22.8 years (95% CI: 16.0–27.2 years).[348] The latency was ~30% longer for women than men in the fully adjusted generalized gamma accelerated failure-time model used to estimate latency. Greater asbestos exposure intensity was not associated with shorter mesothelioma latencies.

Pleura mesothelioma is an aggressive tumor typically presenting at an advanced stage with a unilateral pleural effusion and chest pain; weight loss, dyspnea, and fatigue frequently present later in the course of the disease.[282] Occasionally, mesothelioma patients present with no symptoms after routine chest radiographs reveal a pleural effusion. Peritoneal mesothelioma usually presents with abdominal distension, ascites, abdominal pain/tenderness, and occasionally bowel obstruction. These tumors may grow large enough to produce the superior venal caval syndrome. Common sites of metastasis include supraclavicular, mediastinal, hilar, and internal mammary lymph nodes; however, clinically related symptoms are uncommon.

Malignant mesothelioma is an incurable cancer. This tumor is a highly aggressive neoplasm that is relatively chemotherapy- and radiation-resistant, resulting in a very limited life expectancy after diagnosis (i.e., <1–1.5 years).[349] The median survival for advanced stages is shorter for malignant pleural mesothelioma (12–16 months)[350] than peritoneal mesothelioma (12.5–31 months).[351] In a study of 1,605 German patients with malignant mesothelioma, the estimated mean survival time after diagnosis was ~13–14 months, depending on the pathological type of mesothelioma.[352] Histological subtype is the most consistent predictor of mesothelioma survival. The prognosis for sarcomatoid and biphasic subtypes is substantially worse than that for epithelioid mesothelioma; however, histological subtype alone does not usually alter the management of mesotheliomas.[353]

SINONASAL

Malignant sinonasal cancer is a rare, clinically aggressive neoplasm with an annual incidence of $<1 \times 10^{-6}$ in most developed countries representing <1% of all neoplasms.[354] The overall male/female ratio from 1973–2006 was ~1.8;[355] however, the ratio decreased recently except for higher ratios in some adenocarcinoma subtypes (e.g., intestinal-type adenocarcinoma).[356,357] Although sinonasal cancers account for ~3–4% of head and neck tumors, sinonasal cancers display different epidemiology, etiology, and genetic profiles than histologically similar tumors in the pharynx, larynx, and oral cavity. Long-term sinonasal cancer incidence rates have been relatively stable over the last several decades.

CARCINOGENESIS

Sinonasal tumor genomes contain many, highly diverse chromosomal aberrations. The diversity of sinonasal tumors suggests the occurrence of various carcinogenic mechanisms for the many types and causes of this neoplasm; however, the limited number of genetic studies and rarity of these tumors significantly complicate the determination of driver genes, signaling pathway alterations, and epigenetic mechanisms causing these tumors. Organic dusts (wood, leather) are not directly mutagenic; however, chronic inflammation from continuous mucosal irritation and phagocytosis of organic dust releases cytokines (e.g., IL-1β, tumor necrosis factor), producing activation of transcription factor nuclear factor κB (NFκB) and downstream prostaglandin G/H synthase (also known as COX2).[358] Additionally, alveolar macrophages release mutagenic reactive oxygen (ROS) and nitrogen (oxides, peroxynitrites) species that generate mutagenic DNA adducts. Although chronic inflammation may be involved with the association of organic dusts and sinonasal cancers, inflammation from chronic rhinitis and nasal polyps are not associated with increased sinonasal cancer risks.

Specific data on sinonasal cancer subtypes are limited. Up to ~50% of intestinal-type adenocarcinomas contain aberrations of the canonical Wnt signaling pathway involved with the nuclear expression of β-catenin, particularly in the colonic and papillary subtypes.

TP53 mutations are common events in head and neck carcinomas, including sinonasal cancers with p53 overexpression ranging from 18–77% in different series of sinonasal cancer subtypes. Higher mutation rates typically develop in adenocarcinomas than in squamous cell carcinomas, particularly following prolonged exposure to high wood dust concentrations.[359] KRAS mutations and cyclooxygenase 2 (COX2) expression are usually rare in sinonasal squamous cell carcinomas. PCR amplification and sequencing identified only 7 of 58 (12%) intestinal-type adenocarcinomas with *KRAS* mutations in codons 12/13.[360] BRAF tumor suppressor mutations are usually absent in sinonasal tumors. DNA copy number alterations are common in sinonasal squamous cell carcinomas. Using multiplex ligation-dependent probe amplification and microarray comparative genomic hybridization on 27 sinonasal squamous cell carcinoma tissue samples, the most frequent copy number gains were 8q24, 11q13, 17q12, 19p13, and 20q11–q13.[361] The most common losses included 9q21, 13q14, 17p13, 17q12, and 18q11. Most recurrent gains occurred in *EMS1* and *BCL2L1* (37%), *RECQL4*, *RELA*, and *ERBB2* (25%), and *CCND1* (26%) genes, whereas the most common losses developed in *BRAC1* and *CDH2* (38%), *CRK*

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(33%), and *STCH* and *RB1* (29%) genes. Epigenetic hypermethylation and inactivation of tumor suppressor genes in sinonasal cancer include *CDH13* (cadherin 13, H-cadherin), *ESR1* (estrogen receptor 1), *RASSF1* (Ras association domain family member 1), and *TP73* (tumor protein p73).[362]

EXPOSURE

Similar to mesothelioma, sinonasal cancer is primarily an occupational cancer. In an analysis of data on 1,135 sinonasal cancer cases (878 men, 297 women) from the Italian National Surveillance System, 73% of male cases were attributed to occupational exposures compared with ~35% of the women based on in-person interviews (80% direct, 20% proxy) by trained interviewers.[363] Other studies report slightly smaller attributable risks for sinonasal cancer associated with occupational exposures (e.g., 43% in men and 20% in women).[364] The strongest occupational associations with sinonasal cancer involve adenocarcinomas in cabinetmakers/joiners exposed to wood dust and boot/shoe manufacturing/repair workers exposed to leather dust; less robust associations were reported for strong acid process of isopropyl alcohol production and nickel refining. The IARC lists all four processes as carcinogens with sufficient evidence in humans, whereas the evidence for sinonasal carcinogenicity in humans is limited for formaldehyde, hexavalent chromium, carpentry/joinery, and textile manufacturing. Data on the associations of environmental tobacco smoke, welding fumes, arsenic, textile industry, and human papilloma virus (HPV-16, HPV-18) with sinonasal cancer are conflicting.[365]

In contrast to laryngeal cancer, asbestos is not a recognized cause of sinonasal cancer. A retrospective cohort study of construction workers using Swedish Cancer Registry data did not detect an elevated sinonasal cancer risk after separating 280,222 participants into 4 asbestos exposure categories (very low, low, medium, high) and comparing the exposed group with the general population (i.e., standardized incidence ratio, SIR).[366] Exposure categories were based on job titles. The SIR for sinonasal cancer was 0.85 (95% CI: 0.68–1.03) with no apparent dose-response relationship. The lowest relative risk occurred in the highest asbestos exposure group (RR = 0.71, 95% CI: 0.33–1.53) using the very low asbestos category as referents and adjusting for smoking history. A Scandinavian study of 167 sinonasal cancer cases and age/sex-matched hospital controls reported no association between asbestos and sinonasal cancer based on self-reported asbestos exposures in telephone interviews with surviving cases.[367]

Occupation

The absolute sinonasal cancer risk is very low in the general population; consequently, studies associating sinonasal cancers with specific jobs and/or carcinogens typically involve small sample sizes, with low statistical power resulting in highly variable, imprecise risk estimates. The evidence of an association with sinonasal cancer is strongest for wood and leather dust, primarily hardwood, and suggestive for strong acid process of isopropyl alcohol production and nickel refining. In a mortality study of workers at the South Wales Clydach nickel refinery employed since 1930, the SMR for nasal cancer was 8.70, (95% CI: 1.05–31.41, $n = 2$ cases), with wide confidence intervals and imprecise estimates.[368] The risk of sinonasal cancer is substantially higher in nickel refinery workers employed before 1930 than after 1960, when exposure to soluble nickel compounds was significantly reduced from improvement in production processes using these compounds.[364,369] Other exposures inconsistently associated with sinonasal cancers include formaldehyde and hexavalent chromium. In an Italian study on 113 sinonasal cancer cases and 336 hospital-based controls using data from the Piedmont Region Sinonasal Cancer Registry, the odds ratios for epithelial sinonasal cancers were positive, but statistically nonsignificant (OR = 2.8, 95% CI: 0.55–4.06, $n = 3$ cases/3 controls). The OR for adenocarcinomas in this study was similarly positive, statistically nonsignificant, and imprecise (OR = 2.1, 95% CI: 0.22–21.1) based on one case.

Dusts

Wood

Fine particulate hardwood dust is strongly associated with increased sinonasal adenocarcinoma risks. In the latter 1960s, Acheson et al. identified a case series of 58 nasal adenocarcinomas in British furniture workers heavily exposed to hard wood dust at the Buckinghamshire woodworking industries in the UK.[370] Subsequently, the IARC classified cabinet and furniture manufacturing as Group 1 (human) carcinogen with wood dust being a recognized human carcinogen. The pooled adenocarcinoma relative risk in a meta-analysis of 17 case-control and 12 cohort studies involving workers exposed to wood dust was positive and statistically significant with high heterogeneity (pooled RR = 29.43, 95% CI: 16.46–52.61, $I^2 = 80.3\%$, $P_{\text{heterogeneity}} = <0.001$) using random effects models.[371] Wood dust concentration and cumulative exposure contributed independently to highly elevated risks; however, additional wood exposure other than hardwood did not

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

increase the sinonasal adenocarcinoma risk. The risk of squamous cell carcinomas in workers exposed to wood dust is marginally significant (RR_{pooled} = 1.46, 95% CI: 1.01–2.1), with a possible exposure-response relationship based on duration of exposure of <15 years and ≥15 years. In a Scandinavian population-based, case-control study of 393 male cases of nasal adenocarcinoma, the hazard ratio for wood dust after adjustment for formaldehyde exposure in the highest cumulative exposure category (≥28.82 mg/m^3/year) was 16.5 (95% CI: 5.05–54.1) using healthy, age/country-matched controls as referents.[372] The wood exposure primarily involved softwood-contaminated mixed wood dusts. Cumulative wood dust exposure was not associated with other sinonasal cancer subtypes. A pooled analysis of 12 studies involving 930 (680 male/250 female) cases and 3,136 (2,349 male/787 female) controls used logistic regression to evaluate sinonasal cancer risks based on job-exposure matrixes.[373] Overall, for sinonasal cancer in male furniture workers, the odds ratio was 4.5 (95% CI: 3.2–6.4), whereas the adenocarcinoma sinonasal cancer risk in these workers was 41.1 (95% CI: 24.5–68.7). The risks for the few women in these studies were statistically nonsignificant.

The risks of sinonasal cancer are weaker for softwood than hardwood dust, particularly in North American studies.[374] In a French hospital-based, case-control study of 82 sinonasal adenocarcinomas, only 2 cases had no documented hardwood dust exposure or a combination of hardwood and other wood dusts based on expert assessment of self-reported exposures.[375] Using nonexposed workers as referents, the OR for adenocarcinomas in 80 workers exposed only to hardwood dust plus 2 workers exposed to hardwood and softwood dust for 16–35 years was 261 (95% CI: 57–1,190, n = 32 cases/2 controls). The odds ratio for squamous cell carcinoma did not demonstrate a statistically significant dose-response relationship for softwood workers based on duration of exposure and average estimated concentration or years since first exposure. In a meta-analysis of 12 primarily case-control studies, the summary odds ratio for sinonasal cancer in male wood workers was 2.6 (95% CI: 2.1–3.3), with risks substantially higher for adenocarcinomas than squamous cell carcinomas.[376] The authors opined that the differences may reflect variations in hardwood and softwood cancer risks or other exposure-related differences.

Leather

The IARC lists boot and shoe manufacturing and leather dust as carcinogenic based on sufficient evidence in humans. The pooled relative risk of adenocarcinomas in a meta-analysis of 17 case-control and 12 cohort studies involving workers exposed to leather dust was 35.26 (95% CI: 20.62–60.28, I^2 = 0%, $P_{heterogeneity}$ = 0.818) using random effects models.[371] In an Italian study based on data from the Piedmont Region Sinonasal Cancer Registry, occupational questionnaires were completed by 113 sinonasal cancer cases and 336 hospital-based controls with adjustment of the results for smoking, sex, age, and co-exposures while allowing a 10-year latency period and excluding cases appearing within 10 years of the initial exposure.[377] There were 53 adenocarcinomas and 37 squamous cell carcinomas. Using unconditional logistic models, the adjusted odds ratio (OR) for adenocarcinomas and leather dust was 26.6 (95% CI: 5.09–139.0, n = 7 cases), with a dose-response relationship based on questionnaires administered by unblinded interviewers and evaluated by a blinded occupational epidemiologist or physician. An analysis of pooled data from 8 European studies involving 555 (104 female/451 male) cases and 1,705 (241 female/1,464 male) controls demonstrated a statistically significant excess sinonasal cancer risk in men (pooled OR = 1.7, 95% CI: 1.10–3.35), but not among women (pooled OR = 2.71, 95% CI: 0.78–9.43, n = 7 cases/7 controls), primarily for adenocarcinoma (pooled OR = 2.99, 95% CI: 1.33–6.73, n = 15 cases/49 controls).[378] The pooled sinonasal cancer odds ratio was positive, but statistically nonsignificant for squamous cell carcinoma. A review of 14 studies including a meta-analysis of case-control studies reported 75–88% of the sinonasal cancers were adenocarcinomas in workers exposed to leather dust, with the relationship particularly strong for shoe shining, finishing, and repair work.[378,379]

Formaldehyde

Formaldehyde is an intermediary in industrial chemical manufacturing and production (e.g., melamine, phenolic compounds, polyacetal resins, urea) used in wood products and synthetic vitreous fiber industries. Overall, the association between occupational formaldehyde exposure and sinonasal cancer is inconsistent with positive data primarily involving adenocarcinomas.[380,381] In a pooled analysis of 12 case-control studies involving 195 adenocarcinomas, 432 squamous cell carcinomas, and 3,136 controls, the adenocarcinoma risk in the highest formaldehyde exposure group was increased and statistically significant in men (OR = 3.0, 95% CI: 1.5–5.7) and women (OR = 6.2, 95% CI: 2.0–19.7).[382] In an Italian study on 113 sinonasal cancer cases and 336 hospital-based controls using data from the Piedmont Region Sinonasal Cancer Registry, the odds ratio for sinonasal adenocarcinoma was 9.5 (95% CI: 2.62–34.2,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

n = 6 cases). This study identified no squamous cell sinonasal cancers. Although case-control studies of sinonasal cancer and formaldehyde exposure suggest elevated sinonasal cancer risks, cohort studies do not support the findings of the case-control studies.[383] In a meta-analysis of six case-control and two cohort studies of workers exposed to formaldehyde, the pooled relative risks for sinonasal cancers were 1.68 (95% CI: 1.37–2.06) for case-control studies and 1.09 (95% CI: 0.66–1.79) for cohort studies.[371] A British cohort study of 14,014 men employed in 6 factories using formaldehyde, the SMR for sinonasal cancer was 0.87 (95% CI: 0.11–3.14, 2 cases/2.3 expected 1941–2000).[384] No deaths were recorded in men with high estimated time-weighted average formaldehyde concentrations (i.e., >2 ppm). The IARC concluded the epidemiological evidence of a positive relationship was limited.

Lifestyle

Little epidemiological evidence associates lifestyle factors other than tobacco smoking with sinonasal cancers. Few data are available on diet, alcohol consumption, or obesity. The IARC associates cigarette smoking with an elevated sinonasal cancer risk based on case-control studies demonstrating dose-response relationships between squamous cell carcinomas and smoking, along with reduction in the relative risk with time since smoking cessation. However, the effect is relatively small compared with other body sites (e.g., lungs, larynx).[385] The association is particularly strong for keratinizing squamous cell carcinoma with TP53 mutations. In a pooled analysis of 8 European studies involving 555 (104 female/451 male) squamous cell carcinoma cases and 1,705 (241 female/1,464 male) controls, the odds ratio for sinonasal squamous cell carcinoma subtype (but not adenocarcinoma) in current smokers was elevated (OR = 1.72, 95% CI: 1.16–2.56, n = 103 cases/595 controls) compared with never-smokers.[378] Male ex-smokers had a modest excess overall sinonasal cancer risk (OR = 1.43, 95% CI: 1.03–1.97, n = 186 cases/514 controls); however, the difference in overall sinonasal cancer rates in female never-smokers and current smokers was not statistically different. The study reported no association between tobacco smoking and adenocarcinoma risks ($OR_{current\ smokers}$ = 0.65, 95% CI: 0.35–1.20, n = 39 cases/595 controls). An Italian case-control study on occupational risk factors for sinonasal cancer did not detect an association between epithelial sinonasal cancer and smoking history; however, the authors reported the information on smoking intensity and duration was incomplete for many participants.[377] The few data on environmental tobacco smoke and sinonasal cancer risks are conflicting.

Diseases

The epidemiological evidence for an association between HPV and sinonasal cancer is suggestive, but inconclusive. HPV DNA appears in ~20% of sinonasal carcinomas, with the high-risk type (HPV16/18) being the most common type, particularly squamous cell carcinoma subtypes;[365] however, HPV detection varies with geography and detection method.[386,387] Sinonasal nonkeratinizing squamous cell carcinoma subtypes and some squamous cell carcinoma variants (basaloid, papillomas) have a particularly high prevalence of HPV DNA and p16 overexpression.[388,389] Sinonasal cancer is not associated with non-irritant chronic inflammation (e.g., allergic rhinosinusitis).

HISTOLOGY

Most sinonasal tumors arise from epithelial cells in the nasal cavities or maxillary sinuses and less commonly the ethmoid sinuses; frontal and sphenoidal sinus tumors are very uncommon. Sinonasal tumors are one of the most diverse groups of neoplasms in the human body. These tumors represent ~3–5% of head and neck tumors, with a relatively small percentage of squamous cell tumors compared with other head and neck sites.[390] In a review of sinonasal tumors in the Italian Network of Cancer and US Surveillance, Epidemiology and End Results (SEER) Registries, the location of sinonasal tumors ranged from 45–58% in the nasal cavities compared with 20–30% in the maxillary sinuses and 8–13% in the ethmoid sinuses; the sphenoid and frontal sinuses together contained <3–5% of the tumors.[383]

Epithelial histological subtypes represent ~60–75% of sinonasal tumors with subtypes including squamous cell carcinomas, adenocarcinomas, esthesioneuroblastomas, and adenoid cystic carcinomas; the former two represent the majority of sinonasal tumors. Squamous cell carcinoma subtypes are further classified into keratinizing, nonkeratinizing, and variants (basaloid, papillary, spindle cell carcinoma, adenosquamous carcinoma).[388] Premalignant lesions associated with squamous cell carcinoma primarily involve inverted or oncocytic papillomas. Adenocarcinomas may arise from respiratory surface epithelium or underlying seromucinous glands, with tumors divided into rare multiple salivary subtypes (5–10%) and the rest into non-salivary subtypes; the latter surface epithelial adenocarcinomas are divided into intestinal and nonintestinal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

subtypes. The most common epithelial sinonasal tumors subtypes are squamous cell carcinoma arising in the maxillary sinuses or nasal cavity and intestinal-type adenocarcinomas developing in the ethmoid sinuses.[356] Undifferentiated and miscellaneous tumors account for ~10% of sinonasal tumors; these tumors represent a wide diversity of neoplasms (e.g., neuroectodermal, mesenchymal, and hematolymphoid tumors, undifferentiated carcinomas).[391] The subtypes include rare melanomas, mesenchymal (e.g., angiosarcoma, chondrosarcoma, fibrosarcoma), and hematological (e.g., lymphoma, plasmacytoma) neoplasms.[383]

The distribution of squamous cell carcinomas and adenocarcinomas varies with gender and location. In a US study based on Surveillance, Epidemiology and End Results (SEER) data 1973–2006, the approximate distribution of epithelial histological types included squamous cell (52%), adenocarcinoma (13%), melanoma (7%), esthesioneuroblastoma (6%), and adenoid cystic carcinoma (6%).[355] The Italian National Surveillance System reported squamous cell carcinoma (46%) was more common than adenocarcinoma (18%) in women, whereas adenocarcinoma (46%) was more common than squamous cell carcinoma (33%) in men.[363] Premalignant lesions (e.g., inverted papillomas in squamous cell carcinoma) are infrequently identified.

HOST SUSCEPTIBITY

Few data are available on familial syndromes associated with sinonasal cancer. Currently, no genetic predisposition to sinonasal cancer has been identified in specific familial syndromes.

CLINICAL FEATURES

The population-based incidence rates are age-related with median age at diagnosis in the 6th–7th decade, particularly in men with 20% of cases presenting before the age of 55 years and 38% after 70 years of age.[383] The clinical features of sinonasal cancer are nonspecific, including facial pain, nasal obstruction, epistaxis, and rhinorrhea. Diplopia, proptosis, or other neurological symptoms may occur in sinonasal cancer patients with advanced disease. Distant metastases are unusual (i.e., ~10%) in patients presenting with sinonasal cancers; most patients die of recurrences before metastases become clinically apparent, with possible exceptions of adenoid cystic carcinoma, malignant melanoma, and some sarcomas.[392] Metastasis of other tumors (e.g., kidney) to the paranasal sinuses is very rare.[393]

The prognosis of patients with sinonasal cancer is generally poor, with little change in overall survival during the last few decades; the overall 5-year survival rate is ~30–50% depending on primary tumor size, stage of disease at diagnosis, cervical lymph node involvement, and histological type.[394] In a study of 4,994 cases of sinonasal squamous cell carcinoma (64% men/36% women) in the US Surveillance, Epidemiology, and End Result (SEER) database, the overall 5-year survival was 53% compared with 45% for 10-year survival and 29% for 20-year survival.[356] Although prognosis is not strongly associated with histological subtypes, sinonasal cancer types varies with location within the nasal and paraspinal tissues; tumors are typically diagnosed earlier in nasal cavities than sinuses.

LARYNX

Laryngeal cancer incidence varies dramatically with location; incident rates are particularly high in Brazil, France, Italy, Spain, India, and some Southeast Asian countries.[395] Five of the 10 European regions with the highest laryngeal cancer incidence rates occur in Spain. Laryngeal cancers are much more common in men than women, particularly in Nordic, Eastern European, and Southern European countries. In Europe, during the 1990s and 2000s, laryngeal cancer accounted for ~52,000 new cases annually (~2% of the total cancer burden), with men representing 92% of the total.[396] By 2018, the age-standardized incidence rate for laryngeal cancer in Europe decreased to ~40,000 cases, with a male/female ratio of 7.65.[397] In the United States, the estimated annual laryngeal cancer incidence is ~12,400 with a male/female ratio of 3.9/1 and an estimated annual mortality of 3,800.[398] Although the incidence and mortality of laryngeal cancer has been decreasing, the overall case-fatality rate has increased as a result of the relative decrease in the incidence of localized compared with regional and distant disease. Worldwide, the estimated annual laryngeal cancer incidence is 177,000, with ~95,000 annual deaths.[269] Premalignant laryngeal dysplasia more commonly occurs in men (10/100,000) than women (2/100,000 women).[399]

CARCINOGENESIS

Early changes in the malignant process involve allelic chromosomal losses in regions 3p (possibly *FHIT* tumor suppressor; 57–68% frequency), 9p21 (*CDKN2A* tumor suppressor, p16 protein; 20–35% frequency),

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and 17p13 (*TP53*; 21% frequency).[400] The latter may not be associated with p53 tumor suppressor inactivation in early-stage laryngeal tumors because of the frequent absence of p53 expression during that stage of development. Other common (i.e., ≥20%) copy number alterations include chromosomal losses in 5q, 8p, 11q23–24, 13q, and 18q, whereas chromosomal amplifications or gains occur in 3q, 5p, 8q, 11q13, and 18p. Laryngeal tumors typically contain more chromosomal aberrations than other oropharyngeal cancers particularly chromosomal amplifications.[401] Chromosomal changes associated with these multiple focal, high-level amplifications involve overexpression of 7p12 (*EGF* receptor, transmembrane growth-regulating receptor glycoprotein), 9p24 (*AK3*, *MDS030*, *RNAC*), 11q22 (*BIRC2*, *BIRC3*, *YAP1*), 12q15 (*DYRK2*, *MDM1*, *MDM2*), and 17q23 (*APPBP2*, *PPM1D*).[402] EGFR overexpression dramatically increases during the progression of laryngeal dysplasia to squamous cell carcinoma;[403] however, early loss of *CDKN2A* ($p16^{INK4A}$, $p14^{ARF}$ protein expression, ↓ cell cyclin-dependent kinase inhibitor 2A) and *TP53* downregulation (↓cell cycle arrest, apoptosis) are less frequent in laryngeal than other head and neck cancers.

The protooncogene *BCL-2* is an antiapoptotic, membrane-associated molecule that modulates the interaction of apoptosis-activating factors (APAF-1) with caspase 9; overexpression of BCL-2 protein enhances tumor proliferation and progression by inhibiting tumor cell apoptosis.[404] Signaling pathways involved with the malignant transformation of premalignant lesions include the JAK–STAT, Hippo, and PIK3CA (phosphatidylinositol-4,5-bisphosphate 3-kinase) pathways.

Telomerase reactivation (*TERT* gene, telomerase reverse transcriptase) is a common event in all neoplasms, including in early events during the development of laryngeal carcinogenesis. The hTERT mRNA expression in laryngeal epithelium increases progressively as the degree of epithelial abnormalities increases. In an analysis of 140 frozen laryngeal tissues, hTERT mRNA expression was detectable in 7% of normal laryngeal epithelium compared with 20% of squamous hyperplasias, 75% of atypical hyperplasias, 89% of carcinomas *in situ*, and 85% of squamous cell carcinomas.[405] Innate and adaptive immune mediators enhance the progression of laryngeal tumors by releasing cytokines (IL-10, IL-6, vascular endothelial growth factor) and chemokines into the tumor microenvironment, resulting in suppression of immune responses to tumor evasion. These mediators include regulator T cells (Tregs, CD4+, CD25+ T cells with forkhead box P3), myeloid-derived suppressor cells, and tumor-associated macrophages.[406]

A single miRNA can regulate the expression of multiple mRNAs and several miRNAs can modulate the expression of a single miRNA. MicroRNAs (miRNAs) posttranscriptionally limit tumor growth by downregulating protooncogene activity or upregulating tumor suppressor gene activity. The complexity of these interactions complicates the determination of the effect of individual miRNAs on laryngeal squamous cell carcinoma oncogenes, tumor suppressors, and cancer stem cells. Both genetic (e.g., single-nucleotide polymorphisms) and epigenetic (e.g., aberrant DNA methylation/histone modification) can dysregulate miRNAs and downstream signaling pathways. Genetic targets and cellular effects of miRNAs dysregulation in laryngeal squamous cell carcinomas commonly include upregulation of miRNA-21 (*BTG2*, proliferation) and miRNA-196a (proliferation) along with downregulation of miRNA 26b (*ULK2*, autophagy/antiapoptosis) and miRNA-203 (*ASAP1*, proliferation, cell cycle control, apoptosis, invasion).[407] Autophagy is the process that maintains normal cell function by degrading intracellular macromolecular substances from aging organelles. Downregulation of *ULK2* (unc-51-like autophagy activating kinase 2) enhances laryngeal tumor survival by limiting miRNA-26b-induced cell proliferation and inactivating the PTEN/AKT (autophagy/antiapoptosis) pathway.[408]

EXPOSURE

The main risk factors for laryngeal cancer are tobacco use and, to a lesser extent, alcohol consumption, with some evidence of more than an additive interaction together. Asbestos and sulfuric acid exposures are the main occupational carcinogens associated with laryngeal cancer; however, a British review of occupational cancers estimated the attributable fraction of laryngeal cancers resulting from occupational exposures is relatively small (AF = 2.61%, 95% CI: 0.0083–0.0432).[409] Other studies suggest higher attributable fraction ranging from 1–20% (sulfuric acid, mineral oils) in the United States,[410] whereas a Finnish study reported an attributable fraction of 9.1% (9.3% men/0.5% women) based on combined factors (asbestos, welding fumes, metal dust, irritant gases, polycyclic aromatic hydrocarbons).[411] Asbestos exposure accounted for 8.3% of the attributable fraction among men compared with 0.3% in women. In contrast to sinonasal cancers, laryngeal cancer is strongly associated with lifestyle because of the synergistic interaction of smoking and alcohol consumption on laryngeal cancer risks.[412]

Diet is not a strong risk factor for laryngeal cancer based on limited observational data involving

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 53.5. Statistical data on various occupations in the ICARE (Introduce, Communicate, Acknowledge, Recommend, and Encourage) Study and the 5-Country Nordic Study. Substantial variation exists between studies of laryngeal cancer risks in specific occupations in part from multiple comparisons. The seven occupations in men that reached a statistically significant association in the ICARE study, with the risk of laryngeal cancer compared with standardized incidence ratios in similar occupations from the 15 million 5-Country Nordic Study.[415] The latter study reported statistically significant SIRs in 9 of 54 occupational categories, including mechanics, electrical workers, printers, food workers, public safety workers, building caretakers, hairdressers, and cooks/stewards. Only the latter category was statistically significant for the different measures of risk (i.e., OR, SIR) in the two studies. (Adapted from Paget-Bailly et al.).[414]

Occupation	Laryngeal Cancer Cases	Odds Ratio ICARE	SIR Nordic Countries	95% Confidence Interval ICARE	95% Confidence Interval Nordic Countries
Launderers, dry cleaning, pressing[a]	6	13.3	1.31	2.4–75.0	0.82–1.99
Agricultural, animal husbandry[a]	9	7.9	0.43 (farmers)	2.6–23.9	0.30–0.60
Fishing[a]	6	3.6	1.83	1.1–12.2	0.05–10.18
Plastering	10	3.3	—	1.3–8.2	—
Rubber, plastics production[a,b]	14	3.2	—	1.5–6.8	—
Welding, flame cutting	33	2.4	4.93 (welders)	1.5–4.0	0.60–17.81
Cooks[a]	25	2.4	1.59	1.4–4.2	1.09–2.24

Abbreviation: SIR = standardized incidence ratio.
[a] Although categories varied somewhat in a German meta-analysis of 21 case-control studies on laryngeal cancer, none of these categories were associated with statistically significant meta-effects using a fixed effects model.[416] The highest laryngeal cancer risks were associated with blue-collar jobs (miners, chemical processors, spinners, weavers, knitters, dyers, tailors, dressmakers, sewers, upholsterers, glass formers, potters, blacksmiths, toolmakers, machine tool operators, painters, maids, forestry workers). [b] Excludes tire makers and vulcanizers.

primarily pooled data from retrospective dietary analyses in case-control studies. Using self-reported or interview-administered food-frequency questionnaires, a study using pooled data from 2,452 cases and 5,013 controls in the International Head and Neck Cancer Epidemiology (INHANCE) consortium divided information on 24 nutrients into 3 major categories.[413] The adjusted laryngeal cancer risks were positively associated with animal products and cereals (aOR = 1.57, 95% CI: 1.15–2.15, n = 253 cases/983 control cases, $P_{\text{heterogeneity}}$ = 0.008) and fats (aOR 1.70, 95% CI: 1.23–2.36, n = 210 cases/981 control cases, $P_{\text{heterogeneity}}$ = <0.001) comparing the highest and lowest (referent) quintiles with unconditional logistic regression and fixed effects models on quintiles of factor scores. The highest quintile for antioxidant vitamins and fiber was inversely associated with laryngeal cancer risks (aOR = 0.52, 95% CI: 0.38–0.70, n = 85 cases/977 control cases, $P_{\text{heterogeneity}}$ = <0.001). Analysis indicated high heterogeneity; however, the results were similar using mixed effects models.

Occupation

A French population-based case-control study (ICARE) examined laryngeal cancer risks in men by comparing 33 occupations listed by 456 laryngeal cancer patients with local controls.[414] Table 53.5 lists the odds ratios for the seven occupations that reached statistical significance in an analysis of ICARE data. Determination of a causal association with these seven occupations and laryngeal cancer requires further confirmation.

A systematic review and meta-analysis of 30 case-control, 65 cohort, and 4 record-linkage studies suggested elevated laryngeal cancer risks following exposure to textile dust (metaRR = 1.41, 95% CI: 1.09–1.83), polycyclic aromatic hydrocarbons (metaRR = 1.29, 95% CI: 1.10–1.52), engine exhaust (metaRR = 1.17, 95% CI: 1.05–1.30), and work in the rubber industry (metaRR = 1.39, 95% CI: 1.13–1.71).[417] Egger testing and funnel plot analysis suggest some publication bias for the textile dust studies. The study detected no association between laryngeal cancer and cement dust, formaldehyde, or wood dust. In a meta-analysis of 13 mortality studies on laryngeal cancer in the synthetic rubber-producing industry, the pooled metaSMR was modestly elevated and statistically nonsignificant (metaSMR = 1.19, 95% CI: 0.88–1.60, $P_{\text{heterogeneity}}$ = 0.01).[418] The metaSIR for laryngeal cancer was similarly positive and statistically nonsignificant (metaSIR = 1.39, 95% CI: 0.75–2.59, $P_{\text{heterogeneity}}$ = 0.58). Limiting the meta-analysis to rubber-industry cohorts exclusively producing tires yielded null results (metaSMR = 1.01, 95% CI:

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

0.70–1.48, $P_{heterogeneity}$ = 0.604). A French occupational study of 296 laryngeal cancers and 296 patients with other tumor sites did not detect an association between formaldehyde exposure and laryngeal cancer.[419] A systematic review and meta-analysis of 7 case-control and 16 cohort studies did not detect a statistically significant association between standardized incidence (pooled SIR = 1.50, 95% CI: 0.59–2.42) or mortality (pooled SMR = 1.38, 95% CI: 0.79–1.96) for laryngeal cancer and silica dust exposure.[420]

Asbestos

Although the IARC classifies asbestos as a human laryngeal carcinogen, the association between asbestos exposure and laryngeal cancer remains debatable, primarily because of potential recall bias and the lack in controlling the strongest risk factors (synergistic effects of tobacco smoking/alcohol consumption) in many studies, as noted in a systematic review in 2000.[421] Similarly, a subsequent systematic review of 10 cohort and 5 case-control studies published from 2000–2016 concluded the current medical literature on laryngeal cancer and asbestos exposure is conflicting and lacks support for a correlation between the two.[422] Among the three case-control studies controlling for smoking and alcohol use, the odds ratios ranged from 0.86 (95% CI: 0.51–1.0, n = 350 cases) to 1.0 (95% CI: 0.8–1.3, n = 150 cases). Only 2 of 10 cohort studies accounted for smoking with a relative risk of 1.8 (95% CI: 0.8–4.3, n = 18 ever-exposed cases) for one cohort study after controlling for smoking and mineral wool exposure. The study did not control for alcohol use or demonstrate a dose-response relationship between laryngeal cancer and asbestos exposure.[423] The hazard ratio for the other cohort study was 6.36 (95% CI: 2.18–18.53) using one job-exposure matrix and 1.49 (95% CI: 0.75–2.97) after adjustment for smoking and alcohol consumption using another job-exposure matrix.[424]

A case-control study of 100 men with laryngeal squamous cell carcinoma and 100 age-matched hospital controls reported a strong association between asbestos exposure and laryngeal cancer, with 31% of the cases and 3% of the controls having an "important exposure to asbestos" ($P_{difference}$ = <0.001).[425] The control group contained more nonsmokers than cases; no data were collected on alcohol consumption. Subsequent studies demonstrated a much weaker association based on better control of confounders (i.e., smoking, alcohol consumption).[421,426] In a meta-analysis of four cohort studies on laryngeal cancer mortality, the metaSMR was positive and statistically nonsignificant (metaSMR = 157, 95% CI: 95–245), with a latency of at least 10 years.[427] The data did not demonstrate a dose-response relationship or correlate laryngeal cancer to the percentage of mesothelioma deaths. The proportionate mortality from mesothelioma as a percentage of all deaths was a proxy marker for the semiquantitative estimation of asbestos doses. In the prospective Netherlands Cohort Study of 58,279 men followed for 17.3 years, the adjusted hazard ratio for laryngeal cancer was modestly positive and statistically nonsignificant (aHR = 1.20, 95% CI: 0.84–1.72, n = 52 cases/114 controls).[424] The association was stronger for supraglottic (aHR = 2.14, 95% CI: 1.13–4.04, n = 20 cases/24 controls) than glottic cancer (aHR = 0.94, 95% CI: 0.61–1.44, n = 32 cases/90 controls). Adjusted factors included age, current smoking, daily cigarette use, smoking duration, and alcohol consumption. The trends for almost all measures of cumulative intensity and duration of exposure were statistically nonsignificant.

In a German population-based study of 257 laryngeal cancer cases (236 men, 21 women) and 771 age/sex-matched controls, the odds ratio for laryngeal cancer in ever-asbestos exposed cases was 1.2 (95% CI: 0.83–1.7, n = 73 cases/18 controls) after adjusting for smoking and alcohol using nonexposed controls as referents. Asbestos exposure was determined from in-person interviews using job-specific questionnaires and substance check lists.[428] Although evaluation of crude odds ratios and cumulative asbestos exposures suggested the presence of positive dose responses, all the odds ratios were statistically nonsignificant after adjustment for smoking and alcohol.

Inorganic Acid Mists

Exposure to strong inorganic acid mists (sulfuric acid) is associated with laryngeal cancer in several industries, including the production of isopropanol/ethanol, battery manufacturing, sulfuric acid production, and steel pickling. A Canadian population-based study of 183 laryngeal cancer cases and 183 age/sex-matched controls used logistic regression to estimate odds ratios for laryngeal cancer exposures based on personal questionnaires and blinded, expert retrospective assessment.[429] Using the most sensitive, semiquantitative model, the odds ratio for laryngeal cancer in the high-sulfuric acid exposure group was 4.28 (95% CI: 2.13–8.58) compared with 1.91 (95% CI: 0.97–3.78) for the low-exposure group. Exposure-response gradients were strongly positive after adjustment for tobacco and alcohol consumption using a more specific semiquantitative model. The odds ratio for short-duration (≤10 years), low-level exposure was 1.97 (95% CI: 0.63–6.13) and 6.91 (95% CI: 2.20–21.74) for long-duration (>10 years) high-level exposure. In a retrospective cohort study of the metal pickling industry, Steenland et al. identified 9 incident

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

laryngeal cancer cases in 879 workers (73% participation rate, 26% proxy interviews) exposed to sulfuric acid mists (40% additionally exposed to other acids).[430] The duration of exposure was 9.5 years with an estimated 8-hour TWA of 0.2 mg/m^3. After adjusting for tobacco smoking and alcohol consumption, the estimated standardized incidence ratio was 230 (95% CI: 105–436) using US population data. A review of 25 epidemiology studies on respiratory tract cancer reported a moderate association between sulfuric acid mists and laryngeal cancer with a suggestive dose-response relationship; however, the authors noted the study results were imprecise with inadequate control of confounding (tobacco smoking, alcohol consumption).[431] The authors identified three industries (sulfuric acid production, isopropanol production, metal pickling) with a high potential for sulfuric acid exposure (>1 mg/m^3 sulfuric acid as an 8-hour time-weighted-average typically occurring prior to 1970). Data were inadequate to evaluate laryngeal cancer risks in sulfuric acid and isopropanol production industries. The authors from the Steenland study opined the SIR did not vary with time since first exposure and evidence for a dose-response relationship was not persuasive; however, they noted residual confounding of smoking could not account for the excess laryngeal cancer SIR.

Lifestyle

Tobacco dominates the risk of glottic and vocal cord cancers, whereas alcohol is a stronger risk factor for supraglottic cancers. Overall, alcohol is a weaker risk factor than tobacco smoking. Most investigations indicate the synergistic effect of combined tobacco and alcohol consumption on laryngeal cancer risks is at least greater than additive and potentially multiplicative.[432,433] In the ICARE study, the interactions of asbestos exposure/alcohol consumption and asbestos exposure/smoking were additive, whereas the interaction of asbestos exposure/smoking/alcohol consumption was greater than additive.[434]

Tobacco Smoking

The relative risk of laryngeal cancer comparing ever- and never-smokers is ~10-fold, with a smaller risk in smokers exclusively using filtered cigarettes (RR = 0.5 compared with exclusively plain-cigarette smokers).[435] The laryngeal cancer risk in smokers decreases after smoking cessation (RR = 0.3 after 10 years). Smoking history accounts for an estimated 90–95% of laryngeal cancer cases.[436] The prospective Netherlands Cohort Study of 58,279 men aged 55–69 years identified 166 laryngeal cancers during 17.3 years of follow-up. The study did not detect a statistically significant interaction between smoking and asbestos exposure on laryngeal cancer risks based on self-reported questionnaires and job-exposure matrices.[424] The hazard ratio for asbestos exposure within the strata of cigarette smoking comparing 72 never asbestos-exposed versus 33 ever-asbestos exposed current smokers was 1.23 (95% CI: 0.78–1.94) without evidence of a multiplicative interaction ($P_{\text{multiplicative interaction}} = 0.85$).

Alcohol

The relative and absolute risks are small for moderate alcohol consumption in the absence of smoking (e.g., RR = ~2 for 4 drinks/day compared with nondrinkers).[437] In a Seattle, Washington, population-based, case-control study of 235 laryngeal cancer cases and 547 age- and gender-matched local residents, independent risk factors for laryngeal cancer were alcohol consumption (≥42 drinks/week compared with ≤7 drinks/week; OR = 3.1, 95% CI: 1.2–7.9), cigarette use (≥40 cigarettes/day compared with never-smoking; OR = 23.1, 95% CI: 9.4–52.6), and weighted positive responses to the Michigan Alcohol Screening Test (MAST score of ≥5 compared with 0; OR = 1.9, 95% CI: 1.1–3.4) using unconditional logistic regression.[438] A meta-analysis of 38 case-control studies and 2 cohort studies used random effects modeling to estimate laryngeal cancer risks in predefined consumption levels of light, moderate, and heavy alcohol consumption.[439] As displayed in Table 53.6, light alcohol consumption (≤1 drink daily) is not associated with increased laryngeal cancer risks, whereas the risk increases with increasing alcohol consumption using never/occasional drinkers as referents. Substantial heterogeneity limits definitive conclusions regarding causality following moderate to high alcohol consumption.

Diseases

Infections

The role of human papilloma virus (HPV) in the development of laryngeal cancer tumors remains controversial, in part because of the presence of HPV genotypes in normal pharyngeal tissue and the geographical variation in HPV laryngeal squamous cell carcinoma prevalence rates.[440] In eight studies with laryngeal sample sizes ranging from 86–110, the HPV prevalence ranged from 7–59%, most commonly high-risk HPV-16 and HPV-18.[441] In a meta-analysis of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 53.6. In a meta-analysis of 40 studies using random effects modeling, adjusted meta-odds ratios, and 95% confidence intervals for estimated laryngeal cancer risks were estimated in four alcohol consumption categories (overall, light, moderate, high). The results are consistent with no association with light drinking, modest association with moderate drinking, and ~2.5-fold increase for drinking four or more drinks daily using never/occasional drinkers as referents. The results displayed substantial heterogeneity for overall, moderate, and high categories. The meta-odds ratios were adjusted for age, sex, and smoking by matched analysis, stratified analysis, or adjustments in multivariate models.[439]

Alcohol Category	Dose (Drinks/Day)	Studies (*n*)	Adjusted Meta Odds Ratio	95% Confidence Interval	I^2 Statistic (%)	$P_{heterogeneity}$
Overall	Any	20	1.84	1.50–2.26	81.5	<0.001
Light	>0–1	6	0.88	0.70–1.12	22.6	0.26
Moderate	>1–<4	20	1.50	1.23–1.83	64.2	<0.001
High	≥4	17	2.46	1.88–3.22	79.7	<0.001

55 studies involving 2,559 laryngeal cancer cases, 741 (28%) were HPV$^+$ (95% CI: 23.5–32.9, I^2 = 82.39%) with substantial heterogeneity; in this study 19.8% (95% CI: 15.7–24.6%, I^2 = 78.83%) were HPV-16$^+$ compared with 6.2% (95% CI: 4.0–9.5%, I^2 = 68.53%) for HPV-18$^+$ and 3.7% (95% CI: 2.4–5.7%, I^2 = 39.60%) for low-risk HPV genotypes overall.[442] The presence of HPV DNA alone does not indicate viral involvement in laryngeal squamous cell carcinoma.[443] Using more recent data, E6/E7 oncoproteins positivity of >70%, and high p16 protein positivity as documentation of integrated and transcriptionally active HPV linked to HPV-related carcinogenesis, the fraction of laryngeal cancers potentially associated with HPV infection was small (i.e., <5%).[444,445]

Gastrointestinal Reflux

Data on the association of gastrointestinal reflux disease (GERD) with laryngeal cancer are limited, with substantial potential for confounding (tobacco smoking, alcohol consumption) and misclassification from inaccuracies occurring in the diagnosis of reflux.[446] Gastrointestinal reflux disease, premalignant lesions, and laryngeal cancer commonly coexist; however, the role of GERD in the development of laryngeal cancer remains controversial. In a US study of 92 incident laryngeal cancer cases and 192 age/gender/ethnicity-matched, clinic-based controls, the increased laryngeal cancer risk was statistically significant (OR = 2.11, 95% CI: 1.16–3.85) for any criteria of GERD based on retrospective chart review (ICD-9 codes, symptoms of heartburn/acid regurgitation, multivariate conditional logistic regression).[447] Using univariate analysis, the association was much stronger based on symptomatic GERD (OR = 2.58, 95% CI: 1.11–6.10, n = 13 cases/11 control cases) than ICD-9 codes (OR = 0.52, 95% CI: 0.24–1.09, n = 12 cases/39 control cases). In a US study of 116 incident laryngeal cancer cases and 917 population-based controls, a history of often/extreme heartburn was not associated with an elevated adjusted laryngeal cancer risk (aOR = 0.84, 95% CI: 0.45–1.55) using subjects with no heartburn history as referents.[448] The odds ratio was adjusted for age, sex, race, smoking, alcohol consumption, HPV16 exposure, education, and BMI. A study of US Veterans Health Administration outpatient care files identified 14,449 incident laryngeal cancer cases 1:1 with frequency-matched controls based on the year of cancer diagnosis.[449] Controls were not matched to patient characteristics (e.g., age/sex). Using multivariate logistic regression analysis, GERD was not associated with laryngeal cancer (OR = 1.01, 95% CI: 0.92–1.12, P = 0.780), whereas the P value was positive for tobacco use, alcohol abuse, male gender, and age decile.

HISTOLOGY

Almost all laryngeal cancers (i.e., ~85–90%) are squamous cell carcinomas originating in the glottis, with supraglottic and subglottic tumors being much rarer.[395] Glottic tumors in the United States occur predominantly in the Anglo-Saxon population, whereas the number of glottic and supraglottic tumors is similar in France, India, and African-American populations. Most head and neck tumors including laryngeal cancer probably arise from common premalignant progenitor cells associated with the stepwise increase in genetic alterations during the progression from dysplasia to carcinoma *in situ* and invasive cancer.[450] The estimated progression of dysplastic epithelial lesions to malignant transformation is ~8–15%. In a meta-analysis of 9 observational studies involving 940 laryngeal cancer cases, the overall malignant transformation rate for laryngeal dysplasia was 14% (95% CI: 8–22%) with a mean time to malignant transformation of 5.8 years.[451] A review of 107 laryngeal dysplasia cases identified over 20 years at John Hopkins University reported ~8% of these cases progressed to laryngeal cancer.[452]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. The WHO classification separates precursor lesions into low- and high-grade dysplasia (squamous intraepithelial neoplasia, SIL) with the option of distinguishing carcinoma *in situ* from high-grade dysplasia for treatment purposes.[453] Laryngeal neuroendocrine carcinomas are divided into well- (carcinoid), moderate- (atypical carcinoid), and poorly differentiated neuroendocrine carcinomas; the latter subtypes of poorly differentiated neuroendocrine carcinomas include small cell and large cell neuroendocrine carcinomas.

