regularly enquire of nursing staff or families whether the patient appears distressed, especially on routine turning in bed. A person who enters the terminal phase with analgesia needs to have this continued throughout and not ceased prematurely. An algorithm for terminal pain management is presented in Chapter 55. In this situation the use of parenteral opioids is preferred, with fentanyl being the medication of choice. If pain is solely or predominantly neuropathic in origin and the patient is no longer able to swallow, there is good evidence for the use of parenteral lidocaine [121].

Specific Pain Syndromes in Patients with Advanced CKD

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) may cause acute or chronic pain. It is estimated that up to 70% of patients experience severe pain not controlled by oral analgesia [122]. Acute pain may result from cyst infections, cyst rupture or nephrolithiasis. Both recurrent pain and chronic pain may result from intrarenal causes (capsular distension, traction on the renal pedicle) or extrarenal pressure on other organs, nerve plexuses or structures, such as the lumbar vertebrae. Patients may concurrently have hepatic cysts that, of themselves, can cause severe pain.

As Lanktree and Chapman state, "there is no gold standard modality for pain in ADPKD" [123]. The management of pain secondary to ADPKD consists of three modalities:

1) *Nonpharmacological treatment*: This includes massage, heat packs, and psychological strategies and support [124].
2) *Pharmacological*: Acetaminophen may be all that is required or, if the pain is more severe, a combination of opioids and agents for neuropathic pain [124, 125].
3) *Procedural*: This includes minimally invasive interventions, such as cyst aspiration, cyst decortication, and renal denervation, or invasive interventions, such as partial or, as an "absolute last resort" [123], total nephrectomy.

Calciphylaxis

Calciphylaxis (calcific uremic arteriolopathy) is a rare complication of end-stage kidney disease (ESKD) in which metastatic calcification of small and medium-sized vessels causes ischemic necrosis in the skin and subcutaneous tissue, resulting in intense, severe pain disproportionate to the size of the lesions. Calciphylaxis is associated with a high mortality rate: 1 year mortality rates are reported as 45–80% [126,127]. Management of calciphylaxis includes analgesics, intradialytic sodium thiosulphate, hyperbaric oxygen, and in certain circumstances the amputation of affected limbs.

The pain of calciphylaxis is notoriously difficult to manage. Authorities on this condition recommend the involvement of a multidisciplinary team including the participation of specialists in both pain medicine and palliative care [128]. There are no randomized controlled trials to help guide treatment. Nevertheless, there are several consistent observations in published case reports. First, it is thought that the pain of calciphylaxis has both ischemic and neuropathic components [130]. This helps explain why the pain tends to be only partially opioid responsive [130]. The singular use of opioids and their escalation up to the point of toxicity is fruitless [130]. A degree of analgesia was only achieved in the case reports with simultaneous administration of adjuvant medications for neuropathic pain (such as ketamine) [130, 131]. The final observation is the importance of timely, robust, and regular reassessments of pain to guide the titration of analgesics to reflect the rapid escalation in pain and distress of the patient. Treating the pain of calciphylaxis as a pain emergency reflects the appropriate level of gravity clinicians should place on this condition.

Conclusions

Pain is a highly complex and personal phenomenon with far-reaching physical and psychosocial consequences if it progresses to become a chronic disorder. A summary of the recommendations discussed in this chapter is given in Table 74.10. A multidisciplinary pain team is best positioned to manage chronic pain if it is resistant to simple interventions. The first-line management of chronic pain is a nonpharmacological approach that includes patient education, exercise, weight reduction, thermal therapy, yoga, acupuncture, and CBT as appropriate along with a clear understanding of the patients' goals and expectations for therapy. Pharmacologic treatment should only be used to augment nonpharmacologic therapies as required to meet patient-specific treatment goals. In the context of advanced CKD and the multimorbidity that many patients experience, they will have numerous reasons for ongoing pain and will most likely require some analgesic therapy. This requires the careful selection of analgesics with very close attention to efficacy and safety, keeping in mind the overall goal is to promote functionality and QoL, and not necessarily completely resolve the pain. We suggest that prior to commencing opioids patients be screened for substance use disorder and for those who are considered to be at high risk, naloxone be prescribed and the patient followed by a pain specialist.

Table 74.10 Practice recommendations for a general approach to pain management for patients with advanced CKD.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Screening for substance use disorder	We suggest that prior to commencing opioids patients be screened for substance use disorder	Low	Weak
Multidisciplinary pain management	We suggest that chronic pain, if resistant to simple interventions, be managed by a multidisciplinary pain team	Low	Weak
Nonpharmacological management of chronic pain	We suggest that the first-line management of chronic musculoskeletal pain is a nonpharmacological approach. This includes education, exercise, weight reduction, thermal therapy, yoga, acupuncture, and cognitive behavior therapy as appropriate.	Low-moderate	Weak
Interventional	We suggest that an epidural injection be considered in chronic spinal pain resistant to other interventions	Moderate	Weak
Pharmacological management of chronic pain	We suggest that pharmacologic treatment of chronic pain should only be used to augment nonpharmacologic therapies as required to meet patient-specific treatment goals	Moderate	Weak
Naloxone	We suggest that patients who are prescribed opioids and are assessed as high risk for substance abuse disorder be prescribed naloxone and be followed by a pain specialist	Low	Weak

GRADE assessment of the certainty of evidence: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research dies not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Introduction

Neurocognitive disorders are primarily disorders of cognition that are acquired and represent a significant decline from previous functioning that is not due to delirium, another psychiatric condition, or developmental disorders. Neurocognitive disorders are subclassified as major or mild based on whether activities of daily living are affected. Major neurocognitive disorder is evidence of significant cognitive decline on one or more cognitive domains that interferes with independent activities of daily living. Mild neurocognitive disorder is evidence of one or more cognitive deficits without loss of independent functioning. The Diagnostic and Statistical Manual of Mental Disorders replaced the term "dementia" with "major neurocognitive disorder" in 2013 [1]. Neurocognitive disorders are characterized by cognitive impairment as their core feature, while the term "neuro" indicates they relate to brain disease and altered brain function.

Six distinct cognitive domains can be affected in mild or major neurocognitive disorder (Table 75.1) and may be differently affected by pathological processes. These domains are executive function, complex attention, social cognition, learning and memory, language, and perceptual-motor function. Numerous assessment tests for neurocognitive functioning are used, and range in their focus and scope. Cognitive screening tools can be influenced by age, educational level, and language fluency. Screening assessments may have published language- and age-specific norms that can allow standardization across populations. To our knowledge, there has been no systematic evaluation of the diagnostic test accuracy for cognitive functioning assessment applied to adults with chronic kidney disease. Single studies suggest that the Montreal Cognitive Assessment (MoCA) correlates with a full neurocognitive battery of tests and detects neurocognitive disorders in dialysis patients, while the Mini-Mental State Examination (MMSE) is weakly discriminating for neurocognitive dysfunction [4, 5].

Cognitive impairment in chronic kidney disease is related to vascular and nonvascular mechanisms leading to microvascular injury, and white matter loss and microinfarction. Magnetic resonance imaging among patients with kidney disease demonstrates large vessel ischemia, small vessel lacunar infarction, and white matter lesions arising from small vessel ischemia [6–8]. Nonvascular factors that may be associated with cognitive functioning in chronic kidney disease include anemia, uremia, oxidative stress, intradialytic hypotension, dialysis disequilibrium, hyperviscosity, and vascular calcification [9].

Knowledge of the prevalence of neurocognitive disorders in children with chronic kidney disease is limited due to the high risks of selection and measurement biases in existing studies [10]. Global cognition of children with chronic kidney disease is low average, and varies by severity of kidney disease. Children treated with dialysis are most severely affected, showing significantly lower global cognitive functioning than children with mild-moderate chronic kidney disease and pediatric recipients of a kidney transplant. Children with chronic kidney disease have lower scores in executive function and verbal and visual memory domains, and lower academic skills, including mathematics, reading, and spelling.

Table 75.1 Cognitive domains.

Domain	Subdomains	Examples of everyday activities
Complex attention	Sustained attention; divided attention; selective attention; processing speed	Normal tasks take longer, especially when there are competing stimuli; easily distracted; tasks need to be simplified; difficulty holding information in mind to do mental calculations or dial a phone number
Executive function	Planning; decision-making; working memory; responding to feedback; inhibition; flexibility	Difficulty with multistage tasks, planning, organizing, multitasking, following directions, keeping up with shifting conversations
Learning and memory	Free recall; cued recall; recognition memory; semantic and autobiographical long-term memory; implicit learning	Difficulty recalling recent events, repeating self, misplacing objects, losing track of actions already performed, increasing reliance on lists and reminders
Language	Object naming; word finding; fluency; grammar and syntax; receptive language	Word-finding difficulty, use of general phrases or wrong words, grammatical errors, difficulty with comprehension of others' language or written material
Perceptual-motor function	Visual perception; visuoconstructional reasoning; perceptual-motor coordination	Getting lost in familiar places, more use of notes and maps, difficulty using familiar tools and appliances
Social cognition	Recognition of emotions; theory of mind; insight	Disinhibition or apathy, loss of empathy, inappropriate behavior, loss of judgment

Source: Adapted from American Psychiatric Association [1], Eramudugolla et al. [2], and Hugo et al. [3].

Adults with chronic kidney disease (defined as an estimated glomerular filtration rate below 60 ml/min/1.73 m^2) perform worse than people without chronic kidney disease on orientation and attention, language, concept formation and reasoning, executive function, memory, and global cognition. The evidence for cognitive function in people with kidney disease is limited by risks of bias in available studies as well as clinical and statistical heterogeneity in the existing literature base [11]. Cognitive functioning may fall in parallel with kidney function decline, with specific cognitive domains differentially affected. Notably, cognition (both self-perceived and measured) can alter decision-making of dialysis modality choice and be linked to lower use of self-care dialysis modalities and treatment adherence [12]. Cognitive decline occurs before measurable loss in kidney function [13].

Evaluation of neurocognitive disorder includes identifying potentially reversible causes such as severe uremia, depression, electrolyte disturbances, aluminum toxicity, and neuroactive medication toxicity. Presently, there are few randomized trials in which cognitive function is a clinical endpoint. Specific disease-modifying agents such as cholinesterase inhibitors have not been adequately tested in the presence of chronic kidney disease. Social support, shared decision tools, and advance care planning are especially relevant to the care of adults with chronic kidney disease and a neurocognitive disorder, although high-certainty evidence for their use is lacking.

This chapter examines the evidence for screening and management of neurocognitive disorders in adults and children with chronic kidney disease.

Definition

Neurocognitive disorders are a decline in cognitive functioning in one or more cognitive domains from a previous level of performance. A decline in function is greater than that expected by aging needs to be acquired rather than developmental and not due to an alternative psychiatric condition or delirium. The decrease in functioning should be documented by concern expressed about significant decline by an individual who knows the patient or is observed by a clinician together with impairment documented by standardized neuropsychological testing [1]. Major neurocognitive disorder is characterized by interference with independence in everyday activities, while mild disorder is characterized by independent daily living, although activities may require additional time and effort, support, or compensatory activities. While neurocognitive disorders in the general population require further specification by likely etiology, chronic kidney disease might be considered an explanatory etiology based on the characteristics cerebral imaging findings consistent with predominantly microvascular disease. The *Diagnostic and Statistical Manual of Mental Disorders*, 5th edition details six cognitive domains which may be affected, including complex attention, executive function, learning and memory, language, perceptual-motor function, and social cognition. Dementia is the equivalent of major neurocognitive disorder.

Epidemiology

Many studies have evaluated the prevalence of neurocognitive disorders among people with chronic kidney disease, although summary estimates are uncertain due to the statistical and clinical heterogeneity in the study populations and diagnostic tools used to assess neurocognitive disorders, in addition to the high risks of methodological bias limiting confidence in the findings. The prevalence of neurocognitive disorders is dependent on evidence of decline from a previous level of functioning, which is challenging to measure on a large scale for observational analysis.

The prevalence and severity of neurocognitive disorders and the pattern of altered cognition across the six cognitive domains varies in adults and children, by severity of chronic kidney disease, and in the context of dialysis treatment. Based on a meta-analysis of cohort and cross-sectional studies, children and young adults with chronic kidney disease are shown to experience lower IQ (global, verbal, and performance) compared with their peers, with greater reductions among those treated with long-term dialysis and intermediary values for pediatric recipients of a kidney transplant [10]. Children with mild-moderate chronic kidney disease have impaired behavior regulation, metacognition, and global executive functioning, while deficits are less consistently observed among transplant recipients. Children with chronic kidney disease also show impaired verbal and visual memory. In parallel, children and young adults with chronic kidney disease have lower academic achievement in reading, arithmetic, and spelling, with those on dialysis most severely affected. Neurocognition appears to decrease in children as kidney function declines and impacts children most who have experienced a prolonged duration of kidney disease.

In adults, as in younger persons, neurocognitive functioning is related to severity of kidney function, appears to decrease with lower glomerular filtration rate, and is related to the presence of dialysis [11]. Adults with chronic kidney disease perform worse than those without chronic kidney disease on orientation and attention, language, concept formation and reasoning, executive function, memory, and global cognition, with loss of executive function greatest when the glomerular filtration rate is below 30 ml/min/1.73 m^2. People treated with hemodialysis have worse cognition THAN the general population in the domains of attention, memory, construction and motor functioning, executive functioning and global cognition. There was limited evidence of consistent clinical differences in neurocognitive functioning for hemodialysis patients compared with those treated with peritoneal dialysis or those with end-stage kidney disease and not dialyzed. Study limitations, however, reduced certainty and precision in the ESTIMATED prevalence of neurocognitive disorders in each of these populations [14].

In a study of 374 hemodialysis patients older than 55 years, cognitive functioning in the domains of memory, executive function, and language indicated that nearly 40% had severe impairment and approximately 35% had moderate impairment. Notably, only 3% had previously documented deficits, and neurocognitive disorder was linked to cerebrovascular disease, dialysis dose, and prior educational attainment [15].

Kidney transplantation is linked to moderate to large improvements in the domains of general cognitive function, information and motor processing, spatial reasoning, and verbal and visual memory when compared with functioning in the pre-operative period [16]. Transplanted patients have better cognitive functioning than dialysis-dependent controls and those treated without dialysis. Cognitive performance among transplanted individuals remains lower than in people without chronic kidney disease in the domains of executive functioning, verbal fluency, and language. By contrast, changing from conventional thrice-weekly hemodialysis to frequent nocturnal hours hemodialysis is not associated with clinically important improvements in cognitive functioning [17].

Pathophysiology

Neurocognitive impairment is multifactorial in chronic kidney disease (Figure 75.1). The precise neuropathology is unknown, although it is thought that microvascular pathologies predominate, while direct neuronal injury also occurs. Cerebral imaging among patients with chronic kidney disease reveals a substantial burden of ischemic stroke, small vessel (lacunar) infarction, and white matter changes caused by ischemia. The linked risks of cerebral small vessel disease and end-stage kidney disease for patients with type 2 diabetes suggest that the two conditions may share a common pathological process [19]. The pathological vascular processes in the neurocognitive disorder of chronic kidney disease that cause reduced white matter volume and integrity are distinct from the neurodegenerative processes seen in Alzheimer's disease, which is manifest as hippocampal atrophy. Patients with chronic kidney disease and end-stage kidney disease can also have Alzheimer's disease, but vascular pathologies are more common. Cerebral vascular disease may be superimposed on a neurodegenerative process and be further mediated by uremia, medications, hypoperfusion during dialysis, oxidative stress, and volume and electrolyte changes. Adults with