HOST SUSCEPTIBILITY

Nucleotide excision repair system regulates the main pathway for repairing bulky DNA lesions common in tobacco smokers while maintaining genome stability. Polymorphisms in *ERCC1* and *ERCC5* increase susceptibility to laryngeal cancer, particularly in ever-smokers and alcohol drinkers.[454,455] Genetic polymorphisms of cytochrome P450 family (i.e., *CYP1A1*, *CYP2E1*) are not associated with increased susceptibility to laryngeal cancer.[456]

CLINICAL FEATURES

Laryngeal cancer typically presents in older patients. The diagnosis of laryngeal cancer is rare under 40 years of age, with the risk increasing rapidly with age. Survival varies with sex and tumor location. Approximately one-half of laryngeal cancers in men appear in the glottis, including the vocal cords. Advanced laryngeal cancer presents with pain, dysphagia, and airway obstruction, particularly with supraglottic tumors; however, an asymptomatic neck mass may be the first sign of a laryngeal tumor. The 5- and 10-year survival rates for men in England and Wales diagnosed with laryngeal cancer during the 1990s were 64% and 54%, respectively.[395] Overall survival rates have not improved dramatically in the last several decades, with 5-year survival rates ranging from ~40–60% in advanced stages depending on stage, treatment, location, and age.[457] Laryngeal cancers in the glottis typically have a relatively better prognosis in men from the early onset of hoarseness and diagnosis, smaller tumor size, and greater responsiveness to surgery and radiotherapy. The clinical presentation of supraglottic tumors occurs more often in women with a worse prognosis from delayed diagnosis and less responsiveness to surgery and radiotherapy.

Chapter 54

GASTROINTESTINAL TRACT

Gastrointestinal tract cancers account for ~20–25% of the overall cancer incidence in the United States; these cancers include malignancies of the oropharynx (oral cavity, salivary glands, tonsils, pharynx), esophagus, stomach, colon/rectum, anus, liver/biliary tract, and gall bladder. The wide international variation in the incidence of each type of gastrointestinal cancer suggests the environment and genetics contribute significantly to cancer development in this part of the human body. Dietary and lifestyle factors are important determinants of gastrointestinal cancers; these factors may confound the interpretation of epidemiological studies on the effects of chemical exposures, particularly when the risks are relatively low. Table 54.1 lists the strength of the human evidence (sufficient, limited) for carcinogenic agents and processes associated with gastrointestinal tract cancers based on evaluations by the International Agency for Research on Cancer.[1,2] These evaluations indicate causal associations between gastrointestinal tract cancers and carcinogens primarily involve lifestyle and infectious processes rather than occupational exposures.

OROPHARYNGEAL

Head and neck cancers include tumors of the oral cavity, paranasal sinuses, oropharynx, and hypopharynx. These tumors arise from the lining or mucosa of the upper aerodigestive tract and almost all of these tumors are squamous cell carcinomas. Other than oropharyngeal cancer, head and neck cancers are covered in chapter 53. An estimated 85,000 oropharyngeal cancer cases occur worldwide annually, with enhanced risks for oropharyngeal cancers resulting primarily from lifestyle choices.[3] Most oropharyngeal cancers result from tobacco use; however, oropharyngeal cancer incidence has recently increased dramatically with the emergence of human papillomavirus (HPV)-associated squamous cell carcinomas. This increase occurred despite the reduced oropharyngeal cancer incidence rates since the late 1980s associated with reduced tobacco use since the mid-1960s. In men, the incidence of oropharyngeal cancer continues to increase in the United States, particularly in elderly men, whereas the increase is much less dramatic in women.

CARCINOGENESIS

Previously, tobacco use, including betel quid, snuff dipping (e.g., toombak),[4] and other smokeless tobacco, was the most important oropharyngeal cancer-related carcinogen along with alcohol.[5,6] In a New Zealand study of census and cancer registry data from 1981 and 1996, the standardized incidence rate ratio (SRR) of oropharyngeal cancer in current smokers versus never-smokers was 2.30 (95% CI: 1.94–2.72) after adjustment for age, sex, ethnicity, socioeconomic factors, confounding, and exposure misclassification.[7] Adjustment for residual confounding slightly reduced the SRR for oropharyngeal cancer. *N*-nitroso compounds (tobacco-specific *N*-nitrosamines, *N*′-nitrosonornicotine) in tobacco products are suspected carcinogens causing elevated

TABLE 54.1. International Agency for Research on Cancer (IARC) classification of gastrointestinal tract cancer sites by sufficient and limited evidence of human carcinogenicity. (Adapted from Cogliano et al. and IARC).[1,2]

Anatomical Site	Carcinogens with *Sufficient* Human Evidence (Group 1)	Carcinogens with *Limited* Human Evidence (Groups 2A or 2B)
Oral cavity	Acetaldehyde associated with alcoholic beverage consumption, alcoholic beverages, betel quid with/without tobacco, human papillomavirus type 16, tobacco, smokeless, tobacco smoking	Bitumens occupational exposure during mastic asphalt work and roofing, human papillomavirus type 18
Salivary gland	Acetaldehyde associated with alcoholic beverage consumption, x- and γ-radiation	Iodine radionuclides including ^{131}I
Tonsil	Human papillomavirus type 16	
Pharynx, combined	Alcoholic beverages, betel quid with tobacco, human papillomavirus type 16, tobacco smoking	Asbestos (all forms), bitumens occupational exposure during mastic asphalt work and roofing, opium consumption, printing processes, secondhand tobacco smoke
Esophagus	Acetaldehyde with alcoholic beverage consumption, alcoholic beverages, betel quid with/without tobacco, smokeless tobacco smoking, x- and γ-radiation	Dry cleaning, opium consumption, pickled vegetables (traditional Asian), rubber production industry, very hot beverages (squamous cell carcinoma)
Stomach	*Helicobacter pylori*, rubber production industry, tobacco smoking, x- and γ-radiation	Art glass, glass containers and pressed ware manufacturing, asbestos (all forms), Epstein–Barr virus, inorganic lead compounds, nitrate or nitrite (ingested under conditions causing endogenous nitrosation), pickled vegetables (traditional Asian), salted fish, Chinese-style, processed meat consumption
Colon and rectum	Alcoholic beverages, processed meat consumption, tobacco smoking, x- and γ-radiation, processed meat consumption	Asbestos (all forms), firefighting, night shift work, *Schistosoma japonicum,* red meat consumption
Anus	Human immunodeficiency virus type 1, human papillomavirus type 16	Human papillomavirus types 18, 33.
Liver	Aflatoxins, alcoholic beverages, *Clonorchis sinensis*, 1,2-dichloropropane, Estrogen–progestogen contraceptives, hepatitis B virus chronic infection, hepatitis C virus chronic infection, *Opisthorchis viverrini,* plutonium, thorium-232 and its decay products, tobacco smoking (in smokers and smokers' children), vinyl chloride	Androgenic (anabolic) steroids, arsenic and inorganic arsenic compounds, betel quid without tobacco, DDT, dichloromethane (methylene chloride), human immunodeficiency virus type 1, *Schistosoma japonicum*, trichloroethylene, x- and γ-radiation
Bile duct	*Clonorchis sinensis* infection, 1,2-dichloropropane, *Opisthorchis viverrini*, plutonium, thorium-232 and its decay products, tobacco smokers	Androgenic (anabolic) steroids, arsenic and inorganic arsenic compounds, betel quid without tobacco, DDT, dichloromethane (methylene chloride), hepatitis B virus chronic infection, hepatitis C virus chronic infection, *Schistosoma japonicum*, trichloroethylene, x- and γ-radiation
Gallbladder	Thorium-232 and its decay products	
Pancreas	Smokeless tobacco, tobacco smoking	Alcoholic beverages, opium consumption, red meat consumption, thorium-232 and its decay products, x- and γ-radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. oropharyngeal cancer risks.[8] As tobacco use decreased since the mid-1960s, the incidence of oropharyngeal cancer also decreased along with reductions in some smokeless tobacco related carcinogen concentrations (e.g., *N*-nitrosodiethanolamine, *N*-nitrosomorpholine).[9]

Many of the newly diagnosed cases of oropharyngeal cancer do not have the traditional tobacco/alcohol risk factors for oropharyngeal cancer. In the US and Europe, human papillomavirus (HPV) accounts for 60–70% of oropharynx squamous cell carcinomas. Although there are over 100 HPV serotypes, almost 90% of HPV^+ oropharyngeal cancers develop from HPV16 infections.[10,11] These viruses infect basal keratinocytes in mucous membranes and skin, producing elevated risks of multiple cancers including anus, cervix, penis, vagina, and vulva. Other head and neck cancers (e.g., oral cavity, hypopharyngeal, nasopharyngeal, laryngeal) are usually HPV^-.[12]

HPV is a circular, double-stranded DNA virus encoding eight early genes (E1–E8) involved with host cell transformation and two late genes (L1, L2). HPV-associated carcinogenesis results from viral DNA integration, oncogene activation, cell proliferation, and neoplastic transformation. Integration of viral DNA into the human keratinocyte nuclear DNA and subsequent oncogenic protein E6/E7 mRNA expression promote the carcinogenic process. Integration of high-risk HPV (e.g., HPV16) causes insertional mutagenesis that produces chromosomal instability, double strand breaks, and precancerous lesions. The transcription of E6/E7 promotes cellular transformation by blocking inhibitory cell cycle regulators (p53, Rb1, Rb2). E6 binds tumor-suppressor protein p53 resulting in ubiquitination and proteasomal p53 degradation, whereas E7 binds pRb (retinoblastoma protein) allowing unrestrained cell proliferation and enhanced p16 expression.[13] The combined effects of E6/E7 oncoprotein production cause loss of cell cycle checkpoint control, genetic alterations, and abrogation of p53-dependent apoptosis.[14]

The immunohistochemical staining of p16 and p53 helps distinguish tobacco-induced from HPV-induced oropharyngeal cancers because tobacco-related cancers typically display high p53 and low p16 expression. Late capsid proteins (L1, L2) encapsidate viral genomes in the cornified skin layers followed by shedding of mature virions. The immune system clears most HPV infections with only ~1/2 of the cases developing antibodies to HPV.[10] HPV^- oropharyngeal squamous cell carcinomas are epidemiologically similar to the traditional squamous cell carcinoma of the oropharynx. In contrast to HPV-associated cervical cancer, no screening test reliably predicts neoplastic transformation after HPV exposure.[15]

EXPOSURE

Traditionally, tobacco smoking/chewing and, to a lesser extent, heavy alcohol consumption accounted for most oropharyngeal cancers;[16] residual confounding from inaccurate evaluation of lifetime alcohol exposures complicates the determination of the exact role of alcohol in the development of oropharyngeal cancer. In the INHANCE consortium study, most oropharyngeal cancer cases resulted from tobacco alone or the combined use of tobacco and alcohol with relatively few cases attributed to alcohol drinking alone.[16] The recent increased incidence of oropharyngeal cancer from human papillomavirus (HPV)-associated squamous cell carcinomas has unique epidemiological, molecular, and clinical characteristics, as displayed in Table 54.2. The incidence of HPV-associated oropharyngeal cancer has dramatically increased, particularly in elderly men. In 2005–2006, prior to the introduction of the 9 valent-HPV vaccines in 2014, seropositivity for any of the 9 HPV serotypes included in the Gardasil® vaccine (Merck & Co., Inc. West Point, PA) was ~40% for US females aged 14–59 years and ~20% for US males aged 14–59 years.[17] The highest seropositivity rate was 52.4 (95% CI: 46.5–58.3) for US women aged 30–39 years. The overall seropositive rate for HPV16/18 was 18.3%; however, HPV seropositivity does not necessarily reflect the HPV-related cancer status of an individual patient. Of over ¾ of individuals developing an HPV infection, only a fraction will seroconvert and many of these patients will subsequently lose their seropositivity.[18] Typically, HPV infections are sexually transmitted and asymptomatic with skin-to-skin transmission possible.

HISTOLOGY

Although pharynx commonly refers to nasopharyngeal, hypopharyngeal, and oropharyngeal locations, at least 80% of pharyngeal cancers occur in the oropharynx.[18] The oropharynx exists between the soft palate superiorly and the hyoid bone inferiorly, being continuous with the oral cavity anteriorly, the nasopharynx superiorly, and the supraglottic larynx and hypopharynx inferiorly. Most head and neck cancers are squamous cell carcinomas resulting from hyperplasia of squamous epithelium in the basal layer of the mucosal surfaces. Oral erythroplakia and leukoplakia represent red or white dysplastic, precancerous lesions, respectively, with ~20% of these lesions progressing to oral cancers, primarily tongue and buccal mucosa;[19] however, the absence of precancerous lesions among individuals with oropharyngeal cancer probably reflects the difficulty accessing deep tonsillar crypts.[20]

TABLE 54.2. Tumor characteristics separating human papillomavirus poitive (HPV^+) and human papillomavirus negative (HPV^-) oropharyngeal cancers. (Adapted from Mallen-St Clair).[12]

Characteristic Tumor Signature	HPV^+	HPV^-
Molecular	Wild type p53, ↑p16, ↓Rb, ↓p53	Mutated p53, genomic instability, mutations ↑
Pathogenesis	E6/E7-induced cell transformation	Tobacco/alcohol use, poor oral hygiene with chronic inflammation/free radical formation causing DNA damage
Cell composition	B cells, NK cells, T cells (CD3+, CD4+, CD8+, CD34+), monocytes	Epidermal, dermal, endothelial cells, keratinocytes, fibroblasts
Epidemiological	Younger, white males with multiple oral/vaginal sexual partners, marijuana use, better treatment response	Older, African American population, ethanol/tobacco use, poor oral hygiene, poor treatment response
Clinical	Early T stage with extensive nodal involvement. Cystic, multilevel tumor phenotype	Late T stage with typically less nodal disease
Histological	Non-keratinized, lobular growth infiltrated by lymphocytes, well or undifferentiated histology with basaloid morphology	Keratinized, moderately differentiated
Metastasis	Distant metastasis post-chemotherapy with distinct pattern in liver, lung, bone, and other tissues requiring alternate surveillance strategies	Local and lung metastasis with relatively less distant metastasis pattern to bone, liver, and other sites

The epidermal growth factor receptor (EGFR) signaling pathway is highly upregulated in oral precancerous lesions; increased expression of this pathway strongly predicts the potential for malignant transformation.[21] Most oropharyngeal cancers associated with HPV occur in the lingual/palatine tonsils or base of the tongue; papillomaviruses typically infect basal epithelial cells of the reticulated epithelium lining the tonsillar crypts through localized wounds or abrasions.[11,22] Although HPV DNA exists in squamous cell carcinomas from other subsites of the upper aerodigestive tract (i.e., oral cavity, larynx, hypopharynx), HPV^- squamous cell carcinomas are most common in the oropharynx, whereas the role of HPV in the development of cancer at other aerodigestive subsites is unclear. Consequently, the presence of HPV DNA in a carcinoma does not necessarily imply causality.[10] Histologically, HPV^+ oropharyngeal cancers are usually basaloid, non-keratinizing, lymphoepithelial, or poorly differentiated.[23]

HOST SUSCEPTIBILITY

Genetic polymorphisms and variations in immune function may increase the risk of HPV^+ oropharyngeal squamous cell carcinomas;[24] however, the role of these potential risk factors is not well defined. Retrospective observational studies of diabetics suggest a slightly elevated risk of oropharyngeal cancer in diabetics. In a retrospective cohort study using the Taiwan Longitudinal Health Insurance Research Database containing 89,089 newly diagnosed diabetics and nondiabetic controls matched for comorbidities (coronary artery disease, hyperlipidemia, hypertension, obesity), sex, and age, the adjusted hazard ratio was 1.53 (95% CI: 1.01–2.31).[25] In general, the presence of the germline gene variants of DNA repair genes in Fanconi syndrome increases the risk of non-HPV head and neck cancers.

CLINICAL FEATURES

Overall, the incidence of head and neck cancers is about 2–4 times higher in men than women. The typical oropharyngeal, HPV^+ cancer patient is a middle-aged, nonsmoking Caucasian with higher socioeconomic status and a history of multiple orogenital sexual partners. Compared with tobacco-related oropharyngeal cancer, the diagnosis of HPV^+ oropharyngeal cancer usually occurs earlier (i.e., median age, 55–60 years) than HPV^- oropharyngeal cancer; however, the incidence of HPV^+

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

oropharyngeal cancer in elderly patients (i.e., >65 years) is increasing. In an analysis of 40,264 cases of HPV^+ oropharyngeal cancer from the Surveillance, Epidemiology, and End Results (SEER) database (2000–2012), ~33% were aged ≥65 years and ~80% were male.[26] HPV^+ oropharyngeal cancer often presents as an asymptomatic neck mass. Potential symptoms include dysphagia, odynophagia, and earache.

The TNM staging system refers to the size and extent of the tumor (T), the number of positive local nodes (N), and the presence of metastasis (M). Patients with HPV^+ oropharyngeal cancer usually present with asymptomatic, small primary oropharyngeal tumors (T1, T2) and symptomatic cystic nodal disease (N1–N3). Cervical nodal metastasis without an obvious primary tumor is a classic presentation of HPV^+ oropharyngeal cancer; however, the anatomical distribution of positive cervical nodes is similar between HPV^+ and HPV^- oropharyngeal cancers.[27] Prognosis depends on tumor site, HPV status, age, and overall stage. Despite the presence of advanced nodal disease, survival rates are typically higher and recurrence rates lower in HPV^+ than HPV^- squamous cell cancers, in part, due to the increased chemo-radiosensitivity of HPV^+ tumors.[28,29] Recurrence that occurs in HPV^+ patients usually occurs at distant, nonpulmonary sites. The overall 3-year survival for HPV^+ patients with oropharyngeal squamous cell cancer is 93% for never-smokers or light smokers with a low N stage (ipsilateral disease) and 71% for nonsmokers with tumor stage T2 or T3 compared with 46% in high-risk patients.[29] Analysis of the SEER database indicates the estimated 3-year cause-specific survival is worse in elderly patients (60.8%, 95% CI: 59.6–61.9%) compared with 75.7% (95% CI: 75.1–76.4%, $P < 0.001$) in patients aged 45–64 years.[26] HPV vaccination is a conceptually safer preventative strategy than tonsillectomy based on current data.[30]

ESOPHAGUS

Worldwide in the 2010s, esophageal cancer was the eighth most commonly diagnosed cancer (~450,000 cases/year) and the sixth most common cause of cancer-related deaths (~400,000/year).[31] In the United States, the annual incidence of esophageal cancer is ~18,000 with ~16,000 annual esophageal cancer-related deaths; the lifetime risk of esophageal cancer in the United States is 1/125 men and 1/400 women.[32] The incidence of esophageal cancer modestly declined since 2004 compared with the squamous cell carcinoma subtype that plateaued in the middle 2010s. The geographical distribution of esophageal squamous cell carcinoma is highly uneven between and within countries, with the highest worldwide esophageal cancer incidence rates occurring in two geographical regions, including north central China, Golestan Province in Iran, Kenya, South Africa, Southern Brazil, and Uruguay.[33,34] The two main histological subtypes of esophageal cancer are squamous cell carcinoma and adenocarcinoma, with the prominent histological subtype depending on geography and smoking prevalence. Most esophageal cancers are squamous cell carcinomas, with cigarette smoking and heavy alcohol consumption being the major risk factors; the incidence varies 8–10-fold between countries.[35] Although esophageal squamous cell carcinoma represents ~90% of esophageal cancers worldwide, dramatic increases in esophageal adenocarcinoma cancer incidence in Western countries (e.g., Australia, New Zealand, the United Kingdom, Europe, Canada, the United States) resulted in this subtype becoming the predominant esophageal cancer histological subtype in these countries.[36] Figure 54.1 displays historical changes in the US incidence rates for esophageal adenocarcinoma and esophageal squamous cell carcinoma from 1973–2011. The dramatic increase in Western countries slowed after 2000. Recent data from the latter suggest overall declining esophageal cancer rates in US men and women.[37] The overall rate of increasing age-related, esophageal adenocarcinoma incidence declined from 8.4% 1975–1997 to 1.1% (95% CI: 0.2–2.1%) for the time interval 1997–2014 based on the US National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) data.[33]

CARCINOGENESIS

Tobacco-specific nitrosamines [e.g., *N*′-nitrosonornicotine, NNN; 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone, NNK] and polycyclic aromatic hydrocarbons are major carcinogens in tobacco. Urinary *N*′-nitrosonornicotine was strongly correlated with esophageal squamous cell carcinoma in the Shanghai Cohort Study of 77 esophageal cancer cases (subtype unreported) and 223 matched controls.[38] The odds ratio of esophageal cancer comparing the first and third tertiles of total NNN was 17.0 (95% CI: 3.99–72.8); however, the wide confidence limit suggests an imprecise OR. Esophageal squamous cell carcinomas contain numerous molecular alterations, particularly TP53 alterations. The diversity of TP53 mutations in esophageal squamous cell carcinomas reflects tumor heterogeneity; however,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

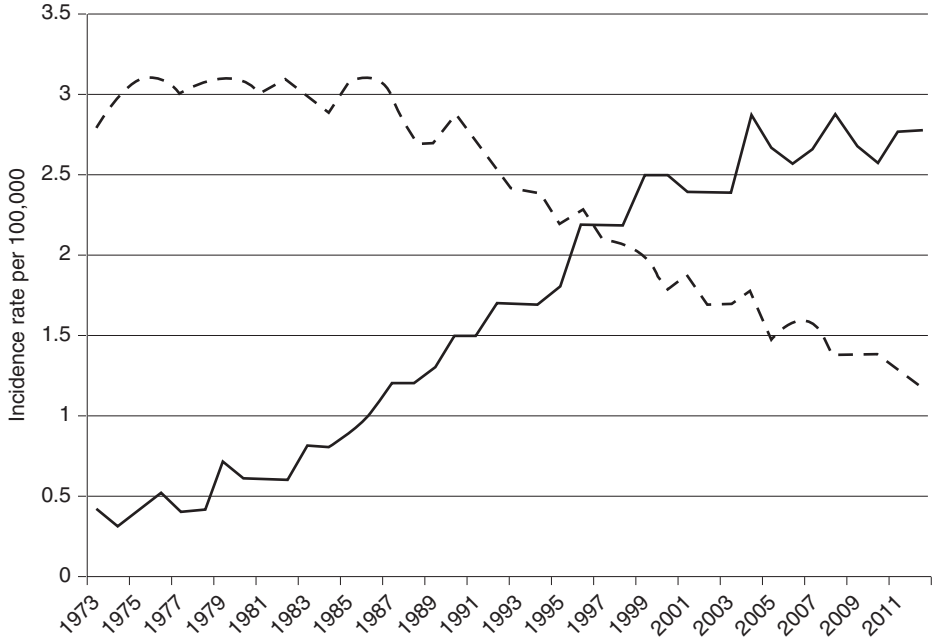

FIGURE 54.1. US historical change rates per 100,000 for declining esophageal squamous cell carcinoma incidence (dashed line) and increasing esophageal adenocarcinoma incidence (solid line) 1973–2011, based on US National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) data. (Adapted from Day).[33]

the proportion of TP53 mutation-containing tumors does not always predict differences in tumor incidence between various geographical regions.[39] In a study of 56 esophageal squamous cell carcinomas in north central China, at least one oncogenetic alteration occurred in 96% of the tumors, including 77% with mutations and 73% with allelic loss in the gene; 75% had ≥2 alterations.[40] Whole exome sequencing detected an average of 83 mutations/esophageal squamous cell carcinoma tumor ($n = 12$), with the most frequent mutations in *TP53* (92%), *NOTCH1* (33%) and *NOTCH3* (25%) genes.[41] Inactivating NOTCH1 mutations appeared in none of the 11 esophageal adenocarcinomas sequenced in this study.

A comparison of US and north central Chinese esophageal squamous cell tumors indicated the NOTCH1 mutation was much more frequent in the US than in Chinese tumors, suggesting environmental factors (e.g., polycyclic aromatic hydrocarbon exposure, thermal injuries, poor nutrition) rather than tobacco/alcohol use are major risk factors for Chinese tumors. Most mutations found in esophageal adenocarcinomas were previously present in patients with Barrett's esophagus, suggesting a clonal evolution promoted by chronic inflammation.[42] Tissues progressing to cancer acquire few alterations to genomic structure (e.g., cop-number alterations, heterozygous events).

EXPOSURE

The main risk factors for developing esophageal adenocarcinoma include gastroesophageal reflux disease, obesity, and cigarette smoking, which account for ~70% of esophageal adenocarcinoma cases in Western populations depending on the country and year. The primary risk factors for esophageal squamous cell carcinoma are cigarette smoking and heavy alcohol consumption, particularly in men. In an Australian population-based, case-control study of 305 esophageal squamous cell carcinoma cases and 1554 controls, the partial population-attributable fraction of these cancers in men attributed to the combination of heavy alcohol (>17 drinks/week) and cigarette smoking (>30 pack-years) was 77.7% (95% CI: 65.5–86.5%).[43] The main risk factors for these two esophageal cancer subtypes differ substantially as displayed in Table 54.3.

Occupation

Esophageal cancer subtypes are not strongly associated with occupational exposures. In a population-based, case-control study of 99 cases of esophageal cancer, logistic regression analyses of 35 occupational agents indicated sulfuric acid exposure (OR = 2.8, 95% CI:

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 54.3. Direction of major risk factors associated with esophageal adenocarcinoma and esophageal squamous cell carcinoma. (Adapted from Day).[33]

Risk Factor	Adenocarcinoma	Squamous Cell Carcinoma
Male sex	↑	↑
Cigarette smoking	↑	↑
Gastroesophageal reflux	↑	None
Barrett's esophagus	↑	None
Helicobacter pylori infection	↓	None
Obesity	↑	↓
Alcohol	None	↑
Nonsteroidal anti-inflammatory drugs	↓[a]	↓

[a] The direction of the effect of nonsteroidal anti-inflammatory drugs on the risk of adenocarcinoma in patients with Barrett's esophagus is conflicting, but probably small to clinically insignificant.

1.2–6.2) demonstrated the strongest association between chemical exposure and esophageal cancer based on retrospective analysis of job histories.[44] After adjusting for risk factors, the statistical significance of the association between carbon black and esophageal cancer was borderline, whereas the association of asbestos, mineral spirits, toluene, and other paints with esophageal cancer was equivocal. Other studies also indicate that the association between asbestos and cancer of the esophagus remains controversial. A large study of insulation workers revealed a small excess risk of esophageal cancer, as defined by a standardized mortality ratio of ~2.[45] Re-evaluation of the cohort data correcting the data for improper classification of lung cancers suggested an elevated risk for esophageal cancer of ~1.5.[46] Subsequent cohort studies have not confirmed the relationship between esophageal cancer and asbestos exposure; a review of these cohort studies did not find a consistent statistical association or a dose-response relationship between asbestos exposure and cancer of the esophagus.[47] In a 10-year follow-up study of 14,515 male subjects in an occupational asbestos exposure program (ARDCo Program), the hazard ratios for esophageal cancer (subtypes unreported) and cumulative asbestos exposure index were borderline (HR = 1.26, 95% CI: 1.00–1.58, $n = 33$) after adjusting for smoking.[48]

A meta-analysis of 92 studies covering 161 populations with results for 23 agents suggested that the following chemical exposures were most strongly associated with esophageal cancer: some chlorinated hydrocarbon solvents, nickel compounds, and hexavalent chromium.[49] Other chemicals potentially associated with esophageal cancer in exploratory studies include silica dust and detergents;[50] however, more data are necessary before a causal link can be established between *any* of these chemicals and esophageal cancer. A Swedish population-based, case-control study of 189 cases of esophageal adenocarcinoma and 820 age- and sex-matched general population controls indicated that airborne occupational exposures probably were not major risk factors for the development of this type of cancer, based on personal interviews.[51]

Lifestyle

In the United States, strong risk factors for the development of esophageal squamous cell carcinomas are smoking and heavy alcohol consumption; esophageal adenocarcinoma is associated with cigarette smoking but not heavy alcohol consumption, as displayed in Figure 54.1. Similarly, the use of betel quid and smokeless tobacco is associated with both esophageal cancer subtypes. Observational studies suggest nonsteroidal anti-inflammatory drug use is associated with a modest reduction in esophageal adenocarcinoma and squamous cell carcinoma,[52,53] whereas *Helicobacter pylori* infections are associated with reduced risk of esophageal adenocarcinoma but not esophageal squamous cell carcinoma.[54] Esophageal adenocarcinoma and probably squamous cell carcinoma are not associated with human papillomavirus (HPV) infection;[55,56] however, the frequency of HPV DNA in esophageal cancer is highly variable. Although some studies suggest a cohort of esophageal squamous cell carcinomas within certain geographical regions may be associated with HPV infections,[57] HPV detection rates are too low to confirm HPV as a definite esophageal squamous cell carcinoma risk factor.[58]

Other potential risk factors include reduced consumption of fruits and vegetables;[59,60] however, controlling bias and confounding, limiting measurement errors, and heterogeneity in nutritional or composite dietary pattern studies are complicated and challenging. Many cohort studies fail to associate individual foods or nutrients with reduced esophageal squamous cell carcinoma risks. Evaluation of dietary and nutritional

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

studies by the World Cancer Research Fund International/American Institute for Cancer Research did not support strong evidence of reduced esophageal cancer risks from the ingestion of any food, nutrient, fiber, or dietary supplement.[61] Limited evidence suggests ingestion of fruits/vegetables reduces esophageal squamous cell carcinoma risks and vegetables reduce esophageal adenocarcinoma risks, whereas processed meats may increase esophageal squamous cell carcinoma risks. Evidence supported a probable association between regular consumption of hot maté and esophageal squamous cell carcinomas in the World Cancer Research Fund International/American Institute for Cancer Research evaluation.

Analysis of the strength of evidence by the World Cancer Research Fund International/American Institute for Cancer Research for vegetable intake and esophageal adenocarcinomas suggested an inverse relationship of $RR_{100\,g/day} = 0.89$ (95% CI: 0.80–0.99, $n = 3$). For esophageal squamous cell carcinoma, the risk for fruit consumption was inverse ($RR_{100\,g/day}$ of 0.84 (95% CI: 0.75–0.94, $n = 3$) and for processed meats increased ($RR_{50\,g/day}$ of 1.59, 95% CI: 1.11–2.28, $n = 3$).[62] Most of the evidence involved small numbers of case-control studies because of the rarity of esophageal adenocarcinoma. In a meta-analysis of 20 case-control and 5 cohort studies on fresh fruit and esophageal cancer risks using random effects models, fresh fruit reduced the relative risk of esophageal squamous cell carcinoma (RR = 0.59, 95% CI: 0.47–0.76, $I^2 = 60.7\%$, $P = 0.002$), whereas fruit intake was not associated with esophageal adenocarcinoma risks (RR = 0.86, 95% CI: 0.74–1.01, $I^2 = 0.0\%$, $P = 0.598$).[63] Of the 25 studies, 10 were from Europe, 6 from Asia, 6 from the United States, and 3 from South America. A meta-analysis of 12 observational Asian studies of green tea and esophageal cancer did not detect a significantly increased risk for green tea drinkers.[64] The pooled summary relative risk was 1.09 (95% CI: 0.76–1.55, $I^2 = 75.5$) comparing the greatest and non/least green tea drinkers; heterogeneity was substantial. The meta-analysis did not evaluate esophageal cancer subtypes.

Tobacco

Cigarette smoking is a major risk factor for esophageal adenocarcinoma and squamous cell carcinoma. In a pooled analysis of 10 population-based, case-control, and 2 cohort studies from the Barrett's and Esophageal Adenocarcinoma Consortium (BEACON), the summary OR for esophageal adenocarcinoma in white non-Hispanic men and women was 1.96 (95% CI: 1.64–2.34) comparing ever- and never-cigarette smokers.[65] The dose-response relationship for esophageal adenocarcinoma and pack-years of cigarette smoking was statistically significant ($P_{trend} < 0.001$) using multivariable logistic regression models adjusted for age, sex, body mass index, education, and gastroesophageal reflux. The effect of cigarette smoking on esophageal adenocarcinoma rates may persist long-term (e.g., for 20 years).[66] In an Australian population-based, case-control study comprising 367 esophageal adenocarcinomas, 309 esophageal squamous cell carcinomas, and 1,580 age-matched general population controls, the OR for esophageal adenocarcinoma comparing ever- and never-cigarette smokers was 1.7 (95% CI: 1.3–2.3).[67]

Case-control studies suggest the relative risks of esophageal squamous cell cancer increase up to 9-fold when comparing current smokers and nonsmokers. The OR for esophageal squamous cell carcinoma in the Australian case-control study was elevated (OR = 2.8, 95% CI: 2.0–4.0) comparing ever- and never-smokers.[67] In the prospective NIH–AARP Diet and Health Study of 474,606 US participants using Cox models adjusted for potential confounders, the hazard ratio for esophageal squamous cell carcinoma was 9.27 (95% CI: 4.04–21.29); however, the wide confidence interval suggests an imprecise hazard ratio.[68] The attributable risks in economically developing countries appear lower (e.g., RR = ~1.5).[69]

Alcohol

Several issues complicate the establishment of alcohol consumption as a risk factor for esophageal cancer, including heterogeneity of consumption patterns, difficulty detecting potential nonlinear, dose-response associations, and misclassification of lifetime alcohol consumption. Most existing studies consistently demonstrate a dose-response relationship between esophageal squamous cell carcinomas and alcohol consumption in low- and high-incidence regions, particularly among heavy drinkers (e.g., 6–9 fold in Western countries with low incidences of this cancer).[70] Evidence for an association between heavy alcohol consumption and esophageal adenocarcinoma is weak and inconsistent, lacking a dose-response relationship, including the risk of developing Barrett's esophagus.[71,72] In an Australian study of self-reported consumption in 1,530 participants from the general population and 365 cases of esophageal squamous cell carcinoma, the overall OR comparing the highest estimated lifetime weekly alcohol consumption (≥420 g) with nondrinkers (<10 g) was 4.67 (95% CI: 2.28–9.55).[73] The dose-response

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

curve was j-shaped with no increased risk below lifetime weekly alcohol consumption below 210 g. In a Spanish case-control study of self-reported alcohol consumption in hospital-based controls and esophageal squamous cell carcinoma cases, the odds ratio comparing never-drinkers and current drinkers was 4.48 (95% CI: 1.69–11.83, $n = 123$) after adjustment for age, sex, province, educational level, and tobacco smoking.[74] A large prospective cohort study (NIH–AARP Diet and Health Study) of 474,606 US participants using Cox models adjusted for potential confounders detected an elevated hazard ratio for esophageal squamous cell carcinoma of 4.93 (95% CI: 2.69–9.03) comparing daily alcohol consumption of >3 drinks and ≤1 drink.[68] However, the hazard ratio for nondrinkers relative to light drinkers (0–1 drink/day) was significantly elevated (HR = 2.06, 95% CI: 1.16–3.68), suggesting a lack of dose-response relationship and/or misclassification.

The Australian study did not demonstrate a similar increased risk for esophageal adenocarcinoma (OR = 0.89, 95% CI: 0.42–1.89) comparing lifetime heavy alcohol drinkers (≥420 g) with nondrinkers (<10 g).[73] Although the age and sex distributions were similar between participating and nonparticipating cases, Australian privacy laws prevented evaluation of the low participation rate because further details on the medical and social characteristics of nonparticipating cases were unavailable. The participation rate for eligible controls was 51%.

Obesity

Although the obesity epidemic in Western countries may account for some of the increased incidence of esophageal adenocarcinoma, the increasing incidence started before the beginning of the obesity epidemic. The association between obesity and esophageal reflux disease complicates the interpretation of studies associating obesity with esophageal adenocarcinoma because of the potential for residual confounding. Abdominal visceral obesity rather than BMI appears to be more closely associated with GERD and erosive gastritis.[75] Qualitative assessments using disease simulation modeling suggest the effect of obesity on esophageal adenocarcinoma rates is a relatively small portion (~6–7%) of the increased esophageal adenocarcinoma risk in the United States.[76] In an analysis of data from the BEACON consortium comprising 12 European, Australian, and North American studies, the OR for esophageal adenocarcinoma comparing cases with BMI of <25 and ≥40 was 4.76 (95% CI: 2.96–7.66), with evidence of a synergistic interaction between the presence of GERD and BMI.[77] In a pooled analysis of a European consortium of seven prospective studies (Metabolic Syndrome and Cancer cohort), BMI was associated with increased risk of esophageal adenocarcinomas (RR = 7.34, 95% CI: 2.88–18.7) comparing the highest (mean = 31.3 ± 3.3) and lowest (mean = 20.7 ± 1.5) BMI quintiles adjusted for sex, age at baseline (continuous), and smoking status.[78] The adjusted relative risk for esophageal adenocarcinoma comparing participants with BMIs of ≥ 30 and 18.5–25 (normal weight) was 3.29 (95% CI: 1.82–5.95).

Childhood and adolescent BMI may correlate more strongly with esophageal adenocarcinoma risks in later life than BMI.[79] Additionally, the effect of typical male obesity (abdominal circumference, ↑ waist circumference) and female obesity (gluteofemoral, ↑ hip and thigh subcutaneous fat) on esophageal adenocarcinoma risks may differ; however, the findings demonstrate inconsistent results and substantial heterogeneity depending on how obesity risk factors are measured. In a pooled analysis of data from the international BEACON consortium, waist circumference was significantly associated with Barrett's esophagus independent of BMI. Comparing the fourth and first quartiles of waist circumference, the OR was 1.87 (95% CI: 1.22–2.87),[80] whereas analysis of data from this consortium suggests an inverse association between gluteofemoral obesity and Barrett's esophagus in women and men.[81] Male predominance as a risk factor for esophageal adenocarcinoma persists at similar levels when comparing lean and overweight individuals.[82] Esophageal squamous cell carcinoma is not associated with GERD and inversely associated with obesity. Analysis of data from the Metabolic Syndrome and Cancer cohort (Me-Can project) demonstrated an adjusted RR for esophageal squamous cell carcinoma in participants with BMI of ≥ 30 of 0.47 (95% CI: 0.24–0.94, $n = 184$) compared with normal weight participants (BMI = 18.5–25).[78]

Diseases

Barrett's Esophagus

Barrett's esophagus is an acquired, dysplastic, precancerous lesion associated with an increased esophageal adenocarcinoma risk, but not squamous cell carcinoma. The lifetime risk of esophageal adenocarcinoma in an analysis of data from the Northern Ireland Barrett's esophagus Register was 5.8% for men and 3.0% for women.[83] About 6–12% of patients with GERD develop Barrett's esophagus, with 0.5–1% evolving into esophageal adenocarcinoma.[84] Although the presence

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of Barrett's esophagus increases esophageal adenocarcinoma risks at least 10-fold, small absolute risks limit the effectiveness of surveillance programs because of the rarity of esophageal adenocarcinoma. In a study of 11,028 patients with Barrett's esophagus from the Danish Pathology Registry and the Danish Cancer Registry followed for a median of 5.2 years, the relative risk of adenocarcinoma among patients with Barrett's esophagus was 11.3 (95% CI: 8.8–14.4) compared with the general population.[85] Barrett's esophagus is more frequently associated with factors that increase esophageal adenocarcinoma risks, including Caucasian men of >50 years of age, smokers, gastroesophageal reflux, and obesity.[86] Positive studies associating Barrett's esophagus with obesity more commonly involve central obesity (abdominal circumference, waist/hip ratio) than BMI or overall body fat content.[87] Potential chemopreventions for reducing increased esophageal adenocarcinoma risks from Barrett's esophagus include aspirin, nonsteroidal anti-inflammatory drugs, statins, and proton pump inhibitors;[88] however, none of these potential therapies have been validated in large-scale studies with long-term follow-up and tight control of confounding factors.

Genetic variants contribute relatively little to the increased risk of esophageal adenocarcinoma.[89] Approximately 7% of Barrett's esophagus occur in families with other familial cases; these esophageal adenocarcinomas usually develop at an earlier age than sporadic cases. Furthermore, typical risk factors for esophageal adenocarcinoma are less common in familial than sporadic cases. Candidate gene and genome-wide association studies suggest up to 1/3 of esophageal adenocarcinoma tumors may result from combinations of germline mutations; however, single nucleotide polymorphisms probably account for <20% of esophageal adenocarcinomas developing from Barrett's esophagus.[90]

Gastroesophageal Reflux Disease (GERD)

Gastrointestinal reflux disease is a major risk factor for esophageal adenocarcinoma. In a Swedish population-based, case-control study of 189 patients with esophageal adenocarcinoma and 820 controls, the odds ratio for esophageal adenocarcinoma was 7.7 (95% CI: 5.3–11.4) comparing participants with at least weekly self-reported symptoms and participants with less than weekly symptoms.[91] The esophageal adenocarcinoma risk was particularly high for participants with more severe reflux lasting for >20 years (OR = 43.5, 95% CI: 18.3–103.5). Classification was based on patient interviews; the large confidence interval suggests imprecise OR estimates.

The risk of esophageal squamous cell carcinoma was not associated with gastroesophageal reflux (OR = 1.1; 95% CI: 0.7–1.9) consistent with most studies.[33] In a pooled analysis of data from five population-based, case-control studies in the Barrett's and Esophageal Adenocarcinoma Consortium (BEACON) involving 1,128 esophageal adenocarcinoma cases and 4,057 controls from the general population, the summary odds ratios for at least weekly self-reported symptoms of GERD were 4.81 (95% CI: 3.39–6.82) and 7.96 (95% CI; 4.51–14.04) for daily symptoms.[92] The results demonstrated a dose-response relationship with duration of self-reported symptoms; for symptoms lasting for >20 years, the OR was 6.24. The results were not adjusted for cigarette smoking or alcohol use.

HISTOLOGY

The two primary histological types of esophageal cancer are squamous cell carcinoma and adenocarcinoma. Barrett's esophagus is a premalignant condition occurring in ~15% of patients with gastroesophageal reflux disease; this condition is a precursor lesion for the development of esophageal adenocarcinoma involving the replacement of the normal squamous cell lining of the distal esophagus with metaplastic columnar intestinal epithelium. Tumor development involves a progression from erosive esophagitis to nondysplastic Barrett's esophagus, low-grade dysplasia, high-grade dysplasia, adenocarcinoma *in situ*, and then invasive adenocarcinoma.[93]

Esophageal squamous dysplasia (ESD) is the primary histopathological precursor of esophageal squamous cell carcinoma, with increasing dysplasia grades predicting increased squamous cell carcinoma risk.[94] In a cohort study of 682 patients from a high-risk rural population in Linxian, China, undergoing endoscopy, 14.7% of 114 patients developed esophageal squamous cell carcinoma during the follow-up period of 13.5 years.[95] The relative risk of esophageal squamous cell carcinoma comparing grades of dysplasia with patients having a normal esophagus was statistically significant for moderate dysplasia (RR = 15.8, 95% CI: 5.9–42.2), severe dysplasia (RR = 72.6, 95% CI: 29.8–176.9), and carcinoma *in situ* (62.5, 95% CI: 24.1–161.9). The wide confidence limits indicate imprecise estimates. Approximately 8% of the endoscoped patients with a normal esophagus developed esophageal squamous cell carcinoma compared with 50% of patients with moderate dysplasia and 74% with severe dysplasia.

HOST SUSCEPTIBILITY

Studies of family cancer histories suggest esophageal squamous cell carcinoma risk increases in families with histories of esophageal cancer. In a Chinese case-control study of 600 esophageal squamous cell carcinomas, the occurrence of esophageal cancer in a first-degree relative increases the odds ratio of developing esophageal squamous cell carcinoma (OR = 2.84, 95% CI: 2.09–3.86) compared with age-, gender-, and neighborhood-matched controls.[96] An Iranian study compared the risk of esophageal squamous cell carcinoma in 2,097 first-degree relatives of 167 esophageal squamous cell carcinoma cases and 2,783 first-degree relatives of the 200 Turkmen controls.[97] The hazard ratio of the risk to age 75 of esophageal squamous cell carcinoma in the first-degree relatives of Turkmen patients was 2.3 (i.e., reported as 34 vs. 14%).

Tylosis is a rare, autosomal-dominant syndrome characterized by non-epidermolytic palmoplantar keratoderma, oral precursor lesions (leukokeratosis), and a very high esophageal squamous cell carcinoma risk (i.e., up to 95% by age 65 years).[98] Genetic studies identified missense mutations in *RHBDF2* that encode the inactive rhomboid 5 homolog 2 protease (iRhom2) on chromosome 17q25 as the underlying cause of tylosis-associated esophageal squamous cell carcinomas. The subsequent dysregulation of the epidermal growth factor receptor EGFR signaling pathway causes cell proliferation and migration.

CLINICAL FEATURES

The clinical presentation of esophageal cancer results from direct effects of tumor growth on local and regional structures, with both main esophageal cancer subtypes demonstrating similar symptoms; the most common symptom is dysphagia following ingestion of solid foods. Esophageal adenocarcinoma incidence increases with age; however, diagnosis of this tumor in patients under 50 years of age is uncommon (i.e., <8%).[99] Multivariable logistic regression analysis of data from eight population-based, case-control studies (BEACON study) demonstrated a stronger association of younger patients (<50 years) with recurrent gastroesophageal reflux (OR = 8.06, 95% CI: 4.52–14.37) and BMI ($OR_{BMI \geq 30 \text{ vs. } <25} = 4.19$, 95% CI: 2.23–7.87) compared with older cases.[100] The epidemiology of esophageal adenocarcinoma demonstrates a marked male predominance in all populations that has changed little over the last three decades. In an analysis of the US National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) 9 data, the RR for esophageal adenocarcinoma comparing men with women was 7.49 (95% CI: 7.17–7.82).[101] Although the male/female ratio ranges up to 9/1, established risk factors do not explain the difference because the distribution of the major risk factors for this tumor is similar between men and women, with the possible exception of severe gastroesophageal reflux disease.[102] Consequently, the pathophysiology of this difference remains unclear. The prognosis for esophageal adenocarcinoma is generally poor, depending on the stage at diagnosis because of the late presentation and tumor aggressiveness. Approximate 5-year survival rates in the Northern Ireland Barrett's registry ranged from 80% for Stage I to 45% for Stage II, 17% for Stage III, and 2% for Stage IV.[89] Overall 5-year survivor rates are ~5–6%, with similar rates for men and women.[103]

Esophageal squamous cell carcinoma is more common in men than women (~2/1) overall, with the ratio varying from 4/1 in low-risk areas (e.g., the United States) to ~1/2 in high-risk areas (e.g., northern China).[104] Esophageal squamous carcinoma is a late complication (i.e., up to 40 years) of severe lye ingestions. The prognosis for esophageal adenocarcinoma is also poor, with an overall 5-year survival rate of ~20% and <3% for patients presenting with distant metastatic disease.[99]

STOMACH

From the 19th and first half of the 20th century to 1975, stomach cancer was the most common cause of cancer-related mortality in Western countries.[105] Worldwide, stomach cancer accounts for ~6% of all cancer diagnoses. Most stomach tumors are sporadic with familial susceptibility being much less common. About 10% of stomach cancers are familial gastric cancers as defined by two first- or second-degree relatives with gastric cancer before age 50 years or three first- or second-degree relatives with gastric cancer independent of age.[106] The most famous historical example of hereditary transmission of gastric carcinoma was Napoleon Bonaparte.[107] He had five first-degree relatives affected by gastric carcinoma in three consecutive generations. Although stomach cancer is now the fifth most commonly diagnosed cancer worldwide, it accounts for the third most common worldwide cause of cancer-related mortality.[108,109] During the last 50 years, the incidence of non-cardia (distal) gastric cancer

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

has declined dramatically, whereas cardia gastric cancer (i.e., gastroesophageal junction adenocarcinoma) more closely follows the increasing incidence rates of esophageal adenocarcinoma as classified by recent stomach cancer subclassifications.[110,111] Potential reasons for the global decrease in non-cardia gastric cancer incidence include: 1) ↑ fresh fruit/vegetable availability with refrigeration; 2) ↓ reliance on preserved/salted foods; 3) ↓ smoking prevalence; and 4) ↓ *H. pylori* infections.

The initial decline of non-cardia gastric cancer corresponded to reduced nitrosamine consumption from preserved food sources and water contaminated by nitrates, particularly fresh fruits and vegetables followed by declines in the incidence of *H. pylori* infections. Stomach cancer incidence and mortality display substantial regional variation, with Japan, Korea, and China accounting for ~60% of newly diagnosed stomach cancers.[112] The distinct geographical differences in stomach cancer incidence strongly suggest that environment is a major determinant for developing stomach cancer, particularly geography, diet, and smoking. Compared with studies of Japan, China, Iceland, Chile, and Eastern Europe, stomach cancer incidence is relatively intermediate in Latin America and low in the United States and Western Europe.[113] Although stomach cancer incidence remains relatively high in East Asia, the implementation of advances in hygiene, sanitation, and food preservation/clean water supplies is rapidly reducing stomach cancer incidence in developing countries.[114]

CARCINOGENESIS

Gastric tumors display a complex and diverse array of genetic and epigenetic alterations. A variety of genes are upregulated in gastric tumors, including *HER2*, *PIK3CA*, *KRAS/NRAS*, *JAK2*, *RTK* (receptor tyrosine kinase), and *EGFR* (epidermal growth factor receptor).[115] These gene affect apoptosis, cell cycle progress, and inhibition of tumor suppressor gene expression/activity resulting in enhanced cell proliferation, invasion, and migration. The Cancer Genome Atlas Research Group (TCGA) molecular classification of gastric tumors includes microsatellite instable, EBV-positivity, chromosomal instable, and genomically stable categories based on next-generation sequencing data, as displayed in Figure 54.2.[116,117] The former two genetic profiles express programmed death-1 (*PD-1*) and programmed death ligand-1 (*PD-L1*) involving immune checkpoints, whereas chromosomal instable gastric cancers contain p53 mutations and receptor tyrosine kinase activating mutations (e.g., *HER2*, *EGFR* genes). Human epidermal growth factor receptor 2 (*HER2*) is a proto-oncogene located on chromosome 17q21 encoding a transmembrane protein with tyrosine kinase activity involving signal transduction pathways that enhance cell growth and differentiation. Overexpression of *HER2* occurs in ~18% of gastric tumors (range, ~4–53%).[118] *HER2*-positivity is a poor prognostic marker associated with decreased survival and tumor aggressiveness (serosal invasion, metastasis, higher disease stage).[119] Somatic mutations (e.g., indels) are also common in microsatellite instable gastric tumors, whereas global hypermethylation appears frequently in EBV-positive gastric cancers.[120]

EXPOSURE

Stomach cancer is a multifactorial disease involving epigenetic and, to a lesser extent, genetic factors; risk factors for stomach cancer vary with the two main subtypes (cardia, non-cardia). Cardia gastric and esophageal adenocarcinomas have similar risk factors, including gastroesophageal reflux, smoking, and obesity;[121] however, the association with the latter is relatively weak.[122] The association of cardia gastric cancer with alcohol consumption is conflicting with some positive[123] but more negative[124] mortality and incidence studies. Non-cardia gastric cancers of the distal stomach are associated with tobacco smoking, *H. pylori*, Epstein–Barr virus (EBV), and diet (primarily high dietary salt intake), but not with gastroesophageal reflux disease or obesity. *H. pylori* infections account for ~89% of non-cardia gastric cancers or more in high-risk areas. The actual risk depends on *H. pylori* virulence (viral genes CAGA, DUPA, ICEA1, NAPA, OIPA, VACA),[125] strain, host genetic diversity/inflammatory response (e.g., interleukin-1), and the presence of additional risk factors (e.g., smoking, high salt intake). In developing countries, ~1–3% of *H. pylori* infections progress to malignant tumors, whereas this rate may increase to 10% in high-risk locations.[108,126]

Environment

Helicobacter Pylori

Helicobacter pylori infections are the most consistent risk factor for non-cardia gastric cancer, with relative risks in the range of 3–6-fold for non-cardia gastric adenocarcinoma using ELISA testing and higher (i.e., up to 20-fold) using the more sensitive Western blot for assessing the prevalence of *H. pylori* infections.[127,128,129] In some high-risk Chinese regions, 50–85% of children

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

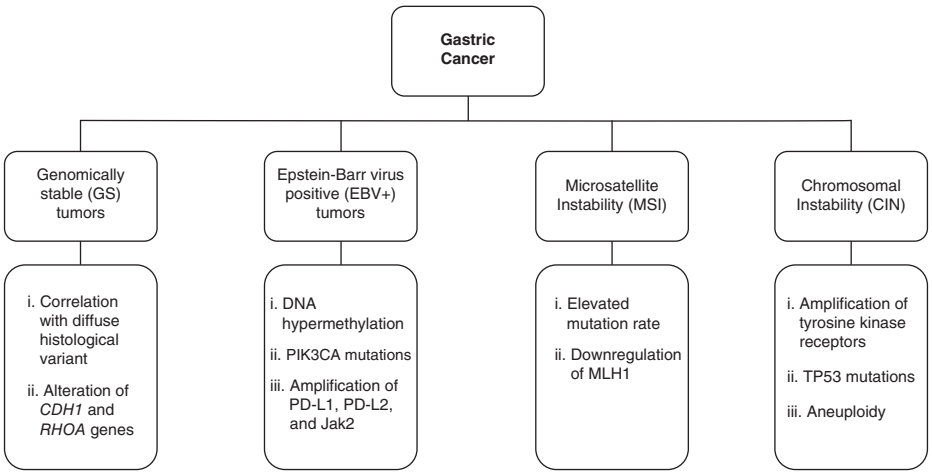

FIGURE 54.2. The Cancer Genome Atlas Research Group classification of gastric tumors with common molecular features. (Adapted from Carlomagno et al.).[116]

aged 3–10 years and 67% of adults with *H. pylori* infection are present in ~50% of the worldwide population and up to 92% in asymptomatic Bangladesh populations.[130,131] The incidence of gastric adenocarcinoma in Asia varies widely, with seropositive rates usually reflecting the incidence of non-cardia gastric adenocarcinoma; however, high seropositive prevalence rates in some Asian regions have relatively low incidence rates.[132] Enhanced risks of non-cardia gastric adenocarcinoma result from the complex interaction of host factors, environment, and *H. pylori* strain/virulence (e.g., CagA-positivity)[133] mediating cytokine-induced inflammatory response (e.g., tumor necrosis factor-α, IL-1β, IL-2, IL-8, IL-10).[134,135]

Epstein–Barr Virus (EBV)

Although ~9–10% of patients with gastric tumors are EBV-seropositive, much larger portions of the worldwide general population have asymptomatic chronic EBV infections.[136] Clinicopathological features of EBV-associated gastric tumors include proximal stomach location, lymphoepithelioma-like histology, male prominence, and relatively favorable prognosis. Gastric tumors contain multiple genetic and epigenetic alterations causing oncogene overexpression and inhibition of tumor suppressor genes, particularly DNA methylation and genetic alterations (e.g., PIK3CA and ARIDIA mutations, *JAK2* and PD-L1/L2 amplifications).[137,138] These abnormalities modify gene expression affecting cell proliferation, immune, migration, and apoptosis signaling pathways. Promoter DNA methylation is probably more frequent than DNA mutations. EBV infection promotes DNA methylation by upregulating DNA methyltransferase-3b (DNMT3b) resulting in transcriptional inactivation of tumor suppressor genes during early stomach carcinogenesis. Genome-wide studies indicate EBV-positive tumors demonstrate recurrent mutations of *PIK3CA* gene (p110α expression) along with *JAK2* (nonreceptor tyrosine kinase), *CD274* (immune inhibitory receptor ligand), and PDCD1LG2 (programmed cell death 1 ligand 2) amplification, among other genetic/epigenetic alterations.[139]

Occupation

The contribution of occupational exposures to the development of stomach cancer is relatively small and probably multifactorial; no single agent is a strong risk factor for stomach cancer. A Swedish population-based, case-control study of 189 cases of gastric cardia adenocarcinoma and 820 age- and sex-matched controls indicates airborne occupational exposures probably were not major risk factors based on personal interviews.[51] Hypothesis-generating studies suggest work in coal and tin mining, metal processing (steel, iron), and rubber manufacturing industries increases stomach cancer risks.[140] The IARC listed the latter as a human carcinogen (Group 1) in 1982. Several analyses of occupational incidence and mortality data demonstrate consistent elevations of stomach cancer rates in rubber workers, particularly in processing, tire building, and manual labor sections where dust, fumes, coal tar products, antioxidants, and carbon black are potential carcinogens;[141,142] however, co-exposure of these workers to other carcinogens (e.g., aromatic amines, asbestos,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

benzene) complicates interpretation of data from earlier studies, particularly for workers employed before the 1960s. A review of epidemiological studies of cancer risks in rubber industry workers including 12 cohort studies in 9 countries, 7 industry-based, nested case-control studies, 48 community-based, case-control studies in 16 countries, and 23 studies based on administrative data was inconsistent with stomach cancer risks below 1.6 in the 7 positive studies.[143] Standardized mortality and incidence studies of rubber workers employed since 1980 have not detected statistically significant elevations in stomach cancer rates. A cohort study of 8,933 German rubber industry workers hired after 1949 and followed from 1981–1991 reported national reference population mortality from stomach cancer of 117 (95% CI: 85–157, $n = 44$).[144] The SMR for stomach cancer (subtype unreported) in a cohort of 8,651 UK rubber factory workers was 86 (95% CI: 23–219, $n = 4$) based on national rates; the standardized registry rate for stomach cancer was also not statistically significant (SRR = 137, 95% CI: 66–252, $n = 10$).[145] In a cohort mortality study of 6,246 Italian rubber workers employed from 1954–2008, the standardized mortality rate (SMR) for stomach cancer (subtype unreported) was 99 (95% CI: 69–138, $n = 34$) without increasing with duration of employment.[146] Some older studies of coal miners revealed elevations for stomach cancer mortality (SMR = 140–275), particularly in the older age groups;[147,148] however, statistically negative case-control studies from the Netherlands (SIR = 1.15, 95% CI: 0.89–1.47)[149] and the United States (RR = 1.55, 95% CI: 0.72–3.30)[150] suggest the lifestyle of the coal mining community may be a more important stomach cancer determinant than occupational dust exposure.

A 1979 population-based, case-control study in Montreal suggested several substances as potential gastric carcinogens, including crystalline silica, leaded gasoline, grain dust, lead dust, zinc dust, hydraulic fluids, and glycol ethers;[151] however, this hypothesis-generating study did not establish a firm link between any of these substances and gastric cancer. A case-control analysis of mortality from gastric cardia/lower esophagus cancers reported no statistically significant excess of these stomach cancers in white men exposed to sulfuric acid mists based on an analysis of death certificates.[152] Dust alone is a potential risk factor for stomach cancer, particularly in occupations associated with woodworking, steel polishing, or abrasive working;[153] however, consistently elevated stomach cancer rates were not reported in studies of occupations with substantial dust exposure.[154] A retrospective cohort mortality study of 2,294 white male wood model makers with follow-up from 1940–1984 did not detect a statistically significant increase in mortality from stomach cancer (SMR = 1.6, 95% CI: 0.9–2.6) with no trend for increasing wood dust exposure.[155] A case-control study of an area in England where the prevalence of stomach cancer is high attributed only 23% of stomach cancer incidence to work in dusty industries (coal mining, iron and steel, ceramics, rubber).[156] Limited epidemiological evidence supports a modest association between asbestos exposure and stomach cancer. Mortality studies also suggest an association between asbestos exposure and stomach cancer;[157] however, outcomes between various studies have not demonstrated consistent, dose-related elevated stomach cancer rates in asbestos-exposed workers. The overall meta-SMR for stomach cancer in a meta-analysis of 40 mortality case-control and 14 cohort studies of asbestos workers was 1.15 (95% CI: 1.03–1.27), with moderately heterogeneous results across studies ($I^2 = 61.9\%$).[158] Statistically significant stomach cancer excess risks were reported in North American and Australian studies but not European studies.

Lifestyle

Historically, poor socioeconomic class (e.g., low income and education) has been a major determinate of stomach cancer risks that potentially confounds observational studies on the stomach cancer etiology.[159,160] Using the relative index of inequality (RII) as a measure of socioeconomic class, the overall combined pooled estimate of gastric cancer risk was 2.64 (95% CI: 1.05–6.63), comparing the lowest and highest socioeconomic categories.[161] These categories included income, occupation, and education.

Smoking

Smoking is a modest risk factor for non-cardia gastric cancers. A meta-analysis of nine studies on non-cardia gastric cancer reported an estimated summary relative risk of 1.60 (95% CI: 1.41–1.80; $I^2 = 18.9\%$) comparing current smokers and never-smokers.[162] The overall gastric cancer risk was greater in men than women. In the prospective NIH–AARP Diet and Health Study of 474,606 US participants using Cox models adjusted for potential confounders, the hazard ratio for non-cardia gastric cancer was 2.04 (95% CI: 1.32–3.16).[68] The population-attributable risk for ever smoking was 19% compared with 47% for cardia gastric cancer. The Netherlands study reported similar risks for non-cardia gastric cancer. The multivariable adjusted incidence rate ratio comparing current smokers and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

never-smokers was 1.86 (95% CI: 1.40–2.48, $n = 177$).[163] The P_{trend} for quartiles of pack-year smoking was statistically significant ($P_{trend} = 0.004$); in continuous 10 pack-years smoking, the RR was 1.08 (1.02–1.15). In a population-based, prospective cohort study (Hisayama study) of 1,071 Japanese men aged ≥40 years followed for 14 years (1998–2002), the multivariate-adjusted hazard ratio for non-cardia gastric cancer in participants currently smoking over 20 cigarettes daily was 1.88 (95% CI: 1.02–3.43) using current nonsmokers as controls.[164] The impact of smoking cessation is somewhat conflicting with some benefit from ≥20 years of abstinence.[165]

Diet

A modest association between diet and non-cardia gastric cancer remains controversial because of a lack of convincing evidence and the difficulty in measuring lifetime dietary intakes. Limited epidemiological evidence supports the association of high salted/smoked fish diets and low fruit and vegetable consumption with an increased stomach cancer incidence.[5] In the Hisayama study, the multivariate-adjusted hazard ratio of the highest quartile of daily dietary salt intake (≥16 g) was statistically significant (HR = 2.67, 95% CI: 1.36–5.24, $n = 30$) compared with the lowest quartile (<10 g).[166] Although the P_{trend} was 0.01, the comparison of the third and first quartiles was not statistically significant (HR = 1.88, 95% CI: 0.91–3.89, $n = 20$). A meta-analysis of 11 observational studies comparing highest and lowest categories of dietary salt intake reported a summary odds ratio of 1.22 with substantial heterogeneity (95% CI: 1.17–1.27, $I^2 = 92\%$); subanalysis of European studies did not demonstrate a statistically significant association between gastric cancer risk and dietary salt intake (OR = 1.15, 95% CI: 0.88–1.52, $I^2 = 41\%$, $n = 2$).[167] The presence of substantial heterogeneity weakens the positive association.

In a Portuguese population-based, case-control study of 305 non-cardia gastric tumors, the odds ratio comparing the highest versus lowest tertile of fruit consumption was 0.53 (95% CI: 0.35–0.80), whereas this comparison for vegetables was not statistically significant (HR = 0.85, 95% CI: 0.58–1.26).[168] In a meta-analysis of six prospective cohort studies (2,209 stomach cancer patients) and nine case-control studies (2,495 cases), the estimated summary relative risks of stomach cancer for an increase in processed meat consumption of 30 g/day (~1/2 an average serving) were 1.15 (95% CI: 1.04–1.27) for the cohort studies and 1.38 (95% CI: 1.19–1.60) for the case-control studies.[169] The effect size was relatively small, and confounding/bias could not be excluded, particularly when the effect size for qualitatively better cohort studies was lower than that for case-control studies.

Alcohol

The association between alcohol consumption and non-cardia gastric cancer is weak compared with diet and smoking. Several large prospective Asian and European cohort studies reported no significant association between alcohol and gastric cancer.[68,163] In the prospective Netherlands Cohort Study, the multivariable adjusted incidence rate ratio for non-cardia gastric cancer was 1.00 (95% CI: 0.68–1.47, $n = 59$), comparing daily consumption of ≥30 g ethanol/day with abstainers.[163] The P_{trend} for quartiles of alcohol consumption was 0.68. A meta-analysis by the World Cancer Research Fund suggested a weak, nonlinear association between heavy alcohol consumption (>45 g alcohol daily) and non-cardia gastric cancer.[61] The RR for men increased by 3%/10 g daily alcohol consumption (RR = 1.03, 95% CI: 1.01–1.05) after removal of a study using especially high alcohol consumption. However, the association for women was not statistically significant (RR = 1.02, 95% CI: 0.90–1.15).

HISTOLOGY

Several subsites separate the stomach anatomically into the cardia and more distal non-cardia sites (fundus, body, pylorus, antrum). Although previously stomach cancer was defined by anatomical location in the stomach, stomach cancer now usually refers to distal (non-cardia) cancer rather than the etiologically different proximal (gastroesophageal junction) stomach cancer. Gastric adenocarcinoma accounts for ~90–95% of stomach cancers, with the remainder being lymphomas, leiomyosarcomas, neuroendocrine tumors, and gastrointestinal stromal tumors.[108] Many more recent epidemiology studies subclassify gastric tumors into two main sites: cardia (proximal stomach involving gastroesophageal junction and proximal 5 cm) and the more distal non-cardia (body/fundus, pyloric antrum, or distal), with these subtypes having distinct epidemiological and clinical characteristics.[113] The latter subtype is further subclassified into intestinal and diffuse types, classically stratified by Lauren.[170] The World Health Organization (WHO) subclassified adenocarcinomas into tubular, papillary, mucinous, poorly cohesive including the signet ring cell variant, and mixed types. Gastric atrophy is strongly associated with atrophic gastritis produced by *H. pylori*. Chronic, progressive gastritis contributes significantly to the development

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. of non-cardia gastric cancer with long-term mucosal inflammation, initially producing mucosal atrophy and metaplasia followed by intraepithelial neoplasia and finally a malignant tumor.[171]

HOST SUSCEPTIBILITY

Most gastric cancers are sporadic, whereas inherited cancer predisposition syndromes account for relatively few cases (~1–3%). The complex interactions of host factors (e.g., polymorphisms encoding pro- and anti-inflammatory cytokines, environment/socioeconomic influences) modulate gastric cancer risks following potentially oncogenic viral infections (i.e., *H. pylori*, EBV). The three recognized hereditary syndromes of gastric cancer are: 1) hereditary diffuse gastric cancer; 2) gastric adenocarcinoma and proximal polyposis of the stomach; and 3) familial intestinal gastric cancer. Compared with sporadic tumors, these hereditary cancers act more aggressively and occur at earlier ages.[172] Germline E-cadherin/CDH1 mutations occur in families with a rare autosomal dominant inherited predisposition to diffuse gastric cancer conferring a cumulative gastric cancer risk for CDH1 mutation carriers of 70% for men and 56% for women by age 80 years.[173] The diffuse type of non-cardia gastric cancer includes signet ring adenocarcinoma associated with hereditary gastric cancer, loss of E-cadherin expression, and relatively earlier onset.[174] The median age at diagnosis for this syndrome is 38 years.[175]

CLINICAL FEATURES

The incidence of gastric cancer increases with age; the median age at diagnosis is ~70 years with <1% presenting under 35 years of age.[176] Gastric cancer rates worldwide are 2–3-fold greater in men than women.[31] The diagnosis of gastric cancer typically occurs during advanced stages (i.e., with metastatic disease) because of the vague, nonspecific symptoms associated with this cancer, including weight loss, early satiety, anorexia, fatigue, epigastric discomfort, indigestion, and nausea/vomiting. None of these symptoms are unique to stomach cancer. The prognosis is usually poor (e.g., <20–30% 5-year survival and <1 year for the most advanced stages).[177] The case fatality rate (mortality rate/incidence rate for a specified time period) is ~75% compared with ~50% for colorectal cancer and ~97% for pancreatic cancer; however, the case fatality rate is better in high-income (~58%) than low-income (~82%) countries.[178]

COLORECTAL

Colorectal cancer is the second most common malignancy in the United States, with ~160,000 new cases annually, and the third leading cause of cancer-related deaths, with ~60,000 annual US fatalities and accounting for ~8% of cancer-related deaths worldwide.[32] The lifetime risk of developing colorectal cancer in the general population is ~2%, with higher risks in Western countries (i.e., ~3–4%).[31] The overall incidence of colorectal cancer increased by ~19% during 1950–1985; however, the mortality rate decreased by 20% during this period,[179] and subsequently, screening programs and lifestyle changes reduced colorectal cancer incidence by ~45%.[180] In contrast to the reduction in colorectal cancer among adults of ≥50 years of age, the incidence and mortality of colorectal cancer increased recently in the age group 20–49 years in the United States and Canada.[181,182] Significant geographical variation occurs in colorectal cancer incidence based on the common occurrence of colorectal cancer in industrialized Western countries (e.g., North America, Europe, Australia) and the less frequent occurrence of colorectal cancer in poorer countries in Africa, South America, and Asia.

CARCINOGENESIS

Most colorectal cancers develop from the adenoma–carcinoma sequence, beginning as a small, benign polyp that progresses to a large polyp (>1 cm), a dysplastic lesion, and then cancer typically over at least 10 years.[183] Gene mutations (aneuploidy, microsatellite instability), epigenetic factors (CpG island methylator phenotypes), and local inflammation involving many different signaling pathways drive this progression with the mutation of *APC* gene; an early event in the multistep process occurring in ~70% of colorectal adenomas.[184] These changes transform normal glandular epithelial cells into invasive adenocarcinomas.[185] Other mechanisms involve origins in right-sided, non-polyploid (flat) colonic lesions and morphologically normal areas of genetically altered epithelial cells.[186] Table 54.4 outlines the major genetic pathways involved in nonfamilial colorectal cancer, along with key genes. The main signaling pathways affected in hereditary colorectal cancers involve DNA repair and Wnt, PTEN/PI3K, Tgf-β/BMP, and RAS/MAPK signaling pathways.[187]

TABLE 54.4. Major genetic pathways and genes involved with nonfamilial (sporadic) colorectal cancer cases. The adenomatous polyposis gene (*APC*) is the most common initially mutated gene in at least 70% of sporadic colorectal adenocarcinomas. Other frequently mutated genes include *TP53* and Kirsten Rat Sarcoma Viral Oncogene Homolog (*KRAS*). Approximately 15% of sporadic colorectal cancers develop from serrated precursor lesions in the proximal colon characterized by CpG island methylator phenotype and activating *BRAF* oncogene mutations. Most adenocarcinomas arising from sessile serrated adenomas in the proximal colon display high-level microsatellite instability phenotype from *MLH1* gene promoter methylation. (Adapted from Aran et al.).[188]

Genetic Pathway (% cases)	Description	Key Genes
Chromosomal instability (~70–85%)	Adenoma–carcinoma transformation sequence involving oncogene activation/tumor suppressor gene inactivation	*KRAS*, *c-Myc*, *c-Src*, *APC*, *TP53*, *PIK3CA*, tumor suppressor genes (*DCC*, *SMAD2/4*)
Microsatellite instability (~15–20%)	Clonal change in repeated DNA nucleotide units in microsatellites causing mismatch repair gene inactivation from insertion/deletion mutations often localized in the proximal colon	*APC*, *MLH1*, *MSH2/6*, *PMS2*
CpG island methylator phenotype	Global hypermethylation of promoter CpG islands inactivating tumor suppressor genes (e.g., p16)	*CACNA1G*, *CDKN2A*, *IGF2*, *NEUROG1*, *RUNX3*, *SOCS1*

EXPOSURE

Colorectal cancer is a multifactorial disease resulting from genetic, epigenetic, and lifestyle factors, with no single risk factor accounting for most colorectal cancer cases. This type of cancer is not typically associated with environmental exposures. A population-based study of cancer incidence in residents associated with increased tetrachlorethylene concentrations suggested the possibility of an association with colorectal cancer;[189] however, the small numbers, short latency period (7 years), low precision of odds ratios, and lack of statistical significance limit conclusions regarding causation.

Occupation

The role of occupational exposure in the etiology of colorectal cancer is probably relatively small.[190,191] Of all agents associated with the development of colorectal cancer, asbestos has been the most widely studied, with limited evidence of an association in humans. In 1964, Selikoff et al. reported a colorectal cancer relative risk of 3.7 in insulation workers exposed to asbestos for ≥20 years.[192] Subsequent studies of over 30 cohorts have not confirmed the magnitude of this risk in asbestos-exposed workers. Although early reviews supported the association between asbestos and colorectal cancer,[193] subsequent reviews have not supported a strong association.[47] A review of the medical literature from 21 cohorts of asbestos workers did not detect a dose-response relationship between latency period and colorectal cancer risk.[194] The summary SMR was 1.03 for 6 inception cohorts with observation periods beginning <20 years after the onset of exposure compared with a summary SMR of 0.86 (no 95% CI reported) for 7 inception cohorts of workers followed for ≥20 years after their initial exposure. All eight cross-sectional studies demonstrated no statistically significant increase in the summary SMR of 1.14. A meta-analysis of the medical literature revealed a small (SMR = 161) but statistically significant increase in the SMR for cohorts that had a SMR >200 for lung cancer.[46] The potential for misclassification (i.e., metastatic vs. primary colorectal cancer) and the dilution of the SMR by nonmalignant causes of death reduce the validity of the association between high lung SMR and colorectal cancer incidence. A case-control study of 261 cases of colon and rectal cancer did not demonstrate an increased odds ratio for asbestos exposure, as defined by employment in occupations with historically heavy asbestos exposures.[195] In a retrospective cohort study of 7,887 male and 576 female Danish cement workers exposed primarily to chrysotile asbestos, men employed from 1923–1950 had an SIR of 1.47 (95% CI: 1.05–2.01) with a 15-year lag; however, the overall SIR (1928–1984) was not statistically significant (1.22, 95% CI: 0.99–1.48, $n = 102$).[196] A retrospective study of 2,024 asbestos reprocessing plant workers reported a positive trend toward statistical significance ($P_{trend} = 0.02$) for average asbestos exposure level but not for exposure duration,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

asbestos fiber type, or cumulative exposure.[197] Information on potential confounding factors associated with lifestyle behavior was not available.

Cohort studies of rubber workers (SMR = 231, $n = 6$) suggest a potential association between the rubber industry and colorectal cancer.[198] In an analysis of standardized mortality ratios in styrene-butadiene rubber workers' cause-specific mortality (1943–1998) and the general US population for colorectal cancer, the slightly increased SMR was not statistically significant (SMR = 109, 95% CI: 94–125).[199] In a cohort of German workers in areas producing technical rubber goods, the elevated SMR was not statistically significant (SMR = 131, 95% CI: 86–191, $n = 27$).[200] Some cohort studies of chemists demonstrate excess colorectal cancer mortality;[201] however, the lack of a specific carcinogen limits conclusions about causation. A cluster of colorectal cancer occurred among employees of a polyolefin unit manufacturing polypropylene, particularly among mechanical (SIR = 10.6, 95% CI: 3.4–24.7) and process (SIR = 5.0, 95% CI: 0.6–17.8) workers.[202] However, a follow-up study of this cohort did not confirm the excess colorectal cancer risk among workers in the manufacture of polypropylene consistent with the lack of precision in the earlier SIR and the bias associated with including clusters in observational studies.[203] Other substances associated with potentially elevated colorectal cancer risks include wood dust,[204] solvents and fuel oil,[205] and methacrylate;[206] however, inadequate human evidence is available to confirm any association. A retrospective cohort mortality study of 2,294 male wood model workers did not confirm an increased risk of colon cancer in these workers.[155]

Lifestyle

Tobacco

Although the association between cigarette smoking and colorectal cancer is inconsistent between observational studies, some studies suggest a modest effect. A meta-analysis of 19 case-control and 6 cohort studies reported a pooled adjusted risk estimate of 1.18 (95% CI: 1.11–1.25) for colorectal cancer incidence comparing ever- and never-smokers.[207] A statistically significant dose-response relationship between colorectal cancer risks and increasing pack-years and intensity of cigarette smoking occurred only after 30 years of smoking. In the Nurses' Health Study, cigarette smoking was unrelated to colorectal cancer incidence until 35 years after smoking began, with a progressive stronger relationship suggesting a long latency period.[208] A modest increase (RR = 1.47, 95% CI: 1.07–2.01) in the risk of developing colorectal adenomas and cancers was reported in women smoking >10 cigarettes/day for >35 years. The association between cancer incidence and mortality was stronger for rectal than colon cancer. Some observational studies suggest smoking is not a strong colorectal cancer risk factor, even after long induction periods.[209] In an Italian case-control study of 955 colon cancers, 629 rectal cancers, and 2,879 hospital controls, the overall multivariate OR for colorectal cancer was 0.9 (95% CI: 0.8–1.1) in ex-smokers and 0.7 (95% CI: 0.6–0.8) in current smokers compared with never-smokers.[210] The results were adjusted for sex, age, diet, alcohol consumption, and family colorectal cancer history using multiple logistic regression analysis. Cox proportional hazard regression analysis of data from 465,879 participants in the European Prospective Investigation into Cancer and Nutrition study ($n = 2{,}741$ colorectal cancer cases; mean follow-up, 8.7 years) indicated a weak association between smoking and colorectal cancer.[211] Although colon cancer risk was increased among ever-smokers (HR = 1.18, 95% CI: 1.06–1.32) and former cigarette smokers (HR = 1.21, 95% CI: 1.08–1.36) compared with never-smokers, the colon cancer risk was not increased in current smokers (HR = 1.13, 95% CI: 0.98–1.31, $n = 285$). The results were adjusted for weight, height, physical activity, education, and diet. The study did not detect a dose-response relationship between colon cancer and duration or intensity of smoking. Twenty years after smoking cessation, the colon cancer risks of former-, ever-, and never-smokers were similar.

Alcohol

Heavy alcohol consumption is a recognized colorectal cancer risk. Although heavy alcohol consumption is probably an independent risk factor for colorectal cancer, the risks are not homogeneous across countries, chronic alcohol doses, intestinal tumor location, or possibly gender. In a meta-analysis of 16 cohort studies involving ~6,300 colorectal cancer patients comparing the highest and lowest alcohol consumption, the overall meta-RR for colorectal cancer was positive but not statistically significant (1.34, 95% CI: 0.92–1.96, $I^2 = 71\%$); however, the overall meta-RR was marginally significant for heavy alcohol consumption (>200 g/week) for men (RR = 1.73, 95% CI: 1.00–2.98, $I^2 = 74\%$), but not for women (RR = 0.88, 95% CI: 0.61–1.27, $I^2 = 0$).[212] Other meta-regression analyses indicate the relative risk of cancer was significantly increased for men in the colon and rectum, whereas the risks were marginally significant for the colon but not the rectum in women. In a pooled analysis of eight cohort studies from five

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

North American and European countries, the pooled multivariate relative risk for colorectal cancer was statistically significant only for participants consuming >45 g/day (~3 drinks) when compared with nondrinkers (RR = 1.41, 95% CI: 1.16–1.72).[213] Significant heterogeneity was not detected by study location or sex. Colorectal cancer incidence in Japan is particularly high compared with the rest of the world, potentially because of the greater prevalence of the slow-metabolizing aldehyde dehydrogenase variant. Analysis of data from 5 Japanese studies involving 2,802 colorectal cancer cases reported a multivariate-adjusted, pooled hazard ratio of 2.96 (95% CI: 2.27–3.86) for daily alcohol intake of ≥92 g (~7 standard sake drinks) compared with nondrinkers.[214] The colorectal cancer risk was increased for women drinking >23 g/day (HR = 1.57, 95% CI: 1.11–2.21) compared with nondrinkers. The risk correlated with alcohol dose (P_{trend} ≤0.001) and was similar for colon and rectal cancer.

Diet

Low-fiber, high-fat diets, including the consumption of substantial amounts of red meat along with reduced physical activity in industrialized countries, may contribute to some of the excess colorectal cancer rates; the strongest evidence for increased colorectal cancer risk is the consumption of red and processed meat.[215,216] In a dose-response meta-analysis using random effects models, the estimated increased summary relative risk was 1.12 (95% CI: 1.04–1.21; $I^2 = 70\%$ $P_{heterogeneity} \leq 0.01$) for each 100 g/day increase in red and processed meat intake.[217] Foods containing fiber reduce colorectal cancer risk. Colorectal cancer risk decreased by ~17% (95% CI: 11–21%, $I^2 = 0\%$, $P_{heterogeneity} = 0.21$, $n = 6$) for each 90 g/day increase in whole grain consumption and by 13% (95% CI: 10–17%, $I^2 = 18\%$, $P_{heterogeneity} = 0.27$, $n = 10$) for each 400 g/day increase in dairy product intake. Evidence for a reduction in risk from vegetable and fish consumption was unconvincing. Cheese, coffee, fruit, legume, poultry, and tea consumption did not alter colorectal cancer risk. Random controlled trials do not support the use of low-fat, high-fiber diet to reduce the recurrence of colorectal adenomas.[218]

Physical Activity

Physically active occupations have been associated with a decrease in colorectal cancer risks;[219] however, confounding with lifestyle, diet, and social class limits the extrapolation of the studies demonstrating a negative association between physical activity and the development of colorectal cancer. Additionally, the potential for reporting bias from self-reports of activity/sedentary behavior and the lack of a universally accepted definition of insufficient physical activity complicate the evaluation of physical exercise as a colorectal cancer risk factor. Although objective and subjective physical activity measures give qualitatively similar results regarding gender and age patterns of physical activity, adherence to physical activity recommendations is substantially lower for accelerometer-measured than self-reported activity (e.g., <10% vs. 60%, respectively).[220]

In a systematic review and meta-analysis of leisure time physical activity, meeting WHO guidelines for leisure activity was associated with a reduction in colon cancer (RR = 0.81, 95% CI: 0.75–0.88, $I^2 = 4.2\%$) but not rectal cancer (RR = 1.07, 95% CI: 0.93–1.24, $I^2 = 0.0\%$) risks.[221] Dose-response analysis indicated the benefit of physical activity did not increase 2-fold above WHO recommendations. Systematic reviews and meta-analyses typically estimate that physical activity reduces colon cancer risk by ~20–25%, comparing the highest and lowest levels of assessed physical activity with a somewhat stronger risk reduction for case-control than cohort studies (i.e., 24% and 17%, respectively).[222] Clinically significant cancer incidence reduction may require 30–60 minutes of moderate to vigorous physical activity daily to lower colon cancer risks.[223]

Obesity

Excessive weight and adipose tissue induce tumor necrosis factor-α (TNF-α), plasminogen activator inhibitor 1 (PAL-1), free fatty acid, leptin, and resistin along with decreasing adiponectin. These changes enhance insulin resistance and increase insulin-like growth factor-binding protein 1 (IGFBP1) and growth factor-binding protein 2 (IGFBP2), resulting in the inhibition of apoptosis and enhanced cell proliferation.[224] Direct measurement of visceral adipose tissue (VAT) using computed tomography indicates VAT is a better predictor of insulin resistance than waist circumference or BMI; however, most observational studies use BMI as the measure of obesity.[225] Cumulative lifetime excess weight may be a stronger risk factor than weight measured at a single point in time. In meta-analyses of colorectal cancer and obesity as measured by BMI, the increased relative risk of colorectal cancer with obesity was <1.5–2.0 in men and weaker in women (<1.2). Increasing BMI in a meta-analysis of 28 articles was associated with an increased overall risk ratio per 5 kg/m^3 of 1.24 (95% CI: 1.20–1.28, $I^2 = 20.7\%$, $P = 0.189$) in men and 1.09 (95% CI: 1.04–1.14, $I^2 = 39.1\%$, $P = 0.042$) in women.[226] The pooled relative risk of colorectal cancer per 5 kg/m^2

increase in BMI using random effect models in a meta-analysis of 15 cohort studies was 1.37 (95% CI: 1.21–1.56) for overweight and obese men compared with 1.07 (95% CI: 0.97–1.18) for overweight and obese women.[227] Comparing the highest and lowest quantiles of waist-to-hip ratio, the pooled RR for colon cancer was 1.91 (95% CI: 1.46–2.49) for men and 1.49 (95% CI: 1.23–1.81) for women. Analysis of data from the prospective Nurses' Health Study II enrolling 85,256 female nurses aged 25–42 years at study enrollment detected 114 cases of early-onset colorectal cancer (median age at diagnosis, 45 years).[228] Based on biennially self-reported anthropomorphic measures and lifestyle information, the adjusted, multivariable relative risk of early-onset colorectal cancer was associated with obese women (BMI $\geq$ 30, RR = 1.93, 95% CI: 1.15–3.25) but not overweight women (BMI, 25.0–29.9, RR = 1.37, 95% CI: 0.81–2.30) when compared with women with a BMI of 18.5–22.9. Adjustments included height, history of diabetes, smoking, physical activity, alcohol intake, aspirin/nonsteroidal anti-inflammatory drug use, multivitamin use, menopausal status, hormone use, dietary intake (total calories, red meat, fiber, folate, calcium), and Alternate Healthy Eating Index 2010.

Diseases

Patients with inflammatory bowel disease have increased colorectal cancer risks, particularly the chronic colonic inflammation associated with ulcerative colitis; however, no significant colorectal cancer risk occurs in patients with Crohn's disease isolated to the small bowel.[229] The colorectal cancer risk is significantly higher in patients with longer disease duration, extensive disease, and the diagnosis of inflammatory bowel disease at a young age. Compared with the general population, colorectal cancer risk increases 2- to 5-fold, with the risk increasing throughout life after diagnosis (e.g., from 2% at 10 years to 18% at 30 years). In a meta-analysis of population-based, cohort studies of colorectal cancer and inflammatory bowel disease adjusting for isolated small bowel Crohn's disease, the pooled standardized incidence ratio (pSIR) for colorectal cancer was 1.7 (95% CI: 1.2–2.2).[230] High-risk groups were patients with extensive colitis (pSIR = 6.4, 95% CI: 2.4–17.5) and disease diagnosis before age 30 (pSIR = 7.2, 95% CI: 2.9–17.8). In a meta-analysis of eight population-based, cohort studies, the pooled SIR for colorectal cancer in ulcerative colitis patients was 2.4 (95% CI: 2.1–2.7) and 4.8 (95% CI: 3.9–5.9) in patients with extensive colitis involving >50% of the colon.[231]

Epidemiological studies have not consistently reported an association between pre-diagnosis, systemic inflammatory marker concentrations (e.g., tumor necrosis factor-α, interleukin-6, C-reactive protein), and colorectal cancer. However, the association of obesity with colorectal cancer risks suggests the presence of a low-grade inflammatory condition (e.g., obesity) may influence colorectal cancer risks. The empirical dietary inflammatory pattern (EDIP) score is a weighted sum of 18 food groups that assesses the inflammatory potential of a diet validated by comparing quintiles of the EDIP score with concentrations of systemic inflammatory markers (interleukin-6, C-reactive protein, tumor necrosis factor-α receptor 2) and adiponectin.[232] Pro-inflammatory foods included processed meat, red meat, organ meat, non-dark fish, tomatoes, vegetables other than green leafy and dark yellow vegetables, refined grains, and high-energy/low-energy beverages, whereas beer, wine, tea, coffee, dark yellow and leafy green vegetables, snacks, fruit juice, and pizza were considered anti-inflammatory. EDIP scores were calculated from food frequency questionnaires administered every 4 years in the Health Professionals Follow-up Study (46,804 men) and the Nurses' Health Study (74,246 women).[233] The hazard ratios for colorectal cancer comparing the highest and lowest quintile EDIP scores were modestly elevated for men (HR = 1.44, 95% CI: 1.19–1.74) and less for women (HR = 1.22, 95% CI: 1.02–1.45). Potential confounders in the analysis included higher BMI, increased rates of diabetes, and lower physical activity in the highest EDIP quintiles, limiting conclusions about causation.

Diabetes is probably an independent risk factor for colorectal cancer. In a systematic review and meta-analysis of 30 cohort studies using random effects models, diabetes was associated with an increased colorectal cancer risk with a summary relative risk of 1.27 (95% CI: 1.21–1.34); moderate heterogeneity appeared among the studies ($P = 0.002$, $I^2 = 48.4\%$).[234] Subgroup and meta-regression analysis with control of confounding demonstrated that the increased colorectal cancer incidence was independent of sex, smoking, physical activity, body mass index, geographic locations, and family colorectal cancer history.

Several meta-analyses suggest chronic *H. pylori*-induced gastritis is associated with an ~50% increased colorectal cancer incidence.[235,236] In an analysis of a database containing 156,000 surgical pathology reports, the odds ratio of colorectal adenocarcinoma in patients with chronic *H. pylori* gastritis compared with patients having normal gastric mucosa was 2.35 (95% CI: 1.98–2.80).[237] The risks of adenomatous polyps (OR = 1.52, 95% CI: 1.46–1.57) and villous adenomas or

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

adenomas with high-grade dysplasia were also elevated (OR = 1.97, 95% CI: 1.82–2.14) in patients with chronic *H. pylori* infections.

HISTOLOGY

Most (i.e., 90–95%) colorectal cancers are adenocarcinomas arising from epithelial cells in the colonic crypts as polyps, with the sigmoid colon being the most common anatomical site.[238] Precancerous polyps include the following: 1) the common sessile, raised, or pedunculated tubular adenomas with conventional dysplasia; 2) sessile serrated adenomas without cytological dysplasia; and 3) relatively rare traditional serrated adenomas presenting as flat or villous, right-sided polyps with slit-like serrations and pink cytoplasm.[239] APC (adenomatous polyposis coli) gene mutations characterize tubular adenomas,[240] whereas CpG island methylation with epigenetic gene silencing characterizes traditional serrated adenomas.[241]

HOST SUSCEPTIBILITY

Although most colorectal cancers are not hereditary, genetic factors may contribute significantly to the occurrence of colorectal cancers. In the Nordic Twin Study of Cancer involving 39,990 monozygotic and 61,443 same-sex dizygotic twins, the familial risk ratio for colorectal cancer was 3.1 (95% CI: 2.4–3.8) relative to the cohort risk compared with 2.2 (95% CI: 1.7–2.7) for dizygotic twins of affected co-twins.[242] The authors suggested interindividual genetic differences could account for up to 35–40% of the variation in colorectal cancer susceptibility. A systematic review and meta-analysis of 27 case-control and cohort studies reported a relative risk of 2.25 (95% CI: 2.00–2.53) for individuals with a first-degree relative previously diagnosed with colorectal cancer and 2.26 (95% CI: 1.87–2.72) for a history of a parent with colorectal cancer when compared to controls without a family history of colorectal cancer.[243]

Approximately 5% of patients with colorectal cancer have an inherited predisposition.[188] The two well-defined inherited colorectal cancer syndromes accounting for the majority of colorectal inheritable syndromes are adenomatous polyposis coli (~1% of total colorectal cancer cases) and hereditary nonpolyposis colorectal cancer (Lynch syndrome, ~4–5% of total colorectal cancer cases). The lifetime risk of colorectal cancer in these hereditary diseases approaches 100% if untreated. These two diseases may reflect different susceptibilities to neoplastic transformation in proximal and distal tumors.[244,245] A family history of colon cancer is also a risk factor for the occurrence of sporadic colorectal cancer that does not demonstrate a family pedigree consistent with genetic transmission. Certain genetic abnormalities (e.g., allelic deletions on chromosomes 5, 17, 18; C-MYC amplification; *RAS* point mutations) may predispose patients to colorectal cancer by enhancing the progression from normal to malignant colonic mucosa.[246]

CLINICAL FEATURES

Older age is associated with increasing colorectal cancer risks, with an ~2-fold higher incidence in men than women.[247] The mean age of colorectal cancer diagnosis in sporadic cases is ~67 years compared with earlier onset in the 40s and 50s for hereditary colorectal cancer syndromes.[187] The classical symptoms of colorectal cancer (e.g., hematochezia, anemia, weight loss, abdominal pain) typically occur at relatively late stages of the disease. The diagnosis of 90% of colorectal cancer cases occur in patients over 50 years of age, with 40% of the cases involving localized disease.[37] However, the most rapidly increasing early-onset cancers (i.e., patients <50 years of age) are gastrointestinal cancers, particularly colorectal and gastric cancers. The 5-year survival rate ranges from 90% in patients with Stage I (localized, T1/T2N0M0) disease to ~10% in Stage IV (distant metastatic) disease. Although somewhat controversial, the survival rates are generally similar between the molecular subtypes noted in Table 54.4.[248,249] Approximately 1/2 of recently diagnosed patients with colorectal cancer will die from the disease; the 5-year survival rates decrease from 70% for regional disease to 10–13% for patients with distant metastasis.

ANUS

Anal cancer is a relatively uncommon malignancy; however, anal cancer incidence has increased since the late 1990s along with the increased prevalence of human papillomavirus (HPV) infections and improved survival of human immunodeficiency virus (HIV)-infected individuals treated with antiretroviral therapy, particularly among young men.[250] Anal cancers represent an estimated 2.7% of all US gastrointestinal malignancies and <0.5% of all US cancers, causing ~8,600 new cases and ~1,150 deaths per year.[32] In a study of 13 North American cohorts from 1996–2007, the unadjusted

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

anal cancer incidence rate for HIV-infected homosexual men was 131/100,000 person-years compared with 46/100,000 person-years for other HIV-infected men and 2/100,000 person-years for men without HIV infections.[251] Approximately 80–90% of anal cancers are associated with HPV infections.[252] In a systematic review of studies on anal cancer incidence, the incidence of anal cancer among HIV-infected women ranged from 3.9–30/100,000.[253] Among women with a history of cervical cancer or high-grade cervical intraepithelial neoplasia 3, the anal cancer incidence rates ranged from 0.8–63.8/100,000 person-years compared with 0.55–2.4/100,000 person-years in the general population. Anal HPV infection is relatively common in the general population of women; however, healthy women clear HPV infections more easily from the anus than the cervix. Anal epithelial cells are less transformable than cervical cells, resulting in a substantially lower incidence of anal than cervical cancer in women.[254] The estimated age-adjusted incidence of invasive anal squamous cell carcinoma is higher in US women (~1.5/100,000) than US men (~1/100,000).[255] Most anal HPV infections in men are concentrated in high-risk groups (HIV-infected and homosexual men).

CARCINOGENESIS

The HPV genome is a double-stranded circular DNA with over 150 HPV types that infect the host genome of stratified epithelial cells with varying carcinogenic potency and preferential epithelial cell tropism; the highest carcinogenic risk occurs with HPV-16 and, to a lesser degree, HPV-18.[256] Biopsies from the vast majority of patients with anal cancer or precursor lesion contain DNA from human papillomavirus. In anal cancer specimens from 324 women and 93 men, HPV-16 was detected in 84% of the samples compared with none in the rectal cancer control group.[257] Detectable HPV DNA occurred in 94% of 72 participants in a study of patients with metastatic anal cancer; however, the prognostic value of HPV is unclear in contrast to the improved prognosis in HPV-associated head and neck cancer.[258]

HPV is a necessary but not sufficient factor for the development of anal cancer because only a small fraction of HPV-infected individuals develop squamous cell anal cancer from the infection. Over 90% of HPV infections in healthy individuals are undetectable within a few years after the initial infection; however, the infection may remain dormant for several decades.[259] HPV infects only epithelial cells spreading from one epithelial surface to another when the cells slough off or die.[260] The HPV genome encodes early structural genes (E1, E2, E4–E7) involved with viral replication and late structural genes (L1, L2) encoding major and minor capsid proteins, respectively. After entering the basal epithelial layer, the viral genome maintains a quiescent state with the E1 and E2 proteins coordinating viral replication with host cell division. The outcome of the infection depends on oncogenic potency of the HPV type, host immune response, host genetics, epithelial infection site, and other factors that modulate the HPV infection, including other sexually transmitted infections. Active viral replication produces low-grade squamous intraepithelial lesions important for HPV transmission, but not involved with cancer progression. An aborted infection results in the expression of oncogenic early region genes that progress to high-grade squamous intraepithelial lesions with greater risk of malignant transformation depending on the host immune response. Epigenetic factors (e.g., DNA methylation, histone deacetylation, cellular microRNAs, cellular transcription factors) may also enhance the malignant transformation of squamous intraepithelial lesions and oncogene expression produced by HPV infections.[260] Table 54.5 outlines the function and effect of HPV proteins on the malignant transformation of infected anal epithelial cells.