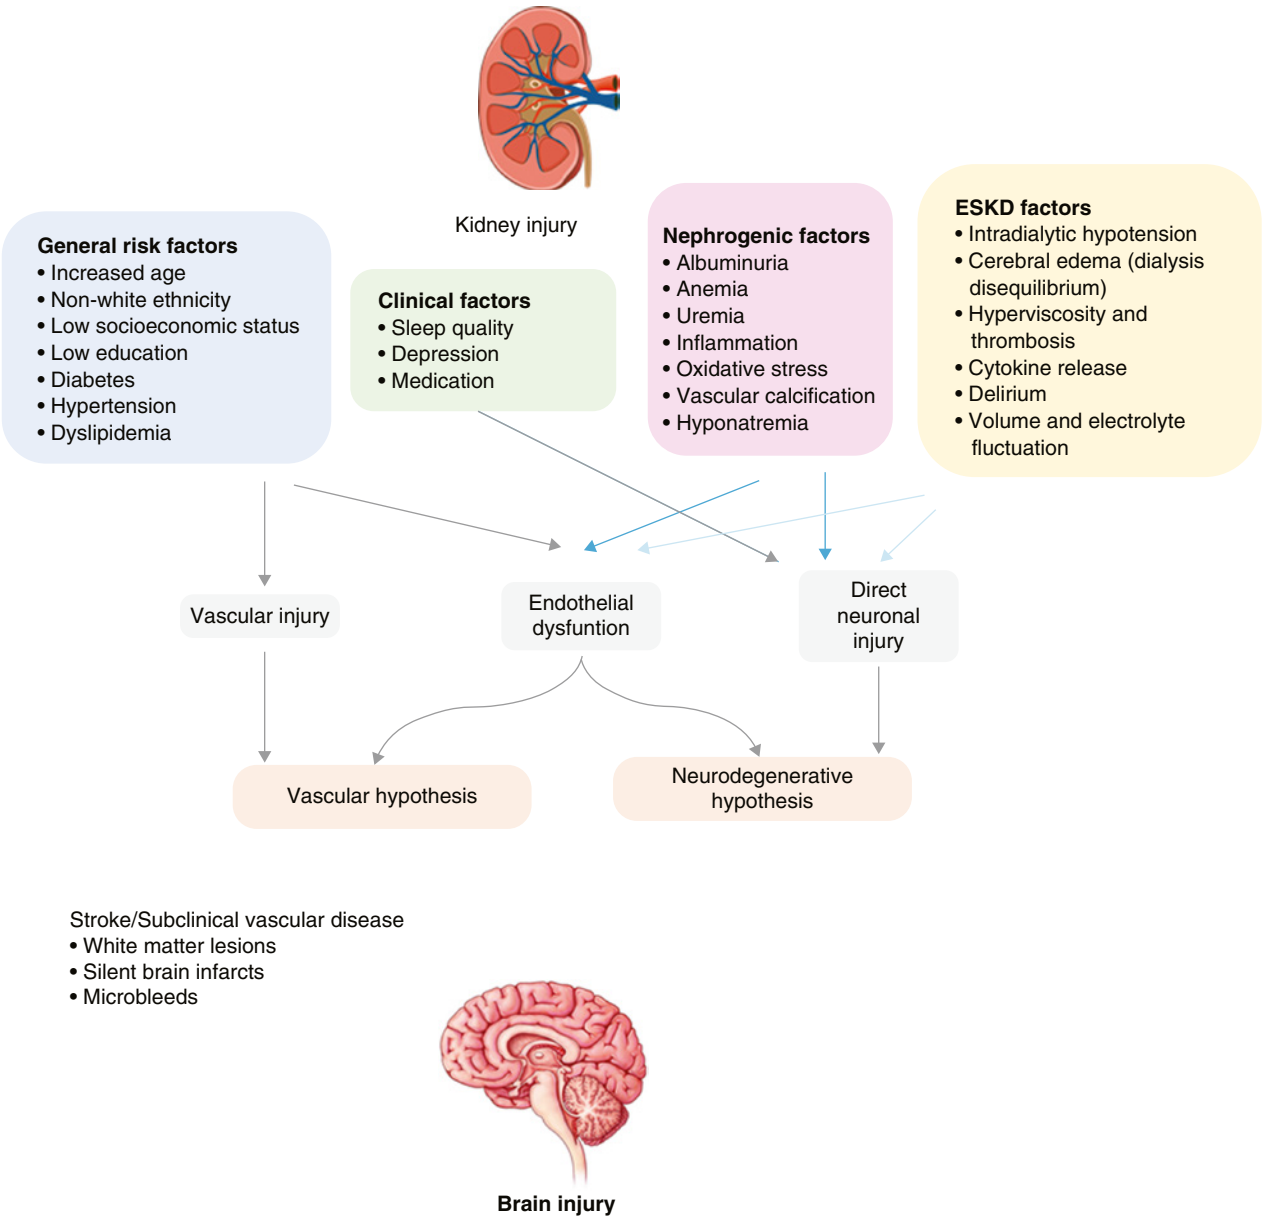

Figure 75.1 Risk factors associated with neurocognitive disorders in chronic kidney disease. *Source:* Adapted from [9, 18].

chronic kidney disease have traditional risk factors for cognitive impairment, including age, lower educational attainment, diabetes, hypertension, dyslipidemia, and non-white ethnicity.

In addition to the traditional risk factors shared with the wider population, clinical factors specific to renal disease are present that are associated with neurocognitive problems. These include a high prevalence of depression, adverse effects of medications or their interactions, fatigue and poor sleep quality, and anemia. Chronic kidney disease increases oxidative stress, cytokines, and inflammation, which may accelerate vascular disease and small vessel cerebral infarction.

End-stage kidney disease and the actual process of dialysis can potentiate cerebral vascular changes including volume and electrolyte shifts and related dialysis-disequilibrium. Dialysis may lead to hypotension and cerebral hypoperfusion, exacerbating the tendency to microvessel infarction. Extracorporeal blood flow incurs intravascular thrombosis, which can be potentiated by fluid removal and hyperviscosity. Hyperparathyroidism may lead to altered cerebral calcium and vascular dysfunction [20].

The observation that kidney transplantation provides a sustained improvement in cerebral functioning is supported by the finding of reduced latency and increased amplitude of cortical potentials throughout the brain. These suggest that the active alleviation of uremia and associated phenomena by normalization of kidney function may lead to improved neurocognitive performance [21].

In children, uremia may be associated with periventricular white matter changes, cortical atrophy, slower nerve conduction, and impaired myelination and synaptic development [22].

Diagnosis

The clinical diagnosis of neurocognitive disorders is based on reporting of concern by a reliable informant or clinician together with standardized neuropsychiatric assessment. A central component of a diagnosis is demonstration of decreased functioning over time, more than the normal aging process.

Clinical History

At the start of a clinical assessment, it is important to be aware that a patient may or may not have recognized any change, and the neurocognitive issue has been highlighted by a family member or care giver. Family members may attribute changes to the normal aging process or not recognize a slowly progressive process. In contrast to neurocognitive disorders, cognitive changes due to aging consist of isolated changes in memory or information processing and often fail to progress. Patients with a neurocognitive disorder may demonstrate difficulty holding on to new information, get lost in familiar or unfamiliar surroundings, not complete complex tasks that they were previously able to, have problems with reasoning such as dealing with treatment choices, have difficulty finding words, or show new unexpected behaviors.

The initial clinical assessment of the patient will include obtaining a full and complete history of the timing of the changes in cognition and behavior from both the patient and the informant, in addition to a medical history exploring medications, particularly medications that may impact cognition. Assessment for depressive symptoms, anxiety, and delirium is required.

Neurocognitive Tests

Cognitive testing is an important component of the clinical assessment to corroborate the history. A combined assessment of the history (indicative of the longitudinal progression of signs and symptoms) together with cognitive testing suggesting abnormalities in one or more cognitive domains underpins the diagnosis. There is a wide range of neurocognitive tests, none of which are specifically designed to assess all cognitive domains simultaneously or used routinely in nephrology care. A comprehensive battery of tests is required to examine all areas of cognitive performance, although these can be time-consuming and resource-intensive to administer.

The most commonly-used screening tools for cognitive function in chronic kidney disease are the MMSE [23], the MoCA [24], and the Trail Making Test [25]. The MMSE is a simple 30-point questionnaire and requires a short interview to gather information on orientation, visual and auditory memory, attention, language, comprehension, and visual construction. The MMSE has low sensitivity for neurocognitive disorders and is particularly poor at detecting executive dysfunction in dialysis patients [4, 5]. The MoCA has higher sensitivity for mild neurocognitive disorder and executive function, which are both particularly relevant in chronic kidney disease. It is a brief screening instrument composed of 12 items assessing visuospatial and executive function, naming, attention, abstraction, short-term memory, and orientation. The Trail Making Test is a test of visual attention and task switching to provide information about visual search, scanning, speed of processing, cognitive flexibility, and executive function.

There is limited evidence for the diagnostic test accuracy of screening tools for neurocognitive disorder in chronic kidney disease. In a small study with 30 patients receiving hemodialysis and 30 matched controls, neurocognitive deficits in attention, visuospatial performance, language, memory, and executive function were documented using 13 cognitive measures [26]. While half of hemodialysis patients showed scores greater than 1 standard deviation (SD) below the mean across the domains, the average score on the MMSE and corresponding *z*-scores for the MMSE based on normative data were not different from controls, while the total MoCA scores were statistically significantly lower, explaining 66% of the variance in cognition measured by the comprehensive battery. This suggests the MMSE may lack sensitivity to identify neurocognitive deficits in the presence of end-stage kidney disease.

A more extensive battery of neurocognitive testing can explore the cognitive domains, although these require more specialist knowledge to conduct and interpret. A list of these tests categorized according to cognitive domain is shown in Table 75.2. Evidence is lacking for the diagnostic test accuracy for these tests to assess neurocognitive function in the presence of chronic kidney disease.

Table 75.2 Examples of cognitive assessments as noted in the *Diagnostic and Statistical Manual* 5th edition.

Cognitive domain	Objective assessment	Example	Measures
Complex attention	Sustained attention	Press a button every time a tone is heard, over a period	Symbol digit modalities
	Selective attention	Hear numbers and letters but count only numbers	Trail Making Test A
	Divided attention	Tap rapidly while learning a story	Simple reaction time
	Processing speed	Carry out any timed task	Choice reaction time
Executive function	Planning	Maze puzzles, interpret sequential pictures, or arrange objects in a sequence	Digit span backwards Trail Making Test b
	Decision-making with competing alternatives	Simulated gambling	Stroop color word test
	Working memory	Hold information for a brief period and manipulate it, e.g., repeat a list of numbers backward	Zoo map (bads) Game of dice test
	Feedback utilization	Use feedback on errors to infer rules to carry out tasks	Go no-go test
	Inhibition	Override habits; choose the correct but more complex, less obvious solution, e.g. read printed names of colors rather than naming the color in which they are printed	
	Cognitive flexibility	Shift between sets, concepts, tasks, rules, e.g. alternate between numbers and letters	
Language	Expressive language	Naming of, e.g., objects or pictures; fluency for words in a given category (e.g. animals) or beginning with a given letter, in a limited time period (e.g. 1 min)	Letter fluency Boston naming test Spot the word test
	Grammar and syntax	Using articles, prepositions, helper verbs	
	Receptive language	Comprehend/define words, carry out simple commands	
Learning and memory	Immediate memory	Repeat a list of words or digits	California verbal learning test Benton visual retention test
	Recent memory	Free recall: recall as many items as possible from a list of words or a story or a diagram Cue recall: with an examiner providing cues, e.g. "recall as many food items as you can from the list" Recognition: with examiner asking, e.g. "was there an apple on the list?"	
	Semantic memory	Recall well-known facts	
	Autobiographical memory	Recall personal events	
	Implicit (procedural) memory	Recall skills to carry out procedures	
Perceptual-motor function	Visuoconstructional reasoning	Draw, copy, assemble blocks	Purdue pegboard test
	Perceptual-motor coordination	Insert blocks or pegs into appropriate slots	Benton visual retention copy
	Praxis	Mime gestures such as "salute" or actions such as "use hammer"	Ideomotor praxis
	Gnosis	Recognize faces and colors	
Social cognition	Recognize emotions	Identify pictures showing happy, sad, scared, angry faces	Reading the mind in the eyes test
	Theory of mind	Consider another person's thoughts, intentions when looking at story cards

Imaging

Neuroanatomical imaging in patients with chronic kidney disease shows white matter changes, and ventricular and hippocampal atrophy with more severe changes observed among patients with greater global cognitive impairment [27]. In three-dimensional magnetic resonance imaging, hemodialysis patients may have more severe neuroimaging abnormalities THAN those treated with peritoneal dialysis. In arterial-spin labeling magnetic resonance imaging, a noninvasive technique to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

evaluate cerebral blood flow changes, cerebral blood flow is reduced in dialysis patients and may correlate with hemoglobin levels [28]. In adults with diabetes, glomerular filtration rate or albuminuria correlated with gray matter volume suggesting neuroanatomical changes may occur early in chronic kidney disease [29].

Overall, for children and young adults with chronic kidney disease, lower gray matter and higher white matter volumes may occur in some cortical regions, but these can be relatively subtle and do not appear to correlate with cognitive impairments, suggesting a potentially functional rather than structural basis to neurocognitive difficulties in childhood chronic kidney diseases [30].

The evidence for using neuroanatomical or neurofunctional imaging to detect neurocognitive disorders and their subtype in chronic kidney disease is currently of very low certainty due to a lack of systematic evaluation of the available data. Neuroanatomical imaging can rule out alternative diagnoses.

Treatment

Although cognitive disorders are highly prevalent in people with chronic kidney disease, the evidentiary basis for management to improve clinical outcomes remains largely absent (Table 75.3). Systematic reviews of the evidence are principally limited to characterization of disease prevalence, patterns, and severity together with impact on prognosis and functioning. A systematic review and meta-analysis of potential treatments was not identified to guide clinical decision-making for management, patient or caregiver support, or therapeutic interventions specifically in adults or children with chronic kidney disease.

In this chapter, potential interventions are discussed together with a summary of the current level of evidence (Table 75.3).

Screening

At present, there is no high-level evidence that screening for neurocognitive disorders in adults or children with chronic kidney disease improves clinical endpoints.

Cognitive Remediation

There is little or no randomized controlled trial evidence for cognitive rehabilitation or remediation among children or adults with chronic kidney disease. Although not necessarily generalizable to chronic kidney disease, evidence among adults with stroke shows there are insufficient data to confirm or refute the long-term effects of cognitive rehabilitation on functional outcomes [31]. Similarly, adults with stroke may report short-term subjective improvement in memory with cognitive rehabilitation, but persistent effects on memory are not proven [32, 33]. For adults with stroke or nonprogressive brain injury, there is no high-quality evidence that cognitive rehabilitation alters executive functioning [34].

At present, there is no high-quality evidence for cognitive remediation interventions for children with chronic kidney disease and the data are generated in children with other learning or cognitive difficulties. Candidate interventions include age-specific cognitive remediation programs designed to improve attention and working memory, attention and executive function, attention and memory, and attention, memory, processing speed, social cognition, social navigation, and intelligence [35]. Randomized trials have evaluated cognitive remediation strategies in the settings of attention deficit hyperactivity disorder, learning disabilities, trisomy 21, low birth weight, post-traumatic stress disorder, and traumatic brain injuries. As the burden of kidney disease includes loss of schooling time and time-intensive therapies, evaluation of online remediation programs focused on academic outcomes would be appropriate.

Support Interventions for Caregivers

As patients with chronic kidney disease may be unaware of neurocognitive changes, evidence on the role of caregiver support in functional outcomes related to cognitive problems would be informative. The present evidence for support of informal caregivers is extremely limited and unable to inform clinical practice. Outcomes measured in such research is limited to caregiver knowledge [36].

In the general population, there is no high-quality evidence for the benefits of respite care for adults with neurocognitive disorders [37]. Similarly, there is little evidence for telephone counseling support for caregivers [38]. Cognitive reframing may reduce caregiver anxiety, depression, and subjective stress, but there is no good-quality evidence for improved coping, burden of care, reactions to behaviors, or institutionalization of the person with a neurocognitive disorder [38]. There is some information that case management may assist reducing admission to institutional care and overall health costs in the medium term among people with major neurocognitive disorders [39].

Decision Aids

Neurocognitive disorders in adults with chronic kidney disease alter decision-making about dialysis treatment and reduce self-care dialysis. There is no high-quality evidence

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 75.3 Treatment for neurocognitive disorders in adults and children with chronic kidney disease.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Screening	We suggest that the certainty of the evidence for screening to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent (data from randomized controlled trials are absent)	No recommendation
Cognitive remediation or rehabilitation	We suggest that the certainty of the evidence for cognitive remediation or rehabilitation to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation
Support interventions for caregivers	We suggest that the certainty of the evidence for support interventions for caregivers to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation
Decision aids	We suggest that the certainty of the evidence for decision aids to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation
Depression treatments	We suggest that the certainty of the evidence for depression treatment to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation
Cholinesterase inhibitors and *N*-methyl D-aspartate receptor antagonists	We suggest that the certainty of the evidence for cholinesterase inhibitors and *N*-methyl D-aspartate receptor antagonists to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation
Vascular risk factor management	We suggest that the certainty of the evidence for vascular risk factor management to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation
Kidney transplantation	We suggest that the certainty of the evidence for kidney transplantation is low (based on a consistent and temporal association in nonrandomized studies) such that transplantation may be considered as a clinical practice that may improve neurocognitive functioning for people with chronic kidney disease	Low	Low
Longer hours or frequent hemodialysis	We suggest that the certainty of the evidence for longer hours or more frequent hemodialysis to manage neurocognitive disorders is low. Frequent or longer hours hemodialysis may make little or no difference to neurocognitive disorders in adults with CKD. Data for children are limited.	Low	Low
Anemia treatment	We suggest that the certainty of the evidence screening to manage neurocognitive disorders is so low that a recommendation regarding use in clinical practice is too speculative	Very low or absent	No recommendation

These recommendations reflect a belief that most adults, children, and their caregiver would place a high value on avoiding risks of adverse events and uncertain treatments. GRADE assessment of the certainty of the evidence: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

for the use of decision aids to assist in decision-making about dialysis treatment or end-of-life care for people with chronic kidney disease and neurocognitive deficits. In older adults without cognitive impairment, decision aids may increase knowledge and risk perception, lower decisional conflict, and increase patient participation in the decision process [40]. The evidence to support palliative care interventions including decision aids, advance care planning, and end-of-life care in severe dementia is currently lacking and insufficient to inform care [41].

Therapy for Depression

Depression and neurocognitive disorders may coexist in chronic kidney disease. At present, there is no evidence that pharmacological or psychosocial interventions improve neurocognitive function in chronic kidney disease [42, 43].

Physical Activity

There is no high-quality evidence for exercise on neurocognitive functioning in chronic kidney disease, although a pilot study suggests exercise training during dialysis may help to preserve neurocognitive function [44]. There is no high-level evidence that aerobic exercise or increased fitness improves cognitive performance in older people, although potential benefits of high-intensity exercise have not been excluded [45]. Similarly, evidence is lacking for exercise in adults with major neurocognitive deficits.

Cholinesterase Inhibitors and *N*-Methyl D-Aspartate Receptor Antagonists

There are no high-level data published on cholinesterase inhibitors (tacrine, donepezil, rivastigmine, and galantamine) and *N*-methyl D-aspartate receptor antagonists (memantine), which are indicated for Alzheimer's disease and dementia with Lewy bodies and for major neurocognitive impairment [46]. Evidence of long-term benefits for these agents is currently limited for vascular disease-related neurocognitive deficits and may lead to withdrawal due to side effects in a substantial proportion of patients [47, 48].