EXPOSURE

Lifestyle is the most important risk factor for anal cancer, particularly the presence of HPV. Major risk factors for the development of anal cancer correlate to sexual promiscuity (e.g., >10 sexual partners) and anoreceptive intercourse typically associated with HPV and HIV infections. No specific occupational exposures are associated with the development of anal cancers.

Human Papillomavirus (HPV)

Homosexual men with high-grade anal intraepithelial neoplasia grade 3 and HPV-16 infections are particularly vulnerable to developing anal cancer.[261] Recurrence of these high-grade lesions often occurs despite treatment (e.g., electrocautery). In a cohort of 100 HIV-infected homosexual men treated with electrocautery for high-grade anal intraepithelial neoplasia, the probability of recurrence at 24 months of follow-up was ~53% (95% CI: 34–73%).[262] Surviving patients with squamous cell carcinoma of the anus have an increased risk of developing HPV-related, second primary malignancies (e.g., oral cavity, pharyngeal, genital), particularly in never-married men.[263,264] In a cross-sectional observational study of 324 women with

TABLE 54.5. Human papillomavirus (HPV) factors involved in the pathogenesis of anal cancer.

HPV Factor	Function	Effect
E1, E2	Insertion of viral DNA into host genome	Loss of E2 function and integration of the viral genome into the host genome increases the production of E6 and E7 oncogenes
E5	Accessory role in malignant transformation	Reduces epidermal growth factor receptor turnover resulting in increased susceptibility to mitogenic effects and inhibits cell-mediated immunity by decreasing cell surface major histocompatibility complex class 1 expression
E6	Binds and inactivates tumor suppressor protein p53	Formation of protein complex destroys p53 proteins and causes chromosomal instability from loss of p53 DNA repair and cellular apoptosis functions that normally removes DNA mutations. Also reduces immune surveillance by decreasing E-cadherin on keratinocyte surface
E7	Binds retinoblastoma (Rb) protein	Enhances cell proliferation by promoting progression past the mid-G1 restriction point into the S-phase along with accumulation of DNA mutations produced by HPV E6 protein
L1	Major capsid formation	Envelops HPV genome to form fully infectious viral particles when the infected epithelial cell sloughs or dies
L2	Minor capsid formation	Envelops HPV genome to form fully infectious viral particles when the infected epithelial cell sloughs or dies

anal cancer and age-matched controls (general population and patients with rectal adenocarcinoma) using telephone interviews, logistic regression indicted an increased anal cancer risk associated with anoreceptive intercourse, venereal infections in their partner, and sexual promiscuity, particularly for the first intercourse before age 30 years.[257] The adjusted odds ratio for ≥10 lifetime sexual partners was 4.5 (95% CI: 2.7–7.4) and 2.4 (95% CI: 1.3–4.5) for history of sexually transmitted diseases in their partner. The incidence of anal cancer is 10 times higher among HIV-seropositive homosexual men than among women with cervical cancer.[265] Examination of data from the Danish National Patient Register suggests an association between the presence of genital warts and an increased risk of anal cancer.[266] The standardized incidence ratio of anal cancer comparing individuals with genital warts and the general Danish population was 21.5 (95% CI: 14.4–30.9, $n = 29$) for men and 7.8 (95% CI: 5.4–11.0, $n = 33$) for women. Genital warts usually result from nononcogenic HPV types of infections (e.g., HPV6, HPV11).[267]

Tobacco/Alcohol Use

Case-control studies associate anal squamous cell carcinoma, but not anal adenocarcinoma with cigarette smoking in a dose-response relationship. In a meta-analysis of 45 observational studies, the overall summary prevalence estimate for anal cancer was ~2.5 times greater for current smokers (54%, 95% CI: 49–59%) than US adults in the general population (20–23%), with substantial heterogeneity (I^2 = 99%) in the studies.[268] Obesity and alcohol consumption were not associated with increased anal cancer risks. The population-based prospective study of 1.3 million women recruited via the UK National Health Service Breast Screening Program identified 517 anal squamous cell carcinoma cases; the relative risk of anal cancer in ever- versus never-smokers was 1.49 (95% CI: 1.24–1.83). The relative risk increased to 2.16 (95% CI: 1.65–2.83) in current smokers using >15 cigarettes/day. Alcohol use was not associated with an increased anal cancer risk. This study did not collect information on sexual behavior of the participants. A case-control study of 126 patients (67 women, 31 heterosexual men, 28 homosexual men) with anorectal squamous cell carcinoma and 372 randomly selected control subjects in the San Francisco Bay Area reported that the risk of anorectal cancer in homosexual men increased with self-reported pack-year history of cigarette smoking.[269] The relative risk for a 20-pack-year history was 1.9 (95% CI: 1.7–2.2) compared with 5.2 (95% CI: 4.2–6.5) for a 50 pack-year history, with higher risks for current smokers. In a study of 72 patients with metastatic anal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancer, a 30-pack-year history of smoking was relatively more common in HPV^- than HPV^+ tumors.[258]

HISTOLOGY

The anal canal is the last 3–5 cm of the gastrointestinal tract between the anorectal junction and the outer opening of the gastrointestinal tract (i.e., squamous-mucocutaneous junction with perianal skin termed the anal verge). The dentate line is the anatomical division of the rectum and the anal canal. The region proximal to the dentate line contains columnar glandular epithelia, whereas the distal region has stratified squamous epithelia. Anal cancer typically arises from mucosa-lined anal canal 1–2 cm proximal to the dentate line to the intersphincteric groove separating the anal canal and anal margin; this heterogeneous transitional zone contains un-keratinized squamous, transitional basal, columnar, and cuboidal cells. The specific cell of origin does not affect the outcome.[270] Approximately 80–85% of anal cancers are squamous cell carcinomas, with ~10% adenocarcinomas and the rest much rarer tumors (e.g., melanomas, small cell carcinomas). The anal canal is a very uncommon site for metastatic tumors.[271] The development of precancerous lesions (high-grade squamous intraepithelial lesions, HSIL) precedes the development of anal cancer. These lesions do not regress in most individuals with HSIL, despite antiretroviral therapy that increases CD4 concentrations and reduces viral loads;[272] however, the progression rates to anal cancer appear lower in anal than in cervical cancer.[273]

HOST SUSCEPTIBILITY

As mentioned above, the risk of developing anal malignancies is higher in immunocompromised and immunodeficient patients, particularly those with chronic active HIV infection and chronic immunosuppression in transplant patients.[274] The risk of anal cancer is ~12-fold greater in HIV patients who have been seropositive for 15 years compared with those with a 5-year history irrespective of highly active antiretroviral therapy (HAART).[275] Relatively rare forms of anogenital pre-malignancies associated with an increased risk of anal cancer include Bowen's disease, Bowenoid papulosis, and erythroplasia of Queyrat.

CLINICAL FEATURES

A substantial lag occurs between HPV infection and the diagnosis of anal cancer with the diagnosis uncommon before 40 years of age; anal cancer incidence increases with age, with occurrence more common in women than men.[276] The most common age at diagnosis of anal cancer in men is 40–49 years followed by men aged 50–64 years, whereas the most common age in women is ≥65 years followed by 50–64 years.[250] Anal squamous cell carcinoma develops up to two decades earlier in HIV-infected men than in non-infected men.[277] Analysis of the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) data from 39 cancer registries for cases diagnosed from 1998–2003 indicated the overall mean age at diagnosis of invasive anal cancer was 62 years, with a majority of the cases staged as *in situ* or localized.[255] The most common clinical feature of anal cancer is rectal bleeding with or without pain, often attributed to hemorrhoids.[278] Less common symptoms include intense pruritis, altered bowel habits, and enlarged inguinal nodes. For localized disease, the 5-year survival rates for anal cancer range from 40 to 70% depending on the overall tumor/node/metastasis (TNM) stage.[279]

LIVER AND BILE DUCTS

Substantial variation in the occurrence of hepatocarcinoma exists worldwide. Liver cancer is the second most common cause of cancer-related deaths among men globally, with the highest incidence and mortality rates among both sexes in Eastern/Southeastern Asia and middle/western parts of Africa (e.g., southern Sahara).[280] Southern Europe has intermediate liver cancer incidence rates. Worldwide, liver cancer is the sixth most common human cancer. Liver cancer is the fourth leading cause of cancer deaths in the United States after lung, colorectal, and stomach cancers.[281] The age-adjusted mortality rates from 2000–2016 for liver cancer increased by 43% for US men (10.5 to 15.0/100,000) and 40% for US women (4.5 to 6.3/100,000).[282] Among men, global liver cancer incidence rates range from 1.9/100,000 (Algeria) to 41.3/100,000 (Korea) compared with 0.8/100,000 (Netherlands) to 13.9/100,000 (Zimbabwe) among women. Mongolia has the highest liver cancer rates (78/100,000) reflecting the high prevalence of HBV, HCV, and excessive alcohol consumption. Approximately 50% of liver cancer cases and deaths occur in China. However, these rates are decreasing in low-income countries as public health programs reduce HBV infections and aflatoxin exposures,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

while liver cancer mortality rates are increasing in high-income countries (e.g., North America, Oceania, Central/Northern Europe).[283] In the United States, increased prevalence of chronic HCV infections from contaminated blood and intravenous drug abuse during the 1960s and 1970s contributed to the increased rates, along with increasing rates of obesity and type 2 diabetes more recently.[284] The prevalence and incidence of liver cancer are similar because of very poor overall survival from late-stage presentations, aggressive tumors, and limited treatment options.

Primary liver tumors typically are classified based on their specific histology, including hepatocellular carcinoma (liver cell carcinoma), cholangiocarcinoma (intrahepatic duct carcinoma), angiosarcoma, and hepatoblastoma. Hepatocellular carcinomas account for most (75–90%) primary liver cancers, particularly in developing nations in Africa and Asia, where hepatitis B and C infections are common cocarcinogen. The biliary tract consists of the biliary ducts and the gall bladder; biliary duct cancers (intrahepatic and hilar/distal biliary duct cholangiocarcinomas) are rare cancers in the United States compared with primary liver cancer.

HEPATOCELLULAR CARCINOMA (HCC)

Although hepatic cancer commonly occurs in animal models in response to chemical carcinogens, these chemicals are an uncommon cause of liver cancer in the United States. US liver cancer-related death rates are the highest among all cancer sites in the United States.[285] HCC typically arises in patients with underlying cirrhosis in up to 90% of HCC cases.[286] Worldwide, liver cancer is the fifth most common cancer among men and ninth most common cancer among women; overall, liver cancer is the second most common cause of cancer death after lung cancer globally.[287] Although overall cancer rates declined by ~1.5% annually from 2003–2012, liver cancer-related death rates increased for most ethnic groups in the United States, with liver cancer incidence also increasing during this time.[288]

CARCINOGENESIS

Primary liver cancer is a common tumor in experimental animals exposed to a wide variety of chemicals. A number of factors modulate HCC incidence and yield in animal models including chronic exposure to peroxisome proliferators, pesticides, microsomal enzyme inducers, surgical alterations of blood supply, modification of dietary protein, and parasitic liver infections.[289] HCC is the prototypical inflammation-associated cancer commonly occurring in patients with advanced hepatic fibrosis and/or cirrhosis from chronic liver disease, particularly damage resulting from HBV/HCV infections and high alcohol consumption. This disease also develops in chronic, non-cirrhotic inflammatory conditions (e.g., non-alcoholic steatohepatitis, NASH; non-alcoholic fatty liver disease, NAFLD). Epigenetic changes (DNA methylation, histone modifications, and RNA-mediated alteration/silencing of gene expression) contribute to the promotion and progression of hepatocellular carcinoma by inducing genomic instability from global hypomethylation and tumor suppressor gene inactivation from hypermethylation of specific promoter genes.[290] Histone (chromatin) modifications involve covalent post-translational changes in histone proteins that affect cellular processes (e.g., DNA replication/repair, gene transcription). Alteration of non-coding RNA (microRNA, miR) deregulates several important cellular processes, including inhibition of apoptosis (miR-221), silencing of proliferation inhibition (miR23b), promotion of cell invasion (miR-9), and inhibition of tumor suppressor genes (miR-101, miR-122, miR-195, mir-338).

HBV is a DNA virus that causes insertional mutations in the setting of chronic inflammation; HCV is an RNA virus that also produces tumors after prolonged hepatic fibrosis and/or cirrhosis.[291] A hepatocellular carcinoma typically contains at least 40 genomic abnormalities; however, few of these mutations are drivers or necessary for the development of HCC tumors as defined as a statistically significantly mutated gene above background mutation rates. Common mutations involve Wnt pathway activation (e.g., β-catenin encoded by *CTNNB1*), p53 inactivation (*TP53*), and telomere maintenance (telomere reverse transcription mutations in *TERT* that evade the replicative senescence of cirrhotic hepatocytes), particularly in the late stages of HCC development.[292] A compilation of 1,340 multiethnic hepatocellular carcinomas confirmed a complex landscape of HCC driver genes, including the following three core drivers: 1) *TP53* (tumor suppression); 2) *CTNNBA* (Wnt signaling); and 3) *TERT* (immortalization, genomic instability).[293] The estimated latency period for HCC ranges from 10–40 years, with a typical latency of 20 years in patients with chronic HBV and/or HCV infections causing cirrhosis.[294,295] In Africa, aflatoxin consumption acts synergistically with HBV to produce a higher incidence and earlier onset of HCC compared with other parts of the world.[296]

EXPOSURE

The main risk factors for hepatocellular carcinoma (HCC) in humans include cirrhosis (chronic liver inflammation and fibrosis), hepatitis B (HBV) and hepatitis C (HCV) virus infections, adeno-associated virus 2 (AAV2), alcohol abuse, and metabolic dysfunction-associated steatotic liver disease (e.g., diabetes, obesity).[292,297] Contributing factors include cigarette smoking, liver flukes in endemic areas, aflatoxin ingestion, and possibly excess body fat. Approximately one-quarter of HCC cases do not have known risk factors.[298] In humans, epigenetic mechanisms (DNA methylation, histone modulation, RNA interference) contribute to the development of hepatocellular carcinoma in response to the major risk factors.[299,300]

Almost all HCV-related HCCs occur among patients with cirrhosis. Other than HBV integration into the host genome targeting cellular genes involved in cell signaling,[301] there are no consistent genetic changes associated with liver cancer other than a few genes expressing axin (a negative regulator of Wnt/β-catenin signaling), β-catenin, and p53.[302] Aberrant DNA methylation is an epigenetic mechanism for gene silencing in human cancers, including hepatic cancer that promotes hepatocarcinogenesis by inactivating tumor suppressor and other cancer-associated genes. A study of hepatocellular carcinomas from France and Thailand found a high frequency of aberrant hypermethylation of specific genes (*CHRNA3*, *DOK1*, *GSTP1*, *RASSF1A*) in hepatocellular carcinoma tumors compared with cirrhotic and normal liver tissue.[303]

Occupation

There are no persuasively positive associations between occupational exposure to chemicals and the development of hepatocellular carcinoma, particularly for women.[304] A case-control study of 80 cases of hepatocellular carcinoma did not detect any statistically significant association between occupation and hepatocellular cancer.[305] This study suggested the possibility that pesticide exposure and road construction work with asphalt exposure may increase the risk of hepatocellular carcinoma, but to date, cohort and mortality studies have not validated this association.[306,307] A review of 15 studies demonstrated no consistent association between pesticide exposure and liver cancer using job exposure matrices, self-reported questionnaires, and geographical residence, with most case-control studies reporting no association.[308] Although weak, the strongest association involved exposure to organochloride pesticides (e.g., DDT).

Lifestyle

Tobacco

Tobacco smoking is a potential risk factor for HCC based on IARC evaluations;[309] however, the studies associating tobacco use and HCC remain somewhat inconsistent, even in the presence of HBV or HCV.[310] The interaction between HCC and viral infections appears more than additive for HBV and cigarette smoking and more than multiplicative for HCV and cigarette smoking.[311] The increased prevalence of high alcohol consumption and chronic viral hepatitis confounds the interpretation of studies on HCC risks and smoking. In a meta-analysis of 38 cohort and 58 case-control studies using never-smokers as controls, the estimated meta-RR for liver cancer (mostly HCC) in current smokers was 1.51 (95% CI: 1.37–1.67), whereas the estimated mRR for former smokers was not statistically significant (mRR = 1.12, 95% CI: 0.78–1.60) with substantial heterogeneity.[312] In a prospective cohort study of 17,363 London-based male government employees followed up to 38 years and the risk of liver cancer-related deaths using never-smokers as controls, the hazard ratio (HR) was not statistically significant for current smokers (HR = 1.43, 95% CI: 0.69–2.95) or former smokers (HR = 1.03, 95% CI: 0.49–2.16).[313] The Singapore Chinese Health Study reported an increased HCC risk in current smokers (HR = 1.63, 95% CI: 1.27–2.10) with a dose-response relationship.[314] Other studies suggest liver cancer risk and smoking are related in a dose-response relationship.[312]

Alcohol

The contribution of high alcohol intake to liver cancer risks is modest compared with HBV/HCV infections, with evidence associating HCC with high alcohol consumption weaker in cohort studies than case-control studies.[283,315] The primary difficulty in evaluating the effect of alcohol on HCC risks is a consistent definition of high alcohol consumption given the variability of alcohol use criteria in observational studies. In a systematic review and meta-analysis of 19 primarily Asian cohorts and nested case-control studies (4,445 liver cancer cases and 5,550 deaths), the pooled RR (pRR) for heavy drinking (≥3 drinks/day) was 1.16 (95% CI: 1.01–1.34) compared with nondrinkers.[316]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The results for moderate drinkers (<3 drinks/day) were statistically nonsignificant (pRR = 0.91, 95% CI: 0.81–1.02). A meta-analysis compared adjusted relative risks of liver cancer in light (≤1 drink/day), moderate (≤4 drinks/day), and heavy (>4 drinks/day) alcohol drinkers compared with nondrinkers in 9 cohort and 27 case-control studies.[317] A standard drink had 12.5 g alcohol. The adjusted pooled RR was statistically different than nondrinkers only in heavy alcohol users with the pRR in cohort studies (pRR = 1.12, 95% CI: 1.02–1.23, I^2 = 0%, n = 7 studies) lower than in case-control studies (pRR = 2.79, 95% CI: 2.00–3.87, I^2 = 76%, n = 24 studies). The adjusted pRR for liver cancer in heavy drinkers was also significantly different than nondrinkers in men (pRR = 1.59, 95% CI: 1.21–2.09, I^2 = 69%, n = 11 studies), women (pRR = 3.89, 95% CI: 1.60–9.48, I^2 = 10%, n = 3), Asian studies (pRR = 1.59, 95% CI: 1.27, I^2 = 69%, n = 15), and North American studies (pRR = 3.40, 95% CI: 2.54–4.55, I^2 = 0%, n = 7).

Obesity

The presence of hepatic steatosis along with obesity and diabetes mellitus increases the risk of HCC, particularly in patients with chronic HCV. In a Japanese cohort study of 1,431 patients with chronic HCV followed for up to 10 years, obesity was an independent risk factor for HCC.[318] Compared with underweight patients (≤18.5 kg/m^2, n = 112), hazard ratio for HCC in overweight patients was 1.86 (95% CI: 1.09–3.16, P = 0.022, n = 265) and 3.10 (95% CI: 1.41–6.81, P = 0.005, n = 31) in obese patients. In a meta-analysis of 11 cohort studies (7 European, 2 United States, 2 Asian) using standard BMI measures, the summary RR for liver cancer compared with normal BMI participants was 1.17 for overweight individuals (95% CI: 1.02–1.34, I^2 = 52.5%) and 1.89 (95% CI: 1.51–2.36, I^2 = 86.4%) for obese individuals. The strong association of obesity with diabetes mellitus, fatty liver, and increased insulin resistance confounds these results.[319] Diabetes mellitus increases the risk of non-alcoholic fatty liver disease (NAFLD) and the more aggressive form, non-alcoholic steatohepatitis (NASH); NAFLD is independently associated with an increased risk of HCC.[320]

Diet

Contamination of foodstuffs (e.g., corn, peanuts) with aflatoxins occurs during the storage of foodstuffs in damp, warm conditions, particularly in eastern Asia and sub-Saharan Africa. Certain *Aspergillus* species produce these mycotoxins with aflatoxin B1 (AFB_1) being the most carcinogenic based on animal studies. Epidemiological studies indicate aflatoxins interact multiplicatively with chronic HBV infection to increase HCC risks. In a systemic review and meta-analysis of 1,680 HCC cases and 3,052 controls from Taiwan, China, and sub-Saharan Africa, the summarized OR of HCC from the combined effects of aflatoxin and HBV was 73.0 (95% CI: 36.0–148.3) compared with 11.3 (95% CI: 6.75–18.9) from HBV alone and 6.37 (95% CI: 3.74–10.86) from aflatoxin alone based on HBV biomarkers and urine aflatoxin concentrations, respectively.[321]

Other than aflatoxins, no other dietary factor consistently produces elevated HCC risks in epidemiological studies.[283] The results on meat intake and liver cancer risks are conflicting, with the Shanghai Women's and Men's Health Studies[322] and the EPIC cohort study[323] reporting no association between HCC risks and meat consumption, whereas the NIH-AARP cohort associated high red meat consumption with increased HCC risks.[324] In a Chinese systematic review and meta-analysis of 7 cohort and 10 case-control studies, the pooled relative risks of HCC for the highest versus lowest consumption levels were 1.10 (95% CI: 0.85–1.42) for red meat, 1.01 (95% CI: 0.79–1.28) for processed meat, and 0.97 (95% CI: 0.85–1.11) for total meat.[325]

Several epidemiological studies across multiple countries report an inverse relationship between liver cancer risk and coffee use, primarily high coffee consumption (i.e., >3–4 cups daily) when compared with non-coffee drinkers.[326] In a Finnish study of 27,037 male smokers with 194 liver cancer cases and light coffee drinkers (0–<1 cup/day) as controls, the RR of liver cancer in participants drinking >4 cups coffee/day was 0.53 (95% CI: 0.30–0.95) and 1.35 (95% CI: 0.65–2.82) for never-coffee drinkers.[327] The pooled analysis of two large, prospective Japanese cohorts compared never, occasional, and ≥1 cup daily coffee drinkers based on self-reported consumption.[328] After adjustment for potential confounders and using never-drinkers as a reference group, the pooled RR of occasional and ≥1 cup/day coffee drinkers were 0.71 (95% CI: 0.46–1.09) and 0.58 (95% CI: 0.36–0.96), respectively, with a P_{trend} of 0.024.

Infections

Hepatitis B virus infections are major etiological factor in the development of hepatocellular carcinoma particularly in regions where the prevalence of hepatocellular carcinoma (HCC) is high.[329] Of the six

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

genotypes of HBV, HCC is usually associated with genotypes C, D, and possibly B. In the United States, HBV genotypes A and D occur more commonly in Afro-Americans and whites, whereas genotypes B and C are more common in people with Asian ancestry.[290] HCC risks in HBV-infected persons are ~15- to 20-fold greater than those in uninfected persons, with the HCC risk doubling in persons co-infected with HCV.[330] The risk of co-infection with HBV and HCV is probably sub-additive.[331] Hepatitis C virus also promotes tumor progress through cell proliferation and immune suppression rather than initiation because HCV is an RNA virus that does not insert into host DNA. Consequently, HCV is usually associated with cirrhosis in patients with HCC. HCC risks in HCV-infected patients vary with geography (10- to 20-fold) and HCV genotypes (↑↑ with 3 and 1b). HCV is more common in Mediterranean countries (e.g., Egypt from mass schistosomiasis treatment campaigns using non-sterile equipment in the 1950s), whereas HBV occurs more frequently in eastern Asia. The latter infection usually develops perinatally or in early childhood, resulting in the occurrence of HCC below the age of 40 in high-risk populations.

Diseases

Diseases associated with cirrhosis and increased incidence of HCC include non-alcoholic steatohepatitis (NASH), non-alcoholic fatty liver disease (NAFLD), α1-antitrypsin deficiency, and hemochromatosis, whereas HCC is less commonly associated with cirrhosis produced by Wilson disease, cholestatic liver disorders, and autoimmune hepatitis.[332] HCC occurs in patients with NASH, NAFLD, or metabolic syndrome without advanced hepatic fibrosis and/or cirrhosis. In a cohort of 1,500 US veterans with verified HCC, the unadjusted odds ratio of HCC in patients with NAFLD and no cirrhosis was 5.4 (95% CI: 3.4–8.5) and 5.0 (95% CI: 3.1–7.8) for patients with metabolic syndrome in the absence of cirrhosis compared with patients with HCV-related HCC.[333] Diabetes mellitus is associated with a 2–3-fold increased HCC risks in case-control studies, even in the absence of major risk factors. In a population-based, case-control study of 2,061 HCC patients and 6,183 non-cancer controls, the adjusted odds ratio was 2.87 (95% CI: 2.49–3.30).[334] A meta-analysis of 21 cohort studies involving 2,528 HCC cases among 35,202 participants followed for a median of 6.4 years reported summary HCC relative risks for diabetic patients with chronic liver disease from various causes. For patients with type 2 diabetes mellitus, the overall OR for HCC was 1.86 (95% CI: 1.49–2.31) compared with 1.90 (95% CI: 1.37–2.63) for nondiabetic patients with hepatitis C virus infection, 1.93 (95% CI: 1.35–2.76) for patients with cirrhosis, and 1.69 (95% CI: 0.97–2.92) for nondiabetic patients with hepatitis B virus infection.[335]

HISTOLOGY

HCC is an epithelial solid tumor that originates from several cell types, including stem cells, progenitor cells, and mature hepatocytes.[336] The multistep process of HCC tumor formation typically begins as premalignant cirrhotic nodules with low-grade dysplasia that progress to high-grade dysplastic nodules and subsequently transform into early malignant lesions (stages 0 and A) as a result of the accumulation of multiple somatic genomic changes. Each tumor contains a unique combination of genetic mutations and epigenetic modifications contributing to the highly diverse pathology of HCC. Most individuals with HBV or HCV never develop cirrhosis or HCC.

HOST SUSCEPTIBILITY

Although some case series associate rare genetic syndromes (e.g., Wolf-Hirschhorn syndrome)[337] with hepatocellular carcinomas, some clinical data associate these tumors with specific genetic syndromes. Hereditary diseases associated with increased HCC risks include hemochromatosis, porphyria cutanea tarda, acute intermittent porphyria, and α_1-antitrypsin deficiency. Studies on genetic susceptibility based on enzyme deficiencies (e.g., glutathione-*S*-transferase, epoxide hydrolases, aldehyde dehydrogenase 2) are conflicting and inconclusive.[283] Familial clustering of HCC occurs in part from the transmission of HBV/HCV, lifestyle habits, and environmental factors including obesity, cigarette smoking, and high alcohol consumption; however, increased HCC risks develop in families in studies adjusting for hepatitis and other major risk factors.

In an Italian study of 229 hepatocellular carcinoma (HCC) cases and 431 hospital-based controls excluding diseases associated with HCC, the odds ratio for HCC in participants with ≥1 first-degree relative with HCC was 2.38 (95% CI: 1.01–5.58).[338] In the Shanghai Women's and Men's Health Studies, liver cancer risks increased with an adjusted hazard ratio of 2.60 (95% CI: 1.77–3.80) for any first degree relative with liver cancer when compared with controls without a family history of liver cancer.[339] Adjustments included age, sex, education, income, BMI, vegetable and fruit intake,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

history of chronic hepatitis, history of cirrhosis or other chronic liver disease, history of diabetes, and history of cholelithiasis or cholecystectomy. The authors also reported results of a meta-analysis of 21 case-control and 6 cohort studies on familial risks of liver cancer, with an overall pooled relative risk of 2.55 (95% CI: 2.05–3.16) and substantial heterogeneity ($I^2 = 78.4\%$). The liver cancer risks determined by case-control and cohort studies were similar.

CLINICAL FEATURES

The incidence of HCC is 2- to 4-fold higher in men than women, in part because of the higher prevalence of risk factors (e.g., alcohol abuse, smoking, viral hepatitis) in men.[286] In contrast to most neoplasms, the staging of liver tumors relies on the Barcelona Clinic Liver Cancer classification rather than the TNM system.[332] Most patients with HCC are ≥40–45 years of age, with the exception of relatively younger patients in sub-Saharan Africa exposed to aflatoxins and HBV.[340] The mean age at HCC diagnosis is 55–59 years in China compared with 63–65 years in North America and Europe.[290] Although cirrhosis is the major risk factor for developing HCC (i.e., 75–90% of cases), cirrhosis was previously undiagnosed in ~20% of patients presenting with HCC.[341] Five-year survival rates for primary liver cancer are generally poor (i.e., 5–15%) depending on the country.[283] Historic median survival rates are ~36 months; however, treatment of early stages (i.e., 0, A) with potentially curative therapies (resection, transplantation, local ablation) increases the median survival to 60 months and beyond.[292] The estimated median survival for intermediate stage B is 26 months compared with 11 months for advanced stage C.

CHOLANGIOCARCINOMA

After hepatocellular carcinoma, cholangiocarcinoma is the most common primary hepatic malignancy accounting for 10–20% of newly diagnosed liver cancers.[342] The incidence of cholangiocarcinomas in the United States is ~1/100,000 persons. Worldwide, cholangiocarcinomas account for ~15% of liver cancers; the incidence rates are particularly high in parts of Asia where infection with the liver fluke is common.[343,344] Cholangiocarcinomas are divided into intrahepatic (ICC) and extrahepatic (hilum and distal bile duct, ECC); the pathogenesis, morphology, risk factors, and prognosis of these two types differ with hepatocellular carcinoma features more similar to ICC than ECC. The worldwide incidence of intrahepatic cholangiocarcinoma ranges from 0.2/100,00 in Australian men to 96/100,000 in Thai men.[345] Previously, ICC was contained within the HCC staging system; most cancer registries combined cholangiocarcinomas with other hepatobiliary tumors (e.g., hepatocellular carcinoma, gallbladder cancer). Hence, earlier epidemiology studies on cholangiocarcinoma may not reflect current classifications.

CARCINOGENESIS

Malignant transformation of cholangiocytes in the biliary duct epithelium and the development of cholangiocarcinoma probably result from bile stasis and chronic inflammation followed by a multistep-process initiated by cytokines (e.g., IL-6) and growth-promoting factors (e.g., tumor growth factor-β, TGF-β). The resulting generation of reactive nitrogen and oxygen species induces a variety of oncogenic mutations in cell cycle control, cell signaling pathways, and chromatin dynamics including BRAF, KRAS, MLL3, PEG3, RNF43, ROBO2, SMAD4, and TP53 mutations along with epigenetic modulators of genes (e.g., *BAP1*, *PBRM1*).[346,347] Whole exome sequencing of eight cholangiocarcinoma tumors associated with Southeast Asian liver fluke (*Opisthorchis viverrini*)-related tumors identified 2,016 somatic mutations in 187 genes using Sanger sequencing.[348] Focusing on 15 genes for mutation prevalence screening in these and 46 additional cholangiocarcinoma samples, the most common mutations occurred in *TP53* (44%), *KRAS* (17%), and *SMAD4* (17%) along with genes associated with genomic stability, G protein signaling, and histone modification.

Cholangiocarcinomas are heterogenous tumors that demonstrate molecular differences between ICC and ECC types. Using next-generation sequencing and gene expression data in three ICC cases and eight ECC cases, mutations in *IDH1* (33%) and *NRAS* (33%) genes were the most common mutated genes in ICC tumors compared with *TP53* (75%), *KRAS* (50%), and *BRAF* (12.5%) in ECC tumors.[349] *KRAS* and *BRAF* genes produce mitogen-activated protein kinase/extracellular-signal-regulated kinases that mediate cellular responses to growth signals. Somatic mutation analysis also indicates molecular heterogeneity between ICC subtypes (mass-forming, periductal infiltrating, intraductal growth types).[350]

EXPOSURE

Risk factors are less well defined for ICC than HCC; frequently, detection of ICC occurs in patients without known risk factors or during screening processes for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 54.6. Estimated summary odds ratios for suspected cholangiocarcinoma risk factors based on a meta-analysis of eleven case-control studies by Palmer. The studies demonstrated modest heterogeneity (cirrhosis, diabetes mellitus II) and high degrees of heterogeneity (alcohol, HBV, HCV, smoking) with relatively little heterogeneity in the obesity studies as determined by the I^2 statistic. Alcohol use was variously defined as >80 g/day (three studies), the presence of alcoholic liver disease (four studies), or alcohol use for ≥6 months. The odds ratio for smoking was not statistically significant. Tobacco use was based on ICD-9 coding (three studies) and history of use (five studies). (Based on Palmer and Patel).[352]

Risk Factor	Summary Odds Ratio	95% Confidence Limit	I^2 Statistic (%)	Number of Studies
Cirrhosis	22.92	18.24–28.79	62.4	7
Hepatitis B	5.10	2.91–8.95	86.3	8
Hepatitis C	4.84	2.41–9.71	83.6	8
Alcohol use	2.81	1.52–5.21	90.0	10
Diabetes mellitus type II	1.89	1.74–2.07	57.8	9
Obesity	1.56	1.26–1.94	0.0	3
Smoking	1.31	0.95–1.82	83.1	8

patients at risk for HCC.[351] Although several risk factors are associated with intrahepatic cholangiocarcinoma (e.g., HCV, HBV, heavy alcohol consumption, primary sclerosing cholangitis, and less strongly with diabetes and obesity), most patients with ICC in Western countries have no recognized risk factors. In a United States case series of 73 surgically treated intrahepatic cholangiocarcinomas, no identified risk factor accounted for 48 (66%), HCV for 13 (18%), HBV for 5 (7%), and primary sclerosing cholangitis for 3 (4%).[345] Cirrhosis appeared in 8 (11%) of the cases, whereas 3% had nonalcoholic steatohepatitis

Similar to hepatocellular carcinoma, the presence of cirrhosis increases the risk of intrahepatic cholangiocarcinoma (i.e., ~10- to 20-fold). A meta-analysis of 11 case-control studies from low and high prevalence regions of ICC identified several risk factors, including cirrhosis, diabetes, obesity, alcohol use, and chronic HBV/HCV infections, as displayed in Table 54.6.[352] Suspected extrahepatic cholangiocarcinoma (ECC) risk factors involve chronic biliary tract inflammation, including primary sclerosing cholangitis in Western countries, hepatolithiasis and liver fluke infections (*Clonorchis sinensis* in Southwest China, *Opisthorchis viverrini* in Laos/Thailand), various biliary malformations (choledochal cysts, congenital hepatic fibrosis, polycystic ovary syndrome), and thorium dioxide (Thorotrast) exposure.[353,354,355] In a case-control study of 246 cholangiocarcinoma cases (ICC, 83; ECC, 163) and 236 hospital-based controls from the National Cancer Institute's Surveillance, Epidemiology, and End Results (SEER) data, the prevalence of anti-HCV antibodies, anti-HBc antibodies, and heavy alcohol consumption was statistically different than controls; however, the 95% CI were extremely wide, indicating poor precision in the estimates.[356] The prevalence of heavy alcohol consumption was the only ECC risk factor that was statistically different than controls (17.8 vs. 3.8%, $P = 0.003$); the prevalence of diabetes and smoking was also not statistically different in ICC patients and controls. The prevalence of cirrhosis was higher in ICC patients than ECC patients (24.1 vs. 4.9%, $P < 0.0001$).

Lifestyle

The association between smoking and ICC risks is relatively weak compared with HCC. In a meta-analysis of eight case-control studies from low and high prevalence regions of ICC, the summary relative risk for developing ICC tumors in smokers was statistically nonsignificant, with a high degree of heterogeneity based on administrative data and patient histories as demonstrated in Table 54.6.[352] The association of ICC with obesity is inconsistent. In a Danish population-based, case-control study using 764 histologically confirmed ICC cases from the Danish Cancer Registry and 3,056 age-/sex-matched hospital controls, the odds ratio for obesity persisting for >1 year and ICC risk was statistically nonsignificant (OR = 1.83, 95% CI: 0.54–6.14, $n = 4$).[357] The association between heavy alcohol consumption and ICC is somewhat inconsistent but strongest for patients with alcoholic liver disease.[352]

Diseases

In a meta-analysis of 10 case-control and 5 cohort studies, the summary relative risk of cholangiocarcinoma in diabetic patients was 1.60 (95% CI: 1.38–1.87;

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

$P_{\text{heterogeneity}} = 0.992$).[358] In contrast to HCC, infection with HBV or HCV is a modest risk factor (i.e., ~2-fold) for intrahepatic cholangiocarcinomas; the association with ICC is weaker for HBV than HCV. In a Danish case-control study, chronic liver diseases associated with increased ICC risks included alcoholic liver disease (OR = 19.22, 95% CI: 5.55–66.54) and unspecified cirrhosis (OR = 75.9, 95% CI: 10.2–565.7).[357] Bile duct diseases were also associated with increased ICC risks, including cholangitis (OR = 6.3, 95% CI: 2.3–17.5), choledocholithiasis (OR = 23.97, 95% CI: 2.9–198.9), and cholecystolithiasis (OR = 4.0, 95% CI: 2.0–7.99); however, the wide confidence limits indicate imprecise odds ratios. The lifetime risk of cholangiocarcinoma in patients with primary sclerosing cholangitis ranges from 7–14%, with most tumors located in the hilum (i.e., ECC).[359] In a case series of 41 patients with primary sclerosing cholangitis, the estimated cumulative risk of cholangiocarcinoma (ICC + ECC) was 6% (95% CI: 2–15) after 10 years, 14% (95% CI: 4–25) after 20 years, and 20% (95% CI: 6–40) after 30 years.[360] The presence of primary sclerosing cholangitis in patients with inflammatory bowel disease (IBD) complicates the determination of an association between IBD and cholangiocarcinoma. A meta-analysis of seven case-control studies (four Asian, one pooled European, two American) on nonalcoholic fatty liver disease (NAFLD) suggested the presence of NAFLD modestly increased the risk of cholangiocarcinoma, with similar adjusted pooled risks for ICC and ECC.[361] The overall pooled adjusted odds ratios were 2.09 (95% CI: 1.49–2.91, $I^2 = 42\%$) for ICC and 2.05 (95% CI: 1.59–2.64, $I^2 = 0\%$) for ECC.

Medical

Cholangiocarcinoma is a common histological type of liver cancer along with hepatocellular carcinoma and angiosarcomas among patients receiving chronic α-particle radiation from thorium dioxide (Thorotrast) exposure. In a Danish study of 127 liver cancer patients diagnosed a median of 35 years (range, 18–48 years) after Thorotrast injection, 45 patients had hepatocellular carcinoma, 41 had cholangiocarcinoma, and 35 had angiosarcomas.[362] The increased ICC risks exceeding 300-fold suggest Thorotrast is more carcinogenic to bile duct epithelial cells and sinusoidal lining cells than hepatocytes. This imaging agent was banned over 50 years ago; consequently, the impact of this carcinogen is primarily of historical interest.[363] The latent period between exposure to Thorotrast and the diagnosis of cholangiocarcinoma is long (>20 years),[364,365] with a mean of 34.7 ± 6.6 years (range, 23–45 years) for a series of 44 cases.[366] In this series, cholangiocarcinoma represented ~43% of all histological types of liver cancer related to Thorotrast. Cholangiocarcinoma has been associated with the administration of some medications (isoniazid, methyldopa, oral contraceptives); however, the associations are relatively weak.

Occupation

The association between cholangiocarcinoma and chemical carcinogens (nitrosamines, dioxin, polychlorinated biphenyls) is relatively weak. Although the number of cases was small ($n = 15$), a hypothesis-generating, case-control study of patients with cholangiocarcinoma did not correlate exposure to organic solvents with the development of cholangiocarcinoma.[367] The International Agency for Research on Cancer lists 1,2-dichloropropane as a human carcinogen (Group 1). In 2014, Kubo et al. collected a cluster of 18 workers with cholangiocarcinomas (ICC, ECC) from a group of 111 offset proof-printing plant workers in Osaka, Japan.[368] Although these workers were exposed to several organic solvents (e.g., 1,1,1-trichloroethane, dichloromethane), all affected workers had long-term, high-dose exposure to 1,2-dichloropropane ranging from 6–16 years (median, 12.5 years) in estimated concentrations of 150–620 ppm during ink removal operations and shift TWA concentrations of 62–240 ppm.[369] Examination of these workers indicated that all had chronic bile duct injuries with dilated intrahepatic bile ducts.

HISTOLOGY

Cholangiocarcinomas (bile duct carcinomas) are usually adenocarcinomas in the biliary duct epithelium that originate from cholangiocytes in small intrahepatic biliary ductules (intrahepatic cholangiocarcinomas, ICC) or large hilar (Klatskin tumors)/extrahepatic bile ducts (extrahepatic cholangiocarcinoma, ECC). The cystic duct separates the hilum and distal ECC tumors. These two anatomical subtypes are divided into mass-forming, periductal infiltrating, and intraductal growth ICC histological types and polypoid, nodular, scirrhous constricting, and diffusely infiltrating ECC histological types. Cholangiocarcinomas usually are similarly distributed between ICC and ECC tumors. Other rarer histological types of cholangiocarcinomas include papillary carcinoma and mucinous carcinoma.[370] Classical ICC cancer is a moderately well-differentiated glandular, tubular, or nested type of large tumor (>5 cm)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

that develops in the absence of underlying liver disease (e.g., severe fibrosis), whereas nonclassical ICC cancer contains a trabecular pattern that has mixed features of extrahepatic carcinomas and intrahepatic carcinomas derived from hepatic progenitor cells.[345] Nonclassical cholangiocarcinomas are usually small tumors that develop in fibrotic livers infected with HCV. Less than 1% of liver tumors contain HCC and ICC areas (combined hepatocellular/cholangiocarcinomas) that are often associated with HBV/HCV infections and cirrhosis. Hepatocytes and cholangiocytes have the same progenitor cells. Since 2010, the American Joint Committee on Cancer Staging Manual has a specific TNM (tumor-node-metastasis) staging system for ICC.

In the workers developing cholangiocarcinomas after long-term 1,2-dichloropropane exposure, the tumors consist of mass-forming type with variously differentiated adenocarcinoma ICC, intraductal growth type ICC, or well-differentiated papillary type ECC.[371] Precancerous lesions precede the formation of these cholangiocarcinomas, including biliary intraepithelial neoplasia and intraductal papillary neoplasms of the large intrahepatic or hilar bile ducts.

HOST SUSCEPTIBILITY

In contrast to HCC, well-defined inheritable diseases are not prominent in patients with ICC. Biliary stasis and reflux of pancreatic secretions producing chronic inflammation probably predispose patients to developing ICC. Diseases potentially associated with chronic inflammation of the biliary duct include choledochal cysts (congenital dilation of the bile duct), primary sclerosing cholangitis, and hepatolithiasis.

CLINICAL FEATURES

Painless jaundice is the most common presentation (i.e., ~70–90%) for a tumor obstructing the biliary tree, with cholangiocarcinoma being the second most common cause after pancreatic cancer. Other clinical features include pruritus, abdominal pain, weight loss, and, less commonly, fever. Jaundice typically occurs earlier with ECC than ICC. Cholangiocarcinoma tumors rarely present before age 40 years; however, most workers develop cholangiocarcinoma following long-term 1,2-dichloropropane exposure at young ages (e.g., 25–45 years).[369] The overall average age of patients presenting with cholangiocarcinoma is ~60–65 years, with a male–female ratio of ~1.3:1 depending on age, with increasing male prominence >60 years of age.[355] ICC typically is diagnosed in the fifth or sixth decade, remaining asymptomatic longer than ECC. Consequently, ICC tumors are frequently not resectable; the median survival time from diagnosis in 51 cases of advanced intrahepatic cholangiocarcinoma was short (i.e., 2 months).[372] Hence, the long-term survival of patients with intrahepatic cholangiocarcinoma is very poor (median ≅ 6 months without surgery) in part because of the high propensity for regional/distant metastases and very limited systemic therapy options; the 5-year survival rate is 20–40% after resection producing clear margins. ECC usually presents early, with signs of biliary obstruction affecting men more than women, with a peak age in the sixth or seventh decade. Surgery is the only curative option for early-stage ICC and ECC patients because advanced tumors are very resistant to chemotherapy and radiotherapy.

ANGIOSARCOMA

Hepatic angiosarcomas are rare, aggressive tumors with an incidence of <0.25/1,000,000 (i.e., ~25 cases/year in the United States, 200 worldwide).[373,374] Although these tumors represent <1–2% of primary malignant hepatic lesions, hepatic angiosarcomas are the most common liver tumor of mesenchymal origin. Approximately one-half of thorium dioxide-associated tumors occur in the liver, involving all three major types of liver cancer.[375,376]

CARCINOGENESIS

Angiosarcomas are high-grade malignant tumors that develop in the endothelial cells of blood and lymph vessels in the liver and other organs. Primary hepatic angiosarcomas consist of pleomorphic or spindle cells that grow in the lumina of vascular spaces (e.g., sinusoids, terminal hepatic venules).

EXPOSURE

With the exception of a strong correlation between vinyl chloride monomer in the plastic industry and thorium dioxide exposure from previous radiological imaging, the etiology of over 3/4 of these cases is unclear.[377] The human evidence for an association between Fowler's solution (potassium arsenite) and angiosarcoma is limited, based on small series of German vintners in the 1940s and 1950s along with occasional case reports;[378,379] the human evidence for androgenic-anabolic steroid-induced hepatic angiosarcoma is also limited.[380,381] In contrast to hepatocellular

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

carcinoma, hepatic angiosarcoma is not strongly associated with viral hepatitis.[382] Most angiosarcomas are now idiopathic.

Occupation

A summary of studies of workers exposed to vinyl chloride monomers indicated an ~5-fold increased risk of developing hepatic angiosarcomas compared with controls.[110] Like other solid tumors, the minimal latency period between initial vinyl chloride exposure and the diagnosis of cancer is at least ~9–10 years, with a mean often near 20 years. In a study of vinyl chloride workers, the average latent period for the development of hepatic angiosarcoma was 20 years with a range of 12–28 years.[383] In a case series of 20 British workers developing angiosarcomas after vinyl chloride monomer exposure, the mean latency period (from first exposure to diagnosis) of the angiosarcoma was 25 years (range, 9–35 years).[384] The mean duration of occupational exposure to vinyl chloride was 15 years (range, 3–29 years). In a case series of 64 cases of angiosarcomas in polymerization workers exposed to vinyl chloride monomer, the median latency period between initial exposure and the diagnosis of angiosarcoma was 21 years (range, 9–38 years).[385] A follow-up study of 25 highly exposed German vinyl chloride workers reported a mean latency period (from first exposure to diagnosis) of 22 years (range, 12–34 years).[386]

Chronic exposure to inorganic arsenicals is a possible risk factor for angiosarcomas based on autopsy reports from vineyard workers dying after chronic arsenic exposure[387] and case reports of short-term exposure to medicinal trivalent inorganic arsenic compounds (Fowler's solution).[388] However, a cohort study of patients exposed to Fowler's solution did not confirm an increased hepatic angiosarcoma incidence.[389]

Medical

Thorium dioxide (^{232}Th) is a radioactive powder used as an imaging agent (Thorotrast) beginning in 1928. Approximately 50,000–100,000 patients received Thorotrast as a contrast agent for radiographic procedures from 1928 to the mid-1950s.[390] The first reported case of angiosarcoma associated with Thorotrast appeared in 1947.[391] Thorotrast is primarily (i.e., 90%) an α-emitter that is retained by the hepatic reticuloendothelial system with a biological half-life of 200–400 years. Several histological types of liver cancer are associated with the infusion of thorium dioxide besides angiosarcoma, including cholangiocarcinomas and hepatocellular carcinomas.[392,393] Following exposure to Thorotrast, the risk of developing angiosarcoma is ~2 orders of magnitude above the risk of developing cholangiocarcinoma and ~10 times the risk of developing hepatocellular carcinoma; the latent period ranges from 16–40 years.[394]

HISTOLOGY

Angiosarcomas originate from mesenchymal tissues in intrahepatic blood vessels; on presentation, most of these hepatic tumors are bilobular and multicentric involving large portions of the liver. Tumor expansion typically follows preexisting sinusoids with invasion of the portal or hepatic veins common. Endothelial markers (CD31, CD34), ERG expression, and factor VIII-related antigen are frequently positive molecular markers along with mutations of *TP53* (vinyl chloride monomer) and *KRAS-2* (thorium dioxide, sporadic).[395]

HOST SUSCEPTIBILITY

No specific diseases are associated with the development of hepatic angiosarcomas.