Vascular Risk Factor Management

There is existing moderate or high certainty evidence that statin therapy and blood-pressure lowering therapy reduces cardiovascular events and death in adults with chronic kidney disease [49, 50], although evidence in dialysis patients suggests limited benefit for cholesterol-lowering therapy and treatment estimates for transplant recipients are imprecise [51]. The evidentiary basis for vascular risk factor management on neurocognitive functioning in chronic kidney disease is absent. There is high-quality evidence that statins given in later life to people at risk of vascular disease do not modify cognitive decline or major neurocognitive disorders [52].

Transplantation

Kidney transplantation is temporally associated with sustained but incomplete improvements in neurocognitive functioning for both adults and children with end-stage kidney disease [16]. Such clinical changes are moderate to large and appear to be directly related to kidney transplantation with documented biological changes in brain functioning, indicative of causality. Delayed transplantation in children is associated with greater cognitive disability, indicating the need to offer transplantation early among children to maximize social, educational, and vocational opportunities [53].

Longer Hours or Frequent Hemodialysis

Frequent or longer hours hemodialysis may facilitate greater clearance of uremic toxins, but there is a growing body of evidence indicating that hemodialysis may have deleterious effects on the brain, particularly because of cerebral ischemia and intradialytic hypotension. In the Frequent Hemodialysis Network (FHN) trials, there was no evidence that frequent (six times weekly) hemodialysis changed the cognitive subscale of the Beck Depression Inventory compared with conventional (three times weekly) facility hemodialysis [54]. In a nonrandomized longitudinal cohort study, there was no evidence of an association of cognitive dysfunction with hemodialysis compared with peritoneal dialysis after adjustment for potentially confounding factors [55], while in a second study, patients treated with peritoneal dialysis had higher cognitive function at 1 year [56].

Anemia Treatment

Although anemia may be associated with greater white matter change in people with chronic kidney disease, to date there is no high-quality evidence that anemia correction alters neurocognitive functioning [57].

Patient and Caregiver Needs and Preferences

Reporting of patient experiences, needs, and preferences related to neurocognitive function in the context of chronic kidney disease is limited. This information is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

needed to offer insights into the level of distress experienced by patients and caregivers and their perspectives on treatment preferences that can shape the future research priorities on cognitive dysfunction. In an editorial written by a patient who had experienced end-stage kidney disease since the age of 12, she spoke of being home schooled to maximize her schooling opportunities and described how teachers and administrators did not have high expectations for her survival, leading to low motivation "to help me succeed." She advocated for interventions to support positive outcomes of children and adolescents with chronic kidney disease to manage low cognition and information retention, and the loneliness of being different to peers [58]. Adult patients report being too sick to make sense of the information they have been given about treatment options for advanced kidney disease "The doctor might have mentioned it [continuous ambulatory peritoneal dialysis] but I was so sick at the time I didn't catch on to it." Often clinicians increase decisional burden on patients as their kidney function decreases and hence when their cognitive functioning may be more impaired [59]. The experience of caregivers for adults treated with hemodialysis is one of "progressive exhaustion," accentuated by psychological and behavioral changes experienced by patients [60]. Direct qualitative research evaluating patient and caregiver experiences of cognitive dysfunction is limited. Patient experiences of information provision about kidney transplantation correlate with a substantially higher likelihood of listing for kidney transplantation, suggesting that patient information processing is important to ensure access to optimal treatments in end-stage kidney disease [61].

Conclusions

In conclusion, neurocognitive disorders are common and variable among children and adults with all stages of chronic kidney disease. Neurocognitive disorders are characterized by white matter cerebral changes and are linked to cerebral microvascular pathology. For children, cognitive disorders are linked to worse educational and social outcomes, and become more entrenched with delays to kidney transplantation. Among adults, neurocognitive disorders may fail to be recognized and impair reasoning, executive functioning, information processing, and decision-making. Adults treated with dialysis are likely to be worst affected, while transplantation provides important but incomplete resolution. Adults with neurocognitive disorders may be less likely to choose self-care dialysis due to impaired information retention. Treatments to support educational, social, and independent functioning for children and adults and their informal caregivers affected by neurocognitive disorders are absent.

Introduction

Pruritus attributable to kidney dysfunction, or uremic pruritus (UP), is a common and distressing symptom that affects patients with chronic kidney disease (CKD). Multiple studies imply that nephrologists underestimate the prevalence of pruritus among their patients with end-stage kidney disease (ESKD) [1–4]. When identified, many clinicians are unaware of the effective treatments available for UP, while generally ineffective therapies (e.g. antihistamines) are among the most prescribed treatments [1, 4]. Determining the causes, effective treatments, and preventative measures for UP was found by a steering committee of patients, caregivers, researchers, and clinicians in 2014 to be among the top 10 research priorities for kidney disease [5]. Despite this, many obstacles to its effective identification and management remain.

This chapter reviews the available evidence surrounding the symptom of pruritus as it affects patients with CKD. It outlines the epidemiologic data reported worldwide, describes what is known regarding the pathogenesis of UP, and outlines its clinical presentation, diagnosis, assessment tools, and available treatment options. The available studies on the treatment of UP are generally limited in quality and size but do allow for the proposal of a rational approach to diagnosis and management.

Epidemiology

Pruritus is common in patients with progressive CKD. The most comprehensive epidemiologic data on UP come from the Dialysis Outcomes and Practice Patterns Study (DOPPS) [4, 6], a large-scale observational study of over 35 000 hemodialysis patients compiled from 21 countries over the past 20 years. The most recent data from DOPPS-5, collected from 7629 patients from 17 countries in 2012 to 2015, reported a prevalence of moderate-to-extreme pruritus of 37% [4].

In addition to the DOPPS data, another 46 studies available via PubMed from over 20 countries from 1973 to 2018 reported the incidence of pruritus in ESKD patients; these data pooled together include another 11 032 total independent dialysis patients, with a mean weighted prevalence of pruritus of 50.5% [7–52]. Similarly, a meta-analysis by Hu et al. [53] compiled 42 studies published between 1988 and 2016 of 11 800 dialysis patients (including 17 studies and 3447 patients from China or Taiwan) and yielded a cross-sectional prevalence of pruritus of 55%, which is virtually the same prevalence reported in a systematic review of English-language studies by Murtagh et al. in 2007 [54].

Severity of pruritus is variably measured as further outlined below. Of the above prevalence studies, 19 included an assessment of severity of pruritus, including DOPPS [4] (Figure 76.1). If you pool the other 18 studies, the prevalence of moderate-to-severe and severe pruritus is 37.1 and 17.8%, respectively, among 6489 dialysis patients [18–35].

The prevalence of UP in ESKD patients has declined significantly over the past half century since the advent of dialysis [55], presumably related to improvements in dialysis modalities, access, and adequacy. Over the past two decades, however, the rate of decline has abated somewhat, with prevalence continuing to decrease only very slowly [4, 6, 56] (Figure 76.1).

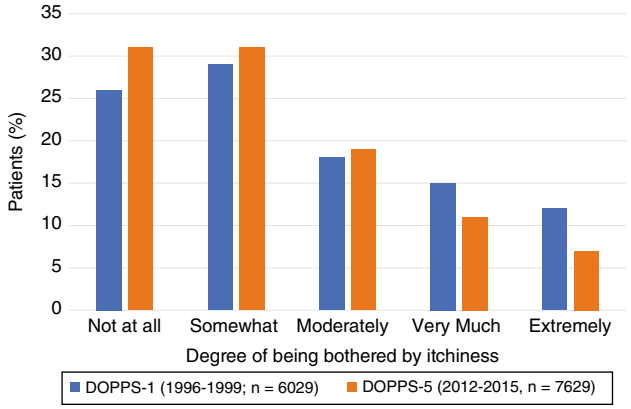

Figure 76.1 Prevalence and severity of uremic pruritus in hemodialysis patients in developed nations worldwide, 1996 to 2015. Question wording: "To what extent were you bothered by itchy skin during the past 4 weeks?" Data are from phases 1 and 5 of the Dialysis Outcomes and Practice Patterns Study (DOPPS). Overall, the percentage of hemodialysis patients being moderately, very, or extremely bothered by pruritus decreased somewhat from 45% to 37% between DOPPS-1 in 1996 to 1999 and DOPPS-5 in 2012 to 2015. DOPPS-1 data were compiled from 288 dialysis units in France, Germany, Japan, Spain, the UK, and the United States. DOPPS-5 data were compiled from 337 sites in Bahrain, Belgium, Canada, Germany, Italy, Japan, Kuwait, Oman, Qatar, Russia, Saudi Arabia, Spain, Sweden, Turkey, the UK, the United Arab Emirates, and the United States. Created using data from Pisoni et al. [6] and Rayner et al. [4].

Prevalence appears to vary significantly by geographical region and, within a given region, from center to center. DOPPS-5 reported a prevalence of moderate-to-extreme pruritus that ranged from as low as 26% in Germany to as high as 48% in the U.K [4]. Prior DOPPS reports reported a range between facilities of UP prevalence of 5–75% across nations and of 20–70% within Japan [6, 56].

The prevalence of UP in less developed countries has been far less studied but appears to be similar. Five studies from Burkina Faso, Cameroon, Nepal, and Nigeria published since 2008 collectively reported an incidence of pruritus of 37.3% among 351 dialysis patients [44–48].

Relatively few studies include data on the prevalence of UP in both patients on hemodialysis and those on peritoneal dialysis (PD). Comparisons are limited by variability in study size, measures of pruritus, and dialysis adequacy. The data overall are quite mixed. While some studies report higher rates or severity of UP in hemodialysis patients [8, 11] and others report higher rates in PD patients [35–37], the majority report rates of pruritus that are similar or statistically the same [13–18, 53]. Interestingly, only two observational studies have been carried out to explicitly compare UP rates in hemodialysis and PD; both were published in 2016, included several hundred patients, and adjusted for confounding factors, but came to opposite conclusions [11, 36].

The prevalence of UP in patients with CKD not requiring or not electing to undergo dialysis is not well reported, but it appears to be common. In a study of 49 ESKD patients managed without dialysis whose symptoms were analyzed in the month preceding death, pruritus, with a prevalence of 74%, was the second most common of 39 symptoms assessed and was very distressing in 32% [57]. However, it is not clear that conservative kidney management of ESKD results in more severe pruritus. In a study in Hong Kong of 45 ESKD patients managed with nondialytic palliative care services and 134 managed with dialysis, pruritus was the third most common and the sixth most intense out of 23 ESKD-related symptoms; however, the nondialytic group had statistically lower pruritus intensity and a nonsignificant trend toward lower pruritus prevalence (57.8% vs. 65.7%) [58]. The finding that dialysis may not reduce the prevalence of pruritus among ESKD patients has been reproduced in several other studies [18, 46–51].

The largest study of pruritus in exclusively predialysis CKD patients was published in 2016 by Solak et al. in Turkey [59]. Among 402 patients with CKD stages 2–5, including 83% stages 3–4, the prevalence of UP was 18.9% [59]. When pooling the available predialysis CKD data, the weighted mean prevalence of pruritus is 24.0% among 804 patients [46–51, 59].

Data on pruritus after renal transplant are limited. Some reviews report that pruritus is uncommon after transplant, even in those with recurrent CKD [55, 60], citing data from 1982 that only 2% of post-transplant patients experience pruritus [40]. However, modern studies report the prevalence of pruritus indeed decreases substantially (by roughly half) after renal transplantation, but it remains significant at 25–38% [61, 62].

Similarly, data about UP in children are limited. A 1999 study of 199 children in Germany reported that pruritus among children on dialysis is less common (9.1% vs. 18.8% prevalence) and less severe than in adult dialysis patients [55]. Another study of 30 children with advanced CKD in the United States reported incidences of pruritus closer to those reported in adults, specifically 50%, 69%, and 25% among those treated with transplant, dialysis, and conservative kidney management, respectively [63].

A variety of patient and dialysis characteristics have been associated with an increased burden of UP, including lower dialysis adequacy (i.e. Kt/V) [12, 36, 64, 65], use of certain dialysis membrane types [33, 66], viral hepatitis infection, liver disease, and/or elevated transaminases [4, 6, 11–14, 24, 56, 67], smoking [6, 56], older age [4, 6, 41, 56], male gender [6, 13, 30, 56], and underlying depression [6, 28, 29, 68]. However, multiple studies analyzing these very same factors have failed to replicate these associations and a few have yielded contrary associations, particularly with regard to Kt/V, age, and gender [4, 7, 27, 31, 33, 64].

Clinical Significance

UP has been repeatedly demonstrated to decrease quality of life (QoL), to contribute to other symptoms, especially poor sleep, that further impair QoL, to be associated with depression, and to be an independent predictor of poor outcomes, including mortality [6, 10, 17, 28–32, 39, 46, 56, 68–70].

In specifically the DOPPS-1 and -2 cohorts (1996–2004, $n = 18\,801$), dialysis patients with moderate-to-extreme pruritus were statistically more likely to feel drained, have poor sleep quality, and be diagnosed with depression [6]. Those with extreme pruritus had physical and mental QoL scores 15–20% lower than patients without pruritus [6]. They also found a 17% increase in mortality associated with moderate-to-extreme UP, but this difference was no longer statistically significant when adjusting for sleep quality [6]. The associations between UP and feeling more drained, poorer sleep quality, increased rate of depression, lower physical and mental QoL scores, and increased mortality were replicated in the Japanese DOPPS-3 cohort (1996–2008, $n = 6480$), with the exception that the mortality relationship persisted even after adjustment [56]. The independent association between moderate-to-severe UP and mortality was replicated in a prospective multivariate survival analysis of 321 chronic hemodialysis patients in Taiwan [26]. In a cross-sectional study of 980 hemodialysis patients in Brazil, patients with severe pruritus had a 25% decrease in kidney disease burden-related QoL, a decrease driven primarily by sleep disturbance, depressive symptoms, and dry skin [32]. Another study of US hemodialysis patients by Mathur et al. also reported a statistically significant impact of UP on QoL and on mood, social relations, and sleep; they noted that a decrease in intensity of UP of 20% was sufficient to produce a significant improvement in QoL [10]. Similar findings have been reproduced in Germany, Italy, Poland, and the UK [17, 28, 39, 69]. Yamamoto et al. followed the Japanese DOPPS cohort longitudinally and showed, interestingly, that baseline depressive symptoms predicted the subsequent development of severe pruritus in hemodialysis patients [68].

Limited data have also demonstrated a statistically significant impact of pruritus on QoL in both renal transplant recipients [61, 62] and predialysis CKD patients [46].

Clinical Presentation

The clinical presentation of pruritus in CKD varies greatly from patient to patient. Prospective observational longitudinal studies of hemodialysis patients in both the United States ($n = 103$) [10] and Germany ($n = 860$) [31, 70] have detailed a variety of the clinical aspects of UP. The majority of patients have itching daily or nearly daily [10, 31, 70]. Most patients have itching that affects large, discontinuous but bilateral and symmetric areas of skin [10]. Itching generally is worse at night than during the day [10, 13, 70]. Interestingly, in the German cohort, over 50% of the patients described their UP with terms suggestive of a neuropathic process, such as "tingling, sharp, burning and painful" [70]. The affected areas most commonly include the back, arms, legs, and scalp [13, 31, 70] and may remain constant or migrate over time [10]. Precipitating or aggravating factors vary significantly among patients but commonly include heat, dialysis, stress, cold, physical activity, showering, and rest or sleep [13, 38, 39, 70]. Unfortunately, most affected patients will continue to have the pruritus for months to years [10, 31, 70].

On examination, apart from near-universal xerosis, many patients with UP will have normal skin. However, others may have secondary cutaneous phenomena such as pigment changes, excoriations, nodule formation (i.e. prurigo nodularis), skin thickening (i.e. lichenification), and less commonly perforating or blistering lesions such as acquired perforating dermatosis or pseudoporphyria (Figure 76.2) [8, 18–20, 45, 47–50, 70–72]. However, in patients with abnormal appearing skin, nonuremic causes of pruritus must be considered.

Indeed, as the presentation of UP can be variable, it may be difficult to differentiate it from other causes of itch. A nonuremic cause for pruritus should generally be considered in patients who are refractory to a reasonable trial of treatment, whose symptoms are largely asymmetric, with bullous or ulcerating lesions, or with clinical findings characteristic of other systemic diseases. Additionally, pruritus may manifest as a reaction from recently initiated or long-standing drug. Table 76.1 outlines a differential diagnosis of nonuremic and treatable causes of itch in patients with CKD [74].

Pathophysiology

The pathophysiology underlying pruritus in general has been increasingly elucidated over the last few decades, though much remains to be explained. The first neuron type found to transmit itch was the histamine-dependent slowly conducting unmyelinated C-fiber, but a variety of nonhistaminergic neurons have subsequently been discovered that are likely also involved in the neural pathways that produce itch, which may account for the common clinical finding of pruritus being unresponsive to antihistamines [75, 76].

UP has been less extensively studied than pruritus in general and may be caused by mechanisms different than those underpinning pruritus from other etiologies. Five

Figure 76.2 Typical skin changes observed in patients suffering from uremic pruritus. (a) Scratch marks with excoriations at the lower leg. (b) Prurigo nodularis: typical hyperkeratotic partly excoriated nodules located on the forearm. (c) Deep scars and prurigo nodules on the shoulders and back of a female patient. (d) Acquired perforating dermatosis: multiple papulonodular lesions over the lower extremities with central crusting in a 45-year-old woman with ESKD. (e) Pseudoporphyria: multiple erosions associated with skin hyperpigmentation involving the dorsal aspect of the hands of a 60-year-old man with ESKD. *Source:* Reproduced with permission from Mettang and Kremer [71] and Kurban et al. [72].

abnormalities specific to CKD that have been proposed to mediate UP include (i) changes associated with hyperparathyroidism, (ii) structural skin alterations, (iii) systemic inflammation and immune dysregulation, (iv) imbalance of the endogenous opioid system, and (v) primary alterations in nociceptive sensory pathways [73, 77, 78].

The possible role of hyperparathyroidism and calcium-phosphate balance in the pathophysiology of UP was first proposed over a half-century ago [79]. Though data to support this theory are limited at best, per the most recent DOPPS-5 data most practicing nephrologists worldwide still believe phosphorus control to be the most important

factor in treating pruritus in ESKD [4]. While multiple observational studies have revealed associations between UP and higher serum calcium, phosphorus, and/or calcium-phosphorus product [6, 9, 11, 27, 30, 35, 56, 64, 66, 80] or serum parathyroid hormone (PTH) [9, 14, 19, 29, 30, 56, 66], these findings have not been replicated consistently [4, 7, 8, 10, 12, 13, 16, 17, 22–24, 32, 34, 36, 37, 41, 42, 59, 65, 81]. For example, DOPPS-5, the largest observational cohort of UP currently available, failed to reveal any statistically significant correlation between pruritus and calcium, phosphorus, their product, or PTH levels [4]. A direct role of PTH on the skin appears unlikely as intradermal injection of human PTH fragments elicits no cutaneous response and PTH itself is not present in the skin of ESKD patients with UP [82]. Limited data also suggest that UP does not correlate with the presence of radiographic renal osteodystrophy [80]. However, the role of mineral metabolism in UP may be more complex than can be appreciated from serum analyses alone. For example, small studies have demonstrated increased deposition of calcium and phosphorus in the skin tissue of ESKD patients with UP [83, 84].

Multiple studies have found UP to be associated with xerosis (dry skin) [20, 31–35, 43, 50, 59, 70], which specifically correlates to reduced stratum corneum hydration in ESKD patients with UP [35]. The possible pathogenic role of xerosis in UP is implied by some evidence that improving skin hydration can ameliorate UP [35, 85]. However, some patients with severe xerosis do not have pruritus, suggesting that it is more likely to be an aggravating rather than a principal causative factor [71]. Other skin changes documented in patients with ESKD that may play a role in UP include abnormal skin pH, reduced sebum and sweat excretion, sweat gland atrophy, and impaired skin perfusion during hemodialysis [86–88]; however, the data linking these abnormalities specifically to UP are limited and inconsistent [88].

An increasing body of evidence links UP to inflammation. Multiple reports, including DOPPS-5, have found UP to be associated with increased serum C-reactive protein [4, 7, 12, 24, 26, 42, 89] and depressed serum albumin [4, 6, 36, 90, 91], the latter having been proposed to be primarily a marker of inflammation in ESKD [92]. Furthermore, patients with UP have been shown to have elevated serum levels of interleukin-2 [93], interleukin-6 [89], and interleukin-31 [12], three proinflammatory cytokines that have been implicated as mediators of pruritus from psoriasis and other dermatologic diseases [94–96]. A variety of other inflammatory mediators, such as the neuropeptide substance P (the proposed target of capsaicin) [97] and various proteases [98], may also be involved in UP, although data to support their roles remain limited or inconsistent [14, 71, 74, 99].

Investigation of the possible role of opioid receptors in pruritus stems from the common clinical observation that mu-receptor agonists, especially if given by the epidural or spinal route, can cause or worsen pruritus [99]. A series of animal studies has further elucidated the role of central opioid receptors in mediating pruritus, including histamine-independent pruritus mediated by substance P [100–102].

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Whereas central mu-receptor agonism enhances pruritus induced by substance P or histamine, central kappa-receptor agonism inhibits this effect (Figure 76.3) [100–102]. Contrary to the antipruritic effect of scratching (i.e. pain), the pruritus induced by mu-opioid agonists is felt to be mediated by disinhibition of a central itch response associated with their antinociceptive properties [103]. The importance of this opioid system in UP is suggested by several studies showing that serum levels of endogenous opioids, such as beta-endorphin, are elevated in patients with ESKD [106–108] and/or increase during hemodialysis [109], though other studies have failed to replicate these findings [110, 111]. Furthermore, an increasing number of therapeutic trials, discussed below, have been carried out using opioid modulators and have shown promise.

The central role of the nervous system in mediating chronic itch (which would include UP) has been increasingly elucidated over the last few decades [76, 112]. The tendency for UP to be distributed with "striking mirror symmetry" has been proposed to be a reflection of a central or neurogenic etiology [10]. Similarly, altered itch perception is implied by a study in which histamine- and serotonin-induced skin flares in hemodialysis patients were found to be statistically smaller than in non-ESKD controls despite similar or higher perceived itch in the hemodialysis patients [113]. As previously mentioned, some patients describe their UP with neuropathic terms such as "tingling, sharp, burning, and painful" [70]. Prior immunohistochemical studies have shown patients with ESKD with or without pruritus, but not healthy controls, "sprout" small unmyelinated cutaneous nerve fibers in an abnormal distribution throughout the epidermis [114]. Clinically, UP and neuropathy and/or paresthesia have also been found to coexist in a substantial proportion of patients and to be statistically correlated [25, 115], with one study reporting that over 70% of ESKD patients with neuropathic pain, including those with electromyography-proven neuropathy, also have pruritus [116]. Finally, the efficacy of gabapentin in the treatment of UP serves as fairly compelling support for the neuropathic theory of UP [117].

The putative role of histamine in UP warrants specific discussion given antihistamines remain, even as recently as 2015, the most prescribed agents by nephrologists for UP [4]. While histamine may play some role in UP, with some proposing histamine release from mast cells as a final common pathway for the various mechanisms underpinning UP [74], data to support this remain inconsistent, with some reports showing a correlation between

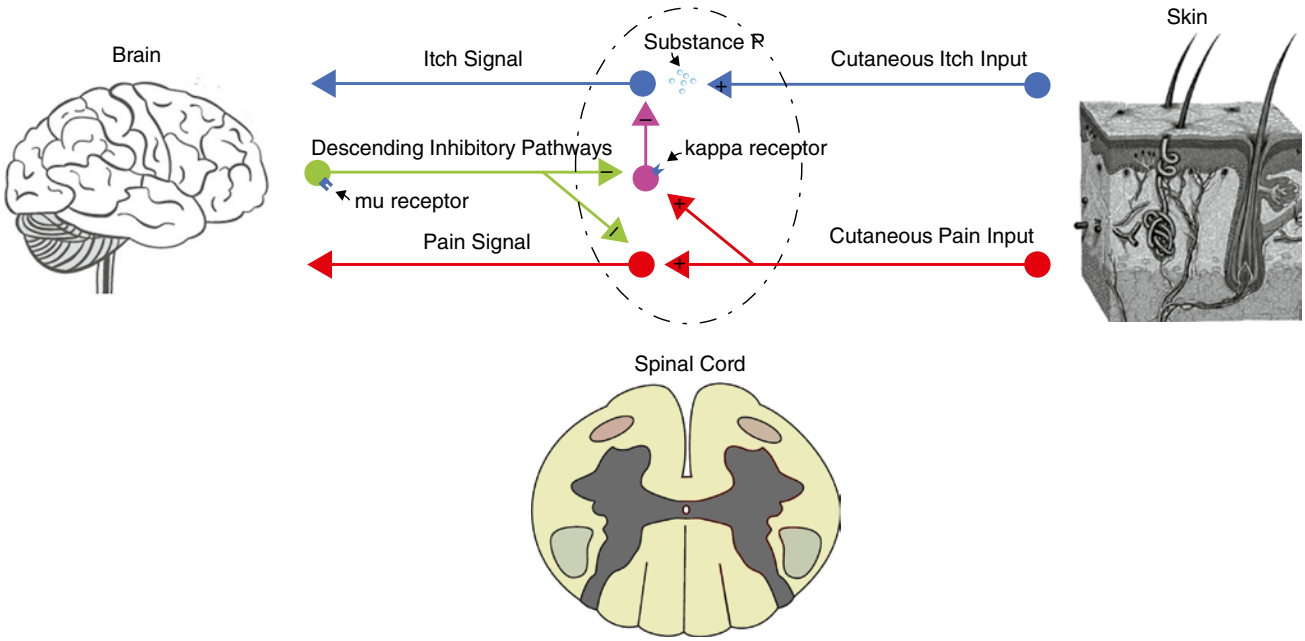

Figure 76.3 Simplified schematic of the opioid hypothesis of pruritus and of the interplay of pruritus and pain. Histamine-independent afferent cutaneous itch fibers transmit itch signal to the brain via release of neurotransmitters such as the neuropeptide substance P in the spinal cord (blue). Scratching is thought to inhibit the sensation of itch via stimulation of cutaneous pain fibers (red) which activate inhibitory interneurons (magenta) in the spinal cord. Mu-opioid receptor antagonists are thought to cause pruritus in the central nervous system via stimulation of descending inhibitory pathways (green) which, in addition to mediating (in part) their antinociceptive properties, disinhibit central itch signaling. Kappa-opioid receptor agonists, in contrast, inhibit itch signaling by binding to their receptors on inhibitory interneurons in the spinal cord. *Source:* Figure adapted with permission from Schmelz [103], incorporating content from Akiyama et al. [104] and Kardon et al. [105].

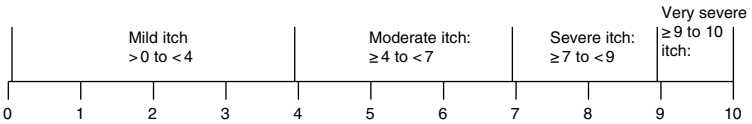
UP and plasma histamine levels and/or skin mast cell number, proliferation, or activation [51, 91, 98, 118] while others have not [16, 84, 119]. Possibly the strongest and most clinically relevant argument against a principal role for histamine in the mediation of UP, as further discussed and referenced below, is the consensus that H1 receptor antagonists are generally ineffective in the treatment of UP [120].

Evaluation

Prior to initiating treatment for pruritus, it is helpful to obtain information regarding its severity to track response to therapy. Pruritus is a symptom and is thus inherently subjective. Scratch lesions can be quantitated; however, this assessment method often fails to capture the significance of pruritus to patients. Therefore, pruritus is typically assessed via patient-reported outcomes (PROs). Because QoL, sleep disturbance, anxiety, and depression are strongly associated with pruritus intensity, these measures are often included in UP assessment tools. Several PRO scales have been validated for use in UP [121]. Monodimensional measures, such as the visual analogue scale (VAS; Figure 76.4a), address one symptom at a time with one scale and are simple and fast but are subject to confounding factors that affect QoL. Multidimensional measures, such as the ABC questionnaire [10] (Figure 76.4b), track more than one symptom, change in symptoms over time, or more than one assessment of a particular symptom, but often do not provide quantitative values and may be difficult for patients who must make unequivocal selections of a category. Table 76.2 lists several PRO scales validated for use in UP and recommendations for their use.

Treatment

Most of the published data regarding treatment of UP are either retrospective or derived from underpowered prospective studies, therefore treatment recommendations remain largely based on expert opinion. Here we outline the most common available therapies for UP and the evidence that supports them (Table 76.3).



(a)

Which of these patients are you most like? (Mark One)

Patient A:

I do not generally have scratch marks on my skin.
I do not generally have a problem sleeping because of itching.
My itching does not generally make me feel agitated or sad.

Patient B:

I sometimes have scratch marks on my skin.
I sometimes have problems sleeping because of itching.
My itching can sometimes make me feel agitated or sad.

Patient C:

I often have scratch marks on my skin that may or may not bleed or get infected.
I often have a problem sleeping because of itching.
My itching often makes me feel agitated or sad.

(b)

Table 76.2 Symptom scales validated for use in the evaluation and treatment of uremic pruritus.

Measurements	Tools (and references)	Advantages	Disadvantages	Recommended use
Pruritus intensity (unidimensional)	Visual Analogue Scale (VAS) [123] Numerical Rating Scale (NRS) [122, 123] Verbal Rating Scale (VRS) [123]	Simple and fast	Score may reflect other nonitch factors	Routine clinical use
Pruritus intensity (multidimensional)	Itch Severity Scale [124]	Simple and fast	Patients may face difficulties in unequivocal selection of a category	Clinical trials
	Self-Assessed Disease Severity (ABC Scale) [10]	Simple and fast	Not quantitative	Routine clinical use and screening for clinical trials
	Brief Itching Inventory [10]	Assesses quality of life and dermographic distribution	Not quantitative	Clinical trials
	Skindex-10 [10]	Assesses quality of life	Not quantitative	Clinical trials
	Itch MOS (Medical Outcomes Study) [10]	Assesses sleep disturbance		Clinical trials
Pruritus course	5-D questionnaire [125]	Comprehensive	Not yet conclusively validated	Clinical trials
Tracking response to treatment	Patient Benefit Index for pruritus (PBI-P) [126]	Assesses response to treatment	Longer survey (27 variables); harder to use systematically in routine clinical care	Especially useful for setting patient-specific therapy goals

Topical Treatments

As discussed, xerosis is found in most patients with ESKD and frequently aggravates pruritus. Skin hydration with aqueous cream emollient [35] and baby oil [127, 128] have both been demonstrated to effectively reduce skin dryness and severity of UP and improve patient QoL when applied two to four times daily. Given the benign side effect profile of emollients and the burden of xerosis in patients with ESKD, the cornerstone of UP therapy is adequate skin hydration.

In addition to pure emollients, other topical agents have been used with some success to treat pruritus (Table 76.3). For example, several small placebo-controlled trials have demonstrated symptom relief with 0.025–0.03% capsaicin ointment applied two to four times daily to affected areas [129–131]. Capsaicin was generally well tolerated apart from initial burning on application and, as such, is presumed to be more useful in patients with localized rather than generalized pruritus [129–131]. Similarly, 1% pramoxine hydrochloride lotion was tested in a single-center randomized double-blind study of hemodialysis patients and demonstrated statistically significant effectiveness when applied twice daily for 4 weeks [132].

Tacrolimus, formulated as a 0.1% or 0.03% ointment (Protopic, Astellas Pharma US, Inc.), is a topical immunomodulating agent that has been approved for the treatment of atopic dermatitis. Its use in treating UP has been tested in a few small single-center studies with conflicting results [134–136]. Additionally, in response to case reports and animal studies reporting rare associated malignancies such as lymphoma and skin cancer, the United States Food and Drug Administration (FDA) issued a black box warning in 2005 for tacrolimus ointment and recommended that its use be limited to those who have failed other therapies and to treatment periods of less than 6 weeks. However, as discussed, most patients with UP are affected for months to years [10, 31, 70].

Systemic Treatments

Of all the systemic therapies currently used for treatment of UP, gabapentinoids have most consistently demonstrated success in small clinical trials. Recently Simonsen et al. published a systematic review of UP treatments and found nine studies of adequate quality evaluating gabapentin or pregabalin; they concluded that, though long-term data are lacking, there was an overall statistically

Table 76.3 Summary of evidence: treatment of uremic pruritus.

Treatment (and references)	Recommended dose in ESKD	Recommendation	Common side effects/toxicity	Certainty of evidence (GRADE)	Strength of recommendation
Topical					
Emollients [35, 127, 128]	Apply 2–4 times daily	We suggest routine use in all patients with uremic pruritus, particularly in those with dry skin	Minimal	Very low	Weak
Capsaicin [129–131]	Apply 0.025–0.03% ointment 2–4 times daily	We suggest a trial of capsaicin be used on affected areas in those with localized uremic pruritus	Local skin burning, stinging, or redness	Low	Weak
Pramoxine [132]	Apply 2–4 times daily	We suggest pramoxine be considered as alternative topical therapy prior to systemic treatment	Minimal	Low	Weak
Gamma-linolenic acid [133]	Apply four times daily	We suggest gamma-linoleic acid be considered as alternative topical therapy prior to systemic treatment	Minimal	Low	Weak
Tacrolimus ointment (Protopic) [134–136]	N/A	We suggest tacrolimus ointment not be used in patients with UP	Skin warming; FDA black box warning (concern for malignancy)	Very low	Weak
Pharmaceutical					
Gabapentin [117, 137–141]	100–300 mg PO thrice weekly after HD; 100–300 mg PO qHS in PD[a]; 100 mg PO every other night to 300 mg PO qHS in CKD5-CKM	We suggest a trial of gabapentin be used, starting at lowest dose, for generalized UP not responding to topical therapy	Somnolence, dizziness, drowsiness, loss of balance, tremulousness, risk of misuse	Low to moderate	Weak
Pregabalin [116, 142–144]	25–75 mg PO thrice weekly after HD; 25–75 mg PO qHS in PD[a]; 25 mg every other night to 75 mg qHS in CKD5-CKM	We suggest a trial of pregabalin be used, starting at lowest dose, for generalized UP if not responding to or intolerant of gabapentin	Somnolence, dizziness, drowsiness, loss of balance, tremulousness, risk of misuse	Low	Weak

Table 76.3 (Continued)

Treatment (and references)	Recommended dose in ESKD	Recommendation	Common side effects/toxicity	Certainty of evidence (GRADE)	Strength of recommendation
Antihistamines [38, 73, 97, 113, 120, 145–149]	N/A	We suggest antihistamines not be used for UP	Anticholinergic side effects, confusion, sedation	Low	Weak
Naltrexone [37, 150]	N/A	We suggest naltrexone not be used in patients with UP	Stomach upset	Very low	Weak
Nalfurafine [151, 152]	5 μg PO daily or 5 μg IV thrice weekly after HD	Consider, if available[b], for those who fail trial of gabapentinoids	Insomnia, constipation, nausea, somnolence	Low	Weak
Nonpharmaceutical					
UVB phototherapy [153–157]	Variable	We suggest UVB phototherapy be used as second- or third-line therapy in refractory severe UP	Sunburn, tanning; possible increased risk of skin cancer (especially if immunosuppressed)	Low	Weak
Acupuncture [158]	N/A	We suggest acupuncture be considered as second- or third line therapy in interested patients with refractory severe UP	Mild pain	Very low	Weak
Dialysis prescription modification [12, 36, 64, 65, 117, 159]	N/A	We suggest high-flux HD and adequate dialysis adequacy as treatment for UP	N/A	Low	Weak

CKD5-CKM, stage 5 chronic kidney disease treated with conservative kidney management; ESKD, end-stage kidney disease; HD, hemodialysis; IV, intravenous; KDIGO, Kidney Disease: Improving Global Outcomes; KDOQI, Kidney Disease Outcomes Quality Initiative; N/A, not applicable; PD, peritoneal dialysis; PO, by mouth; qHS, nightly; UP, uremic pruritus.
[a] No data available specific to treatment of UP in setting of PD; suggested doses provided are derived from use in other settings.
[b] Currently not available except for in Japan.

significant benefit of gabapentinoids versus placebo [117]. More specifically, Nofal et al. studied 54 hemodialysis patients with pruritus and measured the efficacy of gabapentin versus placebo for 1 month. Gabapentin was initiated at 100 mg thrice weekly after dialysis and titrated up to a maximum of 300 mg thrice weekly, and 88.4% of treated patients had a 50% or more decrease in VAS score versus 22.2% of placebo patients [137]. Cheikh Hassan et al. published a single-center retrospective cohort study testing the use of gabapentin for the treatment of pruritus in CKD ranging from stage 3 to ESKD [138]. Gabapentin successfully reduced pruritus with a median daily dose of 100 mg; 14% of hemodialysis patients and 47% of nondialysis patients experienced one or more side effects, leading to a 17% discontinuation rate in the nondialysis group [138]. Gunal et al. enrolled 25 hemodialysis patients in a randomized placebo-controlled, double-blind trial of gabapentin at 300 mg thrice weekly after dialysis for 4 weeks and reported a significant decrease in mean VAS score from 7.9 to 1.2, with no dropout secondary to side effects [139]. Other small-scaled studies have demonstrated similar improvement in pruritus with similar doses of gabapentin following hemodialysis [140, 141]. Pregabalin (Lyrica, Pfizer, Inc.) has been demonstrated to be similarly effective for the treatment of UP [116, 142–144].