CLINICAL FEATURES

The usual presentation for an angiosarcoma has a male predominance (3:1–4:1) in the sixth to seventh decade of life. Clinical features associated with angiosarcoma are vague and nonspecific, including weakness, fatigue, weight loss, jaundice, fever of unknown origin, hepatomegaly, and right upper quadrant pain; consequently, the stage of cancer is typically advanced resulting in a poor prognosis. Complications in advanced cases resulting in death include gastrointestinal hemorrhage, recurrent hemoperitoneum, and hepatic failure.[396] In a case series of 20 workers with angiosarcoma from high concentrations of vinyl chloride monomer, metastasis was uncommon (3/20 cases).[384] The median survival of five cases of hepatic angiosarcoma was 6 months;[397] only ~2% of patients diagnosed with hepatic angiosarcoma lived more than 2 years.[398]

HEPATOBLASTOMA

CARCINOGENESIS

Most hepatoblastoma cases are sporadic, with an estimated incidence of 1.2–1.5/1,000,000 population and little variance between countries.[399,400] The presence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

some hepatoblastomas at birth and particularly in very low-weight, preterm infants (i.e., <1,500 g) suggests the possibility of developmental factors in pregnancy along with genetic and epigenetic interactions.[401] The most frequent genetic aberration in hepatoblastoma tumors involves the Wnt signaling pathway (e.g., *APC* and *AXIN* genes) that expresses cyclin D1, MYC, and survivin;[402] less frequently, alteration of telomerase activation and expression occurs from changes in expression of *TERT* (human telomerase reverse transcriptase) gene.[403]

EXPOSURE

The incidence of hepatoblastomas is too infrequent to reliably associate this very rare pediatric tumor with specific exposures. The highest incidence of hepatoblastoma at birth and the resemblance of hepatoblastoma cells to embryonal liver cells suggest initiation during gestation.[399] A case-control study compared the hepatoblastoma risk based on interviews with parents of 75 children from the Children's Cancer Study Group with hepatoblastoma and parents of 75 age-matched controls.[404] In this study, hepatitis infections, smoking, and alcohol consumption were not clearly associated with increased hepatoblastoma risk.

HISTOLOGY

Hepatoblastomas are embryonal tumors that probably originate from hepatocyte precursors (hepatoblast), most commonly containing epithelial components composed of embryonal and fetal patterns.[405]

HOST SUSCEPTIBILITY

The distinctive cytogenetic alteration in hepatoblastoma is the addition (e.g., chromosome 2, 8, or 20) or loss (chromosome 18, Trisomy 18) of whole chromosomes.[401] Although most hepatoblastoma cases occur in children without a family history of hepatoblastoma, ~15% of hepatoblastoma cases involve genetic syndromes, including familial adenomatous polyposis coli and overgrowth syndromes (Beckwith-Wiedemann, Simpson-Golabi-Behmel, Sotos). Adenomatous polyposis coli results from inherited mutation of the *APC* gene (adenomatous polyposis coli),[406] whereas Simpson-Golabi-Behmel patients have alteration of the *GPC3* gene (glypican 3) on chromosome Xq26.[407] A mutation or deletion of the *NSDA* gene characterizes Sotos syndrome.[408]

CLINICAL FEATURES

Hepatoblastomas are extremely rare, pediatric liver tumors that usually occur before 4–5 years of age, whereas hepatocellular carcinomas are the most common liver tumor in adolescents. In between these ages, pediatric liver tumors may contain pathological features of hepatoblastomas and hepatocellular carcinomas (i.e., transitional liver tumors of childhood). Although hepatoblastoma is the most common liver tumor in children of <2 years of age, the medical literature contains extremely rare case reports of adult hepatoblastomas.[409] Common presenting clinical features of hepatoblastoma include expanding abdominal mass, right upper quadrant discomfort, fatigue, weight loss, and less frequently fever and vomiting.[410] Children often do not report any physical abnormalities.[411] Advances in chemotherapy and complete surgical resection of hepatoblastoma have improved the overall survival from ~30 to >80% over the last several decades.[412] The median survival for hepatoblastoma patients is much lower for adults (e.g., ~6 months) than children.[413]

GALLBLADDER

Gallbladder cancer is the fifth most common gastrointestinal cancer in the United States (i.e., ~5,000/year), whereas this cancer is the most common biliary tract cancer worldwide, particularly in less developed countries.[414] Typically, the presentation is late in the course of the disease resulting in a poor prognosis; discovery of this cancer frequently occurs during cholecystectomy for cholelithiasis and biliary obstruction.[415] The estimated age-adjusted, worldwide incidence of gallbladder cancer is ~2.2/100,000 persons, with a female/male predominance of 2–3; there is marked geographical and ethnic variation.[287] The highest gallbladder cancer incidence occurs in the Andes (Bolivia, Chile, Ecuador), India (New Delhi), and China (Shanghai), whereas this cancer is rare in most Western countries, with the exception of certain ethnic groups (e.g., southwestern natives and Mexican Americans, Korean men in Los Angeles).[416,417]

CARCINOGENESIS

The two major pathological causes of gallbladder cancer are: 1) formation of gallstones, biliary stasis, and resultant cholecystitis affecting women more than men;

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and 2) congenital abnormality of the biliary tract (e.g., anomalous pancreaticobiliary duct junction) that allows reflux of pancreatic secretion into the gallbladder.[418] Anomalous pancreaticobiliary duct junction is a structural abnormality causing an abnormal connection between the bile and pancreatic duct outside the duodenal wall and unaffected by the sphincter of Oddi. This pathway occurs more commonly in Asia (Japan, Korea, China).

Gallbladder cancer develops from accumulation of multiple genetic alterations; however, genomic data on gallbladder cancers are limited. Available data indicate these tumors contain multiple mutations (oncogenes, tumor suppressor genes, DNA repair genes), microsatellite instability, and epigenetic changes (e.g., methylation of gene promoters). In a study of 57 Chinese gallbladder cancer samples, the most common driver genes were *TP53* (47%), *ERBB3* (~12%), and *KRAS* (~8%); the most extensively mutated pathway was ErbB signaling (*EGFR*, *ERBB2*, *ERBB3*, *ERBB4* genes).[293,419] The latter pathway involves the epidermal growth factor family of receptor tyrosine kinases (ErbBs) that help regulate cell proliferation, survival, differentiation, and migration; disruption of these processes results in cancer cell growth and immortality. Gallbladder tumors in patients with anomalous pancreaticobiliary duct junction (APDJ) commonly contain KRAS gene mutations that activate the mitogen-activated protein (MAP) kinase pathway and promote inappropriate growth signals (e.g., cell proliferation, differentiation, and death); whereas gallbladder cancer patients with cholelithiasis frequently have less KRAS mutations. The gallbladder tumors in the latter patients also commonly have early-onset TP53 mutations ranging from 35–92% in most studies.[420,421] This tumor suppressor gene helps regulate multiple cellular processes, including DNA repair, apoptosis, and gene expression.

EXPOSURE

The rarity of gallbladder cancer complicates the identification of specific risk factors. The primary risk factors for gallbladder cancer are gallstones, advanced age, and female gender.[422] Other potential risk factors for increased gallbladder cancer risks include obesity, gallbladder polyps, porcelain (calcified) gallbladder, and chronic infections (*Salmonella typhi*/*paratyphi*, *H. bilis*);[423,424] however, the association of the latter two factors with gallbladder cancer is less consistent than the former three factors, particularly with the strong association between gallbladder cancer and gallstones. Insufficient evidence exists to associate gallbladder cancer with parasites, viruses, fungi, or oral contraceptives.[425] Several case-control studies, but not cohort studies, suggest drinking coffee reduces gallbladder cancer risks. Analysis of data from a prospective cohort study of 72,680 Swedish adults (aged 45–83) identified gallbladder cancer in 74 adults.[426] Using Cox proportional hazards regression models and coffee data at baseline, the multivariable hazard ratio of gallbladder cancer was 0.41 (95% CI: 0.20–0.83) for ≥4 cups of coffee daily compared with 0.50 (95% CI: 0.24–1.06) for 3 cup/day and 0.76 (95% CI: 0.41–1.41) for ≤1 cup/day.

Cholelithiasis

Gallstones and subsequent chronic inflammation are the most significant risk factors associated with gallbladder cancer, being present in 60–90% of malignant gallbladder tumors.[427] Although most patients with cholelithiasis do not develop cancer, cholelithiasis is a common disease and most (i.e., 60–80%) patients with gallbladder cancer have cholelithiasis. The association with gallbladder cancer is stronger in case-control studies than cohort studies. Analysis of data from three cohort studies and seven case-control studies on gallbladder cancer risks in patients with a history of gallstones demonstrated a summary RR of 4.9 (95% CI: 3.3–7.4), with significant heterogeneity among all studies. The summary RR for cohort studies was 2.2 (95% CI: 1.2–4.2), whereas the summary RR for case-control studies was 7.1 (95% CI: 4.5–11.2). A prospective cohort study of 113,394 Japanese adults (42.0% males) aged 40–89 years followed for a mean of 11 years did not detect a statistically significant association between a history of gallstones and gallbladder cancer in men (age-adjusted RR = 1.2, 95% CI: 0.3–4.7) or women (age-adjusted RR = 1.1, 0.4–2.9).[428] Some studies suggest gallstone size, volume, and number may increase gallbladder cancer risks, particularly large stones (i.e., ≥3 cm); however, the association of age with these factors confounds the reported elevated gallbladder cancer risks.[415]

Obesity

The association of gallstones with obesity confounds the interpretation of studies on the risk of gallbladder cancer in obese patients. Several meta-analyses suggest the risk of gallbladder cancer increases in overweight women, but not for men, with the risk increasing for both obese men and women (BMI ≥ 30 kg/m^2); however, the pooled relative risks are all <2.[429,430] Analysis of age-adjusted cancer mortality and obesity in a prospectively studied cohort of >900,000 US adults

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

using BMI 18.50–24.99 kg/m^2 as referents reported statistically significant increased relative risk of gallbladder cancer for mildly obese women (RR = 2.13, 95% CI: 1.56–2.90, n = 59, BMI, 30.0–34.9 kg/m^2), but not for overweight women (RR = 1.12, 95% CI: 0.86–1.47, n = 86, BMI, 25.0–29.9 kg/m^2).[431] Similarly, the relative risk for mildly obese US men was elevated (RR = 1.76, 95% CI: 1.06–2.94, n = 20), but not for overweight men (RR = 1.34, 95% CI: 0.97–1.84, n = 94). In a retrospective cohort study of 1,715 gallbladder cancer cases from 2 million Norwegian adults using Cox proportional hazards regression, overweight and obese women had a higher gallbladder cancer risk compared with referent women based on BMI.[432] Compared with the referent (BMI, 18.5–24 kg/m^2), the relative risk for overweight women (BMI, 25.0–29.9 kg/m^2) was 1.27 (95% CI: 1.10–1.47) and 1.88 (95% CI: 1.60–2.2 kg/m^2) for obese women (>30.0 kg/m^2). The risk of gallbladder cancer was slightly increased in obese men, with a relative risk of 1.38 (95% CI: 1.01–1.89), but not in overweight men (RR = 1.00, 95% CI: 0.84–1.17). The P_{trend} was <0.001. In a case-control study of 184 gallbladder cancer cases (26% men, 74% women) from a large UK primary care database using BMI of <25 kg/m^2 as the referents, the odds ratio for the risk of gallbladder cancer was not statistically significant for overweight (OR = 1.03, 95% CI: 0.62–1.72, n = 31) or obese cases (OR = 1.51, 95% CI: 0.83–2.75, n = 19).[433] Substantial data were unavailable for smoking (34% cases, 39% controls), alcohol consumption (46% cases, 49% controls), and BMI (45% cases, 48% controls).

Structural Abnormalities

Polypoid gallbladder lesions occur in ~5% of adults, with most polyps discovered in asymptomatic patients undergoing abdominal ultrasonography for unrelated conditions.[434] In a study of healthy Japanese adults, the prevalence of gallbladder polyps in men increased with a rise in the obesity index, particularly in middle-aged men (i.e., 40–50-year-olds).[435] Although the obesity index increased with age in women, the study detected no similar increase in the prevalence of gallbladder polyps.

Anomalous pancreaticobiliary duct junction (APDJ) produces chronic gallbladder inflammation and increases gallbladder cancer risk, particularly in Japan. Gallbladder cancer is strongly associated with bile stasis intermingled with refluxed pancreatic juice. In a Japanese study of 126 patients with gallbladder carcinoma, 23 (~18%) had APDJ.[436] Compared with non-APDJ cases, patients with this congenital abnormality were younger (mean = 54 ± 9.1 years of age vs. 65 ± 9.7 years of age) and had a lower incidence of gallstones (17 vs. 64%, P < 0.01). This congenital abnormality is also known as pancreaticobiliary maljunction (PBM). In a Japanese case series of 129 PBM patients, gallbladder cancer occurred in 15 (21 %) of 73 patients with congenital biliary dilatation and in 43 (77%) of 56 PBM patients without biliary dilatation.[437]

Chronic gallbladder inflammation is associated with punctate calcium deposition in the gallbladder mucosa, resulting in bluish discoloration of the gallbladder (porcelain gallbladder). Although some studies suggest selective mucosal calcification (but not complete intramural calcifications) is associated with gallbladder cancer risks,[438] other case series involving pathological reports of patients undergoing cholecystectomy have not supported an association between porcelain gallbladder and gallbladder cancer.[439,440]

Chronic Infections

Several case-control studies suggest chronic gallbladder infections from *S. typhi*/*paratyphi* or *H. bilis/pylori* may contribute to malignant transformation in the gallbladder mucosa;[441,442] however, most studies are small without well-matched controls (e.g., gallstones) or well-standardized testing for the presence of carrier states. In an Indian prospective case-control study of 54 gallbladder cancer cases and 54 age-, sex-, and location-matched controls, 1/3 of the cases had positive PCR tests for *S. typhi* compared with none for the controls.[443] Indirect measures of *S. typhi* infections were also more common in the cases (Widal test, 24 vs. 13; indirect hemagglutination assay, 12 vs. 5). Studies associating *Helicobacter* infections with gallbladder cancer are inconsistent, particularly in endemic areas.[444] In an Indian case-control study of 54 gallbladder cancer cases and 55 hospital controls with cholelithiasis using 16SrRNA PCR to identify *H. bilis*, the relative risk of gallbladder cancer in *H. bilis*-positive patients was 1.05 (95% CI: 0.49–2.24, n = 32).[445] The report included a meta-analysis of 3 previous case-control studies involving 108 cases and 152 controls with a pooled odds ratio of 1.24 (95% CI: 0.63–2.44). The authors concluded that their study failed to demonstrate an increased gallbladder cancer risk in the presence of *H. bilis*.

HISTOLOGY

Gallbladder cancer arises from the progression of metaplasia or, much less commonly, the malignant transformation of a preexisting adenoma into an adenocarcinoma.[427] The presence of intestinal metaplasia

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in ~60% and dysplasia in >90% of adjacent mucosa in gallbladder tumors supports a stepwise model of malignant biliary transformation beginning with intestinal metaplasia and progressing to dysplasia, carcinoma *in situ*, and finally, invasive carcinoma over ~15 years.[446,447] Over 80% of invasive gallbladder cancers contain foci of epithelial dysplasia or carcinoma *in situ*.[448] Anomalous pancreaticobiliary duct junction (i.e., pancreaticobiliary maljunction) is more frequently associated with papillary carcinoma rather than other gallbladder cancer types. Adenocarcinomas account for ~80–95% of gallbladder cancers, with ~2/3 being moderately to poorly differentiated; the most frequent histological subtypes are tubular and micropapillary.[427] Very rare histological subtypes include squamous, adenosquamous carcinomas, small cell carcinomas, carcinoids, and stromal tumors.

HOST SUSCEPTIBILITY

Several studies suggest a family history of gallbladder cancer is associated with an increased gallbladder cancer risk; however, the relative risks in some of these studies are imprecise and other studies do not support an increased risk in first-degree (parents, siblings, children) or second-degree (aunt/uncle, niece/nephew, grandparent/grandchild) relatives.[449] In an Italian study of 58 gallbladder cancer cases and 1,408 hospital controls, a family history of gallbladder cancer was associated with an increased relative risk of gallbladder cancer (RR = 13.9: 95% CI: 1.2–163.9).[450] Analysis of data from the Swedish Family-Cancer Database covering 10.2 million individuals from 1961–1998 identified 10 cases of gallbladder cancer in offspring from parents with a history of gallbladder cancer, resulting in an SIR of 5.05 (95% CI: 2.40–9.32).[451] The age at diagnosis of these 10 cases ranged from 45–63, with most familial cases involving females. Of the 18 offspring siblings, only 1 had another cancer (ovarian).

CLINICAL FEATURES

Gallbladder cancer occurs predominately in elderly women, with a peak incidence in the seventh decade of life.[415] Patients with gallbladder cancer typically present late in the course of the disease with few symptoms. Although early gallbladder cancer (pT1a) has 80–90% survival rate, the prognosis for advanced gallbladder cancer is poor (i.e., ~10% survival).

PANCREAS

Pancreatic cancer is a highly fatal disease with similar annual incidence and mortality resulting from a low 5-year survival rate; this cancer is the fourth leading cause of cancer mortality in well-developed countries, with a male/female ratio of ~1.3–2.[452] The highest incidences of pancreatic cancer occur in developed countries, particularly in North America (e.g., US incidence, 7.4/100,000), with trends varying widely between countries.[453] The US, European, Japanese, and Chinese pancreatic cancer incidence rates currently are increasing in both genders[454] with the incidence in the United States increasing by ~0.5–1.0%/year.[455] The main risk factors are lifestyle and genetic predisposition, whereas socioeconomic and occupational factors are probably not significant contributors to pancreatic cancer occurrence.[456]

CARCINOGENESIS

Most pancreatic tumors arise from microscopic, noninvasive epithelial proliferation in the pancreatic ducts (i.e., pancreatic intraepithelial neoplasia). In a global genetic analysis of tissue from 24 pancreatic cancers, the tumors contained an average of 63 mutations with a majority being point mutations involving a core set of 12 signaling pathways;[457] however, key mutations in each pathway varied between each tumor. The four major driver genes for pancreatic cancer are *KRAS*, *TP53*, *CDKN2A*, and *SMAD4*, with mutations of *CDKN2A* and *KRAS* occurring early in the malignant process.[458] The *KRAS* oncogene encodes a small GTPase mediating downstream signaling from growth factor receptors, whereas the other three drivers are tumor suppressor genes. The KRAS mutation also occurs in chronic pancreatitis patients; however, not all chronic pancreatitis patients with this mutation develop pancreatic cancer because multiple mutations are necessary for malignant transformation in the pancreatic ducts.[459,460] *CDKN2A* encodes an important cell-cycle regulator, *TP53* expresses a protein (p53) necessary in the cellular stress response, and *SMAD4* mediates signaling downstream from transforming growth factor β (Tgf-β).[461] The latter two alterations occur relatively late (i.e., pancreatic intraepithelial neoplasia grade 3, invasive carcinoma). In a case-control study of 3,030 pancreatic cancer cases and 123,136 referent controls from the Genome Aggregation Database and 53,105 in the Exome Aggregation Consortium Database, 6 germline mutations were associated with pancreatic cancer in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

7.9% and 5.2% of patients with and without a family history of pancreatic cancer, respectively.[462] These germline mutations occurred in *CDKN2A*, *TP53*, and *BRCA2* genes as well as *BRCA1*, *ATM*, and *MLH1* genes.

In a study evaluating the clonal relationships among primary and metastatic cancers by sequencing the genomes of seven pancreatic cancer metastases, the estimated time between initial mutation until cancer death was ~20 years.[463] The estimated average time from initiation to the development of a parental clone was 11.7 years followed by another 6.8 years until metastatic subclones arose. Death occurred on average 2.7 years later.

EXPOSURE

Many pancreatic cancer cases are sporadic with no specific risk factors. The best-documented risk factors for pancreatic cancer are smoking, chronic pancreatitis, and type II diabetes mellitus, with weaker associations between pancreatic cancer and obesity, alcohol consumption, diet, and infections (HBV, HCV, *H. pylori*). Insufficient evidence currently associates sugar-sweetened carbonated soft drinks, tea, or coffee consumption with alterations in pancreatic cancer risks.[464,465] Although inadequate evidence associates pancreatic cancer risks with aspirin or statin use, some evidence supports a reduction in pancreatic cancer risks with the use of metformin. Using fixed- and random effects models to evaluate data from four studies (one case-control, three cohort), the summary RR for pancreatic cancer in metformin users was 0.38 (95% CI: 0.14–0.91, $P < 0.001$, $I^2 = 89\%$) with substantial heterogeneity.[466] A meta-analysis of nine observational studies (six cohort, three case-control) did not support an association between pancreatic cancer and metformin use. The adjusted OR was 0.76, 95% CI: 0.57–1.03, $I^2 = 86\%$) with substantial heterogeneity.[467] Some data suggest an inverse association between blood type O and pancreatic cancer. In a case-control study of 15,359 cancer patients from an Italian tumor registry, the pancreatic cancer risk was lower in cancer patients with blood type O (OR = 0.53, 95% CI: 0.33–0.83) compared with patients having other blood types.[468] A Chinese case-control study of 908 pancreatic cancer cases and 1,067 population controls reported that the only blood type with an elevated pancreatic cancer risk compared with blood type O was blood type A (OR = 1.60, 95% CI: 1.27–2.03).[469] Data on the protective effects of physical activity and pancreatic cancer risks are limited, with inadequate control of confounders to confirm a reduced risk.[464]

Occupation

Associations between occupational chemical exposures and pancreatic cancer are weak.[470,471] Based on mortality (hypothesis-generating) studies, potential associations between pancreatic cancer and occupational exposure to chemical carcinogens involve the metal, petroleum, and chemical industries; however, there are no confirmed occupational or environmental causes of pancreatic cancer. A meta-analysis of occupational exposure to chlorinated hydrocarbon solvents and pancreatic cancer demonstrated no strong causal association between chlorinated hydrocarbon solvents and pancreatic cancer.[472]

Lifestyle

Although the etiology of pancreatic cancer remains obscure, studies suggest heavy tobacco consumption significantly increases pancreatic cancer risks compared with never-smokers.[473] Other risk factors involve body mass index (BMI), family history of pancreatic cancer, and possibly heavy alcohol consumption and some dietary factors (e.g., increased fat intake associated with diabetes mellitus and obesity, low fruit and vegetable intake).[452,474] The evidence associating excessive alcohol consumption with pancreatic cancer is inconsistent;[475] however, heavy but not moderate or light alcohol consumption may increase pancreatic cancer risk. Poor nutrition, inflammation associated with chronic pancreatitis, and tobacco smoking confound the association between alcohol consumption and pancreatic cancer.[476] Most studies do not indicate coffee is a risk factor for the development of pancreatic cancer.[452]

Smoking

Tobacco smoking is the strongest risk factor for pancreatic cancer, with an attributable risk estimated at ~20–25% (range, 5–50%), depending on the population studied. In a meta-analysis of studies from four continents, smoking cigarettes increased pancreatic cancer risk by ~75% in smokers compared with non-smokers; the increased risk persisted 10–15 years after smoking cessation.[477,478] In an analysis of data from 465,910 participants in the European Prospective Investigation into Cancer and Nutrition (EPIC) study following a median of 8.9 years, 524 first incident pancreatic cancers were identified.[479] Using Cox proportional hazard models, the adjusted hazard ratio for pancreatic cancer in current smokers was 1.71 (95% CI: 1.36–2.15) compared with never-smokers; the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk increased with increasing smoking intensity and pack-years. Adjustment factors included weight, height, and history of diabetes mellitus. Pancreatic cancer risks in former smokers 5 years after smoking cessation and never-smokers were similar. Excess pancreatic cancer risks in smokers were similar to the EPIC study in a meta-analysis of 10 prospective, population-based cohort studies. The pooled RR comparing pancreatic cancer risks in current smokers and never-smokers was 1.66 (95% CI: 1.38–1.98, $I^2 = 70\%$), with moderate heterogeneity, whereas the pooled RR for pancreatic cancer comparing former and never-smokers was 1.40 (95% CI: 1.16–1.67, $I^2 = 63\%$), also with moderate heterogeneity.[480] Examination of three prospective, population-based cohort studies in this study did not detect a statistically significant interaction on pancreatic cancer risk by alcohol and smoking status. An Italian case-control study of 326 incident pancreatic cancer cases and 652 hospital patients without cancer matched for age reported additive effects of cigarette smoking and heavy alcohol consumption on pancreatic cancer risks.[481] Using multiple logistic regression, pancreatic cancer risk was elevated (OR = 4.29, 95% CI: 1.93–9.56) in heavy smokers (≥20 cigarettes/day) with heavy alcohol consumption (≥21 drinks/week) compared with never-smokers drinking <7 drinks/week.

Pooled analysis of data from the International Pancreatic Cancer Case-Control Consortium containing 6,056 cases and 11,338 controls supported an association between pancreatic cancer and cigar smoking, but not pipe smoking or smokeless tobacco use.[482] Using unconditional multiple logistic regression models adjusted for study center and covariates (age, sex, education, race, body mass index, diabetes history, total alcohol consumption), the odds ratio for pancreatic cancer in cigar-only smokers and cigarette smokers was similar, with a cigar-only pooled odds ratio of 1.6 (95% CI: 1.2–2.3, $n = 64$) when compared with never-smokers. The study did not support an association between pancreatic cancer and pipe smoking (pooled OR = 1.1 (95% CI: 0.69–1.6, $n = 38$).

Observational studies on the association of pancreatic cancer with secondhand smoke, and smokeless tobacco are inconsistent and the relative risks are weaker than studies on current or former cigarette smokers. A meta-analysis of 10 observational studies did not detect a statistically significant association between pancreatic cancer and childhood, adult residential, or occupational exposure to environmental tobacco smoke.[483] The summary RR for pancreatic cancer was 1.12 (95% CI: 0.89–1.43, $n = 5$ studies) for childhood environmental tobacco smoke (ETS) exposure, 1.23 (95% CI: 0.86–1.77, $n = 8$ studies) for adult ETS exposure, and 0.94 (95% CI: 0.67–1.33, $n = 3$ studies) for occupational ETS exposure. Most of the studies were North American or European. In a review of multiple cancer studies, the relative risk of pancreatic cancer in smokeless tobacco users was elevated (RR = 1.6; 95% CI: 1.1–2.2) compared with non-tobacco users;[484] however, a review of European and North American studies did not demonstrate a statistically significant increase in pancreatic cancer for smokeless tobacco users compared with nonusers.[485] Pooled analysis of data from the International Pancreatic Cancer Case-Control Consortium did not support an increased pancreatic cancer risk in smokeless tobacco-only users (pooled OR = 0.62, 95% CI: 0.37–1.04, $n = 23$).[482]

Alcohol

Alcohol consumption is a modest suspected pancreatic cancer risk factor (i.e., 20%); however, potential confounding from the association between alcohol and chronic pancreatitis complicates the quantitation of true risk. Evidence of an association primarily occurs in heavy alcohol consumers (i.e., >60 g ethanol/day, ≥21 drinks/week). Meta-analysis of two large, prospective, population-based cohort studies demonstrated a pooled RR for pancreatic cancer in heavy drinkers of 1.29 (95% CI: 1.20–1.38, $I^2 = 28\%$) compared with never-drinkers, whereas the pooled RR in light drinkers was similar to never-drinkers (RR = 0.96, 95% CI: 0.75–1.22, $I^2 = 91\%$) with significant heterogeneity.[480] In a hospital-based, case-control study involving 808 patients with pathologically confirmed pancreatic cancer and 808 healthy frequency-matched controls, only men consuming >60 g alcohol/day had an elevated pancreatic cancer risk ($OR_{adjusted} = 2$, 95% CI: 1.2–3.3, $P = 0.006$); the adjusted odds ratio in women was not statistically significant ($OR_{adjusted} = 1.2$ (95% CI: 0.5–3.5, $P = 0.5$) compared with nondrinkers.[486] A meta-analysis of 19 prospective studies (21 cohorts), including >4 million participants, reported little to no effect on pancreatic cancer rates for individuals consuming low to moderate alcohol doses. High alcohol consumption (>24 g alcohol/day) in men was associated with a marginally increased pancreatic cancer risk (RR = 1.18, 95 % CI: 1.00–1.39; $P = 0.045$, $I^2 = 12.9\%$) compared with the lowest level of alcohol consumption.[487] For women, no significant association was detected between pancreatic cancer risks and low, moderate, high, or total alcohol intake with no heterogeneity between studies.

Obesity

The associations between diet and pancreatic cancer, including obese and overweight patients, are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

modest (i.e., 10–20%) and somewhat inconsistent. In a case-control study of 841 patients with pancreatic adenocarcinoma and 754 healthy individuals, there was an increased pancreatic cancer risk in participants with obesity in early adulthood.[488] The odds ratio for obese individuals (BMI $\geq 30\,kg/m^2$) from ages 20–49 years was 2.58 (95% CI: 1.70–3.90). In an 8-year prospective study of pancreatic cancer in 77,255 men and 90,175 women in the Hawaii-Los Angeles Multiethnic Cohort Study, obesity (BMI $\geq 30\,kg/m^2$) was associated with an increased pancreatic cancer risk in men (RR = 1.51, 95% CI: 1.02–2.26, $n = 237$) and a reduced risk in women (RR = 0.65, 95% CI: 0.43–0.99, $n = 235$).[489] Physical activity did not affect pancreatic cancer risks. In a nested case-control study using pooled data on pre-diagnostic anthropometric measures from the National Cancer Institute Pancreatic Cancer Cohort Consortium (PanScan) involving 2,170 pancreatic cancer cases and 2,209 control subjects, the adjusted odds ratio for pancreatic cancer comparing the highest BMI quartile (severely obese, BMI $= \geq 35\,kg/m^2$) and normal-weight controls (18.5–24.9 kg/m^2) was 1.33 (95% CI: 1.12–1.58, $P_{trend} < 0.001$).[490] A meta-analysis of nine observational studies comparing pancreatic cancer cases with a BMI $> 25\,kg/m^2$ with normal BMI reported a statistically nonsignificant elevated pancreatic cancer risk (RR = 1.30, 95% CI: 0.90–1.87, $I^2 = 97\%$) with high heterogeneity.[491]

Using pre-diagnostic waist circumference and waist-to-hip ratio as measures of centralized fat distribution, the adjusted odds ratios comparing the same highest and lowest quartiles for pancreatic cancer risk were statistically nonsignificant for waist circumference (OR = 1.23, 95% CI: 0.94–1.62) but statistically significant for waist-to-hip ratio (OR = 1.71, 95% CI: 1.27–2.30). The odds ratios were adjusted for cohort, age (categorical), gender, BMI source (self-reported, measured), and smoking (never, former, current).

Diet

Limited data suggest a possible, albeit inconsistent, association between meat (e.g., grilled or barbequed, well-done red or chicken meat containing heterocyclic amines and/or benzo[a]pyrenes) and pancreatic cancer.[492,493] The association with pancreatic cancer involves high-temperature cooked meat and grill/barbequed meat consumption rather than pan-fried or microwaved meats.[494] In a hospital-based, case-control study of 626 pancreatic cases and 530 noncancer, hospital-based controls matched for race, sex, and age (±5 years), a statistically significant portion of cases than controls preferred well-done pork, bacon, grilled chicken, and pan-fried chicken, but not hamburger and steak.[495] Meat preparation and structured risk factors questionnaires collected during a personal interview provided the dietary information, whereas a self-administered food frequency questionnaire was returned by mail. In the prospective NIH-American Association of Retired Persons (NIH-AARP) Diet and Health Study cohort of 537,302 individuals aged 50–71 years, a complete baseline dietary data was ascertained from a food frequency questionnaire at baseline; ~62% completed a meat-cooking module 6 months later.[496] During 5 years of follow-up, 836 pancreatic cancer cases were identified, with 55% of these cases completing the meat-cooking module. Using Cox proportional hazard models, the calculated hazard ratio in men consuming red meat comparing the fifth and first quintiles was 1.42 (95% CI: 1.05–1.91, $P_{trend} = 0.01$) and 1.52 (95% CI: 1.12–2.06, $P_{trend} = 0.005$) for the same quintiles of high-temperature cooked meat intake. A similar association was not present in women. The EPIC study reported no association between red and processed meat intake and pancreatic cancer risk in the 865 nonendocrine pancreatic cancer cases identified in the cohort over 13 years of follow-up.[497] Using multivariable-adjusted Cox hazard regression models, the calculated relative risk of the highest quartile of red meat consumption compared with the lowest quartile (≥80 vs. <20 g/day) was 1.07 (95% CI: 0.83–1.38, $n = 183$) and 0.80 (95% CI: 0.63–1.02, $n = 260$) for the highest and lowest processed meat consumption quartiles (≥40 vs. <10 g/day). The diet was assessed by self-reported questionnaires on the average consumption of each food item over the previous 12 months. Little clear and consistent data supports an increased pancreatic cancer risk related to fruits, vegetables, chicken, or fish consumption, particularly in pooled analyses of cohort study data.[498]

Disease

Potential pancreatic cancer risk factors include chronic pancreatitis and diabetes mellitus with estimation of independent risks confounded by these diseases being both a result and cause of pancreatic cancer. The occurrence of chronic pancreatitis moderately increases the risk of pancreatic cancer.

Chronic Pancreatitis

Chronic pancreatitis is a relatively rare, progressive inflammatory disease that causes acinar cell destruction and fibrosis from several causes, including alcohol abuse, heredity, and idiopathic. The overall 20-year cumulative

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pancreatic cancer frequency for non-hereditary causes of chronic pancreatitis is ~4–5%.[499,500] The lag time between the diagnosis of chronic pancreatitis and pancreatic cancer is typically 1–2 decades. Development of chronic pancreatitis within 2 years of the cancer diagnosis may result from tumor-related ductal obstruction, as reflected in the reduction in pancreatic cancer risk as the lag time between the diagnosis of chronic pancreatitis and pancreatic cancer increases.[501] In a systematic review and meta-analysis of 13 observational (4 case-control, 9 cohort) studies on chronic pancreatitis and pancreatic cancer, the pooled overall effect estimates for pancreatic cancer in chronic pancreatitis patients with a 2-year lag period between the two diagnoses were 16.16 (95% CI: 12.59–20.73, $I^2 = 0\%$); however, the risk declined over time.[502] For a minimum 9-year lag time, the effect estimate was 3.53 (95% CI: 1.69–7.38, $n = 2$, $I^2 = 64.3\%$), with moderate heterogeneity and low precision for the estimates from these two studies. The authors opined some of the excess risk may result from confounding with other risk factors (e.g., smoking, heavy alcohol consumption), detection bias, small case number, and/or initial misclassification of cancer as pancreatitis. The risk of pancreatic cancer in patients with hereditary chronic pancreatitis is markedly elevated.

Diabetes

Diabetes type II is a risk factor for pancreatic cancer, particularly in patients with recent-onset weight loss.[503] In a nested, case-control study of 1,621 pancreatic adenocarcinoma cases and 1,719 matched controls from 12 cohorts, self-reported type II diabetes was associated with a 40% increased pancreatic cancer risk (OR = 1.40, 95% CI: 1.07–1.84) using unconditional logistic regression;[504] however, the risk was not related to the duration of the disease. The pancreatic adenocarcinoma risk was highest for patients with diabetes for 2–8 years (OR = 1.79, 95% CI: 1.25–2.55), whereas no risk was associated with a history of diabetes for ≥9 years (OR = 1.02, 95% CI: 0.68–1.52). The models were adjusted for age, gender, race, study, continuous BMI, alcohol use, smoking, and family history of pancreatic cancer. A meta-analysis of three case-control studies involving 827 pancreatic cancer cases and 2,407 controls reported a pooled adjusted odds ratio of 2.74 (95% CI: 1.63–4.62; $P < 0.01$; $I^2 = 60.4\%$) for history of diabetes with moderate heterogeneity.[505]

Limited studies on type I diabetics receiving routine insulin treatment have not consistently demonstrated an excess pancreatic cancer risk with an inconsistent duration–risk relationship.[506] In a pooled analysis of 3 large case-control studies involving 2,192 pancreatic cancer cases and 5,113 controls, multivariable analyses demonstrated an elevated pancreatic cancer risk for diabetics using insulin compared with no insulin use (OR = 2.2, 95% CI: 1.6–2.2, $n = 173$). However, 70% of the insulin users with pancreatic cancer began insulin use ≤2 years before diagnosis.[507] Compared with non-insulin users with pancreatic cancer, insulin use for >3 years was not associated with an elevated pancreatic cancer risk. For insulin-dependent diabetics using insulin for >10 years, the odds ratio compared with non-insulin users was reduced (OR = 0.5, 95% CI: 0.3–0.9, $n = 18$). The odds ratio was adjusted for age, sex, race, education, smoking, alcohol, BMI, and study site.

Helicobacter pylori

Evidence supporting an association between chronic *H. pylori* infection (gastric colonization) and elevated pancreatic cancer risks is relatively weak and inconclusive. Several studies suggest an independent association between pancreatic cancer and *H. pylori* infection, with some evidence of the association being strain-specific. A case-control study of 580 pancreatic cancer patients and 626 age-/sex-matched population controls did not detect an association between *H. pylori* positivity and pancreatic cancer ($OR_{adjusted} = 1.00$, 95% CI: 0.74–1.35) compared with seronegative patients.[508] Adjustment factors included age, sex, ever-smoking, education, and birthplace. A meta-analysis reported in this paper including the study and 10 observational studies (6 case-control, 3 nested case-control, 1 cohort) reported no statistically significant overall association between *H. pylori* seropositivity and pancreatic cancer risk ($OR_{adjusted} = 1.13$, 95% CI: 0.86–1.50); however, the adjusted odds ratio was elevated for cytotoxin-associated gene A (CAGA)-negative *H. pylori* strains ($OR_{adjusted} = 1.30$, 95% CI: 1.02–1.65). Other studies using overall *H. pylori* seropositivity have not supported a strong association between chronic *H. pylori* infections and pancreatic cancer. In a nested case-control study of 448 pancreatic cancer cases from the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort and age-, sex-, and study center-matched controls, pancreatic cancer was not associated with *H. pylori* seropositivity (OR = 0.96, 95% CI: 0.70–1.31, $n = 196$ cases) or CAGA seropositivity (OR = 1.07, 95% CI: 0.77–1.48, $n = 140$ cases).[509] The study did not exclude an association between chronic corpus atrophic gastritis and pancreatic cancer among *H. pylori* seronegative cases. A meta-analysis of 6 nested case-control studies (4,577

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

observations), 1 prospective cohort study (9,506 observations), and 1 case–cohort study (30,110 observations) did not confirm an association between pancreatic cancer and *H. pylori* seropositivity (OR = 1.09, 95% CI: 0.81–1.47) or atrophic gastritis (OR = 1.18, 95% CI: 0.80–1.72).[510] Subgroup analysis suggested the possibility of an association between CagA-negative *H. pylori* and pancreatic cancer (OR = 1.30, 95% CI: 1.05–1.62); however, sensitivity analysis (leave-one-out method) did not support the association (OR = 1.20, 95% CI: 0.93–1.56).

HISTOLOGY

Most pancreatic tumors (i.e., 85–90%) are highly heterogeneous ductal adenocarcinomas of the exocrine pancreas whereas approximately 5% comprised pancreatic neuroendocrine tumors; rare types of pancreatic cancer include adenosquamous carcinomas, squamous cell carcinomas, and giant cell carcinomas.[511,512] Invasive, gland- and mucin-forming tumors produce an intense stromal desmoplastic reaction (minimal cellular infiltrates in sclerotic collagen bundles) characterized by the degree of differentiation (poor, moderate, well). Most adenocarcinomas arise from microscopic (<0.5 cm), noninvasive epithelial proliferation in acinar cells of the pancreatic ducts (pancreatic intraepithelial neoplasias) that progress to more dysplastic lesions and then to invasive carcinoma.[513] Other less common precursors include intraductal papillary mucinous neoplasms (IPMNs) and mucinous cystic neoplasms (MCNs).

HOST SUSCEPTIBILITY

Family history of pancreatic cancer in first-degree relatives (parents, siblings) approximately doubles the risk of developing a pancreatic tumor, with family history accounting for ~7–10% of pancreatic tumors.[514] Several genetic syndromes predispose patients to pancreatic tumors, including mutations of *BRCA2*, familial atypical mole melanoma (*CDKN2A* germline mutation, p16), Peutz-Jeghers (*STK11* germline alterations), hereditary pancreatitis (*PRSS1*, *SPINK1*, and *CFTR*) and Lynch syndrome (germline mutations of genes expressing DNA mismatch repair proteins). Hereditary pancreatitis is a rare autosomal dominant disease with an ~40–55% lifetime risk of developing pancreatic cancer. In a meta-analysis of three cohort studies on hereditary pancreatitis and pancreatic cancer, the pooled estimate of the summary relative risk for pancreatic cancer was 69.0 (95% CI: 56.4–84.4, $I^2 = 0$).[501] Carriers of the pathogenic *ATM* variant have cumulative increased risks of pancreatic cancer as they age.

CLINICAL FEATURES

Pancreatic adenocarcinoma affects primarily elderly patients (i.e., 60–80 years at presentation), with few pancreatic tumors developing in patients of <45 years of age. The median age at diagnosis is ~70 years. Typically, pancreatic cancer remains asymptomatic until late in the malignant process, depending on the tumor location (e.g., periampullary vs. body/tail); early symptoms are nonspecific with the most common being decreased appetite, indigestion, and change in bowel habits. However, no specific set of symptoms or signs characterize pancreatic cancer. Retrospective analysis of a large UK primary database suggests pancreatic cancer patients complained of back pain, shoulder pain, dysphagia, altered bowel habits, and lethargy in the 6 months prior to their cancer diagnosis.[515] Back pain, lethargy, and new-onset diabetes were particularly associated with pancreatic cancer. Diabetes and abdominal pain were frequently reported in patients with advanced stages of pancreatic cancer. Metastatic tumors to the pancreas result from renal cell cancer and less commonly from lung and colorectal cancers.[516] The survival rates from pancreatic cancer are among the lowest of all cancers, with a 5-year survival rate of ~5–7% as a result of high local infiltration and early distant metastasis rates. Primary squamous cell carcinoma represents 0.5–5% of pancreatic cancers; this aggressive subtype has a particularly poor prognosis (median overall survival ≅ 7 months).[517] Surgical resection is currently the only potentially curative treatment for pancreatic cancer; however, only ~20% of patients presenting with pancreatic cancer are eligible for surgery because of the advanced stage of most pancreatic tumors.

Chapter 55

URINARY TRACT

Genitourinary tract tumors include cancers of the renal parenchyma, renal pelvis, ureters, and bladder. These tumors are relatively rare accounting for ~2–3% of all adult neoplasms;[1] however, in children, genitourinary tract tumors (e.g., nephroblastomas, Wilms tumors) represent 20% of all neoplasms. The ratio of renal parenchyma/renal pelvis tumors is ~5:1, with these two tumors displaying distinctly different etiologies. Most renal parenchyma neoplasms are clear cell adenocarcinomas (renal cell carcinomas, hypernephromas), whereas renal pelvis and bladder tumors usually involve transitional cell carcinomas. Additionally, renal pelvis tumors share similar etiological factors (e.g., aromatic amines) with bladder cancer that do not influence the development of renal parenchyma cancers.[2] Renal pelvis and ureteral tumors are usually multifocal with ~30–50% of upper urinary tract tumors metastasizing to the bladder, whereas only ~2–3% of bladder cancers metastasize to the upper urinary tract.[3] Table 55.1 lists the IARC classification of genitourinary tract carcinogens with sufficient and limited evidence in humans.

KIDNEY

Kidney cancers (i.e., renal cell carcinoma) are relatively rare malignancies (i.e., ~2–3% of the human cancer burden), with ~65,000 new cases and ~14,000 deaths in the United States annually.[4] Renal cell carcinoma (RCC) incidence rates vary between countries. Although these rates are typically higher in developed countries, the overall trend has begun to stabilize, particularly in higher socioeconomic groups in urban areas.[5,6] Despite the increased incidence of renal cell carcinomas that is partly attributable to improved diagnostic imaging, mortality rates have trended lower in developed countries (e.g., Europe, the United States, Australia) since the 1990s. Frequently, discovery of these tumors occurs incidentally when the tumors are smaller and at an earlier stage than tumors in symptomatic renal cell carcinoma patients.[7,8]

CARCINOGENESIS

A major driver for the development of 60–90% of renal clear cell carcinomas is a mutation of the tumor suppressor von Hippel-Lindau (*VHL*) gene that stabilizes the hypoxia response pathway involved in cell metabolism, angiogenesis, and cell migration.[9] The VHL protein is a component of the E3 ubiquitin-ligase complex that targets hypoxia-inducible factor (HIF) transcription factors and regulates vascular endothelial growth factor, platelet-derived growth factor, and glucose transporter 1.[10] Other gene mutations in renal clear cell carcinoma include alterations of chromatin remodeling genes (e.g., *ARID1a*, *PBRM1*, *SMARCA4*), DNA hypomethylation (*SETD2*), and other histone modifiers (*BAP1*, *KDM5a*, *UTX*).[11,12] DNA methylation near promoter regions silences tumor suppressor genes. Mutations of other genes associated with increased RCC risks include *FLCN*, *FH*, *MET*, *PTEN*, *SDHB*, *SDHC*, *SDHD*, *TSC1*, and *TSC2*.[13] MET alterations characterize papillary type I RCC tumors, whereas SETD2 mutations, CDKN2A silencing, and increased NRF2-antoxidant

TABLE 55.1. International Agency for Research on Cancer (IARC) Classification of urinary tract and male reproductive tract cancer sites by sufficient and limited evidence of human carcinogenicity. (Adapted from Bray et al.).[4]

Anatomic Site	Carcinogens with *Sufficient* Human Evidence (Group 1)	Carcinogens with *Limited* Human Evidence (Groups 2A and 2B)
Kidney	Tobacco smoking, trichloroethylene, x- and γ-ray radiation	Arsenic and inorganic arsenic compounds, cadmium and cadmium compounds, perfluorooctanoic acid, welding fumes
Renal pelvis and ureter	Aristolochic acid containing plants, phenacetin and analgesic mixtures containing phenacetin, tobacco smoking	Aristolochic acid[a]
Urinary bladder	Aluminum production, 4-aminobiphenyl, arsenic and inorganic arsenic compounds, auramine production, benzidine, chlornaphazine, cyclophosphamide, firefighting, magenta production, 2-naphthylamine, opium consumption, painting, rubber production industry, *Schistosoma haematobium*, tobacco smoking, *ortho*-toluidine, x- and γ-radiation	4-Chloro-*ortho*-toluidine, coal-tar pitch, diesel engine exhaust, dry cleaning, hairdressers and barbers, 2-mercaptobenzothiazole, outdoor air pollution, pioglitazone, printing processes, soot from chimney sweeps, tetrachloroethylene, textile manufacturing
Prostate		Androgenic (anabolic) steroids, arsenic and inorganic arsenic compounds, cadmium and cadmium compounds, malathion, night shift work, red meat consumption, rubber production industry, thorium-232 and its decay products, x- and γ-radiation
Testis		DDT, diethylstilbestrol (*in utero* exposure), *N*,*N*-dimethylformamide, firefighting, perfluorooctanoic acid
Penis	Human papillomavirus type 16	Human immunodeficiency virus type 1, human papillomavirus type 18

[a] Although human evidence is limited, listed as a Group 1 carcinogen.

response element pathway expression characterize papillary type two RCC subtypes.[14] Chromophobe RCC have a relatively high incidence of Mutations of the *FLCN* gene along with loss of chromosomes 1, 2, 6, 10, 13, and 17. Mutations of *PTEN* and *TP53* genes are particularly common in metastatic chromophobe tumors.[15] Glutathione-*S*-transferase enzymes catalyze conjugation of electrophilic substrates with glutathione, primarily to detoxify reactive intermediates; however, mutations of the *GSTM1* and *GSTT1* genes are not typically associated with renal cell carcinomas.[16]

EXPOSURE

The primary risk factors for renal cell carcinomas are obesity, hypertension, and smoking;[17] however, most renal cell carcinoma patients do not have an established risk factor.[18] Limited data from case-control analyses have not detected renal cell carcinoma subtype differences for associations with smoking, hypertension, or family history of kidney cancer.[19] Although some studies associate specific dietary habits (vegetables, fruit, fat,[20] meat,[21] alcohol), diseases (diabetes type II, acquired cystic kidney disease, kidney stones),[22] and occupational exposures with increased renal cell carcinoma risks, the evidence is inconclusive with the exception of trichloroethylene.[23,24] In the Vitamins and Lifestyle (VITAL) study of 77,260 Washington state residents followed up to 9 years, multivariate analysis of 249 incident cases of renal cell carcinoma did not demonstrate an association between alcohol or fruit/vegetable intake and renal cell carcinoma.[25] The European Prospective Investigation into Cancer and Nutrition (EPIC) study enrolled ~500,000 participants and identified 691 renal cell carcinoma cases during a mean follow-up period of 6.2 years.[26] Country-specific dietary assessment instruments divided meat and fish consumption into quintiles at baseline. Using Cox proportional hazards regression to calculate multivariable-adjusted hazard ratios (HR), the HR for RCC in women within the highest meat consumption category (i.e., ≥80 g/day) was 2.03 (95% CI: 1.14–3.63) using women in the lowest category (<10 g/day) as the comparison. The RCC risk in men did not vary by meat consumption category. The RCC risk for poultry or fish consumption was not statistically significantly different in the consumption categories for men or women.