Many providers reasonably worry about the safety of gabapentinoids in patients, especially older patients, with kidney dysfunction. In the setting of the North American opioid epidemic, concern for misuse or abuse of gabapentinoids is also increasing. In 2016, gabapentin was the tenth most commonly prescribed medication in the United States while pregabalin ranked eighth highest in drug spending [160]. Patients are increasingly taking higher-than-recommended doses of gabapentinoids to achieve euphoric highs, and gabapentinoids are increasingly being identified in post-mortem toxicology analyses [161]. Possible risk factors for gabapentinoid abuse include current or prior substance abuse (particularly of opioids and benzodiazepines) and other underlying psychiatric comorbidities [161]. Specific to ESKD, a recent analysis of United States Renal Data System data revealed that 19% of US hemodialysis patients received gabapentin, of whom 43% received it at inappropriate doses (greater than 300 mg) [162]. Gabapentin use at these higher doses was associated with 50, 55, and 38% higher hazards of altered mental status, fall, and fracture, respectively [162]. Rather than avoiding gabapentinoids when indicated, we recommend that providers caution patients about the risks of taking medications beyond how they are prescribed, particularly in those at high risk for misuse, and to ensure that dosing is appropriate for each patient's kidney function, comorbidities, and frailty.

As mentioned above, a variety of studies have investigated opioid receptor modulators for the treatment of UP. Naltrexone (naltrexone hydrochloride, Teva Pharmaceuticals USA, Inc.), an oral mu-opioid receptor antagonist, was tested in two studies of the treatment of UP in ESKD at a dose of 50 mg daily; while the first study showed benefit, a subsequent larger and longer-term study did not [37, 150].

Nalfurafine (Remitch, Toray Industries, Inc.), a kappa-opioid receptor agonist, has been tested in oral and intravenous form in the treatment of UP. In an open-label single-arm prospective trial of 211 hemodialysis patients treated for 52 weeks with 5 μg of oral nalfurafine daily, 145 patients completed the study and experienced a significant decrease in mean VAS score from 75.2 to 30.9 at study termination [151]. The authors reported no evidence of drug dependence during the trial, though 48.8% of patients had adverse reactions, including insomnia (19.4%) and constipation (7.1%) [151]. At study termination, treatment effects of the medication appeared to rapidly reverse, but the subjects were not followed long enough to determine if VAS scores returned to baseline [151]. Similarly, Wikstrom et al. reported a statistically significant effect in two randomized, double-blind placebo-controlled trials of 144 hemodialysis patients with UP who received 5 μg of intravenous nalfurafine thrice weekly after dialysis for 4 weeks [152].

Nalbuphine ER (Trevi Therapeutics, Inc.) is an oral extended-release dual mu-opioid antagonist and kappa-opioid agonist currently under investigation for the treatment of UP. A recently published phase 2/3 double-blind, randomized, placebo-controlled trial in 47 sites in the United States, Romania, and Poland assigned 371 patients in a 1 : 1 : 1 ratio to placebo, nalbuphine 60 mg twice daily, or nalbuphine 120 mg twice daily for 6 weeks, with a primary outcome of change in numerical rating scale (NRS) scores [163]. The dose of 120 mg twice daily of nalbuphine produced a statistically significant benefit versus placebo with mean change in NRS of 3.5 versus 2.8 [163]. The authors reported "no adverse safety trends other than expected from a centrally acting agonist–antagonist opioid drug class" [163].

Cara Therapeutics, Inc. developed CR845, a "potent peripheral kappa-opioid receptor agonist," for the treatment of UP and presented preliminary results in a 2017 abstract [164]. The phase 2, double-blind randomized placebo-controlled study enrolled 174 hemodialysis patients with moderate-to-severe pruritus in the US and they received intravenous bolus placebo or CR845 at doses of 0.5, 1.0, or 1.5 μg/kg thrice weekly for 8 weeks. The dose of 0.5 μg/kg produced a statistically significant change versus placebo in their primary outcome, mean change in NRS at week 8 from baseline ($P < 0.001$). They

reported that this reduction in itch was associated with a "substantial improvement in multiple measures of itch-related QoL" and that CR845 was "well-tolerated." A phase 3 trial is now underway, and Cara Therapeutics was granted breakthrough designation for CR845 by the FDA in June 2017.

Finally, as previously noted, antihistamines are commonly used to treat UP. However, a few studies and a larger number of reviews all point to their general lack of efficacy in treating UP, with several reviews speculating that any perceived benefit seen with antihistamines is due to sedation rather than a true antipruritic effect [38, 73, 97, 113, 120, 145–149]. One small study specifically suggested that antihistamines are no more effective than emollients [38]. Another small study documented that the ability of antihistamines to prevent pruritus, which can be reproduced experimentally in normal patients, is specifically lost in patients with UP [113]. Furthermore, given the risk of side effects, such as confusion, sedation, and anticholinergic toxicity, particularly in an ESKD population that often is older with multiple comorbidities, antihistamines are generally not recommended as first- or second-line therapies for UP.

Hemodialysis Prescription Modification

There is a paucity of high-quality prospective data aimed at determining the effects of changing dialysis adequacy, modality, duration, or other measures on symptoms of pruritus. The limited prospective interventional [117, 159] and observational [64] data available generally support the use of high-flux hemodialysis, which is now the standard of care in most developed countries.

Phototherapy

In the late 1970s, Gilchrest et al. published several small studies of patients with CKD that demonstrated success of type B ultraviolet light (UVB) therapy in the treatment of UP, noting that some patients had generalized improvement in symptoms even when only part of the affected body parts were treated [153–155]. Tan et al. published a meta-analysis of randomized controlled trials of UP treatments in 1991 and identified UVB phototherapy as the only treatment available at the time that successfully fulfilled the criteria for clinical significance [156]. However, the most recent randomized controlled trial testing UVB therapy efficacy, published in 2011, did not demonstrate significant benefit [157]. Much is still unknown about the long-term effects of UVB therapy and its use should be carefully considered prior to initiation, particularly in patients who are immunosuppressed or in those who may soon undergo renal transplantation.

Acupuncture

Acupuncture is commonly used worldwide as a primary, adjunct, or alternative treatment for pain and other symptoms. Kim et al. published a meta-analysis of prospective clinical studies of needle acupuncture for UP in patients with ESKD and concluded that, despite six separate trials reporting the beneficial effects of acupuncture, most of the trials demonstrated high risk of bias and therefore current evidence is insufficient to support its efficacy [158]. However, acupuncture has virtually no lasting side effects and therefore could be very reasonably offered as an alternative therapy to interested patients with UP who do not respond to first-line treatments, who are unwilling to take systemic medications, or who have a particular interest in acupuncture.

Approach to Therapy

There are no formal published guidelines regarding the treatment of UP; however many reviews have published treatment recommendations [71, 77]. We recommend taking a stepwise approach to the treatment of UP, beginning with addressing contributing factors such as skin hydration, optimization of dialysis adequacy, and patient education on the importance of avoiding or minimizing scratching and the use of drying soaps. If symptoms persist, providers may offer pharmacologic or nonpharmacologic therapy starting with topical therapies, given lower risk of toxicity, before progressing to systemic treatments (Figure 76.5). Providers should approach treatment according to patient preference and with consideration of available resources, of potential drug–drug interactions and adverse drug reactions, and of their own comfort level in prescribing the various therapies.

Conclusion

UP is a common, often distressing, and yet frequently underrecognized symptom in patients with progressive CKD. UP itself and its associated symptoms significantly impair QoL. UP can present variably, but tends to affect large, discontinuous but symmetric areas of skin. A variety of alternative systemic or dermatologic conditions should be considered in the differential diagnosis of itch in patients with CKD, especially those with atypical features. The pathogenesis of UP remains poorly understood. There are likely multiple, coexisting mechanisms involved, beyond abnormal serum biochemistry, which does not appear to be a major driver of UP in the current era of dialysis. Available treatments for UP are suboptimal. Management of UP should focus initially on aggressive

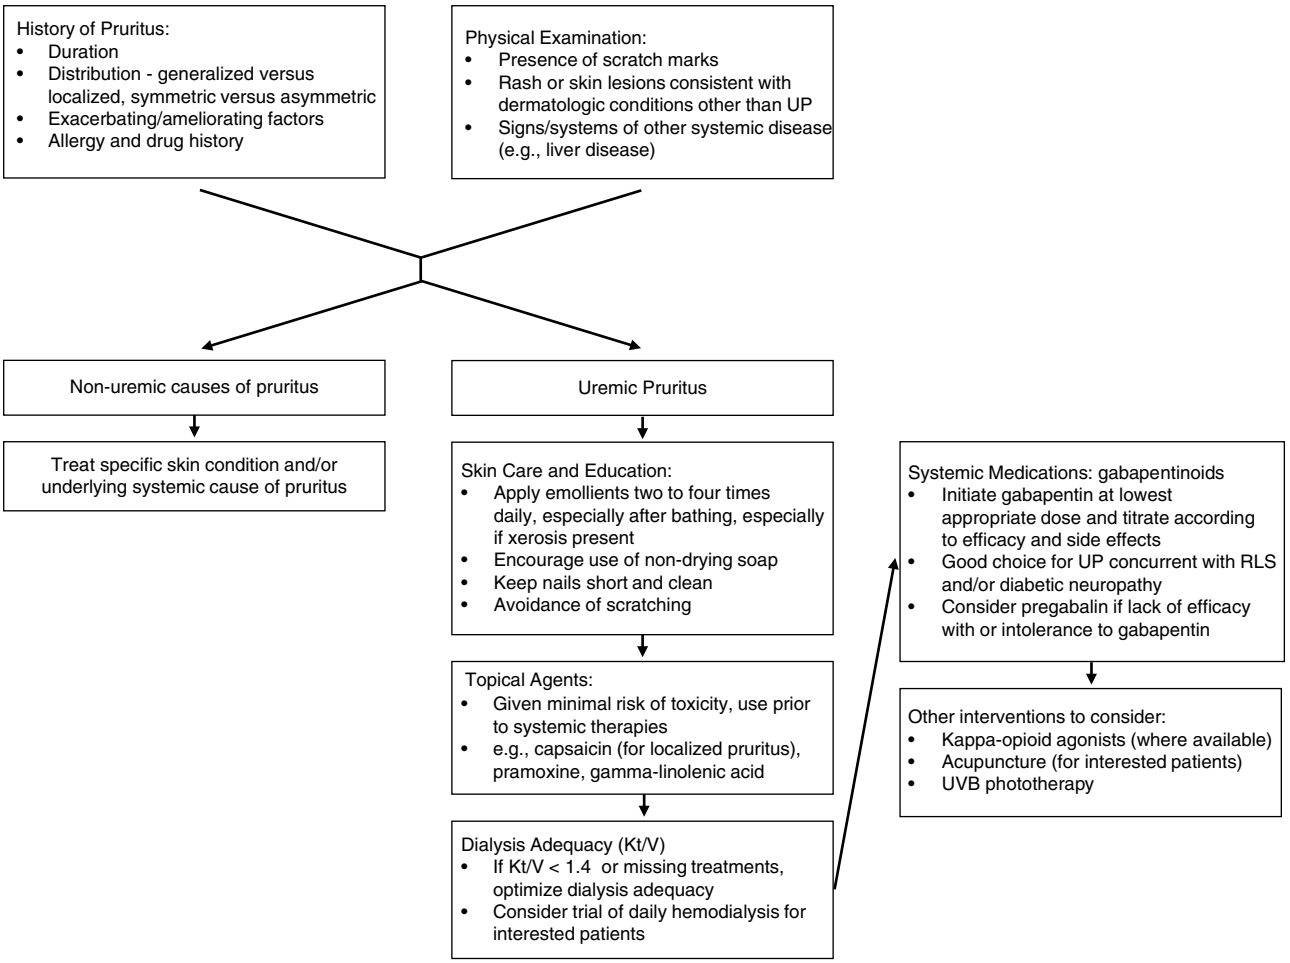

Figure 76.5 Step-by-step approach to the treatment of uremic pruritus. See Table 76.3 for further treatment details including dosing recommendations. UP, uremic pruritus; RLS, restless leg syndrome; UVB, type B ultraviolet light.

skin hydration, avoidance of drying soaps, and patient education on skincare, including minimization of scratching, before considering other therapies given the limited supporting data. A better pathophysiologic understanding of UP is needed for the development of more effective preventive and management strategies.

Introduction

Sexual dysfunction may be frequently experienced by patients who have chronic kidney disease (CKD) as measured by specific tools, although the impact of any sexual dysfunction on patients' lives and relationships may be less than previously understood [1]. The *Diagnostic and Statistical Manual of Mental Disorders 5* (DSM-5) classifies several distinct types of sexual dysfunction for men and women that have been present for at least 6 months and cause significant distress [2]. For men, these include erectile disorder, male hypoactive sexual desire disorder, delayed ejaculation, substance/medication induced sexual dysfunction, and other/unspecified sexual dysfunction. For women, these are female sexual interest/arousal disorder, genito-pelvic pain/penetration disorder, substance/medication induced sexual dysfunction, and other/unspecified sexual dysfunction.

Most information about sexual dysfunction is available for patients with CKD treated with dialysis or transplantation, while studies among those with earlier stages of CKD are infrequent [3]. The prevalence of sexual dysfunction is also challenging as existing measurement scales classify sexual inactivity as dysfunction and cannot completely capture the level of distress that patients may or may not experience in association with specific symptoms. For example, sexual difficulty in the presence of CKD has been reported in 2% of women treated with hemodialysis [4], although the true prevalence may have been impacted by the high prevalence of sexual inactivity among this patient group, which can result in overmeasurement on standardized diagnostic tools [3]. In a Swedish study, less than 45% of women with low sexual interest perceived these experiences as distressing [5]. In a meta-analysis of 50 observational studies, approximately 70% of men reported erectile dysfunction, with increased symptomatology occurring in association with depression, older age, and diabetes [3]. For men and women after transplantation, the frequency and personal importance of sexual activity may decrease, while relationship and life satisfaction may be maintained [6].

CKD leads to altered biological secretion of hypothalamic, pituitary, and gonadal hormones which usually act to maintain sexual function, including luteinizing hormone (LH), follicle-stimulating hormone (FSH), testosterone, estrogen, prolactin, and sex hormone binding globulins. In addition, comorbidities and medications can lead to hypogonadism or erectile dysfunction, including high body mass, diabetes, vascular disease, depression, and anemia, and medications including diuretics, beta blockers, calcium-channel blockers, and methyldopa.

Evidence for treatments of sexual dysfunction among people with CKD is sparse [7]. Therapeutic approaches include treatments leading to vasodilatation (phosphodiesterase 5 inhibitor), increased sex hormone concentrations (zinc supplementation, bromocriptine, testosterone, estrogen), local therapeutic approaches to reduce erectile dysfunction (vacuum tumescence devices, penile prostheses, intracavernous injection, transurethral injection), and psychotherapeutic and psychoeducational interventions. Recent systematic reviews of trials have shown that there is often low or very low certainty that treatment of sexual dysfunction makes a difference to the outcomes that directly impact on patients, including health-related quality of life [7].

Men and women with kidney disease are frequently sexually inactive. For men, there may be a desire for greater sexual activity, while women who are sexually inactive express satisfaction with their sexual function and have low interest in learning about treatments [4, 8]. Patients after transplantation may have lower sexual desire but have stable high relationship and life satisfaction.

This chapter examines the evidence for management of sexual dysfunction in adults with CKD.

Definition

Sexual dysfunction includes a range of clinical symptoms and experiences among people with CKD. A formal definition of sexual dysfunction is provided by DSM-5 [2]. Sexual dysfunction among men is categorized as erectile dysfunction, low sexual desire, delayed ejaculation, and altered sexual function related to substances or medication and other causes. Among women, abnormalities are altered sexual interest and arousal, genital and pelvic pain or pain on penetration, and altered sexual function due to substances or medications in addition to other causes. The DSM-5 indicates that for sexual dysfunction to be clinically present, it should occur at a frequency of 75–100% of the time for at least 6 months and lead to significant distress. Importantly, sexual dysfunction is excluded as a primary diagnosis when it might be explained by an alternative mental health diagnosis as a consequence of severe relationship distress (e.g. partner violence) or other significant stressors.

Epidemiology

The heterogeneity in clinical abnormalities of sexual dysfunction and the ability of diagnostic tools to measure the presence of clinical distress makes it difficult to determine its exact prevalence in patients with CKD. The prevalence of sexual dysfunction as measured by clinical scales, particularly for women, is highly dependent on sexual activity and the presence of a partner. The prevalence also depends on the stage and duration of CKD.

Hypogonadism (lower estrogen and testosterone release) occurs in 40–60% of patients treated with hemodialysis and 15–40% of people with CKD stages 1 to 4, and decreases in parallel with kidney function [9, 10]. The prevalence of erectile dysfunction is highly variable across existing studies (25–90%) and is probably more commonly experienced by men requiring dialysis that those with earlier stages of CKD and recipients of a kidney transplant [3]. It is unclear whether erectile dysfunction improves after kidney transplantation and is likely to relate to age, coexisting low testosterone levels, and comorbidity [11]. Available studies in CKD frequently use the International Index of Erectile Function (IIEF) to assess erectile function, although this measure evaluates symptoms limited to the previous 4 weeks and does not assess the psychological impact of erectile dysfunction on men [12].

The prevalence of sexual dysfunction in women with CKD has commonly been assessed using the 9-item Index of Female Sexual Function (IFSF) score and the 19-item Female Sexual Function Index (FSFI) score [13, 14]. These measures adjudicate that sexual dysfunction is present when a woman is sexually inactive, leading to widely disparate estimates of prevalence based on whether cohort analyses include or exclude sexually inactive women and those without sexual partners. In a recent large multinational cohort study of 1309 women treated with dialysis, about half responded to questionnaires and of the respondents nearly two-thirds reported no sexual activity, while the remaining one-third reported generally low sexual function across the domains measured (desire, arousal, lubrication, pain, satisfaction, and orgasm) [15]. In a different cohort of women treated with hemodialysis and participating in a clinical trial of symptom management strategies, sexual dysfunction was largely related to sexual inactivity in 82% of assessments [4]. Sexual inactivity was most frequently due to a lack of interest (43%) or partner (39%), while sexual difficulty was rare (2%). Approximately 5% of women expressed an interest in learning about the causes and treatment for sexual dysfunction in that study. Increasing focus on the need to measure distress related to sexual function as a component of the patient experience has resulted in the development and validation of scales to quantify sexual and relationship distress [16]. In 27 women with CKD and creatinine clearance ≤30 ml/min and not receiving dialysis, 44% reported distress compared with 22% of age-matched women without CKD [17].

Sexual dysfunction may persist after kidney transplantation despite resolution of abnormalities in the hypothalamic-pituitary-gonadal system. In a cross-sectional study, just over half of male kidney transplant recipients who were sexually active met criteria for erectile dysfunction [18].

Pathophysiology

Sexual dysfunction is multifactorial in CKD. Contributing causes include the hormonal changes associated with CKD leading to altered functioning of the hypothalamic-pituitary-gonadal axis, comorbidity including hypertension and vascular disease leading to altered blood flow to erectile tissues, medications, anxiety and depression, altered life priorities, and competing causes of distress that may lead to partner

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and relational challenges (Figure 77.1). Disturbances in the pituitary-gonadal axis occur with moderate kidney disease, are not recovered with renal replacement therapy, but may be reversed by kidney transplantation.

Progressive kidney disease and uremia alter the amino acid neurotransmitter outflow from the hypothalamus, leading to reduced pulsatile release of gonadotropin-releasing hormone (GnRH), and lower gonadotrophin synthesis and secretion [19]. Altered calcium and phosphorous levels in CKD also alter gonadotrophin release. Circulating plasma levels of LH are increased with renal impairment due to decreased clearance. Peak release of LH during pulsatile secretion is decreased, leading to lower serum testosterone levels, resulting in the diminished normal feedback suppression of LH by testosterone [20, 21]. Pulsatile release of LH may be completely absent for women with CKD.

Prolactin levels are commonly increased in men and women with CKD, and may result from autonomous secretion, normally inhibited by dopaminergic control. Hyperprolactinemia is linked to fertility, loss of libido, low testosterone concentrations, and inappropriately low LH in men with normal kidney function [22]. Zinc deficiency is common in CKD and may be associated with impaired gonadal function.

CKD may also directly impact ovarian and testicular hormones in addition to impairing function of the hypothalamus and pituitary tissues. Low testosterone levels occur for men due in part to reduced production, decreased free testosterone levels, and increased clearance, which result in decreased spermatogenesis. For women, uremia leads to loss of cyclical estradiol levels and impaired luteinization of follicles, impairing the normal rise in progesterone levels in the second half of the menstrual cycle [23, 24]. Altered cyclical hormones lead to anovulation, dysfunctional uterine bleeding, and infertility. In men, CKD is associated with impaired maturation of sperm and aplasia

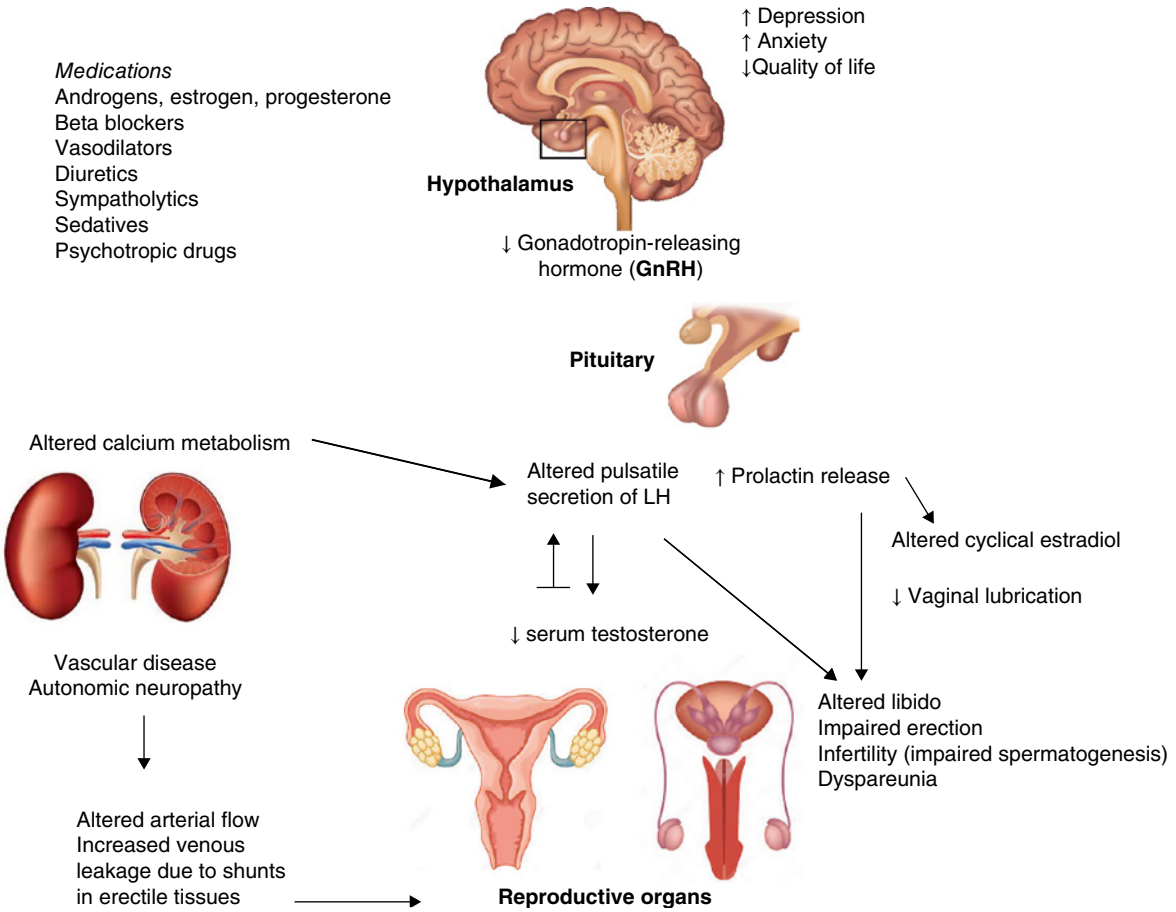

Figure 77.1 Pathogenesis of sexual dysfunction in chronic kidney disease. Some of the complex relationships between the hypothalamic, pituitary, and gonadal activity in adults with chronic kidney disease. Normal hypothalamic function is lost, leading to impaired gonadotrophin-releasing hormone (GnRH) and loss/decrease in pulsatile luteinizing hormone (LH) release. Increased prolactin levels impact the axis and hormonal release by ovarian and testicular tissues. Accelerated vascular disease and neuropathy impact erectile function directly, while circulating levels of testosterone and cyclical estradiol levels are reduced. Medications and cognitive stressors, depression, and anxiety all act to increase social and relational distress that may increase sexual dysfunction.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of germinal elements, damage to seminiferous tubules, interstitial fibrosis, and calcification.

Normal erectile function for men requires adequate arterial penile flow and smooth muscle action to block blood efflux from the cavernous space. Accelerated vascular disease may impair intracavernosal arterial blood pressure, even without clinical evidence of peripheral vascular disease. Men with CKD may first experience delayed erection, then subsequently reduced penile rigidity and nocturnal penile tumescence, and complete erectile loss. Penile erection is a complex sequence of changes in arterial vascular smooth muscle tone that may be impaired by neuropathy associated with renal failure. Medications, including antihypertensive therapies, may directly impair erectile function in CKD.

While the prevalence of depression and anxiety may be increased for men and women with CKD, there is conflicting evidence about the relationship between these conditions and sexual dysfunction among those with CKD [3, 25]. In a systematic analysis of cohort and cross-sectional studies, depression was frequently identified as a variable that showed significant association with sexual dysfunction in several studies [3].

Kidney transplantation is associated with reversal of the hormonal and endocrine abnormalities linked to sexual dysfunction among patients with end-stage kidney disease and may be associated with lower frequency of perceived sexual dysfunction [26–28].

Diagnosis

Men

Clinical History and Examination

The clinical diagnosis of sexual dysfunction is based on a thorough history and clinical examination to identify the primary issue (e.g. erectile dysfunction, low libido, infertility). Table 77.1 lists the potential factors involved in the pathogenesis of sexual dysfunction for men with CKD that can guide clinical inquiry and examination, and investigation.

During the clinical history-taking, a sexual, psychosocial, and medication history should be explored. A brief sexual symptom checklist may assist to identify the priority symptoms experienced by male patients (Table 77.2) [30]. There is no robust evidence from randomized controlled trials (RCTs) that screening for sexual dysfunction among patients with CKD improves patient-centered outcomes; systematic screening for sexual dysfunction in CKD is not currently recommended based on a lack of available evidence.

Table 77.1 Factors involved in sexual dysfunction in men with chronic kidney disease.

Gonadal function
Decreased testosterone production
Impaired spermatogenesis
Hypothalamic–pituitary function
Blunted increase in luteinizing hormone (LH) levels
Decreased amplitude of pulse LH release
Variable increase in FSH levels
Increased prolactin levels
Vascular disease
Impaired arterial inflow and venous drainage of penis
Autonomic neuropathy
Psychological factors
Anxiety
Depression
Medications
Sympatholytic
Beta blocker
Vasodilator
Diuretic
Sedative
Psychotropic drug
Altered calcium metabolism leading to altered pituitary function

Table 77.2 Brief sexual symptom checklist: men.

Over the previous 3 mo or more:

1) Are you satisfied with your sexual function?
2) If no, how long have you been dissatisfied with your sexual function?
3) The problem with your sexual function is: (all that apply)
   1) Problems with little or no interest in sex?
   2) Problems with erection?
   3) Problems with ejaculating too early during sexual activity?
   4) Problems taking too long, or not being able to ejaculate or have orgasm?
   5) Problems with pain during sex?
   6) Problems with penile function during erection
   7) Other
4) Which problem is most bothersome?
5) Would you like to discuss this problem?

Source: Based on Hatzichristou et al. [30].

Self-rating scales are available to evaluate for the presence of sexual dysfunction. Most published studies have used the full (15-item) or shorter (5-item) versions of the IIEF [12]. The IIEF is considered a screening instrument

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for the presence and severity of erectile dysfunction in the 5-item scale, and additionally orgasmic function and sexual interest in the full questionnaire. Cut-off scores in the IIEF scale for men have been proposed based on diagnostic accuracy analyses against blinded clinician interviews in the general population, although the diagnostic utility of these scales have not been critically appraised in the setting of CKD.

Based on the potential factors causing sexual dysfunction in CKD, a targeted history and examination exploring for presence of vascular disease, autonomic neuropathy, hyperparathyroidism, anxiety, depression, and medications is appropriate. Signs of peripheral vascular disease may indicate a contribution of arterial vascular disease to erectile dysfunction, although normal peripheral vascular findings do not exclude penile arterial abnormalities. Loss of secondary sexual characteristics (pubic, facial, and axillae hair, decreased muscle, and bone mass) suggest hypogonadal function. Features of autonomic neuropathy such as postural hypotension, loss of sweating, nocturnal diarrhea, urine retention, or loss of sinus arrhythmia may indicate a neuropathic contribution to sexual dysfunction. As men may have more than one factor contributing to sexual dysfunction, the finding of a physical abnormality can guide investigation and treatment, however additional causes still need to be considered and evaluated.

Investigations

Based on the likely etiology, investigations to evaluate for vascular disease and autonomic neuropathy may provide information about the possible factors leading to sexual dysfunction in men. These include Doppler ultrasound of the peripheral vasculature, remaining cognizant of the fact that erectile dysfunction may occur before the onset of clinically-apparent vascular disease [31]. Penile duplex Doppler ultrasound is rarely used as a diagnostic tool, and a systematic analysis in studies of men without CKD suggests there is currently a lack of standardization in performance and interpretation, and diagnostic cut-off values are extremely heterogeneous [32]. Assessment of autonomic neural function at the bedside may include testing for orthostatic hypotension without compensatory increased heart rate. Specific features of neurogenic bladder function may suggest a neuropathic origin to erectile dysfunction.

Endocrine testing that may assist to identify specific hormonal factors includes measurement of serum LH, FSH, testosterone, and prolactin levels. While patients with CKD have elevated prolactin levels, a serum prolactin level greater than 94 μg/l is discriminatory for a prolactinoma [33] and levels above 500 μg/l are diagnostic of a macroprolactinoma [34]. In the presence of serum prolactin levels >100 μg/l, imaging of the hypothalamic-pituitary region would be appropriate. Total serum testosterone should be measured early in the morning on at least two occasions in the absence of acute illness. A total testosterone level <10 nmol/l (300 ng/deciliter) suggests low testosterone, although the serum results should be interpreted in conjunction with symptoms [35]. Serum zinc levels may indicate zinc deficiency as a factor contributing to gonadal failure. Screening for depression or anxiety may be appropriate.

Women

Clinical History and Examination

As for men, the clinical diagnosis of sexual dysfunction is based on a thorough history and clinical examination to identify the key clinical issues, including menstrual disorders, infertility, and/or symptoms including vaginal dryness, pain or discomfort during sexual intercourse, low libido, decreased genital sensation, or difficulties with orgasm. Table 77.3 lists the potential factors contributing to sexual dysfunction for women.

Table 77.3 Factors involved in sexual dysfunction in women with chronic kidney disease.

Gonadal function
Anovulatory cycles
Loss of progesterone release
Hypothalamic-pituitary function
Blunted increase in luteinizing hormone levels
Decreased amplitude of pulse luteinizing hormone release
Low estradiol levels
Variable increase in follicle-stimulating hormone levels
Increased prolactin levels
Vaginal pathology
Vaginal dryness
Vaginal atrophy
Vascular disease
Impaired arterial inflow in genital tissue
Autonomic neuropathy
Psychological factors
Anxiety
Depression
Medications
Sympatholytic
Beta blocker
Vasodilator
Diuretic
Sedative
Psychotropic drug
Altered calcium metabolism leading to altered pituitary function

Source: Adapted from Palmer [29].

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

During the clinical history-taking, a sexual, psychosocial, and medication history should be explored. Specific questioning should include a menstruation history, including assessments for the presence of irregular menses, menorrhagia, and amenorrhea, and local vaginal symptoms including dryness and pain or discomfort on penetration. A brief symptom checklist may assist in the assessment of sexual dysfunction for women, including an understanding about whether women wish to discuss the problem (Table 77.4). Specific inquiry about the age of onset, frequency, distress, and partner-related issues are relevant. As for men, there is no high-certainty evidence that routine screening for sexual dysfunction in women with CKD improves clinical outcomes.