Observational studies on the beneficial effects of physical exercise on RCC risk are inconsistent. A systematic review and meta-analysis of physical activity and renal cancer in 19 observational studies reported a reduced RCC risk, with a summary relative risk from random effects meta-analysis of 0.88 (95% CI: 0.79–0.97), particularly in the upper tertile of studies with high-quality scores (RR = 0.78, 95% CI: 0.66–0.92), I^2 = 33%).[27] Physical activity in these studies was not well defined, with large variations in physical activity definitions. Stratification of physical activity by assessment (qualitative, energy expenditure, duration, frequency), domain (total, occupational, recreational), or timing in life (recent, consistent, past) did not yield statistically significant reductions in RCC except for recent physical activity. The authors were unable to identify the specific type of physical activity (frequency, intensity, duration) necessary to reduce renal cell cancer risk. The use of Thorotrast® (thorium oxide) as a contrast agent to visualize the kidney and liver has been associated with the development of renal cell carcinoma.[28]

Occupation

Epidemiology studies yield no consistent patterns of elevated renal cell carcinoma risks from occupational exposures, in part because existing studies of this rare cancer have relatively low statistical power and poor exposure documentation. Although epidemiological and experimental animal studies suggest a possible association between renal cell carcinoma and metal salts (arsenic, cadmium),[29] organic solvents (tetrachloroethylene),[30] railroad workers (asbestos),[31,32] and hydrocarbons (tar, pitch, and petroleum products),[33] sufficient evidence of a cause-effect relationship exists only for trichloroethylene based primarily on case-control studies, mechanistic data, and experimental animal studies.[34,35] The IARC lists welding fumes and UV radiation from welding as human carcinogens (Group 1).[36] The IARC noted a statistically significant association between welders and kidney cancer in the range of 20–30% increase in relative risks in large census-based studies. Their analysis reported less precise risks ranging from 1.4–3.8 in cohorts of welders in diverse European and American industries; however, these studies did not adjust for lifestyle (e.g., smoking) or confounding (e.g., trichloroethylene exposure). Case-control studies were also supportive (RR = 1.2–~5.5), but the studies did not reasonably exclude bias, chance, or confounding with little evidence of exposure-response relationships. Overall, the evidence for a causal relationship between welding and kidney cancer was limited.

Case-control studies of patients with renal cell carcinoma suggest a weak, albeit inconsistent association with hydrocarbons,[37,38] gasoline,[39] inorganic lead compounds,[40] asbestos,[41] and organic solvents.[42] A case-control study of 165 women and 273 men with renal cell cancer detected a significantly elevated risk of renal cell carcinoma (OR = 2.3, 95% CI: 1.3–4.2) among women, but not among men, exposed to organic solvents.[43] Exposure to organic solvents was determined retrospectively based on job titles determined from mailed questionnaires and interviews on their usual occupation.

Renal cell carcinomas developed in male rats exposed chronically to unleaded gasoline,[44] but the nephropathy results from a unique sensitivity to a male-specific protein, α-2μ-microglobulin, in the rat that limits extrapolation of these animal studies to humans. To date, epidemiological studies of petroleum workers have not supported the association between gasoline vapor and renal cell carcinoma.[45,46] Standardized mortality studies of a refinery and petrochemical worker cohort reported a statistically nonsignificant excess of renal cancer (SMR = 143, 95% CI: 90–217, n = 22 cases) based on death certificates,[47] with the excess becoming statistically significant (SMR = 193, n = 21 cases) only in smokers in the 13-year follow-up using retrospective analysis of smoking history in medical records.[48] However, nested case-control studies[49] and reviews of cohort studies of petroleum workers[50] have not confirmed an increased kidney cancer risk or an exposure-response trend between nonaromatic, liquid gasoline distillate intensity/frequency, and renal cancer. Generally, these studies report relatively small case numbers with wide confidence intervals.

Lifestyle

Smoking

Cigarette smoking modestly increases the risk of developing renal cell carcinomas, with the risk somewhat stronger for upper urothelial carcinomas than renal cell carcinomas.[24] In a meta-analysis of 19 case-control and 5 cohort studies involving 9,358 RCC cases, the overall adjusted summary RR comparing ever-smokers to lifetime never-smokers was 1.38 (95% CI: 1.27–1.50), with significant heterogeneity in reported adjusted risks. The overall estimated RR for ever-smoking men before excluding any studies was 1.50 (95% CI: 1.37–1.65) compared with 1.27 (95% CI: 1.14–1.40) in women.[51] Analysis of dose-dependency in RCC risk indicated a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

strong increase in RCC with increasing cigarette consumption. Compared with lifetime never-smokers, the RR for RCC in ever-smoking men using >20 cigarettes daily was 2.03 (95% CI: 1.51–2.74) and 1.58 (95% CI: 1.14–2.20) in women with similar smoking habits. The RR for renal cell carcinoma in former smokers quitting >10 years previously was not statistically different from that of lifetime never-smokers; other case-control studies indicate the RCC risk in smokers persists for 20–30 years.[52] In a meta-analysis of 13 case-control and 10 cohort studies using maximum reported adjusted risk estimates for RCC, the overall pooled relative risk for all smokers compared with nonsmokers was 1.31 (95% CI: 1.22–1.40, I^2 = 60.8%) and 1.36 (1.19–1.56, I^2 = 73.7%) for current smokers.[53] All estimates had moderate heterogeneity. The overall RR for RCC in former smokers was lower than in current or all smokers (RR = 1.16, 95% CI: 1.08–1.25, I^2 = 17.6%) with little heterogeneity.

Obesity

Obesity is an established risk factor for renal cell carcinoma independent of smoking and hypertension, as measured by BMI (kg/m^2) with waist circumference (i.e., a measure of central obesity) also associated with modestly elevated RCC risks, particularly renal clear cell carcinomas; the positive association is stronger for women than men.[54] Obesity is a risk factor, particularly in older women overweight since adolescence; however, little increased RCC risk occurs in women for weight gained after midlife (<50 years).[55,56] In a meta-analysis of 21 cohort studies with 15,144 cases and 9,080,052 participants using random effects models and normal weight participants (BMI, 18.5–24.99) as controls, the pooled relative risks were 1.28 (95% CI: 1.24–1.33, I^2 = 35.6%) for BMI 25–29.99 (overweight) and 1.77 (95% CI: 1.68–1.87, I^2 = 44.2%) for BMI ≥ 30 (obese) with slight to moderate heterogeneity.[57] The pooled RR indicated a stronger risk for obese women (RR = 1.95, 95% CI: 1.81–2.10) than obese men (RR = 1.63, 95% CI: 1.50–1.77). Dose-response meta-analysis indicated a nonlinear relationship between BMI and RCC risk after adjustment for age, sex, smoking, and hypertension. The Egger's test suggested the possibility of publication bias (P = 0.001). In a meta-analysis of 17 studies primarily in North America and Europe, with a 5 kg/m^2 increase in BMI above normal weight, the rate ratio for RCC in men was 1.24 (95% CI: 1.15–1.34, I^2 = 37%, n = 11 studies) and 1.34 (95% CI: 1.25–1.42%, I^2 = 45%, n = 12 studies) in women.[58] The increased RCC risk was less in men (RR = 1.18, 95% CI: 1.08–1.29) and similar in women (RR = 1.35, 95% CI: 1.29–1.42) participating in the six studies examining data for both men and women. Analysis of data from the Women's Health Initiative after adjustment for age, smoking, and ethnicity demonstrated a consistently significant increased kidney cancer risk for obese women (BMI ≥ 30 kg/m^2) only with systolic blood pressure of >160 mmHg when compared with obese women with SBP of <120 mmHg (HR = 1.94, 95% CI: 1.07–3.50).[59] Limited data associates renal cell carcinoma subtypes with obesity, primarily renal clear cell cancer. Analysis of case-control data from a US population-based (933 cases, 1,235 controls) and a European hospital-based (905 cases, 1,476 controls) study associated morbid obesity (BMI, ≥35 vs. <25 kg/m^2) with an increased risk of clear cell RCC (OR = 2.0, 95% CI: 1.41–3.0, n = 196 cases, $P_{\text{trend}=}$ 0.001) and a statistically nonsignificant elevated chromophobe risk (OR = 2.0, 95% CI: 0.9–4.4, n = 12, P_{trend} = 0.007), but not papillary RCC risks (OR = 1.3, 95% CI: 0.8–2.2, n = 31, P_{trend} = 0.21).[19] Subtypes were not associated with smoking, hypertension, or family history of kidney cancer.

Diseases

Hypertension

Data from case-control studies suggest hypertension is an independent risk factor for renal cell carcinoma. In a case-control study of health maintenance organization members in western Washington State, the diagnosis of hypertension was associated with a statistically significant increased risk of renal cell carcinoma for women (OR = 2.5, 95% CI: 1.2–5.1), but not for men (OR = 1.3, 95% CI: 0.7–2.5).[60] The use of hypertensive medication was not associated with increased renal cell carcinoma risks when adjusted for hypertension. The European Prospective Investigation into Cancer and Nutrition (EPIC) study interviewed ~300,000 participants and identified 250 renal cell carcinoma cases during a mean follow-up period of 6.2 years.[61] Using <120 mmHg systolic and <80 mmHg diastolic as referents and adjusting for age, sex, body mass index, education, and smoking status/duration, the relative risk for renal cell carcinoma in the highest systolic blood pressure group (≥160 mmHg) was 2.48 (95% CI: 1.53–4.02, n = 57 cases) and 2.34 (95% CI: 1.54–3.55, n = 39 cases) for the highest diastolic group (≥100 mmHg). Difference in renal cell carcinoma rates in the middle two quartiles of systolic and diastolic blood pressure groups compared with the referents was not statistically significant in men or women. These studies indicated that antihypertensive medications are probably not a causal RCC risk factor.[62]

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Diabetes

The association between diabetes and kidney cancer remains inconsistent and relatively weak, particularly when controlled for obesity and hypertension.[63] Pooled data from Italian and Swiss case-control studies identifying 767 renal cell cancers and 1,534 controls did not demonstrate an elevated RCC risk in diabetics.[64] After adjustment for age, study center, interview year, education, alcohol consumption, tobacco smoking, and body mass index, the odds ratio in diabetics was 1.26 (95% CI: 0.91–1.75); however, RCC was weakly associated with BMI. The large, population-based Japanese cohort study did not detect a statistically significant increased incidence of RCC in diabetics (age-/sex-adjusted HR = 1.72, 95% CI: 0.51–5.79).[65]

HISTOLOGY

Renal clear cell and papillary cell carcinomas arise from the epithelium of the proximal convoluted renal tubules in various locations within the kidney parenchyma, whereas chromophobe subtypes develop from distal nephrons.[66] Collecting duct carcinomas, renal medullary carcinomas, and urothelial carcinomas are highly distinct diseases from renal cell carcinomas. Renal cell cancers are histologically and molecularly heterogeneous tumors. Classical histological subtypes of renal cell carcinomas (RCC) include ~65–70% clear cell (clear to yellowish or eosinophilic cytoplasm surrounded by a delicate, dense vascular network with necrosis and hemorrhage), ~15–20% papillary (parenchymal tumor with a papillary or tubulopapillary architecture, foamy histiocytes, basophilic cytoplasm, necrosis, and hemorrhage), and ~5–7% chromophobe (large, pale cells with prominent cell membranes and perinuclear clearing). Each subtypes has distinct genetic characteristics, with the latter having the lowest rate of metastasis.[67,68] In a study of 2,385 patients undergoing their first radical nephrectomy for unilateral RCC, the distribution of histological subtypes was as follows: 1,985 (83.2%) clear cell; 270 (11.3%) papillary; 102 (4.3%) chromophobe; 6 (0.3%) collecting duct; 5 (0.3%) purely sarcomatoid RCC with no underlying histological subtype; and 17 (0.7%) RCC not otherwise specified.[69] The 2016 WHO classification added seven new, relatively uncommon RCC subtypes, including clear cell papillary RCC associated with end-stage renal disease and von Hippel-Lindau (VHL) syndrome, representing up to 5% of renal tumors.[70]

HOST SUSCEPTIBILITY

Approximately 2–3% of RCC cases have familial, autosomal dominant syndromes predisposing them to renal cell carcinomas, with an increased risk of ~1.5–2-fold among first-degree relatives of RCC patients.[71] In a Central European case-control study of 1,097 kidney cancer cases and 1,555 controls, the odds ratio for RCC in participants with at least one first-degree relative with kidney cancer was 1.40 (95% CI: 0.71–2.76) adjusting for tobacco smoking, body mass index, and medical history of hypertension.[72] The association was strongest for participants with affected siblings (OR = 4.09; 95% CI: 1.09–15.4, n = 9 cases). The most common familial syndrome is a defect on the tumor suppressor *VHL* gene (von Hippel-Lindau syndrome) present in 1/36,000 births that predisposes affected patients to early onset, multifocal renal clear cell carcinomas, CNS hemangioblastomas, and pheochromocytomas.[73] Most sporadic (i.e., non-inherited) renal clear cell carcinomas acquire defects in both alleles of the *VHL* gene resulting in dysfunction of the tumor suppressor VHL protein causing unifocal neoplasms that present later than tumors with germline VHL mutations.

Familial syndromes producing papillary renal cell carcinoma include multifocal papillary type I involving the proto-oncogene *MET* and hereditary leiomyomatosis involving the *FH* (fumarate hydratase, familial type II papillary renal cell carcinoma) gene. The *c-MET* proto-oncogene encodes a growth-factor receptor that expresses a tyrosine kinase membrane receptor and promotes angiogenesis/tumor growth, whereas *FH* is a tumor suppressor gene encoding an enzyme for the tricarboxylic acid cycle (Krebs cycle conversion of fumarate to malate) leading to upregulation of hypoxia-inducible factor. The Birt–Hogg–Dube syndrome causes a germline mutation in the folliculin (*FLCN*) gene and the familial syndrome of chromophobe tumors.

CLINICAL FEATURES

Most renal cell tumor incidence increases with age and presents between the ages of 50 and 70 years, with a male/female ratio of ~2:1 reflecting, in part, the higher incidence of smoking in men.[74,75] In a case-control study of 706 US kidney cancers and 917 European kidney cancers reported papillary cases (n = 237) were older (OR = 1.2, 95% CI: 1.1–1.4/10-year increase), less likely to be female (OR = 0.5, 95% CI: 0.4–0.8), and more likely to be African-American (OR = 2.6, 95% CI: 1.8–3.9) compared with renal clear cell carcinoma (n = 1,524).[19] Renal clear cell carcinomas are the most

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

common and aggressive renal cell carcinomas, with the highest incidence of local invasion, metastasis, and mortality rates among the RCC subtypes. These tumors are very vascular, resulting in frequent hemorrhage.[76] The prognosis is typically better for papillary than clear cell subtypes, with the prognosis being better for papillary type 1 than type 2; however, the prognosis is usually worse for metastatic papillary than clear cell renal carcinomas.[77] The tumor node metastasis (TNM) system correlates with RCC prognosis, with ~5-year survival rates of 80–95% for Stage I, 80% for Stage II, 60% for Stage III, and <10% for Stage IV (median survival ~2 years).[78,79] Overall, the 5-year survival rate is ~74% for men and ~78% for women.[80] Approximately 20–30% of renal cell carcinomas present with metastatic disease, and ~20–30% of patients undergoing nephrectomy will develop metastasis during follow-up.[81,82] Increased survival correlates to early diagnosis, small tumor size, and the absence of distant metastases.

RENAL PELVIS AND URETER

Upper-tract urothelial carcinomas are relatively uncommon tumors representing ~5–10% of all urothelial cancers with the incidence currently increasing; the estimated incidence ranges from 1–2 cases/100,000 population.[83] The incidence of these tumors is high in areas with endemic nephropathies (e.g., Balkan endemic nephropathy in Eastern Europe, Chinese herbal nephropathy in Taiwan, China), primarily as a result of contamination of food and medicines with aristolochic acid.[84] The association between upper-urinary tract urothelial carcinomas and Blackfoot disease from elevated drinking water arsenic levels remains unclear because of the presence of aristolochic acid exposure in Taiwanese residents.[85] Upper-tract urothelial carcinomas in Taiwan occur in areas without Blackfoot disease and in residents unaffected by the disease.[86] Although upper-tract urothelial carcinomas (UTUC) share some characteristics and risk factors with bladder cancer, the two cancers are distinct diseases, with UTUC displaying some unique etiologies (e.g., aristolochic acid, nonpolyposis colorectal cancer spectrum disease), prognosis, and pathology.[87]

CARCINOGENESIS

Aristolochic acid consumption causes a unique renal disease (aristolochic nephropathy, Balkan endemic nephropathy) frequently associated with upper-tract urothelial cancer. Aristolactam-DNA adducts formed by aristolochic acid in the renal cortex are unique biomarkers of aristolochic acid exposure. The presence of these adducts is a signature mutation associated with A:T-to-T:A transversions in the tumor suppressor *TP53* gene at codon 139.[88] In a Taiwanese study of 152 upper-tract urothelial carcinomas where aristolochic acid nephropathy is common, the presence of aristolactam-DNA adducts in the renal cortex of 93 patients indicated frequent aristolochic acid exposure in patients with these tumors.[89] Compared with patients without this biomarker, the patients were relatively younger, female, and nonsmokers with more severe renal disease. Chronic inflammation and irritation (e.g., urinary tract stones, chronic urinary tract infections) may slightly increase renal pelvic tumor formation;[90] however, data are limited. Although upper urinary tract and bladder urothelial carcinomas share similar pathology, their molecular pathways differ with hypermethylation and microsatellite instability more common in upper urinary tract urothelial tumors than bladder tumors.[91,92]

High-grade, upper-tract urothelial carcinomas and urothelial bladder carcinomas share a similar genetic landscape; however, upper-tract urothelial carcinomas are more often invasive at surgery than urothelial bladder carcinomas, suggesting the former has a more aggressive phenotype. Next-generation sequencing of 83 upper tract urothelial carcinomas and 102 urothelial bladder carcinomas detected similar genes that were mutated (e.g., *CDKN2A*, *FGFR3*, *KDM6A*, *KMT2D*, *TP53*), with differing frequencies in other genes (e.g., *HRAS*, *RB1*, *TP53*).[93] Compared with urothelial bladder cancer, upper-tract urothelial carcinomas had more frequent mutations of *CDKN2B*, *FGFR3*, and *HRAS* genes, and fewer in other genes (*ARID1A*, *TP53*). No RB1 mutations occurred in the latter cohort compared with 18.6% in the urothelial bladder carcinoma cohort. Whole-exome sequencing of 31 untreated, snap-frozen upper urinary tract urothelial cancers identified mutations in *FGFR3* (74%), chromatin modifier *KDM6A* gene (44%), *PIK3CA* (26%), and *TP53* (22%) genes, with C > T transitions at *APOBEC* and CpG islands being the most common mutational signatures.[94]

EXPOSURE

Most renal pelvic and ureteral tumors are urothelial (transitional) cell carcinomas that share more similar risk factors (e.g., aniline, benzidine dyes) with bladder cancer than renal cell carcinomas. Smoking is the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

major risk factor for developing upper-tract urothelial carcinomas; occupational exposure to aromatic amines (benzidine, 2-naphthylamine) and phenacetin abuse has dramatically decreased with improved industrial hygiene and the banning of phenacetin in pharmaceutical preparations for over 40 years. The incidence of upper urothelial carcinomas was high among patients using analgesic medication, primarily in abusers with renal disease. Case reports associate upper urinary tract urothelial carcinomas with the previous use of Thorotrast® (thorium oxide) as a contrast agent to visualize the kidney and liver.[95] In the Western Swedish Cancer Registry of 930 renal pelvic and ureteral tumors, 34 (8.7%) of 389 female patients had a history of gynecological malignancy and radiotherapy with a median of 21 years (range, 1–42 years) earlier.[96]

Occupation

Heavy occupational exposure to aromatic amines (e.g., benzidine, β-naphthalene) in the chemical, dye, rubber, and textile industries, prior to banning these substances in the 1960s and 1970s was associated with an increased incidence of upper-urinary tract urothelial carcinomas, particularly in a case series of dye workers (e.g., ~4–18%).[97,98] These studies suggested a mean latency period of 20–25 years for urothelial carcinomas; however, exposure categories were poorly defined, and reported odds ratios were highly imprecise, as reflected in 95% confidence limits ranging from 80–100 fold. In a multicenter, population-based, German case-control study involving 1,035 incident urothelial cancer cases and 4,298 controls matched for region, sex, and age, chemical exposure was evaluated retrospectively by self-reports and experts (2 job-exposure matrices, 1 job task-exposure matrix).[99] Using conditional logistic regression to calculate smoking adjusted odds ratios and control for age and study center, the adjusted OR for aromatic amine exposure was slightly elevated without reaching statistical significance for high aromatic amine exposure in men. The odds ratio using assessment by self-report was 0.6 (95% CI: 0.3–1.0, n = 14 cases) compared with 0.9 (95% CI: 0.7–1.2, n = 55) using the British job-exposure matrix. Although high PAH exposure in men assessed with the British job-exposure matrix demonstrated a marginally statistically significant elevation of urothelial carcinomas (OR = 1.3, 95% CI: 1.0–1.7, n = 123), other methods did not support statistically significant associations. The study reported >50 odds ratios for chemical exposures in men and women.

Lifestyle

Smoking is a major risk factor for renal pelvis and ureteral cancers, with case-control studies indicating a reduction in risks following smoking cessation, particularly after 10 years. In a population-based, case-control study involving 187 Los Angeles residents identified in a Cancer Surveillance Program with renal pelvis or ureteral cancers (60% response rate) and 187 age-, sex-, and race-matched controls, the relative risk of urinary tract urothelial cancer comparing current smokers and never-smokers was 5.2 (95% CI not reported, P_{trend} = <0.0001).[100] The P_{trend} comparing smoking duration (≥26 years vs. nonsmokers) and ≥1 pack/day and <1 pack/day current smokers was also P_{trend} = <0.0001 based on self-reported cigarette use. A larger, US population-based case-control study recruited 502 cases (58% of ascertained cases) including some cases from the previous study and 496 age- and sex-matched controls. The odds ratio comparing current and never-smokers was 4.4 (95% CI: 2.9–6.5) based on self-reported use determined by telephone interviews.[101] Comparisons of current smoking intensity (≥2 pack/day vs. <1 pack/day), smoking duration (<26 years vs. ≥ 46 years), and cumulative smoking history (≥60 vs. ≤20 pack-years) indicated a statistically significant difference (P_{trend} = < 0.001). Compared with current smokers, the reduction in the RR for renal pelvis and ureteral cancer in former smokers quitting ≥10 years previously was statistically significant (RR = 0.3, 95% CI: 0.2–0.5). In a German case-control study of 51 renal pelvic and 25 ureteral carcinomas, the odds ratio for renal pelvic and ureteral urothelial cancer in current smokers compared with age- and sex-matched never/non-daily smokers was 6.20 (95% CI: 2.04–18.81, n = 41).[102] The odds ratio for ex-smokers defined as not smoking for ≥2 years was 1.00 (95% CI: 0.31–3.21, n = 15) based on self-reported smoking history obtained at discharge from the hospital. The wide confidence limits reflect imprecise OR estimates.

Medications

Phenacetin

Case reports and small case series from large academic hospitals, along with limited case-control studies of renal pelvic carcinoma, suggest the presence of renal papillary necrosis and renal dysfunction following heavy phenacetin abuse increases renal pelvic urothelial carcinoma risk based on self-reported histories (i.e., personal interviews, questionnaires).[103,104] Analgesics without phenacetin are not causally related to renal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pelvic carcinomas.[85] In a study of 170 patients with renal pelvic or ureteral tumors from a Berlin urology clinic diagnosed from 1948–1981, 18/83 (21.4%) of renal pelvic tumors and 4/35 (11.4%) of ureteral tumors were associated with phenacetin abuse defined by self-reported use of >1 kg total dose of phenacetin or >1 g/day for ≥1 year. [105] The average total phenacetin dose was 5.6 kg for renal pelvic cancer patients and 4.9 kg for ureteral tumors, with mean latency periods of 24 years and 26 years, respectively. The Swedish Cancer Registry identified 930 cases of renal pelvic and ureteral tumors diagnosed from 1971–1998 in Western Sweden.[96] This case series identified 41 cases (4.4%) with a history of phenacetin-containing analgesic abuse. The replacement of phenacetin with other analgesics (e.g., acetaminophen) dramatically reduced the development of analgesic-associated urothelial tumors.

Aristolochic Acid

This compound is an extract of *Aristolochia fangchi* and *Aristolochia clematis* that can be ingested as a traditional Chinese herbal medicine or bread contaminated with *Aristolochia* seeds. The IARC classifies plants containing aristolochic acid as human carcinogens (Group 1) based on increased urothelial tumors in patients with aristolochic acid-associated renal failure (Balkan endemic nephropathy, Chinese herb nephropathy).[4] These plants are associated with end-stage renal failure and increased risks of upper- and lower-tract urothelial carcinomas.[106] The incidence of urothelial cancer in Taiwan has been declining since aristolochic acid-containing herbal products were banned in the early 2000s.[107] A Taiwanese molecular epidemiology study examined tissues from 151 cases of upper urinary tract urothelial carcinomas and 25 patients with renal cell carcinomas. Using aristolactam adducts and the *TP53* tumor suppressor gene as mutational signatures, 60% of all cases and 84% of patients with A:T to T:A mutations in *TP53* contained the aristolactam-DNA adduct uniquely associated with aristolochic acid exposure.[89] This transversion was identical to the mutations associated with Balkan endemic nephropathy. The study design excluded residents of southwestern and northeastern Taiwan, where high arsenic concentrations occur in the drinking water.

Lithium

Chronic lithium therapy produces epithelial proliferation of the renal collecting ducts; however, there is no direct evidence that lithium therapy induces neoplastic changes in the urinary tract epithelium, including inhibition of the glycogen synthase kinase-3β (GSK-3β) pathway that promotes apoptosis and reduces cell proliferation. A Danish case-control study identified 829 cases of renal pelvic and ureteral cancer in the Danish Cancer Registry, along with 259,080 age- and sex-matched cancer-free controls.[108] Using conditional logistic regression, the fully adjusted odds ratio (i.e., medication use, diseases, education) for long-term lithium use (≥5 years) was 1.3 (95% CI: 0.8–2.2) compared with non-lithium users. Duration of lithium use was not associated with an increased risk of renal pelvic or ureteral cancer. The authors opined that lithium use was not associated with an increased upper urinary tract cancer risk.

HISTOLOGY

Urothelium is the epithelial lining of the upper (i.e., calyceal system to distal ureter) and lower (bladder to urethra) urinary tracts; urothelial neoplasms vary in location along the urinary tract, with distal ureter being the most common location for ureteral tumors.[96] About 90–95% of the urothelial carcinomas derive from urothelium; however, upper-tract urothelial carcinomas represent only ~5% of urothelial neoplasms, with the vast majority of these tumors occurring in the bladder.[109] Urothelial carcinomas in the renal pelvis are twice as common as more distal ureteral tumors.[110] Upper-tract urothelial carcinomas and urothelial bladder cancers are histologically similar. Typically, upper-tract urothelial carcinomas are more invasive at diagnosis than urothelial bladder carcinomas.[111]

Very rare renal pelvic tumors include squamous cell carcinomas and carcinosarcomas; squamous cell carcinomas of the upper urinary tract represent <10% of the calyceal urothelial tumors and a much smaller portion of upper urinary tract neoplasms.[112] The latter are highly malignant mesenchymal and epithelial tumors that grow rapidly, infiltrate widely, and usually arise from the bladder.[113] Squamous cell carcinomas of the renal pelvis and ureter derive from dysplastic squamous metaplastic epithelium and typically are associated with chronic inflammation from urolithiasis or hydronephrosis.[114] Retrospective review of medical records at a large Texas referral center from 1990–2004 identified 16 patients with primary nonurothelial tumors of the upper urinary tract; the tumors consisted of 12 squamous cell carcinomas, 2 adenocarcinomas, 1 sarcomatoid carcinoma, and 1 small cell carcinoma.[115] Squamous cell carcinomas frequently invade the renal parenchyma and retroperitoneal soft tissues, with >95% of the tumors displaying advanced stages when initially diagnosed.[116]

HOST SUSCEPTIBILITY

Familial/hereditary forms of upper-tract urothelial carcinomas account for ~10–20% of all these tumors, with hereditary nonpolyposis colorectal carcinoma (Lynch syndrome type II) being the most common familial form. Upper-tract urothelial carcinoma is the third most frequent extra-colonic tumor site in patients with Lynch syndrome type II.[117]

CLINICAL FEATURES

Upper-tract urothelial carcinoma is a male-predominant disease (~2:1 ratio) that typically presents in the 7th–8th decade (mean ≅ 73 years), with presentation at <50 years of age being rare.[118,119] Many presentations (i.e., ~30%)[120] are incidental during imaging/endoscopic procedures. The presence of symptoms (e.g., palpable abdominal mass, flank pain, hematuria) usually indicates advanced disease and a poor prognosis, particularly when associated with systemic symptoms (fever, night sweats, fatigue, anorexia, weight loss).[121] In a Swedish case series of 930 renal pelvic and ureteral tumors, bloody urine was the presenting clinical feature of these tumors in 58% of cases, with 17% complaining of abdominal pain.[96] Symptoms other than hematuria suggest more advanced disease.[122] Hydronephrosis or hydroureter may develop from obstruction of the ureters by tumors. Known metastatic disease at presentation occurs in <10% of cases at diagnosis, with concurrent disease in the bladder present in ~10–30% at the initial diagnosis depending on the location of the primary urothelial tumor; however, ~50% of tumors at diagnosis are locally invasive.[123]

Systemic symptoms frequently represent paraneoplastic disease or metastases producing secretory proteins (e.g., parathyroid-hypercalcemia, renin-hypertension, erythropoietin-erythrocytosis) along with fever and wasting syndromes. Staging of urothelial cancers for prognosis usually involves the tumor, node, metastasis (TNM) classification system, with invasion of the muscle wall having a poor prognosis.[124] The survival rate for low-stage upper-tract urothelial carcinoma after radical nephroureterectomy is good (i.e., 90%), with the rate dropping to <30% with advanced stages; the 5-year survival for invasion of the renal pelvis or ureter is <50 and <10% for invasion of the kidney or adjacent organs.[125,126] In contrast to bladder cancer, gender does not affect survival from upper-tract urothelial carcinomas.[127] Typically, tumors associated with phenacetin abuse appear with a latent period of 10–20 years following heavy ingestion (>5 kg) that produces renal papillary necrosis.[128]

BLADDER

Bladder cancer is the second most common genitourinary system cancer after prostate cancer, with the age-standardized rate of bladder cancer much higher in industrialized and urban areas (16.9/10,000) than in less developed and rural areas (5.3/100,000).[4] Worldwide, bladder cancer is the ninth most common cancer, with the highest incidence rates in men from Southern (32–37/100,000) and Western Europe, North America, North Africa, and Western Asia.[129] In the United States, bladder cancer is the fourth most common cancer in men.[83] Although gender differences vary widely between countries, bladder cancer incidence rates are substantially higher in men than women; however, the age-standardized incidence of bladder cancer rates from 1990–2013 in *developed* countries decreased by 12.5% in men and 10.4% in women.[130] Bladder cancer incidence rates are significantly higher than mortality rates (9th vs. 13th most frequent worldwide) because of the slow progression of the disease.[131] In general, bladder cancer mortality rates have declined recently, except in regions undergoing rapid economic development, whereas bladder cancer incidence is decreasing in men while increasing in women *worldwide*. The latter probably reflects previous changes in smoking habits among men and women. Bladder cancers associated with schistosomiasis typically are squamous cell rather than urothelial carcinomas; the latter has increased reflecting smoking habits, whereas squamous cell bladder cancer is declining with reduced *Schistosoma* infections.[129,132]

CARCINOGENESIS

A potential mechanism of action for the association of smoking with bladder cancer is a multiplication effect with bladder carcinogens (e.g., aromatic amines).[133,134] Urothelial bladder carcinoma is a highly heterogeneous disease with a high somatic mutation frequency rate. Analysis of 131 urothelial bladder carcinomas by the Cancer Genome Atlas Research Network detected 32 recurrent gene mutations involving cell-cycle regulation, kinase signaling pathways, and chromatin regulation.[135] Genetic alterations of bladder tumor subtypes include oncogene fibroblast growth factor receptor 3 (*FGFR3*) activating mutations in papillary subtypes and inactivating mutations of tumor suppressor genes *TP53* and *RB1* in nonpapillary subtypes.[136] Mutations in genes encoding chromatin-modifying enzymes are frequent in both subtypes. Mutations of *KMT2D* (histone H3 lysine 4 methyltransferase) are more common in nonpapillary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

subtypes, whereas activating telomerase promoter mutations in *KDM6A* (histone H3 lysine 27 demethylase) and inactivating STAG2 mutations are more common in papillary subtypes.[137] Substantial evidence associates chronic inflammation (e.g., *Schistosoma haematobium* infection) with squamous cell carcinomas; however, the link between chronic inflammation and urothelial cell carcinomas is less clear.

EXPOSURE

The major bladder cancer risk factor is tobacco smoking worldwide, whereas infection with *S. haematobium* causes a relatively high burden of bladder cancer in northern and sub-Saharan Africa.[138] Additionally, a variety of occupational chemicals and industries are associated with bladder cancer with an estimated ~7% of bladder cancers in men and ~2% in women attributed to occupational exposures.[139] Implicated chemicals include 4-aminobiphenyl, inorganic arsenic, and aromatic amines (benzidine, 2-naphthylamine) along with painting and work in aluminum, auramine, magenta, and rubber production industries.[140] The carcinogenicity of magenta is difficult to separate from the production process because the latter often involves coexposure to aniline, auramine, benzidine, naphthylamine, and *o*- and/or *p*-toluidine. Radiotherapy of the genital tract (prostate, testis, ovary, cervix, uterus) along with radiation treatment of non-Hodgkin lymphoma are associated with subsequent development of bladder cancer, primarily after a 10-year lag. In a meta-analysis of four studies after multivariable adjustment, bladder cancer risk comparing ever- and never-treatment with radiotherapy was elevated (adjusted hazard ratio = 1.67, 95% CI: 1.55–1.80; $I^2 = 0\%$), whereas using a 10-year lag, the HR was 1.89 (95% CI: 1.65–2.16; $I^2 = 0\%$).[141] Examination of data from the extended Life Span Study of Japanese atomic bomb survivors reveals a dose-response relationship between bladder cancer and x-/γ-ray radiation (excess RR = 1.02/Sv).[142]

Occupation

In 1895, the German physician, Ludwig Rehn, first associated bladder cancer with work in the aniline dye industry theorizing that aniline (the simplest aromatic amine) was the carcinogen.[143] Later studies indicated other aromatic amines (benzidine, 1-naphthylamine, 2-naphthylamine, 4-aminobiphenyl) accounted for the elevated risk rather than aniline.[144] The percentage of bladder cancer cases attributable to occupational exposure in earlier studies ranged from 2–25%, depending on exposure intensity and the portion of the work force exposed to aromatic amines (2-naphthylamine).[145,146] Compared with men, the estimated attributable bladder cancer risk from these studies of occupational exposure in women was smaller (11%).[147] Later studies demonstrated reduced bladder cancer risks as a result of improved industrial hygiene conditions and better control of misclassification and confounders (e.g., tobacco smoking). However, definite conclusions regarding the current attribution of bladder cancer risk to occupational carcinogens remain limited by heterogeneity in accurately classifying exposures within specific groups of workers and controlling confounders (e.g., tobacco use).[148] A Spanish case-control study did not detect a statistically significant association between bladder cancer in women and a specific industry or occupation.[149] Table 55.2 lists chemicals that are known human bladder carcinogens.

TABLE 55.2. Recognized International Agency for Research on Cancer (IARC) human bladder Group 1 carcinogens.

Agent [CAS Number]
Chemicals
4-Aminobiphenyl [92-67-1]
Arsenic and inorganic arsenic compounds
Benzidine [92-87-5]
Chlornaphazine [494-03-1]
N,*N*-Bis(2-chloroethyl)-2-naphthylamine (Chlornaphazine) [494-03-1]
Cyclophosphamide [50-18-0] [6055-19-2]
2-Naphthylamine [91-59-8]
Opium consumption
Painter occupation
Schistomsoma haematobium (chronic infection)
o-Toluidine [95-53-4]
Mixtures
Betel quid with tobacco
Tobacco smoking
Specific Exposures
Aluminum production
Auramine, manufacturing
Magenta production
Rubber manufacturing industry
X- and γ-ray radiation

Industries

Limitations to accurate estimation of bladder cancer risks from occupational exposures include retrospective exposure analysis (misclassification from using job titles instead of tasks), small case numbers, potential publication bias, and inadequate control of confounding (e.g., tobacco smoking). Exploratory case-control studies associate elevated bladder cancer risk with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

~40 occupations (e.g., painters, truck drivers, drill press operatives, textile workers, printers, auto mechanics and maintenance workers, dry cleaners, dyestuff producers, hairdressers, primary metal workers, petroleum refiners) based on relatively low odds ratios (i.e., <2).[150] In a systematic review and meta-analysis of bladder cancer and occupational carcinogen exposure, the highest bladder cancer risks resulted from exposure to aromatic amines (tobacco, dye, leather, and rubber workers, printers, hairdressers) and polycyclic aromatic hydrocarbons (chimney sweeps, aluminum workers, seamen, oil/petroleum workers, nurses, waiters).[151] A review of studies of coke oven workers, chimney sweeps, roofers, and blacksmiths suggests soot and gases from the combustion of coal may produce substances that increase urothelial cell carcinoma incidence in the bladder.[152]

Exposure in several industries is suspected bladder carcinogens (IARC Groups 2A and 2B), with limited or conflicting evidence of human carcinogenicity. A meta-analysis of observational studies on bladder cancer risks and diesel exhaust exposure suggests diesel exhaust exposure may increase bladder cancer occurrence.[153] The summary RR for studies using a job exposure matrix or a similar approach for diesel exhaust exposure was marginal (mRR = 1.13, 95% CI: 1.00–1.27, n = 10 studies), with a mRR for high diesel exposure of 1.44 (95% CI: 1.18–1.76). The authors opined on substantial heterogeneity, misclassification, publication bias, and confounding that limited definitive conclusions regarding risk estimates. A Canadian population-based case-control study identified 658 male bladder cancer cases and 1,360 age- and sex-matched controls with lifetime occupational histories supplemented by a job-exposure matrix for engine emissions exposure.[154] Using logistic regression, the odds ratio for men ever exposed to high concentrations of diesel emissions compared with unexposed controls was elevated but not statistically significant (OR = 1.64, 95% CI: 0.87–3.08, n = 28 cases, P = 0.12). The odds ratio comparing the highest cumulative diesel exposure tertile with unexposed controls was not elevated (OR = 0.93, 95% CI: 0.68–1.28, n = 111 cases, P_{trend} = 0.34). A hospital-based, case-control study of bladder cancer and diesel exhaust exposure did not support an excess bladder cancer risk based on job titles and self-reported diesel exhaust exposure.[155] The odds ratio for bladder cancer and any diesel exhaust exposure based on self-reports was not statistically significant (OR = 1.2, 95% CI: 0.8–2.0) after adjustment for smoking.

The IARC classified painting as an occupation with sufficient evidence of human carcinogenicity in 1989; however, the elevated bladder cancer risk is relatively small and dependent on individual techniques and materials. A meta-analysis of the pooled relative risk of bladder cancer combining four cohort studies on painters published from 1989–2004 was 1.10 (95% CI: 1.03–1.18, n = 893 cases), whereas the corresponding summary RR for four cohort mortality studies in painters was 1.23 (95% CI: 1.11–1.37, n = 370 deaths).[156] The pooled relative risk for 25 case-control studies was 1.35 (95% CI: 1.19–1.53, n = 465 cases), with an overall pooled RR of 1.17 (95% CI: 1.11–1.27, n = 1,728 cases, P = 0.10). Although significant heterogeneity occurred between study types (P < 0.001), the meta-analysis revealed no significant heterogeneity between studies. In a meta-analysis of bladder cancer morbidity/mortality and painting from 1950–2008, the summary risk estimates for bladder cancer were similarly elevated.[157] The summary risk estimate for case-control studies was 1.28 (95% CI: 1.17–1.41, n = 40 studies), whereas the summary risk estimate for cohort *morbidity* studies was 1.14 (95% CI: 1.06–1.22, n = 4 studies) and 1.27 (95% CI: 1.16–1.38, n = 9 studies) for cohort mortality studies. Although restricting meta-analysis to case-control studies adjusting for smoking did not significantly affect the summary odds ratios, adjustment for socioeconomic status reduced the odds ratio to a statistically nonsignificant value. The slight to moderate excess bladder cancer risk among painters appears greater in the distant past than more recent occupational exposures; social class and smoking remain potential confounding factors.

Chemicals

Aromatic Amines

Aromatic amines are chemicals with a nitrogen group attached to an aromatic hydrocarbon, with aniline (a noncarcinogen) being the simplest aromatic amine. Both benzidine and 2-naphthylamine are potent bladder carcinogens; workers exposed to these chemicals in the rubber, leather, and textile industries have elevated standardized mortality rates (SMR = ~2) from bladder cancer compared with the general population based on retrospective studies of death certificates.[158,159,160] The risk of bladder cancer exists primarily in the pre-synthesis stage of dye manufacture rather than in the processes involved with finished dyes.[161]

Many synthetic organic dyes contain benzidine or one of its congeners (*o*-toluidine, *o*-dianisidine). Although these dyes are benzidine analogs rather than parent compounds, animal studies suggest the possibility that intestinal flora or hepatic enzymes may convert the diazo linkage to the carcinogenic parent compound *in vivo*.[162] Dye stuff intermediate workers with low phenotype for *N*-acetyltransferase may be more susceptible

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to the development of bladder tumors when exposed to benzidine compounds and their analogs.[163]

Polycyclic Aromatic Hydrocarbons

Polycyclic aromatic hydrocarbons (PAH) are ubiquitous chemicals containing ≥2 benzene rings and formed from incomplete combustion of organic material (cooked meats, fossil fuels, rubber, plastic). The association of PAH exposure is substantially less consistent with bladder cancer than lung or skin cancers. A review of cohort studies on workers exposed to PAH reported significant excess risks in aluminum production (pooled RR = 1.29, 95% CI: 1.12–1.49), iron and steel foundries (pooled RR = 1.29, 95% CI: 1.06–1.57), and coal gasification (pooled RR = 2.39, 95% CI: 1.36–4.21).[164] An updated review of these estimates yielded borderline increased bladder cancer risk for aluminum production (pooled RR = 1.28, 95% CI: 0.98–1.68, n = 10 studies) and iron and steel foundries (pooled RR = 1.38, 95% CI: 1.00–1.91, n = 9 studies).[165] In a French hospital-based case-control study of 658 male bladder cancer patients and 658 male controls based on semi-quantitative questionnaires, the estimated overall odds ratio for PAH exposure was 1.3 (95% CI: 1.0–1.7, $P < 0.05$) after adjustment for smoking, coffee drinking, and occupational aromatic amine exposure.[166] The dose-response was slight but statistically significant (P_{trend} = <0.05) with an OR of 1.8 (95% CI: 0.8–3.9) comparing the highest PAH exposure category and unexposed controls.

Halogenated Hydrocarbons

Evidence associating halogenated hydrocarbons with bladder cancer primarily involves tetrachloroethylene (perchloroethylene), particularly in the dye cleaning industry; however, the human evidence is limited (IARC Group 2A). A critical review of epidemiological studies published in 2003 concluded that the evidence linking bladder cancer with occupational tetrachloroethylene exposure was inadequate. A more recent meta-analysis reported an increased bladder cancer risk in dry cleaners with some evidence of an exposure-response relationship.[167] The overall meta-RR for bladder cancer risk in dry cleaners was 1.47 (95% CI: 1.16–1.85, n = 7 studies and 139 exposed cases); however, the mRR for case-control studies adjusted for smoking was not statistically significant (mRR = 1.50, 95% CI: 0.80–2.84, n = 4 studies, I^2 = 0%). The mRR for tetrachloroethylene-exposed workers in this meta-analysis also was not statistically significant (mRR = 1.08, 95%% CI: 0.82–2.84, I^2 = 25.3%, n = 3 studies and 463 cases). Although tetrachloroethylene was a common potential carcinogen in the dry-cleaning industry during 1950–1990, mixed carcinogen exposures occurred in this industry.

Environmental

Chronic inorganic arsenic exposure is associated with several cancers, including lung, skin, and bladder cancers, following chronic exposure to high arsenic concentrations in drinking water.[168,169] Typically, arsenic exposure results from chronic ingestion of seriously contaminated groundwater exceeding several thousand ppb, with most positive studies conducted in areas with water containing >200 μg As/L (e.g., Taiwan, Chile, Gulf of Bengal), particularly >600 μg As/L for >40 years. Studies on bladder cancer incidence and chronic ingestion of <100–200 As μg/L are less consistent with wide confidence limits and imprecise exposure estimates (misclassification).[170,171] In the northern Chilean towns of Antofagasta and Mejillones, the arsenic concentration in drinking water averaged 870 μg/L (ppb) from 1958–1970 followed by a dramatic reduction after the installation of water treatment plants.[172] Compared with a Chilean region without arsenic contamination, bladder cancer mortality began increasing 10 years after drinking water became highly As-contaminated, followed by peak mortality in 1986–1987 based on death certificates. Peak bladder cancer relative risks (RR) for men were 6.10 (95% CI: 3.97–9.39) and 13.8 (95% CI: 7.74–24.5) for women.