In women with CKD, the 19-item FSFI [14] is commonly used to evaluate six domains of sexual dysfunction (desire, arousal, lubrication, orgasm, global satisfaction, and pain) in the 4 weeks before questionnaire completion. Sexual inactivity leads to lower scores for rating items and may classify individuals who are sexually inactive as having sexual dysfunction. The diagnostic utility of the FSFI to identify sexual dysfunction causing distress for women with CKD is unknown. A modified FSFI can identify the reasons for sexual inactivity and whether the woman is interested in hearing more about the causes and treatments for sexual dysfunction [4].

Identification of sexual dysfunction causing distress should prompt a targeted history and examination to evaluate for presence of vascular disease, autonomic neuropathy, local genital, vaginal, and uterine abnormalities, secondary sexual characteristics, and hyperparathyroidism.

Investigations

Targeted investigation may identify a specific factor contributing to sexual dysfunction. Laboratory testing should be guided by patient symptoms and examination findings.

Table 77.4 Brief sexual symptom checklist: women [30].

Over the previous 3 months or more:

1) Are you satisfied with your sexual function?
2) If no, how long have you been dissatisfied with your sexual function?
3) The problem with your sexual function is: (all that apply)
   1) Problems with little or no interest in sex?
   2) Problems with decreased genital sensation?
   3) Problems with decreased vaginal lubrication (dryness)?
   4) Problems reaching orgasm?
   5) Problems with pain during sex?
   6) Other
4) Which problem is most bothersome?
5) Would you like to discuss this problem?

Source: Based on Hatzichristou et al. [30].

The presence of menstrual abnormalities may prompt physical examination and uterine ultrasound to investigate for uterine fibroids and other abnormalities. Vaginal symptoms will prompt specific evaluation of vaginal tissue. Endocrine testing may assist to identify women with low serum estradiol levels and elevated circulating prolactin concentrations that warrant imaging (pituitary-hypothalamic) and targeted treatment (estrogen or bromocriptine). Screening for depression or anxiety may be appropriate.

Treatment

The wide range of factors that result in sexual dysfunction with CKD has led to attempts to improve symptoms through targeting of specific pathophysiological factors. Knowledge of the cause of sexual dysfunction for an individual patient may help identify an appropriate therapeutic strategy. Regardless of the cause and putative treatment, the evidence base for treatment of sexual dysfunction in the setting of CKD is of low certainty, limiting the availability of evidence-based recommendations (Tables 77.5 and 77.6) [7]. In a Cochrane review of interventions for sexual dysfunction, 15 studies involving 352 participants were identified, including 13 in dialysis patients and two involving recipients of a kidney transplant [7]. All but one study included only men.

Phosphodiesterase-5 Inhibitors

Phosphodiesterase-5 (PDE) is an enzyme found in the smooth muscle of the corpus cavernosum that degrades cyclic guanosine monophosphate (GMP). PDE inhibitors (sildenafil, vardenafil, tadalafil, and avanafil) competitively bind to PDE_5 and inhibit the hydrolysis of cyclic GMP to increase the action of nitric oxide. This results in smooth-muscle relaxation in the corpus cavernosum and increased blood flow to the penis during sexual arousal.

Despite their widespread use, evidence for the effects of PDE inhibitors in men with CKD is limited to a few studies involving small numbers of men (Figure 77.2). Trials have evaluated vardenafil in 60 male transplant recipients [41] and 39 dialysis patients [42], and sildenafil in 68 dialysis patients [43, 44] and 32 transplant recipients [45]. Evidence from placebo-controlled trials is of very low certainty due to methodological limitations in studies, heterogeneity in the results between studies, and limited evidence for each of the stages of CKD. Based on a minimally important clinical difference in score for a single IIEF domain estimated of 2 for men with mild dysfunction, 5 for men with moderate

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Table 77.5 Treatment for sexual dysfunction in men with chronic kidney disease.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Phosphodiesterase-5 inhibitors	We suggest that men treated with dialysis may reasonably choose to use or not to use phosphodiesterase-5 inhibitors based on the very low certainty that treatment makes a difference to erectile function scores, erection frequency, erection quality, penetration ability, frequency of penetration, and maintenance of erection after penetration. We suggest that the certainty of the evidence for phosphodiesterase-5 inhibitors to manage sexual dysfunction for men with earlier stages of chronic kidney disease or with a kidney transplant is so low that a recommendation regarding use in clinical practice is too speculative.	*Very low* (overall satisfaction, intercourse satisfaction, libido, erectile frequency, erectile quality, penetration ability, maintenance frequency of penetration, maintenance of erection after penetration, erection confidence) *Very low or absent* (adverse events including headache; coronary ischemia).	Weak: men with chronic kidney disease stage 5D [7] No recommendation: men with chronic kidney disease stage 1–5 and 5T
Testosterone replacement	We suggest that the certainty of the evidence for testosterone replacement to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low* (data from randomized controlled trials are absent; data from observational studies suggest variable efficacy and adverse event)	No recommendation [36, 37]
Bromocriptine	We suggest that the certainty of the evidence for bromocriptine to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (outcome data limited to testosterone levels)	No recommendation [7]
Zinc supplementation	We suggest that the certainty of the evidence for zinc supplementation to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (intercourse frequency, libido)	No recommendation [7]
Vitamin E	We suggest that the certainty of the evidence for vitamin E supplementation to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (outcome data limited to hormone levels; adverse event data absent)	No recommendation [7]
Vacuum detumescence device	We suggest that the certainty of the evidence for vacuum tumescence therapy is so low that a recommendation regarding use in clinical practice is too speculative	*Very low* (data from randomized controlled trials are absent; data limited to 26 men treated with dialysis in observational study)	No recommendation [36]
Penile prostheses, intracavernous injections, transurethral injections	We suggest that the certainty of the evidence for local surgical interventions is so low that a recommendation regarding use in clinical practice is too speculative	*Very low* (data from randomized controlled trials are absent; data limited to small numbers of men in observational studies)	No recommendation [38]
Psychotherapeutic/ psychoeducational interventions	We suggest that the certainty of the evidence for psychotherapeutic/ psychoeducational interventions is so low that a recommendation regarding use in clinical practice is too speculative	*Very low* (data from randomized controlled trials are absent)	No recommendation [7]

These recommendations reflect a belief that most men would place high value on effectiveness of treatment and would wish to avoid risks of adverse events, and place low value on minimizing drug and treatment expenditure. GRADE assessment of the certainty of the evidence[39]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Table 77.6 Treatment for sexual dysfunction in women with chronic kidney disease.

Treatment	Recommendation	Certainty of evidence	Strength of recommendation
Phosphodiesterase-5 inhibitors	We suggest that the certainty of the evidence for phosphodiesterase-5 inhibitors to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (data from randomized controlled trials are absent)	No recommendation [7]
Testosterone	We suggest that the certainty of the evidence for testosterone to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (data from randomized controlled trials are absent)	No recommendation [7]
Bromocriptine	We suggest that the certainty of the evidence for bromocriptine to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (outcome data limited to testosterone levels)	No recommendation [7]
Estrogen	We suggest that the certainty of the evidence for estrogen to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (data from randomized controlled trials are absent)	No recommendation [7]
Pelvic floor exercises	We suggest that the certainty of the evidence for pelvic floor exercises to manage sexual dysfunction is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (data from randomized controlled trials are absent)	No recommendation [7]
Psychotherapeutic/psycho-educational	We suggest that the certainty of the evidence for psychotherapeutic/psycho-educational interventions is so low that a recommendation regarding use in clinical practice is too speculative	*Very low or absent* (data from randomized controlled trials are absent)	No recommendation [7]

These recommendations reflect a belief that most women would place a high value on avoiding risks of adverse events and uncertain treatments. GRADE assessment of the certainty of the evidence [39]: High: This research provides a very good indication of the likely effect. The likelihood that the effect will be substantially different* is low. Moderate: This research provides a good indication of the likely effect. The likelihood that the effect will be substantially different* is moderate. Low: This research provides some indication of the likely effect. However, the likelihood that it will be substantially different* is high. Very low: This research does not provide a reliable indication of the likely effect. The likelihood that the effect will be substantially different* is very high. **Substantially different = a large enough difference that it might affect decision-making*.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dysfunction, and 7 for men with severe dysfunction [40], it is uncertain whether PDE_5 inhibitors provide clinically important improvements in erectile function (Table 77.5). Evidence related to adverse events with PDE inhibitor therapy was of very low certainty. Based on a belief that most men would place high value on effectiveness of treatment and would wish to avoid risks of adverse events, placing low value on minimizing drug and treatment expenditure, it would be reasonable to trial treatment with a PDE inhibitor in men who wish to do so, being cautious not to coprescribe with nitrate therapy or in men with coronary artery disease. Data for women are insufficient to inform clinical decision-making [7].

Testosterone

Sexual dysfunction in men with CKD may be associated with low testosterone levels. However, there are no RCTs investigating long-term outcomes of testosterone replacement therapy in men with end-stage kidney disease. Observational studies are available. In six men with end-stage kidney disease, intramuscular testosterone enanthate 400 mg once weekly increased serum testosterone [46]. Oral testosterone undecanoate 240 mg daily in 19 dialyzed men restored pituitary responsiveness to LH and lowered serum prolactin [47]. Testosterone given as a depot injection to 27 men with biochemical hypogonadism and treated with vacuum tumescence therapy with continued erectile dysfunction provided full restoration of a sexual response in three men, of whom two gradually lost the response over 18 months [36]. These data suggest while testosterone replacement may increase serum testosterone levels and improve pituitary function, treatment does not provide long-term improvement in sexual dysfunction. Testosterone replacement has insufficient evidence among women with CKD.

Bromocriptine

Bromocriptine is a dopamine agonist that is used in the treatment of high prolactin levels and associated conditions including hypogonadism, amenorrhea, and infertility. Bromocriptine is a potential treatment for hypogonadism.

In a previous systematic review of randomized trials, bromocriptine (5–7.5 mg/day) for 3–8 months was administered in two crossover studies involving 40 men treated with hemodialysis [48]. In a crossover trial in 15 men, seven completed an 8-week treatment period, with serious hypotension precluding bromocriptine therapy in the remaining eight men, with other side effects including nausea, vomiting, diplopia, and loss of appetite. Bromocriptine reduced prolactin levels, and increased intercourse frequency and erection quality [48]. Similarly, in 25 men on hemodialysis with erectile dysfunction, bromocriptine led to withdrawal due to side effects in one-third of men, while perceived sexual function was improved when men received bromocriptine [49]. Based on methodological limitations and heterogeneity in treatment outcomes, the evidence certainty for these findings is very low and insufficient to guide clinical decision-making about bromocriptine for men with sexual dysfunction. Treatment with bromocriptine in three women with end-stage kidney disease and hyperprolactinemia did not have a consistent effect on gonadotropin responses [23].

Clomiphene

Clomiphene is sometimes used for men with hypogonadism and may increase serum testosterone levels [50]. In an uncontrolled study in five men with CKD and androgen deficiency, clomiphene citrate at 100 mg/day increased serum testosterone, LH, and FSH, although the effect on spermatogenesis and other patient outcomes was inconclusive or not measured [51].

Estrogen

CKD causing low circulating estradiol concentrations can lead to vaginal dryness and atrophy, causing pain or discomfort during intercourse. Women may benefit from local estrogen therapy or lubricant, although data specific to women with CKD is limited. There are no randomized trials evaluating the benefits or harms of estrogen therapy on sexual function for women with kidney disease.

Zinc Replacement

Zinc deficiency may be a factor in gonadal dysfunction and is present in men with CKD. Zinc replacement in oral form (elementary zinc or zinc acetate) [52] or in dialysate (400 μg/l) [53–55] has been evaluated in four RCTs involving 50 men treated with hemodialysis. Treatment was administered for a range of 1.5–6 months. Evidence for the effects of zinc therapy on sexual dysfunction was limited to one or two trials for each evaluated outcome (serum testosterone, plasma FSH and LH, intercourse frequency, erectile dysfunction, libido, nocturnal penile tumescence), leading to very low certainty in the results. The effects of zinc supplementation for sexual dysfunction in men with CKD are speculative and trials are not sufficiently robust to assist clinical decision-making. If men place high value on a trial of therapy and lower value on treatment certainty, evidence from a single trial suggests oral zinc replacement may improve erectile dysfunction [52]. Data for zinc replacement on sexual function in women with CKD are absent.

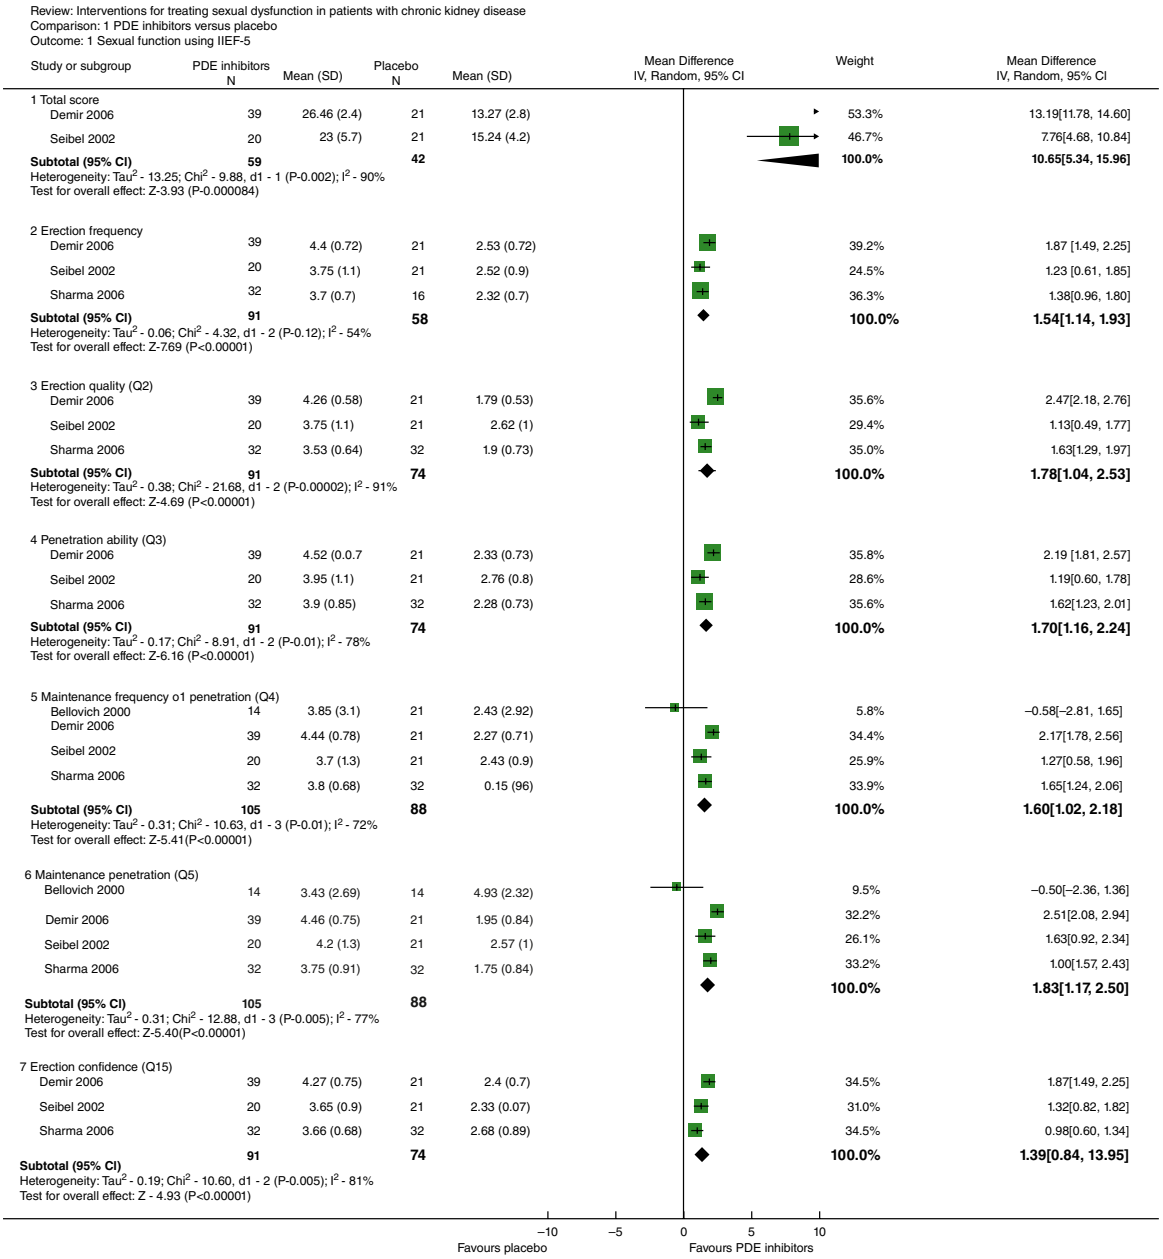

Figure 77.2 Effect of phosphodiesterase-5 inhibitors on sexual function in men with chronic kidney disease. Analysis obtained from Vecchio et al. [7]. Weight refers to the contribution of each study to the overall estimate of treatment effect. The pooled estimate is calculated by using a random effects model. Proportion of studies including dialysis/CKD/transplant. Treatment estimates are expressed as a mean difference with a 95% confidence interval. The minimal clinically important difference in the erectile function domain (question 7) of the International Index of Erectile Function scale (IIEF) is 2 for men with mild dysfunction, 5 with moderate dysfunction, and 7 with severe dysfunction. *Source:* Rosen et al. [40].

Vitamin E

Vitamin E is prescribed for sexual dysfunction based on the potential role of oxidative stress in erectile dysfunction [56]. In a single trial involving 24 men on hemodialysis, oral vitamin E (300 mg/day) was compared with placebo for 8 weeks with a focus on endocrine outcomes, including serum LH, FSH, free testosterone, and prolactin concentrations [57]. Prolactin levels were reduced by vitamin E therapy, while serum LH, FSH, and free testosterone were not altered. It is uncertain whether vitamin E has any effect on patient-centered sexual function outcomes.

Vitamin D

Altered calcium metabolism secondary to CKD may alter the pulsatile secretion of LH (Figure 77.1). In a single trial among men treated with hemodialysis, low serum testosterone, and elevated serum parathyroid hormone levels, calcitriol therapy for 2–4 months had no evidence of effect on libido, intercourse frequency, or masturbation, despite lowering serum parathyroid hormone concentrations [58]. No randomized trials are available for evaluating vitamin D therapy on sexual function in women with CKD.

Vacuum Tumescence Device

A vacuum device consisting of a plastic cylinder that is placed over the penile shaft with a pump used to generate negative pressure to draw blood into erectile tissue has not been evaluated in randomized trials in men with CKD. In a nonrandomized study, the outcomes of a vacuum tumescence device in 26 men treated with dialysis and who had biochemically proven hypogonadism have been reported. Men used the devices after partial response to testosterone replacement [36]. Of these men, 19 experienced full correction of erectile dysfunction, while five did not experience benefit. Based on these data, men who place a high value on treatment of their condition and lower value on evidence uncertainty may reasonably wish to consider vacuum tumescence therapy, although the existing evidence is of very low certainty. Data are limited to the dialysis setting.

Penile Prostheses, Intracavernous Injections, and Transurethral Injections

Evidence for surgical interventions to treat erectile dysfunction are limited to observational data and case series, and evidence is of very low certainty. Information is more commonly provided among recipients of a kidney transplant. In seven men, four penile prostheses implanted after transplantation were effective and no complications were reported up to 40 months following implantation, while of five prosthesis implanted before transplantation, two were removed due to infection, one was removed due to leakage, and one led to sepsis [59]. In another case series in 12 men treated with dialysis or transplantation, 11 men maintained a prosthesis over 8 years, while three required reimplantation due to mechanical failure and one was explanted due to infection [38]. Data are absent for intracavernosal and transurethral injections among men with kidney disease.

Psychotherapeutic and Psychoeducational Interventions

Evidence to support psychological and psychosocial interventions such as group psychotherapy and focused sex group therapy on sexual function and erectile dysfunction is limited. No RCTs have been identified for evaluating these interventions of sexual function in men or women with CKD.

Patient and Partner Needs and Preferences

Reporting of patient experiences, needs, and preferences related to sexual function in the context of CKD is limited. This information is needed to offer insights into the level of distress and patient perspectives on treatment preferences that can shape the future research priorities on sexual dysfunction.

In a structured interview study among 68 men and women treated with peritoneal dialysis for 3 months or longer, 63% of patients reported never having intercourse, 19% had intercourse two times per month or less, and 18% had intercourse more than two times per month [8]. Among those not having intercourse, 44% of patients (mostly men) expressed a desire to have intercourse. Patients reporting a higher frequency of intercourse had lower scores on assessments of depression, anxiety, and physical symptoms.

In women receiving long-term hemodialysis and as part of a clinical trial of symptom management, those who were not sexually active were asked about their reasons for not being sexually active and their preferences about treatment for sexual dysfunction [4]. In 815 assessments women reported they were not sexually active due to lack of interest (43%) and lack of partner (39%). Of those women who reported a lack of interest, 76% were moderately to very satisfied with their sex life. In 5% of assessments, women reported an interest in learning about the causes or treatment of sexual dysfunction. Overall, these findings suggest women on dialysis maintain high levels of satisfaction despite sexual inactivity and have low interest in considering treatment.

After kidney transplantation, patients reported wishing less sexual activity and lower sexual drive, although rates of masturbation and orgasm were unchanged [6]. Despite these changes, 90% of patients reported high relationship and life satisfaction. Similarly, the wish for sexual activity and frequency of sexual activity among partners decreased, and the high personal importance of sexual satisfaction decreased. Couples did not consider separating and partners also reported maintaining high relationship and life satisfaction.

Conclusions

In conclusion, sexual dysfunction may be frequent among men and women with CKD and is caused by a range of endocrine, biochemical, and psychological factors.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Patients may frequently be sexually inactive, although the impact of this on patient lives is incompletely known and may be less than previously thought. Lower sexual activity and desire are uncoupled from life and partner satisfaction among dialysis and transplant patients and partners. There is limited evidence to support clinical decision-making for treatments in this condition. Few women are interested in treatment. Men and women who value treatment efficacy and place lower value on certainty of treatment outcomes may wish to trial treatment based on the cause of their sexual dysfunction. Evidence supporting estrogen or testosterone therapy and PDE inhibitors is of very low certainty due to a lack of robust clinical trials.

Introduction

The aging population and increasing prevalence of chronic kidney disease (CKD) globally has resulted in an increased burden being placed on informal caregivers, namely family members or friends, to provide support and care [1]. Informal caregivers of patients with CKD take on a broad span of responsibilities in care coordination, ranging from management of CKD and related conditions (administering medications, applying dressings, symptom control, health monitoring), to planning and organization (transportation, appointments, supporting dietary and nutritional intake), and personal and emotional care (personal hygiene, decision-making, companionship, and psychological support) [2, 3]. In addition, caregivers of patients using home-based kidney replacement therapies, such as peritoneal dialysis (PD) or home hemodialysis (HD), may need to assist patients in using complex medical equipment such as dialysis machines, catheters, and needles.

These ongoing responsibilities contribute to caregiver burden and can lead to depression, stress, fatigue, isolation, and an inability to cope in caregivers [4–7]. Support interventions, including training, education, and psychosocial care may assist caregivers and improve their quality of life and patient outcomes [1]. This chapter examines the evidence on caregiver burden and support interventions for caregivers of people with CKD.

Caregiver Burden

Caregiver burden is defined as the physical, financial, and psychosocial hardships of caring for someone with a disease or medical condition [8]. This occurs when the demands of care exceed the resources available to cope with these demands [9, 10]. Studies have shown that the majority of caregivers of patients with CKD report moderate to severe burden [11–14].

Factors Contributing to Caregiver Burden

Caregiver burden is associated with declines in the functional and cognitive status of the patient [15–19]. These challenges are highly relevant among caregivers of patients with CKD, as CKD is associated with a multitude of comorbidities which affect a patients' physical function and cognitive capacity [20, 21]. Caregiver burden is associated with the numbers of years the patient has been on dialysis ($r = 0.82$, $P < 0.001$) and the number of hours of care provided per day ($r = 0.30$, $P < 0.001$) [11].

Depression is both a risk factor for and an outcome of caregiver burden [22, 23], with higher levels of depression and anxiety relating to higher levels of burden [13]. This is shown across other chronic diseases, including cardiovascular disease, dementia, and cancer [9, 24, 25].

In low- and middle-income countries, the shortage of resources, infrastructure, and healthcare personnel can place increased burden on caregivers [26]. Family caregivers provide care to their patients even while hospitalized due to the shortage of nursing staff [27]. Additionally, tertiary care centers are usually located in urban areas, meaning that there is a requirement for families living in rural areas to relocate for the patient to access medical care, causing social and financial disruptions [28, 29].

Burden of Caregiving Across Stages of Treatment

The nature, severity, and intensity of the burden experienced by caregivers of patients with CKD may vary depending on the type of kidney replacement therapy. For patients on home HD, some caregivers are integrally involved in the treatment, and this can be physically and cognitively demanding [30, 31]. Caregivers of patients on home HD have a higher perceived caregiver burden compared to conventional in-center HD [32]. For patients receiving in-center HD, caregivers may have additional tasks such as organizing or providing transport for patients. Some caregivers of patients on PD may be involved in technical aspects of dialysis, managing and preventing complications (e.g. infection), and physical aspects such as storing, moving, and disposing of large volumes of dialysis fluids [33]. Elderly patients on continuous ambulatory peritoneal dialysis (CAPD) have an increased risk of transfer to HD if they are experiencing psychosocial difficulty, including caregiver problems [34]. Caregivers of patients with end-stage kidney disease and not receiving kidney replacement therapy may have to contend with the emotional toll and distress as the patient's health deteriorates.

Caregivers of Children with CKD

Caregivers of children with CKD experience considerable psychological, social, and financial stress [35]. Caregivers, usually parents, are required to be "on-call" at all times and take on the role of healthcare provider. They are required to perform invasive and painful procedures (e.g. nasogastric intubation, needles, cannulation) that cause pain and discomfort for the child, which may conflict with their parental role of protecting their child, causing stress [29]. Additionally, parents who perceive themselves as lacking in technical expertise or ability and unable to perform these duties can feel disempowered in having to relinquish caregiving roles to health professionals, which can result in feelings of guilt or inadequacy [36]. Caregivers must help their child with CKD cope with unique challenges related to growth and development [5, 37]. In addition to managing the requirements of the child, parents must also bear the emotional toll of having a chronically ill child.

Parents of children on dialysis have a higher risk of depression compared to parents of healthy children (28% vs. 5%) and the general adult population (28% vs. 9%, $P = 0.001$) [5]. The mean scores in all four domains (physical, psychological, social relationships, and environmental quality) based on the World Health Organization Quality of Life (WHOQOL) measure were significantly lower for caregivers of children on dialysis compared to caregivers of healthy children. Parents associate their own health with that of the child, such that the health status of the caregiver is worse with increasing severity of their child's condition [38, 39].

Parents also face financial burden given the expenses incurred for treatment, medications, diet, accommodation, and transportation to clinics or the hospital, and may also have to take time off work [40–42]. Caregivers of children on dialysis were less likely to work full-time and earned less than caregivers of healthy children [5]. Low socioeconomic status is also associated with parental depression and anxiety, which can impact on the care and health of the child [41].

Measuring Caregiver Burden

A number of measures are available to assess caregiver burden. A systematic review on the burden of care and quality of life among caregivers for adults receiving dialysis identified a number of measures used [43], most frequently the Zarit Burden Interview (ZBI) [44]. The ZBI was originally developed to measure subjective burden among caregivers of adults with dementia. The 22-item self-report inventory examines burden associated with functional/behavioral impairments and the home care situation. Other measures frequently used include the Beck Depression Inventory [45], the Centre for Epidemiologic Studies Depression Scale [46], and the Medical Outcomes Study 36-Item Short Form Survey (SF-36, [47]).

Interventions

Interventions to support caregivers have the potential to improve outcomes for both the caregiver and the patient. Studies in cancer, dementia, stroke, and asthma have shown that education, information, psychosocial, and practical support interventions can improve caregiver burden, satisfaction, and quality of life [48–52], but there is limited evidence in CKD. A summary of findings is shown in Table 78.1.

A systematic review of support interventions for caregivers of people with CKD published in 2008 identified three studies, and all assessed the effect of educational materials on caregiver knowledge [1]. Two of the studies used a pre- and post-test study design to evaluate the impact of information provided to caregivers of dialysis patients [53, 54]. In the third study, participatory action research methods were used to develop an information handbook for transplant recipients and their caregivers [55]. All three studies found that the provision of

Table 78.1 Summary of findings: interventions for caregivers.

Study ID	n	Setting	Participants	Study design	Summary of main findings
Tong et al. [40]	260	International	Caregivers of hemodialysis, peritoneal dialysis, and pediatric transplant patients	Systematic review	There is a need for the development and evaluation of interventions and services that address the informational and support needs of caregivers
Ismail et al. 2014	246	Netherlands	Family members of patients referred for transplant preparation or listed for deceased donor kidney transplantation	RCT	Improved knowledge scores, increase of self-efficacy of family members, improved attitude toward communication, greater willingness to donate
Fathima et al. [53]	30	India	Caregivers of adult HD patients	Pre- and post-test	Overall knowledge score improved
Tornay et al. [55]	135	Spain	Caregivers pediatric Tx patients	Participatory action research	Clarified doubts, diminished stress and fear, facilitated adaptation
Ghane et al. [56]		76	Family caregivers of hemodialysis patients	RCT	Improvements in quality-of-life scores
Chan et al. [58]		29	Caregivers of patients with CKD choosing not to be treated with dialysis or transplantation	RCT	Reduction in caregiver burden scores

CKD, chronic kidney disease; HD, hemodialysis; RCT, randomized controlled trial; Tx, transplantation.

information increased caregiver knowledge. However, the authors concluded that no high-quality evidence was available and that there is a need for the development and evaluation of interventions and services that address the informational and support needs of caregivers. No subsequent systematic reviews of interventions for caregivers of people with CKD have been conducted.

The following section reviews evidence for educational and psychosocial interventions for caregivers of patients with CKD.

Education and Psychosocial Support Interventions

Ghane et al. [56] conducted a randomized controlled trial (RCT) in Iran with 76 family caregivers of HD patients to examine the effect of home care training and problem-focused coping strategies on the quality of life of the caregivers. The intervention consisted of two training sessions focused on how to care for a patient on HD at home, and four training sessions on problem-focused coping strategies delivered by a psychiatric nurse which included communication skills, anger management, stress reduction, and deep breathing. An educational booklet was also provided to participants in the intervention group at the end of the first session. Participants in the control group only received routine training, which included pamphlets, and were provided with an educational booklet after the last assessment. The main outcome of the study was quality of life as measured by the 36-Item Short Form Health Survey (SF-36), which uses a scale ranging from 0 to 100, with higher scores reflecting a better quality of life. The survey was translated into Farsi and validated with this population [57]. The study found that participants in the intervention group had significant improvements in their quality-of-life scores from baseline to the end of the study (from 45.95 ± 14.94 to 63.51 ± 11.55; $t = 6.855$, df = 36, $P < 0.001$). The intervention group also had a significantly higher quality-of-life score compared to the control group at the end of the study (63.51 ± 11.55 vs. 41.74 ± 10.51; $t = 8.596$, df = 74, $P < 0.001$).

Chan et al. [58] conducted an RCT in Hong Kong with 29 pairs of patients with CKD choosing not to be treated with dialysis or transplantation and their caregivers. Caregivers in the intervention group received enhanced psychosocial support, which included education and psychosocial-spiritual support from an on-site palliative care nurse and social worker in a 30-minute session held once or twice monthly for up to 6 months. The first session assessed the needs of the caregivers through questions regarding the types of problems encountered with the patient, the type of information they would like to know, and how to better manage the patient's medical treatment. After the needs assessment, appropriate counseling and information were provided. The control group received standard renal care and caregivers were referred to other allied health professionals if it was deemed necessary. Caregiver burden was measured using the ZBI, which uses a scale ranging from 0 to 88, with higher

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

scores implying greater perceived burden. The intervention group showed significant reductions in caregiver burden scores from baseline to 1 month (32.8 ± 12.2 vs. 22.0 ± 5.3, $P = 0.002$) and 3 months (21.3 ± 6.6, $P = 0.02$). The intervention group also had significantly lower caregiver burden compared to the control group at 1 month (22.0 ± 5.3 vs. 31.6 ± 9.5, $P = 0.006$) and 3 months (21.3 ± 6.6 vs. 33.4 ± 7.2, $P = 0.009$).

Education-only Interventions

A study conducted in India evaluated the effect of an information booklet for caregivers of patients on hemodialysis on their knowledge of home care management using a pre-post-test study design [53]. Caregivers ($n = 30$) were provided with a booklet which was developed from a literature review and expert input. The post-test assessment was conducted 1 week after receiving the booklet. The major findings showed that there was a significant improvement in overall knowledge scores, from 50.35 in the pre-test to 86.25 post-test. The overall improvement in the mean score was 35–89 ($t = 13.4$, $P < 0.001$).

Tornay [55] conducted a study in Spain using participatory action research, in which an information handbook was developed for the post-transplant care of children. Over an 8-year period, data were collected from children and caregivers through semistructured interviews, clinical histories, and written opinions, and these data were used to develop and modify the information handbook. The handbook included information on diet, immunosuppressive mediation, side effects, protection of the implanted organ, signs of rejection, and self-care. The handbook was distributed to pediatric transplant recipients ($n = 135$) aged from 2 to 18 years old from immediately post-transplant up to 7 years post-transplant, and to their caregivers. Evaluation of the handbook found that over 90% of the patients and caregivers felt that it helped reduce distress and fear, adapt to life post-transplant and improve the patient's self-care.

Patient and Caregiver Needs and Preferences

Currently, there are no studies evaluating patient and caregiver preferences for interventions or outcomes specifically regarding family and caregiver support. Further research that elicits and evaluates caregiver needs and preferences is needed to validate the areas that have already been identified, such as depression, stress, fatigue, isolation, and ability to cope, and to identify other topics and outcomes of importance to caregivers. This knowledge can then be used to develop interventions which target the needs and priorities of caregivers to reduce caregiver burden, improve caregiver support, and ultimately improve patient and caregiver health outcomes.

Conclusion

The problems and challenges of caregiving can impair quality of life and impact on caregivers and patient health and outcomes. However, high-quality evidence on effects of interventions to support caregivers remains very limited and consists of randomized controlled studies, participatory action research, and pre- and post-test studies. Studies focus on educational and psychosocial interventions to improve caregiver knowledge, burden, and quality of life. No studies addressed practical support as the intervention. Further research on a range of interventions targeting mental health, and social and practical support is needed. Family-based therapies may also have potential to alleviate caregiver burden and improve outcomes. As recommended by the World Health Organization and UK INVOLVE, we suggest involving caregivers in the decision-making, planning, implementation, and evaluation of interventions that impact their health and their capacity to provide care for their loved ones.

Support for caregivers of patients with CKD is critical. Patient-centered care incorporates the need to support informal caregivers in their caregiving role to ensure that patients and their caregivers have the best possible outcomes.