Lifestyle

Tobacco use is the overwhelming lifestyle risk factor for bladder cancer, with little evidence of an association between bladder cancer and coffee, tea, fluid intake, moderate alcohol consumption, or micronutrient supplement consumption; potentially, diet, exercise, or weight may influence bladder cancer risks, but evidence is relatively weak and inconsistent.[173] There is no clear association between bladder cancer and personal use of hair dyes.[174,175] In a meta-analysis of 15 case-control and 2 cohort studies, the pooled RR for ever-compared with never-use of personal hair dyes was 0.93 (95% CI: 0.82–1.05, I^2 = 34.1%, P = 0.07), with slight to moderate heterogeneity among studies.[176] The results demonstrated a lack of exposure-response relationship between duration, frequency of use, or dye type (permanent, non-permanent) and bladder cancer risks when compared with no use. Artificial sweeteners (cyclamate, saccharine) are potent promoting agents in the rat model of carcinogenesis; however, observational studies indicate these substances are not significant human

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

carcinogens.[177,178] Case series of patients with aristolochic acid nephropathy report urothelial carcinomas developing after kidney transplantations for end-stage kidney disease. In a case series of 38 women requiring kidney transplants followed by immunosuppression for end-stage aristolochic acid nephropathy, 17 patients developed upper-tract urothelial carcinomas, whereas only 3 of 21 patients developed urothelial bladder cancer without upper-tract urothelial carcinomas.[179] Of the 17 patients with upper-tract urothelial carcinomas, 15 developed urothelial bladder carcinomas 5½–14 years after transplant, suggesting the possibility of urothelial cancer metastasis to the bladder.

Tobacco Use

Smoking is the major risk factor (i.e., 2–4 fold elevation) for bladder cancer, displaying a strong dose-response between smoking intensity and bladder cancer; this risk factor accounts for up to 50% of the excess bladder cancer risk, despite reductions in smoking prevalence and cigarette composition.[53,180] Pooled analysis of 11 case-control studies indicates the proportion of bladder cancer cases attributable to ever-smoking was 0.66 (95% CI: 0.61–0.70) for all men and 0.73 (95% CI: 0.66–0.79) for men of <60 years of age, with a threshold limit for bladder cancer of ~15–20 cigarettes daily.[181] Cessation of smoking reduced the bladder cancer risk by >30% after 1–4 years (OR = 0.65, 95% CI: 0. 53–0.79) and >60% after 25 years (OR = 0.37, 95% CI: 0. 30–0.45); however, the bladder cancer risk of former and never-smokers was never similar. In a meta-analysis of 33 case-control and 12 cohort studies using maximum reported adjusted risk estimates for bladder cancer, the overall pooled relative risk for all smokers compared with never-smokers was 2.58 (95% CI: 2.37–2.80; I^2 = 88.8%, $P < 0.001$), 3.47 (95% CI: 3.07–3.91, I^2 = 81.9%, $P < 0.001$) for current smokers, and 2.04 (95% CI: 1.85–2.25; I^2 = 64.7%, $P < 0.001$) for former smokers.[53] All these comparisons had substantial heterogeneity in the types of smoking histories and cut-points used for stratifying smoking intensity and duration. The association was stronger for case-control (pooled RR = 2.76) than cohort (pooled RR = 2.17) studies. Visual inspection of the funnel plot could not exclude publication bias. The bladder cancer risk may be weaker in Japanese than in European or North American populations. In a meta-analysis of 3 cohort and 8 case-control studies of Japanese cigarette smokers, the summary relative risk for bladder cancer in ever-smokers was 2.14 (95% CI: 1.87–2.44) with no significant heterogeneity.[182]

Some observational studies suggest tobacco smoking is associated with a worse prognosis at the diagnosis of incident bladder cancers. A large hospital-based case-comparison study involving 1,544 cases examined the relationship of smoking to the clinical characteristics of bladder cancer at diagnosis. After adjustment for age and gender, current smokers had larger tumors (mean difference = 0.48 cm, 95% CI: 0.04–0.91), a higher T stage (mean difference = 0.25, 95% CI: 0.08–0.41), and a borderline higher grade (mean difference = 0.15, 95% CI: 0.00–0.30) compared with never-smokers.

Limited data on the risk of bladder cancer with cigar and pipe smoking suggest this form of smoking has lower bladder cancer risks than cigarette smoking; however, the actual risks are unclear. In a pooled data set of 2,279 cases and 5,268 controls from 6 studies of bladder cancer, 88 cases and 253 controls smoked only cigars or pipes.[183] Using never-smokers as controls, the odds ratio (OR) of bladder cancer for pure pipe smokers was 1.9 (95% CI: 1.2–3.1) and 2.3 (95% CI: 1.6–3.5) for pure cigar smokers compared with 3.5 (95% CI: 2.9–4.2) for pure cigarette smokers. The elevation of bladder cancer risk with duration of smoking was not significantly different between cigar and cigarette smokers. In a nested case-control study of 619 bladder cancer cases and 3,346 lifelong nonsmokers, age- and sex-adjusted incidence rate ratios for current cigar smokers were 2.88 (95% CI: 1.68–4.93) and 3.03 (95% CI: 1.67–5.50) for pipe smokers. These elevated bladder cancer risks disappeared after adjustments for cigarette smoking.[184]

The association between environmental tobacco smoke and bladder cancer is relatively weak and somewhat inconsistent.[184] A large population-based bladder cancer study in Los Angeles County, California, ascertained lifetime environmental tobacco smoke (ETS) exposure for 148 bladder cases and 292 controls (never-smokers). A statistically significant, dose-dependent increased in bladder cancer risk occurred in never-smoking women exposed to environmental tobacco smoke comparing the highest ETS category with controls (OR = 5.48, 95% CI: 1.06–28.36, P_{trend} = 0.03). The wide confidence intervals indicate imprecise risk estimates. ETS exposure was not associated with increased bladder cancer risks in men. A prospective cohort study established two cohorts from private censuses in Maryland to examine the effect of smoking on bladder cancer risks starting in 1963 (n = 45,749; 93 cases) and 1975 (n = 48,172; 172 cases).[185] Using Poisson regression models and never-smokers unexposed to environmental tobacco smoke as controls, bladder cancer risks among nonsmoking women were marginally elevated (RR = 2.3, 95% CL: 1.0–5.4) in the 1963 cohort and not elevated in the 1975 cohort (RR = 0.9, 95% CL: 0.4–2.3). In a meta-analysis of 83 studies, a random effects model detected no evidence

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. associating environmental smoke with bladder cancer risk (RR = 0.99; 95% CI: 0.86–1.14, I^2 = 35.6%, P = 0.05) comparing nonsmokers with and without environmental smoke exposure.[186] The Q-statistic and I^2 statistic suggested some heterogeneity. Subanalysis of men and women did not reveal a statistically significant elevation of bladder cancer risks in either sex.

Alcohol

The association between alcohol consumption and bladder cancer is weak, with analysis of 594 incident bladder cancer cases and 3,170 subcohort Netherland members demonstrating no linear dose-response between alcohol consumption and bladder cancer risk (P_{trend} = 0.13).[187] The authors corrected for age and smoking in multivariable analyses. Although a case-control study using data from the nationwide Japanese clinical database and age-, sex-matched hospital-based controls suggested an elevated bladder cancer risk comparing ever- and never-drinkers (OR = 1.33, 95% CI: 1.06–1.66),[188] most larger studies have not reported a statistically significant increased bladder cancer risk or a dose-response relationship between alcohol consumption and bladder cancer. In the multicenter European Prospective Investigation into Cancer and Nutrition (EPIC) cohort of 476,160 individuals mostly aged 35–70 years followed for a mean of 13.9 years, men reporting alcohol intake of >96 g/day had an increased urothelial cancer risk (HR = 1.57; 95% CI: 1.03–2.40) compared with moderate intakes (<6 g/day). The data did not support a dose-response relationship between bladder cancer risks and quartiles of average lifetime alcohol consumption.[189] The study reported no association between alcohol consumption and urothelial bladder carcinomas in never-smoking women. A Japanese population-based cohort study identified 354 men and 110 women with newly diagnosed bladder cancer after following 95,915 participants (45,649 men and 50,266 women, aged 40–69 years) for a mean of 18.2 years.[190] Using multivariate Cox proportional hazard models, the hazard ratio (HR) comparing regular drinkers with non- and occasional (1–3 days/month) drinkers was 1.14 (95% CI: 0.91–1.41, P = 0.249, n = 259 cases). Analyzing alcohol consumption by separating regular drinkers into quartiles of alcohol use did not reveal a dose-response relationship between the amount of alcohol and bladder cancer risks ($P_{linear\ trend}$ = 0.412).

Diet

There is no consistent evidence for an increase in bladder cancer risk with tea, coffee,[191] fluid,[192] vitamin/antioxidants,[131] trihalomethanes in chlorinated water,[193] or nitrate[194] consumption.[148,195] Evidence of the reduction of bladder cancer risk by supplementation with common micronutrients is inadequate.[196] Although some studies suggest a protective effect of fresh fruits and vegetables,[131] the effect on urothelial bladder carcinoma risk in these studies is small and subject to recall bias/food misclassification, with little evidence in meta-analyses to support the reduction of bladder cancer risks using diets rich in fruits and vegetables.[197] A population-based case-control study of bladder cancer in New England region of the United States involving 1,171 cases and 1,418 controls detected no association between bladder cancer and fruits or vegetables based on comparing consumption quartiles using self-administered diet history questionnaires.[198] In the large EPIC cohort, the HR for urothelial bladder carcinoma risk comparing participants with high and low Mediterranean diet scores was not elevated (HR = 0.84, 95% CI: 0.69–1.03).[199] Although heterocyclic amines formed in meat and fish during cooking are carcinogenic in animal models, a Swedish population-based case-control study did not detect an increased bladder cancer risk (RR = 1.2; 95% CI: 0.7–2.1) between the highest and lowest quintiles of estimated heterocyclic amine consumption.[200] In a review of observational studies on dietary factors, high meat consumption was not associated with an increased bladder cancer risk (RR = 1.08, 95% CI: 0.82–1.42).[201] A meta-analysis of mostly European and American case-control studies suggests processed or red meat consumption may increase bladder cancer risk based on a linear association between bladder cancer risk and daily red meat consumption/100 g increment in case-control studies (pooled RR = 1.51, 95% CI: 1.13–2.02, n = 7 studies, P < 0.01) and daily processed meat consumption/50 g in case-control studies (pooled RR = 1.20, 95% CI: 1.06–1.37, n = 6, P = 0.02).[202] Prospective cohort studies in this meta-analysis did not support a statistically significant relationship between bladder cancer risks and red meat (pooled RR = 1.01, 95% CI: 0.97–1.05, n = 6 studies, P = 0.62) or processed meat (pooled RR = 1.10, 95% CI: 0.95–1.27, n = 5 studies, P = 0.83).

Obesity/Exercise

Data associating obesity and physical activity with bladder cancer are conflicting and generally weak. In a hospital-based case-control study in East and South China involving 438 incident bladder cancer cases and 427 controls, overall physical activity was not significantly associated with bladder cancer risks (P_{trend} = 0.61).[203] The P_{trend} was also not significant for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

vigorous physical activity (P_{trend} = 0.60) or moderate physical activity (P_{trend} = 0.21).

The use of various obesity measures, inadequate smoking control, and limited studies in women complicate the determination of the association between obesity and bladder cancer risks. In the EPIC cohort study, 1,391 incident bladder cancers (1,018 male; 373 female) occurred during a median follow-up of 11.3 years.[204] Never-smokers did not have an elevated bladder cancer risk, whereas overweight participants (BMI >28.96) had a slightly elevated bladder cancer risk (adjusted HR = 1.25, 95% CI: 1.04–1.50) suggesting confounding with tobacco use. In a meta-analysis of nine cohort studies on bladder cancer risks and obesity that adjusted for cigarette smoking, the pooled RR was 1.09 (95% CI: 1.01–1.17; $P_{heterogeneity}$ = 0.131, I^2 = 35.9%) with slight to moderate heterogeneity.[205] Obesity was self-reported or determined by BMI without specifically defining the BMI level associated with obesity. A meta-analysis of 14 prospective, primarily European and American cohort studies reported a weak positive association between BMI and bladder cancer risk, with the suggestion of a positive, nonlinear relationship between BMI and bladder cancer, primarily >30 kg/m^2.[206] The summary RR for the association of bladder cancer with obesity was 1.10 (95% CI: 1.03–1.17, I^2 = 58.5%, $P_{heterogeneity}$ = 0.003) with moderate heterogeneity.

Diseases

Chronic ingestion of drinking water contaminated by *S. haematobium* sporocysts released by a snail host results in adult parasites laying eggs in the veins surrounding the infected bladder. These eggs traverse the bladder wall, producing chronic inflammation, hematuria, and fibrosis. In Egypt, sub-Saharan Africa, and the Middle East, endemic schistosomiasis is associated with an increased squamous cell carcinoma risk in the bladder.[207] Assessing the bladder cancer risk from schistosomiasis is complicated by the presence of confounders, primarily tobacco smoking. Evidence for increased bladder cancer risks from other urinary tract infections or urinary tract stones is inconclusive. Historically, up to 8–10% of paraplegics using indwelling catheters developed squamous cell carcinomas;[208,209] however, safer methods of bladder emptying reduce the bladder cancer risks.[210]

Some studies suggest an association between diabetes and bladder cancer risks. A meta-analysis of 9 case-control and 27 cohort studies reported an increased bladder cancer risk in diabetics (pooled RR = 1.35, 95% CI: 1.17–1.56, I^2 = 94.7%, P < 0.001) with substantial heterogeneity in study design and adjustment for confounders.[211] The pooled RR for the eight cohort studies specifically on diabetics was not statistically significant (RR = 1.25, 95% CI: 0.86–1.81, I^2 = 97.4%, P < 0.001), also with significant heterogeneity. The data did not suggest a dose-response relationship between the duration of diabetes and bladder cancer risks.

Medications

The use of cyclophosphamide and ifosfamide without urothelial protection agents is associated with hemorrhagic cystitis and dose-related increase in urothelial cell carcinomas.[212] In a cohort of 6,171 2-year survivors of non-Hodgkin's lymphoma (NHL), 48 patients with secondary cancer of the urinary tract were matched to 136 NHL controls without a second malignancy.[213] The overall bladder cancer risk following cyclophosphamide therapy was 4.5 (95% CI: 1.5–13.6), with the risk increasing in a dose-response relationship. The wide confidence limits reflected small case numbers and imprecise estimates. Several meta-analyses suggest limited evidence for an association between pioglitazone, an oral antidiabetic agent, and elevated bladder cancer risk, particularly in doses above 28 g daily. In a meta-analysis of 14 case-control studies, the HR comparing ever- and never-use of pioglitazone was 1.16 (95% CI: 1.06–1.25, I^2 = 0.0%, P = 0.54), with no significant heterogeneity between studies.[214] However, a large cohort study of Kaiser Northern California patients did not confirm an increased bladder cancer risk in long-term pioglitazone users.[215] The adjusted hazard ratio for ever-compared with never-use of pioglitazone was 1.06, (95% CI: 0.89–1.26). The median duration of use was 2.8 years with a range of 0.2–13.2 years. Acetaminophen, non-steroidal anti-inflammatory drugs, metformin, sulfonylurea, and insulin are not associated with increased bladder cancer risks.

HISTOLOGY

Over 90% of bladder tumors are urothelial (transitional cell carcinomas), with squamous cell carcinomas and adenocarcinomas accounting for ~6–8% and 2%, respectively.[216] The percentages of squamous cell carcinomas are slightly higher in blacks and women. Approximately 70–75% of bladder tumors are non-muscle invasive at diagnosis, being confined to the mucosa and submucosa with the remainder

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

muscle-invasive or metastatic; ~50% of patients without muscle-invasive bladder cancers have low-grade tumors in contrast to most high-grade tumors in almost all muscle-invasive or metastatic tumors.[137] Bladder tumors typically are papillary, solid, or mixed, with the papillary type predominant in non-muscle invasive bladder cancers.

HOST SUSCEPTIBILITY

Although urothelial cell carcinomas (UCC) are not well-known familial cancers, several case reports and population-based studies report some familial clustering of this cancer type. The incidence of urothelial cell carcinomas in the bladder is increased in Lynch syndrome, an autosomal dominant genetic disease; however, this increase may result from seeding by upstream upper urinary tract tumors rather than primary bladder tumors.[217] Population-based observational studies indicate the urothelial bladder carcinoma risk in patients' relatives is ~2-fold greater than the general population. Some of the increased risk may be attributed to shared environmental risk factors (e.g., smoking, occupational carcinogen exposures).[218] In a population-based, case-control study using the Utah Cancer Registry and matched 1:5 cancer-free controls, the hazard ratio for urothelial bladder cancer was elevated in first-degree (HR = 1.69, 95% CI: 1.47–1.95, $P < 0.001$) and second-degree (HR = 1.35, 95% CI: 1.2–1.5, $P < 0.001$) relatives.[219] A population-based, family case-control study enrolled 1,193 newly diagnosed UCC patients with bladder, ureter, renal pelvis, or urethra cancers and 853 partners with at least one relative diagnosed with UCC.[220] Using random effect proportional hazards regression analyses to compare disease occurrence among case-relatives and control-relatives, the adjusted hazard ratio was 1.8 (95% CI: 1.3–2.7). Analysis of nationwide family-cancer databases comparing native and immigrant residents indicate no single gene has a major influence on UCC incidence.[221] Segregation analysis of urothelial cell carcinoma in 1,193 families did not find evidence of strong Mendelian inheritance through a single major gene.[222] Consequently, combinations of genetic variants (i.e., "no major gene" or sporadic model) more likely account for the limited familial clustering of urothelial cell carcinomas.

Prominent polymorphisms include *N*-acetyl transferase 2 (*NAT2*) important for carcinogenic aromatic amine detoxification and glutathione *S*-transferase M1 (GSTM1) responsible for conjugating electrophilic substrates (e.g., polycyclic aromatic hydrocarbons). Genetic polymorphisms (i.e., *NAT2* slow acetylator, *GSTM1* null genotypes) may account for some interindividual susceptibility to bladder cancer, particularly for cigarette smokers;[223] however, case-control studies of patients genotyped for polymorphisms are inconsistent.[224] Potentially, slow acetylation of *N*-acetyltransferase 2 (NAT2) reduces the metabolism of aromatic amines and polycyclic aromatic hydrocarbons in tobacco smoke, thereby increasing contact with and risk from tobacco-related and occupational carcinogens. In a meta-analysis of 7 genome-wide association studies (GWAS) collaborating with the National Cancer Institute, analysis of 12 SNPs identified as potentially enhancing bladder cancer risks yielded only *NAT2* genes with a genetic variant that caused significant multiplicative gene-smoking interaction.[225] Analysis of data from >500,000 participants in the European Prospective Investigation into Cancer and Nutrition (EPIC) study did not confirm the influence of *NAT2* variants on smoking-related cancer or occupational bladder cancer risks.[226] Estimated occupational exposure to aromatic amines (OR = 1.37, 95% CI: 1.02–1.84) and PAH (OR = 1.50, 95% CI: 1.09–2.05) increased bladder cancer risk when comparing the highest exposure tercile with never-exposed controls. NAT2 slow acetylation did not modify these risk estimates or independently increase bladder cancer risk (OR = 1.02, 95% CI: 0.81–1.29). The risks were adjusted for age, gender, region, and smoking.

CLINICAL FEATURES

Gender is a strong predictive factor for developing bladder cancer. The male/female ratio of the total age-adjusted incidence of bladder cancer is ~3–4.[227] Bladder cancer incidence increases with age; few bladder cancers present before age 50. Peak bladder cancer incidence occurs in the 7th–8th decade of life; ~2/3 of bladder cancer cases present when patients are >65 years of age.[228] The average onset of bladder cancer is 15 years earlier in workers exposed to bladder carcinogens than in sporadic cases.[2] The latent period between first exposure and diagnosis of bladder cancer is relatively long compared with many other cancers. The estimated average latent period between exposure and development of bladder cancer is ~20 years with a range of 16–45 years.

Hematuria is the most commonly presenting clinical feature of bladder cancer, particularly gross hematuria; other symptoms include dysuria, urgency, incontinence, and urinary frequency. Patients without hematuria typically present with a longer onset of symptoms and signs (recurrent infections, urgency) prior to diagnosis.[229]

Abdominal, pelvic, flank, or bone pain usually suggests advanced, metastatic disease. Although ~75% of bladder tumors are noninvasive at diagnosis, the recurrence rate is high despite local therapy, with ~25% of these patients progressing to muscle-invasive bladder cancer during the course of their disease;[230,231] the higher-stage tumors have poor outcomes despite systemic therapy (radical surgery, radiotherapy).[232]

Chapter 56

MALE REPRODUCTIVE TRACT

PROSTATE

Prostate cancer is a leading cause of death in developed countries and the most common noncutaneous cancer in men worldwide. Although prostate cancer is an indolent disease with ~300,000 incident cases annually in the United States, prostate cancer is the second most common cause of US cancer-related mortality accounting for ~35,000 deaths/year.[1] Globally, prostate cancer mortality accounts for ~366,000 deaths with marked geographical variation reflecting the biological heterogeneity of this cancer.[2]

The estimated overall lifetime absolute prostate cancer risk in men without a familial history of prostate cancer is ~8%.[3] Worldwide, prostate cancer incidence varies 25-fold, with the rate increasing since the early 1990s following the introduction of prostate-specific antigen (PSA) screening;[4] the highest incidence of prostate cancer occurs in the most developed counties, including North America, Oceania, and western and northern Europe.[5] The odds of a 79-year-old man developing prostate cancer range from 1/47 in countries with a low-to-middle sociodemographic index (e.g., Caribbean, Middle-Southern Africa) to 1/6 in countries with a high sociodemographic index. African-Americans have the highest prostate cancer incidence in the world (223/100,000 men) along with a higher disease stage at presentation. The factors responsible for this highly elevated rate are unclear and potentially include genetic variation, socioeconomic status, access to early detection/treatment options, and environmental/lifestyle exposures. Table 55.1 lists substances and processes associated with increased risks of male reproductive tract cancers as determined by the International Agency for Research on Cancer (IARC).

CARCINOGENESIS

Prostate tumors display substantial mutational heterogeneity and a complex mutational landscape, with few recurrent gene abnormalities reflecting the highly variable clinical course. Common genetic and epigenetic abnormalities in prostate tumors involve cell cycle regulation, chromatin regulation (e.g., FOXA1 transcription network, Forkhead BoxA1), potential driver gene mutations in *TP53* and other genes, altered androgen response (e.g., *MLL2* in SET1 family of histone H3K4 methyltransferases), and disruption of several prominent pathways (e.g., tensin homolog/AKT, phosphoinositide 3-kinase) associated with tumor suppressor genes (*PTEN*, *PI3K*, *RB1*).[6,7] Many of the DNA mutations occur in the intron portion of the genome involving non-coding rather than protein-coding sections.[8] At least 10 androgen receptor gene mutations stimulate prostate tumor growth initially by upregulating and expressing androgen receptor activity.[9] A gene fusion between the androgen-regulating gene (*TMPRSS2*) and the *ETS* transcription factor gene family of oncogenic transcription factors (e.g., *ERG*) is the most frequent genetic alteration occurring in ~50% of prostate tumors.[10] Most prostate tumors respond to androgen-deprivation therapy until the establishment of an androgen-independent growth pathway. Pre-diagnostic circulating sex hormones (e.g., total/free testosterone, dihydrotestosterone,

estradiol) are not associated with increased prostate-specific cancer mortality.[11]

Genome-wide association studies on prostate cancer tumors identified genes with high-risk mutations (e.g., *BRCA2*, *HOXB13* genes) and at least 77 low-risk, common alleles (e.g., *c-MYC* oncogene expression).[12] Although the latter have low penetrance, these mutations interact multiplicatively to substantially increase prostate cancer risk. The lack of linkage studies identifying multiple, high-risk genetic abnormalities in genes other than *BRCA2* and *HOXB13* suggests significant polygenic inheritance.[8] Loss or mutation of the tumor suppressor genes *PTEN* and *TP53* along with the abnormal substrate binding unit of a Cullin-based E3 ubiquitin ligase (*SPOP*), reactivation of androgen-receptor signaling in castration-resistant prostate tumors, and disruption of chromatin and histone modelers are frequent events in prostate cancer. Mutation of *BRCA2* is a rare germline event that is a DNA repair gene mutation present in families with high breast/ovarian cancer rates and confers substantially increased prostate cancer rates (i.e., 4–5-fold) in some but not all observational studies.[13] The relative prostate cancer risk in carriers of BRCA1 mutations remains controversial but suggests an increased, albeit much smaller risk than BRCA2 mutations in men of <65 years of age.[14] Compared with age-matched controls, the presence of *BRCA1/2* pathological variants increases the aggressiveness and early onset (<65 years of age) of prostate tumors.[15] Mutations in other DNA repair genes (e.g., *CHEK2*, *NBS1*) may also moderately increase prostate cancer risks in carriers. Dysregulation of *PTEN* is the most consistently identified lesion in prostate tumors and is associated with a poor prognosis. Figure 56.1 displays the ~35% of susceptibility variants associated with excess familial prostate cancer risks.

EXPOSURE

Prostate cancer is a complex, heterogeneous, hormonally driven disease with highly variable outcomes and different risk factors for indolent and progressive (aggressive, metastatic, fatal) prostate cancer as defined by grade, stage, and survival.[17] Similar to breast cancer, prostate cancer is one of the most common cancers without major lifestyle- or infectious agent-associated risk factors. The only established risk factors for developing prostate cancer (i.e., ↑incidence) are older age, African-American race, and positive family history;[16,18] Table 56.1 displays lifestyle and dietary risk factors associated with prostate cancer progression.[17] Genome-wide association studies also indicate genetic predisposition from over 180 genetic risk loci adds to prostate cancer risks.[2,19] Most meta-analyses do not

TABLE 56.1. Prostate cancer *progression* and *mortality* risk factors with direction and strength of the association. The strength and direction of the association with prostate cancer incidence and progression differ significantly. Few epidemiological data associate substantially *increased* prostate cancer risks with lifestyle and dietary factors. (Adapted from Peisch et al.).[17]

Risk Factor	Direction of Risk	Strength of Risk
BMI (obesity)	↑	Strong
Smoking	↑	Strong
Dairy/calcium	↑	Limited
Processed red meat	↑	Weak
Eggs/choline	↑	Weak
Poultry (unskinned)	↑	Weak
Animal fat/saturated fat	↑	Weak
Selenium supplementation	↑	Weak
Metabolic syndrome	↑	Weak
Physical activity	↓	Moderate
Fish	↓	Limited
Tomatoes/lycopene	↓	Limited
Vegetable fat	↓	Limited
Cruciferous vegetables	↓	Limited
Coffee	↓	Weak

support an association between vasectomy and prostate cancer.[20,21,22]

Occupation

Few data associate increased prostate cancer incidence with occupational exposures, with no established occupational causes of prostate cancer. Hypothesis-generating studies suggest farmers, pesticide applicators, metal workers, rubber workers, repairmen, mechanics, and occupations with low physical activity have a slightly increased prostate cancer risk, but the actual risk factors are uncertain.[23,24] A large prospective cohort study of 58,279 men did not confirm previously investigated associations between occupation and prostate cancer risk, with the possible exception of policemen.[25] A meta-analysis of 22 case-control and cohort studies (1995–2001) demonstrated a small but statistically significant increase in the rate ratio for prostate cancer in pesticide applicators (overall pooled RR = 1.13, 95% CI: 1.04–1.22, $P_{\text{homogeneity}}$ = <0.001, n = 22 studies) with significant heterogeneity; the RR for prostate cancer in farmers was not elevated.[26] A prospective cohort study of 55,332 pesticide applicators with no prior history of prostate cancer detected a slightly increased standardized incidence ratio of prostate cancer (SIR = 1.14, 95% CI: 1.05–1.24).[27] Based on questionnaires regarding the use of 45 pesticides, subgroup analysis demonstrated a statistically significant increase in prostate cancer incidence only in workers with a history of methyl bromide use. A meta-analysis of 18 cohort studies on prostate cancer occurrence in pesticide manufacturing published from 1984–2004 using a fixed effect model compared ever- and never-exposed workers.[28] The overall estimated pooled RR demonstrated a modestly increased risk (pooled RR = 1.28, 95% CI: 1.05–1.58, $P_{\text{homogeneity}}$ = 0.973, n = 16 studies). Subgroup analysis did not identify any statistically significant increased prostate cancer risks in specific pesticide classes, except phenoxy herbicides containing dioxin and/or furan contamination (pooled RR = 1.50, 95% CI: 1.06–2.11, $P_{\text{homogeneity}}$ = 0.874, n = 5 studies). Some studies of pesticide applicators[29] and herbicide manufactures[30] have not demonstrated an increased prostate cancer incidence.

Lifestyle

Limited epidemiological data suggest lifestyle and diet may affect the risk of prostate cancer progression (biochemical recurrence, metastasis, hormone-refractory prostate cancer, prostate cancer-specific mortality); however, few data suggest these factors affect prostate cancer incidence.[17] The strongest associations with prostate cancer progression involve smoking, physical activity, and obesity (BMI). Evidence associating consumption of diets high in animal fat and/or red meat with increased prostate cancer risk is weak.

Diet

The complexity of multiple macro- and micronutrients in the diet contributes to the substantial heterogeneity in published dietary studies and complicates the determination of any contribution of dietary nutrients to prostate cancer.[31] Most observational studies do not report clear or consistent associations between prostate cancer incidence and diet including semi-vegetarian or vegetarian diets that exclude protein;[32] however, several risk factors are associated with the progression of prostate cancer. Results from the Health Professionals Follow-up Study suggested some reduction in overall mortality in 4,538 men with nonmetastatic prostate cancer adhering to the Mediterranean diet (HR = 0.78, 95% CI: 0.67–0.90, P_{trend} = 0.0007).[33] The risk of advanced or lethal prostate cancer was not associated with adherence to the Mediterranean diet. In the National Institutes of Health (NIH)-AARP Diet and Health Study containing 23,453 incident prostate cancer cases, reduced total prostate cancer risk occurred only in men reporting a recent history of prostate-specific antigen testing, when comparing the highest and lowest scores on the Healthy Eating Index-2005 (adjusted HR = 0.92, 95% CI: 0.86–0.98, P_{trend} = 0.01) and the Alternate Healthy Eating Index-2010 (adjusted HR = 0.93, 95% CI: 0.88–0.99, P_{trend} = 0.05). Adherence to the Mediterranean diet was not associated with a reduced prostate cancer risk (HR = 0.98, 95% CI: 0.86–1.11, P_{trend} = 0.51).[34] The P_{trend} and hazard ratios were not statistically significant in men with no PSA screening, advanced stages, or fatal prostate cancer. The prospective Melbourne Collaborative Cohort Study identified 1,018 incident prostate cancer cases during an average of 13.6 years for follow-up.[35] Using Cox proportional hazard models and data from a 121-item food frequency questionnaire, comparison of the highest and lowest quartiles of 4 dietary patterns demonstrated no association between overall prostate cancer risk and these dietary patterns, including the Mediterranean (HR = 0.93, 95% CI: 0.74–1.18, n = 193 cases, P = 0.9), meat/potatoes (HR = 0.87, 95% CI: 71–1.08, n = 231 cases, P = 0.2), and vegetable (HR = 1.12, 95% CI: 0.90–1.40, n = 307 cases, P = 0.5) diets.

The association between elevated risks of prostate cancer progression and processed red meat (bacon,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. bologna, hot dogs, salami, sausage), eggs/choline, or animal/saturated fats is weak and inconsistent. Some data support an association between prostate cancer progression and high dairy/calcium intake. A meta-analysis of 15 cohort studies suggests high consumption of total dairy products slightly increases prostate cancer incidence (summary RR = 1.07 per 400 g/day, 95% CI: 1.02–1.12, $I^2 = 43.9\%$) with slight to moderate heterogeneity, but not supplemental/nondairy calcium.[36] The multivariate analysis did not adjust for multiple risk factors. The meta-analysis did not support an association between prostate cancer progression and total dairy products or nondairy calcium. A cohort study in the Physicians' Health Study (n = 21,660) collected information on dairy product consumption at baseline with follow-up over 11 years.[37] Comparing high (>2.5 servings/day) and low total dairy product intake (<0.5 servings/day), high dairy intake was associated with a statistically nonsignificant elevation of prostate cancer incidence (multivariable adjusted HR = 1.12, 95% CI: 0.93–1.35, n = 2,806 cases, $P_{trend} = 0.06$). The association between prostate cancer mortality and whole milk consumption demonstrated a marginally statistically significant increase (multivariable adjusted HR = 1.49, 95% CI: 0.97–2.28, $P_{trend} = 0.01$) comparing intake of 1 serving/day with rarely consumed whole milk. In the Health Professionals Follow-Up Study cohort of 3,918 men diagnosed with localized prostate cancer in the pre- and post-PSA screening era (1986–2006), multivariate analysis demonstrates no increased lethal prostate risk after diagnosis and total milk/dairy intakes.[38] Comparing men with the highest and lowest intake quintiles, the prostate cancer progression risk was increased for whole milk (HR = 2.15, 95% CI: 1.28–3.60; $P_{trend} < 0.01$), whereas low-fat dairy intake did not statistically reduce the risk of progression (HR = 0.62, 95% CI: 0.40–0.95, $P_{trend} = 0.07$). Limited evidence supports a reduced risk of prostate cancer progression with the consumption of fish, tomatoes/lycopene, vegetable fats, or cruciferous vegetables (broccoli, Brussel sprouts, cabbage, cauliflower, kale, or mustard/chard greens).[39] Relatively little evidence conclusively associates reduced prostate cancer progression with coffee, soy, or tea. The epidemiological data associating red and processed meats with prostate cancer is relatively weak and inconsistent, in part because of confounding by family history, age, and PSA screening as well as recall bias (dietary history, diabetes).[40] In the large, prospective NIH-AARP Diet and Health Study of 175,343 US men aged 50–71 years followed for 9 years, the association between red and processed meat was marginal to small.[41] Comparing the fifth and first quintiles of total red meat consumption and overall prostate cancer incidence, multivariate modeling demonstrated a hazard ratio of 1.12 (95% CI: 1.04–1.21), whereas the HR for advanced prostate cancer was higher (HR = 1.31, 95% CI: 1.05–1.65). The hazard ratio of overall prostate cancer incidence comparing the highest and lowest quintiles of total processed meats was 1.07 (95% CI: 1.00–1.14) and higher for advanced prostate cancer incidence (HR = 1.32, 95% CI: 1.08–1.61). A meta-analysis of 19 cohort studies using random effects models to estimate summary relative risks for prostate cancer incidence in high versus low exposure categories did not support an association between red meat consumption and prostate cancer (RR = 1.02, 95% CI: 0.92–1.12), whereas the association with processed meats and total prostate cancer was weakly positive (RR = 1.05, 95% CI: 1.01–1.10).[42]

Physical Activity

Most population-based observational studies report no to little effect of overall total, vigorous, or non-vigorous activity on prostate cancer incidence; however, some studies associate a reduced risk of prostate cancer progression with high levels of physical activity. The European Prospective Investigation into Cancer and Nutrition (EPIC) cohort study identified 2,458 prostate cancer cases during 8.5 years of follow-up.[43] Prostate cancer incidence was not associated with any of the four leisure time activities (cycling, gardening, sports, walking), metabolic equivalent task (MET) hours/week of leisure time activity, participation in any of the four leisure activities, or a higher physical activity index score. Although comparing advanced-stage prostate cancer risks with low (sitting) and high (manual labor) occupational activity levels was not statistically different (RR = 0.75, 95% CI: 0.53–1.05), the overall trend of the three occupational activity levels together (sitting, standing, manual labor) with advanced-stage prostate cancer indicated a significant reduction ($P_{trend} = 0.024$) with increasing occupational activity levels. Using Cox regression in relation to multiple subcategories for prostate cancer in the Health Professionals Follow-Up Study, more frequent vigorous physical activity (↑ sweating, ↑ heart/respiratory rate) was associated with decreased advanced and fatal prostate cancer risks; multivariant analysis on data from men living at least 4 years after their postdiagnosis physical activity assessment yielded an overall reduction in prostate cancer mortality ($P_{trend} = 0.04$).[44] Men with ≥3 hours/week of vigorous activity had a 61% lower risk of death from prostate cancer (HR = 0.39, 95% CI: 0.18–0.84, $P = 0.03$) than men with <1 hour/week of vigorous activity. However,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

comparison of the highest and lowest quintiles of physical activity yielded a modest and statistically significant increase in non-advanced prostate cancer incidence (RR = 1.19, 95% CI: 1.03–1.37, $P_{trend} < 0.01$).[45] The Cancer of the Prostate Strategic Urologic Research Endeavor (CaPSURE) study examined vigorous activity and brisk walking after prostate cancer diagnosis to reduce the potential for reverse causation (bias caused by men reducing physical activity due to disease recurrence).[46] Using Cox proportional hazards regression, the HR for prostate cancer progression in men walking briskly (≥3 hours/week) compared with men walking at an easy pace (<3 hours/week) was 0.43 (95% CI: 0.21–0.91, $P = 0.03$). Independent of pace, prostate cancer progression was not associated with walking duration; similarly, total non-vigorous activity was not associated with prostate cancer progression independent of vigorous activity.

Obesity

Most prospective studies do not support a statistically significant association between prostate cancer incidence and obesity,[47] particularly indolent prostate disease (local, low-grade) in North American studies during the post-PSA screening era.[45] Increasing epidemiological evidence from observational studies suggests obesity is associated with more aggressive prostate cancer (advanced stage, poor therapeutic response, ↑ mortality), particularly in men with the TMPRSS2:ERG gene fusion.[48,49] The Physicians' Health Study identified 2,546 men with prostate cancer and 281 prostate-related deaths during the 24-year study period; the median follow-up between diagnosis and death or termination of follow-up was 7 years, with baseline BMI reported in the pre-prostate screening era (1982–1990) and prostate screening era (1991–2007).[50] Compared with normal-weight men (BMI <25 kg/m^2), the proportional hazard ratio (HR) was 1.47 (95% CI: 1.16–1.88) for overweight men (BMI 25–29.9 kg/m^2) and 2.66 (95% CI: 1.62–4.39, $P_{trend} = <0.0001$) for obese men (≥30 kg/m^2). The trend remained significant after controlling for tumor severity (Gleason grade, clinical stage). In a cohort of 752 middle-aged men with prostate cancer under long-term follow-up for disease progression and mortality during a case-control study, the initial interview documented the BMI in the year before their prostate cancer diagnosis.[51] Using Cox proportional hazards models to estimate the adjusted hazard ratios, the HR for prostate cancer mortality was 2.64 (95% CI: 1.18–5.92, $n = 15$ deaths) in obese patients defined by BMI ≥30 kg/m^2 compared with normal-weight men (BMI <25 kg/m^2). Adjusted risk factors included age, race, diagnostic prostate-specific antigen level, smoking status, primary treatment, clinical stage at diagnosis, and Gleason score. For men with local or regional disease, the adjusted HR for developing metastasis in obese patients was 3.61 (95% CI: 1.73–7.51, $n = 73$ patients with 21 events) compared with normal-weight men. Using random effects meta-analysis to assess relative risks of prostate-specific mortality in six cohort studies, the pooled RR associated with a 5 kg/m^2 increase in weight above normal was 1.15 (95% CI: 1.06–1.25, $P < 0.001$, $I^2 = 59\%$, $n = 6{,}817$ cases) with moderate heterogeneity.[52]

Smoking

Although little epidemiological evidence associates smoking with increased prostate cancer incidence, the association between smoking and prostate cancer progression is relatively strong. In the prospective Health Professionals Follow-Up Study of 5,366 men diagnosed with prostate cancer (1986–2006), multivariable analysis demonstrated an increased prostate cancer mortality risk (HR = 1.61, 95% CI: 1.11–2.32) comparing current smokers with never-smokers.[53] The risk of biochemical recurrence was also elevated in current smokers (HR = 1.61, 95% CI: 1.16–2.22) when compared with never-smokers. Prostate cancer mortality risks were similar in never-smokers (HR = 0.61, 95% CI: 0.42–0.88) and former smokers quitting ≥10 years previously (HR = 0.60, 95% CI: 0.42–0.87) or quitting <10 years previously with a smoking history of <20 pack-years (HR = 0.64, 95% CI: 0.28–1.45) when compared with current smokers. A systematic review and meta-analysis reported a modest but statistically significant association between current- versus never-cigarette smokers and prostate cancer mortality (RR = 1.24, 95% CI: 1.18–1.31, $P_{heterogeneity} = 0.446$, $I^2 = 1\%$, $n = 21$ studies) with little evidence of heterogeneity or publication bias.[54] Other forms of tobacco use (smokeless, cigar, pipe) were not associated with increased prostate cancer mortality (RR = 1.16, 95% CI: 0.81–1.65, $P_{heterogeneity} = 0.017$, $I^2 = 70.6\%$) with significant heterogeneity. A meta-analysis of cohort studies confirmed the increased risk of fatal prostate cancer in current smokers versus never-smokers (summary RR = 1.14, 95% CI: 1.06–1.19, $n = 8$ studies) and no statistical difference in prostate cancer incidence between current smokers and never-smokers (RR = 1.04, 95% CI: 0.87–1.24, $n = 7$ studies).[55]

Alcohol

The association between alcohol consumption and prostate cancer is inconsistent and relatively weak. In a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

meta-analysis of 39 case-control and cohort studies comparing alcohol consumption with nonexposed controls, the effect of alcohol was modest and marginally to nonsignificant with little difference between consumption levels.[56] For light drinkers in cohort studies, the pooled RR was 1.04 (95% CI: 1.01–1.08, $I^2 = 0\%$, $n = 19$) compared with 1.06 (95% CI: 0.99–1.13, $I^2 = 24\%$, $n = 20$) for moderate drinkers and 1.04 (0.90–1.21, $I^2 = 45\%$, $n = 8$) for heavy drinkers with moderate heterogeneity. The pooled RR for case-control studies was similarly modest and statistically nonsignificant. A population-based Finnish cohort study with a median follow-up of 30 years suggests heavy drinking (>14 drinks/week) increases prostate cancer incidence based on lifestyle questionnaires on midlife drinking habits.[57] The adjusted hazard ratio was 1.46 (95% CI: 1.12–1.91, $n = 94$ cases) compared with light drinkers (0.01–3 drinks/week); however, the hazard ratio for prostate cancer-specific mortality was not statistically different than light drinkers (HR = 1.32, 95% CI: 0.66–2.62, $n = 15$ cases). Abstainers (adjusted HR = 1.90, 95% CI: 1.04–3.47, $n = 17$ cases) had a higher prostate cancer-specific risk than heavy or moderate drinkers. Adjustment variables included BMI, smoking, physical activity, education, and social class. An Australian case-control study using self-administered questionnaires examined the association between alcohol intake 2 years prior to enrollment and high-grade prostate cancer. Compared with no beer intake, heavy beer consumption (≥5 days/week) was associated with an increased risk of high-grade prostate cancer (OR = 1.66, 95% CI: 1.12–2.48, $P = 0.012$) after adjustment for intake of other alcoholic beverage types. Red and white wine consumption did not display a dose-response relationship with high-grade prostate cancer, similar to overall alcohol consumption.

HISTOLOGY

Almost all prostate tumors are adenocarcinomas. Human prostates contain pseudostratified epithelium composed of the three terminally differentiated epithelial cells (basal, luminal, neuroendocrine). Although the cellular origin of prostate cancer remains controversial, the most likely sources are stem/progenitor or differentiated cells with basal or luminal phenotypes.[58] The malignant transformation of prostate epithelial cells is a multistep process beginning with prostatic intraepithelial neoplasia followed by localized prostate cancer, advanced prostate adenocarcinoma with local invasion, and finally metastatic prostate cancer.[59] The Gleason grading system from 2–20 is the most widely used classification of prostate cancer aggressiveness with higher scores indicating increased risk of spreading. Hormone responsiveness is a common feature of prostate adenocarcinomas, particularly in untreated prostate cancer. Prostate cancer usually develops in the periphery of the gland, in areas outside those affected by benign hyperplasia.[60] Gleason scores above 7 indicate clinically significant disease.

HOST SUSCEPTIBILITY

Family History

A family history of prostate cancer increases the risk of prostate cancer ~2–4-fold depending on the number/closeness of affected relatives and the age of cancer onset in first-degree relatives;[61] a family history of prostate cancer in first-degree relatives almost doubles prostate cancer risk.[62] Analysis of data from the nationwide Swedish Family-Cancer Database demonstrated increasing hazard ratios of prostatic cancer diagnosis in 5,623 prostate cancer patients with a familial history of prostate cancer; the HR for developing prostate cancer increased with the number of affected relatives and decreased with the increasing age of the affected relative.[63] In a systematic review and meta-analysis using a weighted average model, the pooled RR estimates for prostate cancer in any affected family member were 1.93 (95% CI: 1.65–2.26, $n = 4$ case-control and 3 cohort studies) and 2.22 (95% CI: 2.06–2.40, $n = 11$ case-control and 5 cohort studies) in affected first-degree relatives.[64] Statistical comparison of pooled data demonstrated the relative risk of prostate cancer was significantly higher in brothers than fathers ($n = 8$ case-control and 4 cohort studies, $P < 0.03$). A measure of heterogeneity was not reported. Analysis of data on 635,443 men and 18,105 prostate cancer cases from a large population-based genealogy database supported the increased prostate cancer risk in families with affected members.[65] The prostate cancer risk in men with affected first-degree relatives ranged from 2.46 (95% CI: 2.39–2.53) for one first-degree relative to 7.65 (95% CI: 6.28–9.23) for four first-degree relatives. The study also suggested maternal family history and the presence of more distant affected family members (second-, third-degree relatives) also contributed to prostate cancer risks. The prostate cancer risk is higher, and the age at prostate cancer diagnosis is lower in monozygotic than dizygotic twins, consistent with genetic influence.[66] In an analysis of data from 44,788 pairs of twins listed in the Swedish, Danish, and Finnish twin registries, heritable factors accounted for 42% (95% CI: 29–50%) of incident prostate cancer cases.[67]

Male Pattern Baldness

Male pattern baldness (androgenetic alopecia) is an age-related, androgen-independent genetic disorder caused by dihydrotestosterone-induced activation of androgen receptors in hair follicles; this disorder shares similar pathological mechanisms (e.g., aging, androgen influence) with prostate cancer suggesting the presence of male pattern baldness may be a high-risk factor important for prostate progression and screening.[68] Based primarily on case-control studies, the association between male pattern baldness and prostate cancer risks is inconclusive; however, the studies do not exclude a possible association between self-reported early-onset baldness and prostate cancer progression[69] or overall baldness (any pattern) and high-grade disease. Most epidemiological studies do not support an association between overall baldness (i.e., all patterns) and prostate cancer incidence using non-bald participants as controls; however, some,[70] but not all,[71] studies support an association between vertex male pattern baldness and high-grade disease. In a meta-analysis of seven case-control studies (4,078 cases/4,916 controls), the association between prostate cancer incidence and combined patterns of male baldness was not statistically significant (OR = 1.03, 95% CI: 0.93–1.13, $P_{\text{heterogeneity}} = 0.36$, $I^2 = 9\%$) with little heterogeneity.[72] The odds ratio for prostate cancer risk comparing vertex baldness with non-bald controls was statistically significant (OR = 1.25, 95% CI: 1.09–1.44, $P_{\text{heterogeneity}} = 0.35$, $I^2 = 10\%$). Similarly, a meta-analysis of nine case-control and two cohort studies did not detect a statistically significant difference in the prostate cancer rates between bald and non-bald participants. Subgroup analysis indicated the difference between aggressive prostate cancer rates in vertex baldness and non-bald participants was significant (OR = 1.60, 95% CI: 1.37–1.86, $P_{\text{heterogeneity}} = 0.65$, $I^2 = 0\%$, $n = 5$ case-control studies).[73] The age-varying rate of prostate cancer influences the association between male pattern baldness and prostate cancer risks. In a follow-up study of 9,448 participants in the Melbourne Collaborative Cohort (median follow-up, 11.33 years, $n = 476$ cases), the cumulative probability of prostate cancer comparing men with vertex baldness and non-bald controls was elevated at all ages up to 76 years; thereafter, the probability converged.[74] The age at diagnosis was greater in patients with vertex baldness at age 40 than in non-bald controls.

CLINICAL FEATURES

Prostate cancer is a slowly developing disease of aging with a long preclinical phase; the diagnosis often occurs incidentally in asymptomatic men or older, symptomatic men. The median at diagnosis is 67 years and the latent period for prostate cancer averages 20–30 years; there is no association between prostate hyperplasia and latent prostate cancer.[75] The vast majority of men presenting with prostate cancer have relatively low-risk, indolent tumors that are unlikely to progress or require treatment. Using logistic regression models with random effects, a systematic review of 29 observational studies (1948–2013), the prostate cancer prevalence increased with each decade of age in all populations (OR = 1.7, 95% CI: 1.6–1.8), particularly in studies using Gleason scores for severity. The mean prostate cancer prevalence was nonlinear increasing from 5% (95% CI: 3–8%) for patients aged <30 years to 59% (95% CI: 48–71%) for patients aged >79 years. Consequently, prostate cancer screening often detects nonprogressive cancers or nonmalignant diseases (e.g., prostatitis, benign prostatic hypertrophy), resulting in increased risks associated with overtreatment in men likely to die from other causes. In 2018 with moderate certainty, the US Preventive Services Task Force recommended that clinicians offer prostate-specific antigen (PSA) testing selectively to men aged 55 to 69 years old based on individual discussions of the potential benefits and harms of PSA testing. The Committee recommended against routine PSA testing in men 70 years and older with moderate certainty; however, the amount of evidence was limited. Currently, these recommendations are being reviewed, particularly for younger, high-risk men (e.g., African American men, strong family history of prostate cancer).[76] the ~20–30% of men with localized prostate cancer and some high-risk tumor features are the primary focus of PSA screening.

Approximately 92% of new prostate cancer cases have localized or regional disease with 5-year and 15-year survival rates approaching 100% and 94%, respectively; A PSA <1 ng/mL in a patient over 70 years of age indicates low-risk disease. The 5-year survival rate drops below 30% for patients with metastatic disease.[17] Metastatic prostate cancer is the most common cause of prostate-related deaths occurring primarily in men over 70 years of age. Adjacent lymph nodes are the initial sites of metastases, followed by metastases to bones, liver, and lungs; the osteoblastic lesions in bones cause severe pain, pathological fractures, and hypercalcemia. Treatment usually involves androgen deprivation therapy, and often is associated with erectile dysfunction and hot flashes. Approximately one-third

of prostate cancer patients with localized disease may be managed with active surveillance including serial PSA measurements, magnetic resonance imaging, and prostate biopsies; initiation of treatment begins when the tumor stage or Gleason score increases. For patients with higher-risk disease, radical prostatectomy or radiation therapy are options. The treatment of metastatic prostate cancer typically involves androgen deprivation therapy (e.g., gonadotropin-releasing hormone agonists, medical castration). The addition of androgen receptor pathway inhibitors (abiraterone, darolutamide) improves survival for patients with recently diagnosed metastatic prostate disease.

TESTES

Although rare, testicular germ cell cancer is the most common cancer site among males aged 15–29 years; the incidence of this cancer ranks second among males aged 30–44 years (mean age of diagnosis, 33 years). Figure 56.2 displays the age-related incidence of total testicular germ cell tumors, seminomas, and nonseminomas. Testicular cancer incidence has increased over the last 50 years,[77] varying by ~6-fold worldwide depending on geographical, temporal, and ethnic factors. The highest incidences occur in Western countries, primarily in Caucasians from Western developed

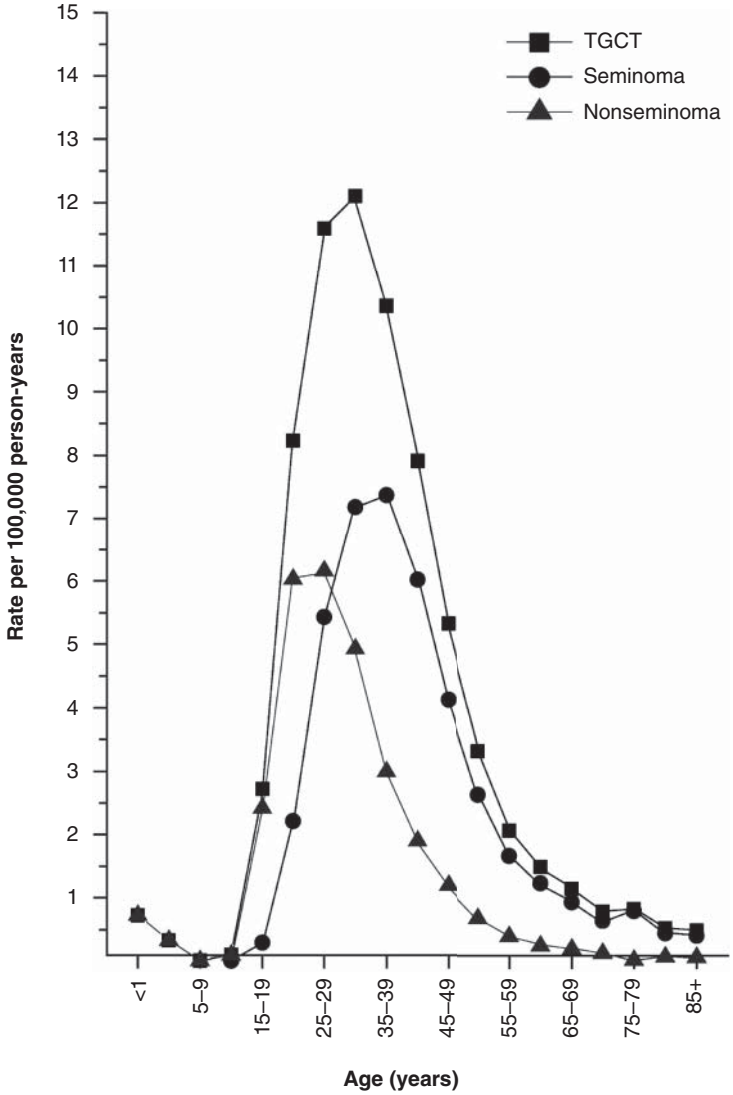

FIGURE 56.2. Age-related incidence of total testicular germ cell tumors (TGCT, square), seminomas (circle), and nonseminomas (triangle). (Adapted from McGlynn and Cook).[78]

countries (e.g., northern Europe, Canada), and the lowest rates appear in Asia and Africa.[78,79] In the United States, testicular cancer incidence is highest among non-Hispanic white men (7.50/100,000, 95% CI: 7.27–7.74/100,000) based on SEER data, whereas the incidence is 2.16/100,000 (95% CI: 1.93–2.43) for Asian/Pacific Islanders and 1.35/100,000 (95% CI: 1.14–1.58) for African-Americans.[80] Approximately 500,000 new testicular cancers develop annually in the world, with most cases being germline tumors in young adult males.[81] In the United States, ~9,300 cases of testicular cancer occur annually, with ~400 testicular cancer-related deaths each year.[1]

CARCINOGENESIS

Seminomas display the features of pluripotent, primordial germ cells (gonocytes) that ultimately form spermatogonia, whereas nonseminomas are mixed germ cell tumors that may contain embryonal cell carcinoma, choriocarcinomas, teratomas, and yolk sac tumors. The development of testicular cancer involves at least 44 SNPs and candidate causal genes producing widespread disruption of developmental transcriptional regulators consistent with failed primordial germ cell differentiation as the initiating event.[82] Genome-wide association studies indicate these changes primarily involve noncoding regions of the genome that influence gene regulation and transcriptional initiation/enhancement through histone modifications and chromatin looping interactions. Two characteristic chromosomal abnormalities in testicular germ cell tumors are polyploidization (multiple double-paired, related chromosomes) and amplification of the short arm of chromosome 12 (i12p); the latter being present in 80% of testicular germ cell tumors and almost all invasive testicular germ cell tumors.[83] Compared with chromosomal abnormalities, specific gene mutations in testicular cancer are less frequent. Identified mutations in germ cell tumors often involve the *KIT* (proto-oncogene receptor tyrosine kinase) driver gene and RAS/MAPK (cell proliferation/migration, angiogenesis, stem cell maintenance) signaling pathways.[84] The most common single affected genes include *KIT*, *BRAF*, *DRAS*, *NRAS*, and *TP53*, depending on the tumor subtype. Mutation of the stem cell growth factor *KIT* gene occurs in ~19% of seminoma and 2% of nonseminoma tumors.[85] Single nucleotide polymorphisms (SNPs) typically affect genes involved in normal germ cell differentiation and apoptosis (e.g., *BAK1*, *KITLG*, *PDE11A*, *SPRY4*).[86] Mutations occur in ~25% of seminomas, whereas their presence in nonseminomas is uncommon.[87]

Most normal epigenetic signatures develop during differentiation with subsequent stabilization to allow multiple functions from the same genetic information. These epigenetic modifications are transmissible over cell generations including DNA methylation of cytosine bases, posttranslational histone protein alteration, and chromatin reorganization. Little CpG island methylation occurs in seminomas, whereas nonseminomas and other solid tumors display much higher levels of CpG island methylation, particularly in specific promoter regions (e.g., *RASSF1A*, a tumor suppressor gene).[88] DNA methylation is a critical epigenetic gene-silencing mechanism for cell-specific genes/transposons, cell differentiation and organ development, X chromosome inactivation, and maintenance of cellular pluripotency, whereas histone modifications involve the post-translational alteration of key proteins regulating gene expression by modification of chromatin conformation and stability. In testicular germ cell tumors, these two epigenetic processes display unique developmental rather than somatic epigenetic patterns. Demethylation occurs throughout the genome in germ cell neoplasia *in situ* and seminomas; however, demethylation involves only a few imprinted genes and *LINE1* (long interspersed nuclear element 1) in nonseminomas.[89] Promotor hypermethylation of piRNA along with corresponding genes (*PIWI1*, *PIWI2*, *PIWI4*, *TDRD1*) and resultant *LINE1* silencing enhances chromatin instability.[90] By altering RNAs and inserting the information back into the genome, Line1 proteins facilitate an epigenetic pathway from transcriptome (RNA) to genome (DNA) allowing the import of extracellular information. The miRNA profiles of germ cell tumors including germ cell neoplasia *in situ* closely resemble those of embryonic stem cells.[91] In contrast to normal testicular tissues, testicular germ cell tumors typically do not express genes in the PIWI/piRNA pathway critical to the normal development of male germ cells.[92]

EXPOSURE

Limited data exist regarding testicular cancer epidemiology or specific cancer subtypes; the lack of definite evidence of associations with occupation, lifestyle, or infection reflects the importance of *in utero* rather than postnatal exposures in the development of testicular cancer. Major risk factors for the development of testicular germ cell tumors are hypospadias (i.e., congenital displacement of urethral opening from tip to underside of penis), previous or family history of testicular cancer, and cryptorchidism (i.e., failure of testes to descend from abdomen to scrotum).[93,94]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

A hypothesis-generating study of 250 cases of testicular cancer found the following factors associated with an increased risk of developing testicular cancer: testis-related abnormalities including low sperm count (OR = 6.0), atrophic testis (OR = 20), cryptorchidism (OR = 5.17), and fertility problems (OR = 10).[95] Although the role of sex hormones, including prenatal exposure, in the formation of testicular cancer remains controversial, case-control studies of children exposed *in utero* to diethylstilbestrol have not demonstrated a definitive increase in testicular cancer risk in this population.[96] Most meta-analyses do not support an association between vasectomy and testicular cancer.[97] Higher socioeconomic status and especially professional occupations are associated with the development of testicular cancer in older studies.[98] More recent New Zealand cohort studies suggest testicular cancer rates are higher in men with low than high incomes (pooled rate ratio for lowest to highest income groups = 1.23; 95% CI: 1.05–1.44).[99] There is no strong evidence that disparities in testicular cancer incidence have varied by ethnicity or household income over time. Although testicular microlithiasis (i.e., seminiferous tubular calcifications) often occurs in the setting of testicular malignancy, prospective studies do not support microlithiasis as a risk factor for testicular cancer.[100]

Occupation

Occupational exposures are not strong risk factors for developing testicular cancer because of the probable prenatal and/or early life origin of this cancer and the difficulty of evaluating exposures retrospectively in case-control studies.[101] Little epidemiological evidence supports a strong association between specific chemical exposures in the work environment and the development of testicular cancer including endocrine disrupting chemicals.[102,103] Epidemiological data are particularly weak for occupational exposures and seminomas.[104] Although testicular germ cell cancer risk is often higher in studies of white-collar than blue-collar occupations,[105] socioeconomic status may contribute to this difference.[106] No single profession is conclusively associated with testicular germ cell tumors, including occupational exposure to ionizing radiation based on a systemic review (study heterogeneity prevented a pooled analysis)[107] and the relative insensitivity of the human testis to low levels of ionizing radiation in BEIR V data.[108] Evaluation of four cohort and five case-control studies suggests a possible association between occupational electromagnetic fields (EMF) and testicular cancer; however, most of the published evidence associating EMF with testicular cancer exists in the older medical literature with crude exposure estimations and often inconsistent findings. More recent, higher-quality studies have not demonstrated a statistical relationship between occupational EMF exposure (e.g., radar units, radiofrequency emitters, electrical machines, high-voltage lines or transmission installations) and testicular cancer incidence[107] or mortality.[109]

Job Classifications

Poor exposure data limit the ability of these studies to detect associations between specific chemicals and testicular cancer incidence. In the population-based Nordic study of 15 million residents followed up to 45 years, physicians had the highest seminoma risk (SIR = 1.48, 95% CI: 1.07–1.99), followed by artistic workers (SIR = 1.47, 95% CI: 1.06–1.99) and religious workers (SIR = 1.33, 95% CI: 1.14–1.56).[110] The lowest seminoma risks occurred in cooks and stewards (SIR = 0.56, 95% CI: 0.29–0.98) and forestry workers (SIR = 0.64, 95% CI: 0.47–0.86). The testicular cancer incidence was not increased in occupations involving pesticide exposures, including farmers (SIR = 0.97, 95% CI: 0.89–1.06) or gardeners (SIR = 1.03, 95% CI: 0.88–1.20). A Swedish register-based study reported a statistically nonsignificant increased SIR of 1.55 (95% CI: 0.92–2.45) for agricultural workers using pesticides;[111] a follow-up study including an additional 10 years of follow-up demonstrated a testicular cancer risk of (SIR = 1.09, 95% CI: 0.68–1.67, $n = 18$ cases).[112] A case-control study of 495 germ cell testicular cancers suggests the possibility of an association between nonseminomas and the following occupations: mining (OR = 12.39; CI: 2.22–69.27), food and beverage processing (OR = 3.2, 95% CI: 1.39–7.35), utilities (OR = 3.15, 95% CI: 1.15–8.61), and other service workers (OR = 1.05, 95% CI: 1.05–4.56).[113] The large confidence limits indicate imprecise estimates of the true odds ratios. A case-control study of leather workers initiated after the recognition of a cluster of three testicular cancer cases reported an elevated, age-adjusted odds ratio of 7.2 (95% CI: 1.89–27.2) for the development of testicular cancer in leather workers;[114] however, no specific carcinogen was identified, and the OR estimates were imprecise. In a cohort of 2,026 workers employed at least 1 year from 1900–1989 in 3 Swedish leather tanneries and followed from 1958–1989, the odd ratio using a 20-year latency period demonstrated no association between their work and testicular cancer (SIR = 0.97, 95% CI: 0.32–2.27, $n = 5$ cases).[115] Studies associating firefighters, military service, or aircraft maintenance with testicular cancer are inconsistent.[116]

Chemical Exposures

Dimethylformamide

Limited human evidence associates the development of testicular cancer with dimethylformamide exposure, and the association remains controversial.[117] Studies associating dimethylformamide exposure with testicular cancer are older case-control studies with poor exposure data involving cancer cluster evaluations.[118] A cohort study of 3,859 workers followed from 1956–1984 for cancer incidence after dimethylformamide exposure during the manufacture of synthetic fibers did not detect an increased testicular cancer risk (1.7 cases expected/1 case observed).[119] No clear biological mechanism explains the association with testicular cancer; however, experimental studies suggest dimethylformamide is moderately genotoxic with experimental evidence that dimethylformamide increases oxidative stress and alters cell proliferation.[120] The IARC considers dimethylformamide a probable human carcinogen (Group 2A) based on limited human evidence and sufficient evidence in animals.

Endocrine Disrupters

Endocrine disrupting chemicals include the estrogenic dichlorodiphenyl-trichloroethane (DDT), polyvinyl chloride (PVC), bisphenol A, anti-androgenic DDT metabolite dichlorodiphenyl-dichloroethylene (DDE) phthalates, and 209 congeners of polychlorinated biphenyls (PCBs) with varying estrogenic and androgenic effects. Theoretically, these chemicals may impair androgen signaling during early development and potentially slightly increase testicular cancer risks; however, current organochlorine classification schemes do not separate or quantitate their estrogenic and anti-androgenic effects. The estrogenic/antiandrogenic effects of these chemicals are hundreds- to thousands-fold less potent than diethylstilbestrol, a chemical with limited evidence of human carcinogenicity. A meta-analysis of 6 case-control studies with 36 risk estimates did not detect a statistically significant association (OR = 1.20, 95% CI: 0.78–1.89) between testicular cancer and exposure to endocrine disrupting chemicals included in the European Commission's list of Category I endocrine disrupting chemicals.[121] This systemic review and meta-analysis did not detect exposure-response relationships.

In a review of organochlorine compounds and testicular cancer, the authors reported a weak association between DDE, *cis*-nonachlor, and *trans*-nonachlor and testicular germ cell cancer, whereas the review revealed no association between testicular germ cell cancer and DDT, PCBs, or other organochlorine compounds.[122] Although three of four case-control studies found a positive association between DDE exposure and testicular germ cell cancer,[123,124] only the STEED Study reported a statistically significant odds ratio (P_{trend} = 0.0002) that was limited to comparing the highest (>39 μg/g lipid) and lowest exposure quartiles (OR = 1.71, 95% CI: 1.23–2.38).[125] Additionally, the review did not demonstrate an association between organochlorines (DDT, DDE) or PCBs and congenital abnormalities (cryptorchism, hypospadias, fertility). A population-based, case-control study of 18–44-year-old male residents of three Washington State counties observed no clear association between testicular germ cell tumors and 11 serum organochlorine concentrations including comparison of high to low *p*,*p*′-DDE concentrations (adjusted OR = 0.61, 95% CI: 0.32–1.14, *n* = 21 cases).[126] Organochlorine atmospheric and biological concentrations are declining as a result of the elimination of more persistent organochlorine compounds (e.g., DDT, DDE, chlordane). Epidemiological data are insufficient to determine the association between other endocrine disrupting chemicals (e.g., bisphenol A, phthalates, PVC) and testicular germ cell cancer.[127,128]

Lifestyle

Lifestyle does not strongly affect testicular germ cell cancer risks including maternal smoking,[129] overall adult/adolescent BMI,[130] diet,[131] heat,[132] trauma, or physical activity (riding, recreational, occupational).[133,134] The development of testicular cancer is probably not significantly associated with residential electromagnetic field exposure. In a German population-based case-control study, the OR for testicular cancer in 145 Hamburg residents living within a 100-m corridor of high-voltage lines in Hamburg was 1.3 (95% CI: 0.56–2.80) compared with 313 controls (age-adjusted Hamburg residents with no excessive EMF exposure).[135] The risk was higher but statistically nonsignificant when comparing high EMF exposures to controls (OR = 1.7, 95% CI: 0.91–3.32).

The strongest epidemiological evidence associates taller heights with increased testicular germ cell cancer risk, particularly for seminomas.[136] A cohort of 557,032 adult Norwegian men registered 1,357 cases of testicular cancer.[137] Using proportional hazards regression, the RR comparing adults over 180 cm with adults measuring 170–179 cm in height was 1.09 (95% CI: 0.96–1.24, *n* = 1,004 cases, P_{trend} = 0.004). The same comparison for seminomas was borderline significant (RR = 1.17, 95% CI: 1.00–1.37, P_{trend} = 0.006, *n* = 693 cases). The difference in testicular cancer risk comparing obese

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

men and referents (BMI = 18.5–24.9 kg/m^2) was not statistically significant (RR = 0.83, 95% CI: 0.58–1.17, n = 1,004 cases); however, the trend of <18.5–≥30 kg/m^2 was inversely related (P_{trend} = 0.02). A random effects meta-analysis of 12 case-control and 1 cohort study reported a relatively weak but statistically significant association between testicular germ cell cancer and height (per 5 cm) with an estimated OR of 1.13 (95% CI: 1.07–1.19, I^2 = 76.5%) and substantial heterogeneity.[138] The meta-analysis demonstrated no significant association between testicular germ cell cancer and BMI (OR per kg/m^2 = 0.99, 95% CI: 0.97–1.00, I^2 = 45.4%) with moderate heterogeneity.

Diseases

Cryptorchidism (undescended testes) is the antecedent medical condition most closely associated with testicular germ cell tumors accounting for ~5–10% of these tumors.[78,139] In a review of mostly retrospective studies, the relative risk of testicular cancer in cryptorchidism cases ranged from 2.75–8, with the RR dropping to 2–3 for patients undergoing prepubertal orchiopexy.[140] The relative risk of testicular cancer in a population-based, case-control study of 387 cases of cryptorchidism and 416 controls was 3.6 (95% CI: 1.8–6.9); the study detected no clear association of testicular cancer with inguinal hernias or testes that spontaneously descended after birth.[141] The relative risk of testicular cancer increased as the age at orchiopexy increased. The testicular germ cell cancer risk associated with perinatal risk factors (low birth weight, decreased gestational age, low maternal parity, low birth order, sibship size) is inconsistent and relatively weak.

Drugs

Diethylstilbestrol

Diethylstilbestrol (DES) is a synthetic nonsteroidal estrogen previously used to prevent miscarriages in the late 1940s–mid-1970s until withdrawn from the market because of the increased risk of clear cell vaginal and cervical adenocarcinoma in offspring following *in utero* exposure. Limited human data associate *in utero* DES exposure and testicular germ cell cancer. Although some,[94,142] but not all,[96,143] case-control studies suggest an association between *in utero* DES exposure and testicular cancer, a prospective cohort study of 3,613 men with prenatal DES exposure followed from 1978–1994 provided equivocal support for the association with testicular cancer. The relative risk of testicular cancer in exposed versus unexposed men was 3.05 (95% CI: 0.65–21.96, n = 6 cases) based on imprecise RR estimates and few cases. Using population-based rates, the SIR for testicular cancer in 1,787 exposed men was also not statistically significant (RR = 2.04, 95% CI: 0.82–4.29, n = 7 cases).

Cannabis

A systematic review and meta-analysis of studies regarding cannabis use and testicular cancer risk published from 1980–2015 yielded three case-control studies that used face-to-face interviews (two studies) or self-completed paper-based questionnaire (one study) to evaluate cannabis use.[144] All studies adjusted for cryptorchidism. The association between current cannabis use and testicular cancer was strongest for nonseminomas (pooled OR = 2.09, 95% CI: 1.29–3.37, I^2 = 0%) and total testicular germ cell tumors (pooled OR = 1.62, 95% CI: 1.13–2.31, I^2 = 0%) when compared with never users. Subanalyses indicated the pool OR was not statistically significant for seminomas (pooled OR = 1.25, 95% CI: 0.80–1.96, I^2 = 0%) when compared with never users. Similarly, the pooled OR for nonseminomas and total testicular cancers was statistically elevated for frequent (≥weekly) and chronic users (≥10 years), but not for ever users.[145] Some of these studies did not demonstrate simple dose-response patterns over categories defined by frequency or duration of cannabis use.[146] A Swedish cohort study of 49,343 military recruits followed up to 42 years did not demonstrate a statistically significant relationship between ever-cannabis users and testicular cancer (adjusted HR = 1.42, 95% CI: 0.83–2.45, n = 119 cases) based on non-anonymous questionnaire concerning drug use.[147] Heavy cannabis use defined by >50 lifetime cannabis usage at conscription was associated with an increased testicular cancer risk (adjusted HR = 2.57, 95% CI: 1.02–6.50, n = 119 cases).

HISTOLOGY

Testicular germ cell tumors arise from various locations in the testis and account for >95–98% of testicular malignancies; these tumors display substantial histological heterogeneity because of aberrant somatic differentiation and retained pluripotency. Stromal tumors of somatic origin (e.g., Leydig cells and Sertoli-cell tumors) along with rare, poorly defined histological types account for the remaining 2–5%. Testicular germ cell tumors and testicular cancer are terms often used interchangeably because the vast majority of testicular

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancers are germ cell tumors. Testicular germ cell tumors initially arise from germinal cell neoplasia *in situ* (i.e., previously testicular intraepithelial neoplasia, intratubular germ cell neoplasia unclassified, carcinoma *in situ*) with the vast majority being malignant. These abnormal cells resemble fetal germ cells overexpressing the OCT4 protein encoded by the *POU5F1* gene critical to regeneration of undifferentiated embryonic stem cells. Noninvasive intermediate precursor lesions include intratubular seminoma and the much less common intratubular embryonal carcinoma; microinvasive germ cell tumors are a relatively frequent invasive intermediate precursor lesion in testicular germ cell tumors.[148]

Seminomas (i.e., ~55–60%) and nonseminomas (40–42%) are the most frequent histological types of testicular germ cell tumors, with spermatocytic tumors accounting for 1–5%.[149] Classically, seminomas are much more homogeneous than nonseminomatous germ cell tumors and spermatocystic seminomas; the former occurs in a younger age group (fourth to fifth decade) than the latter (sixth to seventh decade). Highly anaplastic and malignant embryonal cell carcinomas appear in ~30% of germ cell tumors, with the remaining 10–15% being more differentiated nonseminomas forms (yolk sac, teratoma, choriocarcinoma).[150] Rare nonseminoma tumors include adult teratomas and choriocarcinomas. The latter tumor is the most malignant testicular tumor, frequently appearing in combination with other histological testicular tumor subtypes. Spermatocytic tumors occur only in the testis. Epidemiological studies (e.g., age patterns, time trends) on seminoma and nonseminomas suggest different etiologies among newborns, infants, and elderly men, but not in the majority of patients with testicular tumors (i.e., adolescents, young men).[151] Table 56.2 displays the histological types of germ cell cancers based on the World Health Organization (WHO) classification of testicular and paratesticular tumors along with the typical onset of these tumors,[152] their origin, and immunohistochemical markers to help pathologists determine the tumor subtypes.[153]

These tumors contain all cell lineages, including somatic and extra-embryonic tumors. Seminomas are homogeneous tumors with characteristics of embryonic germ cells, whereas nonseminomas are highly heterogeneous tumors representative of specific characteristics of embryonic (germ) cells with multiple lineages (ectoderm, endoderm, mesoderm), particularly teratomas.[154] Nonseminoma germ cell tumors may present as pure or mixed (i.e., multiple histological subtypes), including elements of a seminoma. Approximately 5% of patients with unilateral testicular germ cell tumors have a contralateral testicle with neoplasia *in situ*.[127]

TABLE 56.2. Main testicular germ cell tumor histological categories based on the World Health Organization (WHO) classification of testicular and paratesticular tumors with associated onset, origin, and immunohistochemical markers. Nonseminomas include embryonal carcinomas, teratomas, yolk sac tumors, choriocarcinomas, and other trophoblastic tumors. (Adapted from Rajpert-De Meyts et al.).[128]

Tumor	Onset	Origin	Immuno-histochemistry
Seminoma	Median ≅ 35 years	Germ cell neoplasia *in situ* (malignant primordial germ cell/gonocyte)	OCT4+, CD117+, CD30−, SOX17+, SOX2−
Embryonal carcinoma[a]	≅25 years[b]	Germ cell neoplasia *in situ* (malignant primordial germ cell/gonocyte)	CD30+, CD117−, SOX17−, SOX2+
Teratoma[a]	≅25 years[b]	Germ cell neoplasia *in situ* (malignant primordial germ cell/gonocyte)	CD30−, OCT4−
Yolk sac tumor[a]	Postpubertal	Germ cell neoplasia *in situ* (malignant primordial germ cell/gonocyte)	CD30−, OCT4−
Choriocarcinoma/other trophoblastic tumor[a]	Postpubertal	Germ cell neoplasia *in situ* (malignant primordial germ cell/gonocyte)	CD30−, OCT4−
Childhood teratoma[a]	Prepubertal	Non-germ cell neoplasia *in situ* (embryonic germ cell)	CD117−, CD30−, OCT4−
Childhood yolk sac tumor[a]	Prepubertal	Non-germ cell neoplasia *in situ* (embryonic germ cell)	CD117−, CD30−, OCT4−
Spermatocytic tumor	Mid-life adult	Non-germ cell neoplasia *in situ* (spermatogonia/spermatocyte)	CD117−, CD30−

Abbreviations: OCT4+ = positive for octamer-binding transcription factor 4; CD117+ = positive for the proto-oncogene coding the stem cell factor for V-Hardy-Zuckerman feline sarcoma viral oncogene homolog KIT (KIT) ligand receptor; CD30+ = positive for a member of the tumor necrosis factor superfamily of receptors; SOX2/SOX17 = nuclear transcription factors important for cell differentiation into organs during embryonic development.

HOST SUSCEPTIBILITY

Familial risks associated with testicular germ cell cancer are relatively high (i.e., ~50%) compared with other cancer sites; however, the rarity of testicular cancer results in a relatively low attributable risk (i.e., ~5%) for hereditary causes.[155] In a joint European, population-based cohort study of 97,402 first-degree relatives of 21,254 testicular cancer patients diagnosed from 1955–2010, the lifetime cumulative risk of testicular cancer (any histology) in brothers of a testicular cancer patient was 2.3% with an SIR of 4.1 (95% CI: 3.6–4.6, $n = 270$ cases) compared with the general population.[156] The testicular cancer risk increased by ~2-fold (SIR = 2.0, 95% CI: 1.7–2.4, $n = 140$ cases) in sons of fathers with testicular cancer. The risk was dramatically increased (SIR = 20, 95% CI: 13–31, $n = 23$ cases) in a twin when the other twin developed testicular cancer.

Moderate- and low-risk single-nucleotide polymorphisms identify only ~1/3 father-to-son familial risk of germline testicular cancer. *CHEK2* gene encodes a protein kinase (CHEK2) that regulates >20 downstream effector proteins (e.g., BRCA1, BRCA2, p53, pRb) important in double-stranded DNA repair, cell cycle regulation, and apoptosis. Using gene-level enrichment analysis of germline pathogenic variants in a multistage, case-control study involving 884 men with testicular cancer, carriers of germline pathogenic variants of the *CHEK2* gene were four to six times more likely to develop testicular cancer than cancer-free controls.[157] The mean age at cancer diagnosis was ~6 years earlier in the variants than in carriers of the wild-type *CHEK2* alleles.

CLINICAL FEATURES

Unlike most adult cancers, testicular cancer incidence with the exception of spermatocytic seminomas does not increase with age; the peak occurrence of nonseminomas develops at 25–29 years of age compared with 35–39 years for seminomas.[158] Spermatocytic seminomas are less aggressive tumors that present in older men (e.g., 50–54 years of age). Germ cell neoplasia *in situ* is asymptomatic that is typically discovered during evaluations of fertility abnormalities or cryptorchidism, whereas patients with testicular germ cell tumors usually present with a unilateral painless testicular mass confirmed by ultrasound. Metastatic disease is often asymptomatic; symptoms may include cough, hemoptysis, dyspnea, flank pain, or gynecomastia. Clinical staging frequently involves the American Joint Committee on Cancer Staging Manual based on World Health Organization histological classifications.[159] Approximately 75% of testicular germ cell tumors (i.e., 80% seminomas, 60% nonseminomas) present with localized disease (Stage I, no regional or distant metastasis); spermatocytic tumors seldom metastasize, whereas choriocarcinomas metastasize early through the bloodstream to multiple locations (e.g., lungs, brain).[160] Teratomas usually invade locally. In a German case series of 422 patients with testicular germ cell tumors, the median age was 36 years (IQR, 31–45 years) compared with 41 years (IQR, 34–47 years) for seminomas and 31 years (IQR, 26–37.5 years) for nonseminomas.[161] The presenting clinical stage 1 represented ~67% of all tumor patients, ~79% of seminomas, and ~48% of nonseminomas, with higher clinical stage and metastasis more common in nonseminomas than seminomas.

Over 95% of intratesticular masses are malignant; however, the overall prognosis for testicular germ cell tumors is excellent with modern chemotherapy. Orchiectomy alone cures 80% of seminomas and 70% of nonseminomas; however, clinical stage I seminomas have 13–19% relapse rate compared with 30% for nonseminomas.[127] The 5-year survival rate for testicular cancer is excellent (i.e., ~97%) even when wide metastasis occurs (i.e., ~80%), particularly seminomas.[162]

PENIS

Penile cancer is a rare genital malignancy with an annual global incidence of ~26,000 cases that varies between countries depending on the prevalence of important risk factors (e.g., phimosis, HPV, chronic penile inflammation). The highest age-adjusted incidence occurs in developing countries of Asia, Africa (e.g., Uganda, 1.2–3.3 cases/100,000),[163] and South America (e.g., Brazil, 1.5–3.7 cases/100,000),[164] particularly in low-income, uncircumcised men.[165] The penile cancer incidence is much lower in developed countries, including North America (e.g., United States, 0.3–1.8 cases/100,000) and Western Europe (0.45–1.7 cases/100,000),[166] with higher socioeconomic status and religious practices that encourage circumcision (e.g., Israeli Jews, 0.1 cases/100,000).[167] About 1,000–1,500 new cases of penile cancer occur in the United States annually.[168,169]

CARCINOGENESIS

Penile cancer has distinct molecular pathways with diverse genetic and epigenetic alterations. The two major mechanisms responsible for the development of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

penile cancer are: 1) HPV-independent, chronic inflammation (phimosis, poor penile hygiene, lichen sclerosis); and 2) HPV-dependent oncogene formation.[170] Examination of archival tissues from penile tumors suggests gene alterations (i.e., somatic p53 mutations, gene promoter methylations including *CDKN2A*) are more common in HPV-independent than HPV-dependent tumors.[171,172,173] Although HPV-independent (negative) and HPV-dependent (positive) penile tumors have different molecular abnormalities, these tumors disrupt similar tumor suppressor gene pathways (e.g., p16INK4a/cyclinD/Rb, p14ARF/MDM2/p53). Genome-wide methylation and transcriptome analysis suggest CpG hypermethylation and underexpression of multiple genes (e.g., *TWIST1*, *RSOP2*, *SOX3*, *SOX17*, *PROM1*, *OTX2*, *HOXA3*, *MEIS1*) along with alteration of stem cell regulatory pathways may contribute to the development of penile cancer.[174]

In patients with phimosis, the inability to retract the foreskin over the glans allows smegma (urinary products, desquamated epidermal cells) to accumulate and prevents adequate penile hygiene. Lichen sclerosis is a chronic inflammatory skin condition that affects the anogenital area including the foreskin, glans, and coronal sulcus. The role of lichen sclerosis in penile cancer is unclear; however, some case series associate HPV-negative squamous cell carcinomas of the penis with lichen sclerosis. Analysis of 159 Italian cases of lichen sclerosis revealed 7 cases of penile squamous cell carcinoma and 7 cases of penile intraepithelial neoplasia.[175] In a Belgian study of 76 archived penile cancer specimens with ~71% positivity for HPV DNA, the presence of lichen sclerosis was similar in HPV+ and HPV− specimens ($P = 0.944$). The high prevalence of HPV in the population may have limited the power of the study to detect a statistically significant difference.[176]

Human papillomavirus is a DNA virus with >100 known genotypes. Viral infections are usually transient with most HPV infections failing to initiate premalignant lesions; however, morphologically low-grade lesions (e.g., mild dysplasia, condyloma) develop when the squamous epithelium maintains virion production. Precancerous lesions (e.g., penile intraepithelial neoplasia) result from the incorporation of the viral genome into the host genome producing overexpression of oncogenes (i.e., E5, E6, E7) that cause cell proliferation and malignant transformation. Most invasive hrHPV+ penile squamous cell carcinomas probably develop from undifferentiated hrHPV+ penile intraepithelial neoplasia that stains positive for p16INK4a.[177] In HPV-positive penile squamous cell carcinomas, the viral oncogenes E6 and E7 bind to tumor suppressor genes producing p53 and pRb (p107, p130), respectively; subsequent genetic changes enhance uncontrolled cell growth and impair DNA repair, resulting in genome instability, progression to invasive squamous cell carcinoma, and overexpression of cyclin-dependent kinase inhibitor p16INK4A. E5 enhances metastasis by upregulating epidermal growth factor receptor (EGFR) that reduces E-cadherin expression and increases matrix metalloproteinase with subsequent reduction in cell-to-cell adhesion.[178]

HPV DNA appears in up to 100% of the premalignant lesions, including penile intraepithelial neoplasia (carcinoma *in situ*) that contains Bowen's disease (keratinized cutaneous lesions of the shaft) and erythroplasia of Queyrat (lesions of the glans or inner prepuce).[179] Lichen sclerosis and lichen planus are penile dermatoses associated with erythroplasia of Queyrat. In a collection of 12 cases of condyloma, 30 cases of dysplasia, and 155 cases of penile squamous cell cancer from US and Paraguay medical institutions, the presence of HPV DNA as measured by the SPF10 HPV polymerase chain reaction assay was as follows: condyloma, 100%; dysplasia (penile intraepithelial neoplasia), 90%; and squamous cell carcinoma, 42%.[180] Table 56.3 displays the major HPV genotypes associated with HPV+ specimens.

HPV genotypes are classified as low-risk (lr) or high-risk (hr) based on their association with cervical malignancy. Benign penile lesions are related to the low-risk HPV genotypes (6, 11), whereas squamous cell carcinomas are associated with the high-risk genotypes (16, 18). Immunosuppressed patients have a higher risk of dysplasia and progression to carcinomas (i.e., 2–3 fold) compared with men in the general population as a result of higher viral loads and higher prevalence of coinfections in their benign lesions.[179] Most HPV infections clear within 12 months.

TABLE 56.3. Incidence of major human papillomavirus (HPV) genotypes reported in samples of 60 HPV-positive squamous cell carcinoma genotypes, 27 dysplasia cases (penile intraepithelial neoplasia), and 12 penile condyloma. (Adapted from Christodoulidou et al.).[166]

HPV$^+$ Tissue Type	Number of Cases	HPV6 (%)	HPV11 (%)	HPV16 (%)	HPV18 (%)
Condyloma	12	75	16.7	8.3	0
Dysplasia (penile intraepithelial neoplasia)	27	22.2	3.7	40.7	0
Squamous cell carcinoma	60	8.3	0	60.0	3.3

EXPOSURE

The two most important risk factors for developing penile cancer are a history of phimosis (chronic penile inflammatory conditions) and human papilloma virus infection (HPV), with a substantially reduced risk associated with neonatal circumcision. The association of penile cancer with other risk factors is much weaker and less consistent, including smoking, socioeconomic status, and penile trauma.

Occupation

Although data are limited, no evidence causally associates specific occupations or chemicals with penile cancer.

Lifestyle

Phimosis/Circumcision

A history of phimosis is strongly associated with increased penile cancer risks, whereas neonatal circumcision is strongly associated with a reduced penile cancer risk. In a population-based case-control study of 62 men with invasive penile carcinoma, the penile cancer risk was significantly elevated in men with a history of phimosis (adjusted OR = 7.4, 95% CI: 3.7–15.0) compared with men without a history of phimosis.[181] The odds ratio was adjusted for age, cigarette smoking, lifetime sex partners. Penile cancer occurs predominantly in uncircumcised men, whereas these tumors rarely develop among groups practicing routine circumcision during the neonatal or childhood periods. Uncircumcised men also have a higher prevalence of high-risk, oncogenic HPV infection (HPV 16/18) in the glans/corona than circumcised men.[182] A retrospective case-ascertainment study reviewed clinical information on 89 patients with invasive penile carcinoma and 118 with penile intraepithelial neoplasia diagnosed from 1954–1997.[183] Only 2 (2.3%) of the 89 patients with penile carcinoma were circumcised at birth and 87 (97.7%) were uncircumcised, whereas 16 (15.7%) of the 118 cases with penile intraepithelial neoplasia had neonatal circumcisions. In a population-based, case-control study of 110 men with penile cancer and 355 age-matched controls in western Washington state and British Columbia, the age- and penile trauma-adjusted odds ratio for penile cancer in uncircumcised men was 3.2 (95% CI: 1.8–5.7, n = 69 cases) compared with men circumcised at birth.[184] Little evidence associates adult circumcision with reduced penile cancer risks.[185] In a meta-analysis of three case-control studies, the summary OR was significantly reduced for circumcised men (OR = 0.33, 95% CI: 0.13–0.83, I^2 = 55%, $P_{\text{heterogeneity}}$ = 0.11) compared with uncircumcised men; however, there was moderate homogeneity.[186] Adult circumcisions were not associated with a protective effect (summary OR = 2.71, 95% CI: 0.93–7.94).

Socioeconomic Status

Indicators of socioeconomic status include education, income, marital status, and the number of household individuals. Evaluation of the impact of socioeconomic status on penile cancer incidence is complicated by the confounding associated with social differences in lifestyle and health behavior. In general, the penile cancer risks comparing socioeconomic levels are relatively weak and inconsistent, despite the differences in penile cancer risks between developed and developing countries. In a Swedish population-based register study of 1,676 cases and 9,872 randomly chosen controls, the penile cancer risk in men with grade school education compared with men with some college education was not statistically different (adjusted OR = 1.05, 95% CI: 0.91–1.22).[187] Similarly, comparing penile cancer risks in the lower and upper 50% of incomes was not statistically different (adjusted OR = 1.04, 95% CI: 0.93–1.17). Smoking history was not available.

Smoking

Data associated with smoking and penile cancer primarily involve case-control studies with the usual issues of recall bias, imprecise risk estimates, and confounding. In a Los Angeles-based case-control study of 100 matched pairs, the adjusted OR for penile cancer in current smokers of >20 cigarettes/day was 4.0 (1.2–21, n = 26 cases/12 controls, P = 0.006) compared with never-smokers.[188] The adjusted odds ratios comparing ex-smokers and current smokers of <20 cigarettes/day with never-smokers were not statistically different. In a population-based case-control study of 62 invasive penile cancer patients and 671 controls, the adjusted odds ratio (age, number of sex partners) of penile cancer in current smokers was significantly elevated (OR = 4.5, 95% CI: 2.0–10.1, n = 28 cases/9 controls), but not in former smokers (OR = 1.8, 95% CI: 0.8–3.9, n = 25 cases/9 controls) compared with never-smokers.[181] The response rate for interviews was relatively low (55% for cancer registry patients, 66.4% for eligible controls).

Infection

The risk of HPV infection increases with several factors including concomitant sexually transmitted diseases, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. number of sexual partners, and a history of genital warts. The estimated overall prevalence of HPV in penile cancer is 30–50%, with the most common subtypes being HPV 16 and, to a lesser extent, HPV 18 and HPV6, depending on the geographical location.[166,189] The association of these HPV genotypes with penile high-grade squamous cell intraepithelial neoplasia is relatively stronger than that of penile cancer. In a sample of 85 specimens of these lesions from 25 different countries, HPV DNA appeared in 87% (95% CI: 78.0–93.4%) of the samples.[190] The most common squamous cell carcinoma subtypes associated with HPV infections are warty and basaloid tumors. Penile intraepithelial neoplasia is associated with other HPV genotypes (e.g., 11, 31, 33, 35); however, the risk of malignant transformation with these HPV genotypes is low.[191]

HISTOLOGY

The vast majority of penile cancers are squamous cell carcinomas (i.e., 93–95%).[192] Table 56.4 lists penile cancer subtypes along with their approximate frequencies. Low-risk squamous cell carcinoma subtypes include condylomatous, papillary, verrucous, and warty tumors, whereas the intermediate risk group includes usual, some cases of mixed tumors, and pleomorphic condylomatous (warty) carcinoma.[193] Basaloid tumors, adenosquamous sarcomatoid tumors, and poorly differentiated solid squamous cell carcinomas are high-risk tumors. Basaloid and warty squamous cell carcinoma subtypes are closely associated with HPV with the former being the most common HPV-related penile carcinoma. These tumors typically present at relatively early ages (e.g., in the 50s).[189,194] Classification of premalignant penile intraepithelial neoplasia (PIN I–III) involves the site, appearance, and risk of progression to invasive penile cancer. The most likely PIN to progress to invasive cancer (i.e., ~30%), based on small, retrospective case series, is erythroplasia of Queyrat (PIN III, non-keratinizing carcinoma *in situ*), which presents as velvety red plaques on the glans penis or inner prepuce.[185] HPV-independent tumors arise from differentiated rather than undifferentiated penile intraepithelial neoplasia; the latter is associated with HPV+ penile squamous cell carcinomas.[172]

HOST SUSCEPTIBILITY

Family history or specific genetic anomalies are not recognized risk factors for penile cancer.

TABLE 56.4. Approximate relative frequency of histological subtypes of penile cancer. (Adapted from Arya et al.).[185]

Histological Subtype	Histological Type	Relative Frequency (%)
Usual type	Squamous cell carcinoma	60–70
Papillary	Squamous cell carcinoma	7
Condylomatous	Squamous cell carcinoma	7
Basaloid	Squamous cell carcinoma	4–10
Verrucous	Squamous cell carcinoma	7
Sarcomatoid	Squamous cell carcinoma	1–4
Malignant melanoma	Other	2
Basal cell carcinoma	Other	2
Extra-mammary Paget's disease	Other	<1
Sarcoma	Other	<1

CLINICAL FEATURES

The incidence of penile cancer increases with age; the peak incidence occurs between 50 and 70 years, with <20% presenting at an age under 40 years and a median age at diagnosis of ~65–69 years depending on the histological subtype.[177] In a US study, the penile cancer rate increased with age among all ethnic groups; however, Puerto Rican men had a substantially higher penile cancer incidence (standardized rate ratio = 3.33, 95% CI: 2.80–3.95) compared with non-Hispanic whites and presented at an earlier age than other ethnic groups. Most men present with a penile lump or ulcer and less often with an erythematous lesion on the penis; penile bleeding and foreskin discharge are uncommon presentations.[195] Approximately ½ of these lesions appear on the glans and ¼ on the prepuce.

In an analysis of data from 12 European cancer registries (3,297 cases) and the US Surveillance, Epidemiology, and End Results (SEER) Program (1,820 cases), the 5-year relative survival of penile cancer patients from 1985–2007 increased from 65% to 70% in Europe and decreased from 72%–63% in the United States.[196] Trends in age-specific, 5-year relative survival were not statistically different for this time period in Europe or the United States. In a French study of long-term survival rates for penile cancer, the 5-year survival rate was 65% compared with 59% for 10-year survival; little change in the rates occurred over the previous several decades.[197] France has a relatively low rate of HPV infections.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

In general, 5-year survival is higher for HPV-positive than HPV-negative patients;[198] however, the 5-year survival rates for HPV+ penile cancer are the lowest among all HPV-related cancers (i.e., anal, rectal, vulvar, vaginal, cervical, oropharyngeal).[199] In multivariate analysis of specimens from 171 patients with penile carcinoma, HPV status was an independent predictor for disease-specific mortality ($P = 0.01$) with a hazard ratio of 0.14 (95% CI: 0.03–0.63).[200] Approximately 30% ($n = 50$) of the tumors had high-risk HPV DNA, primarily HPV16. Disease-specific 5-year survival was 78% in the high-risk HPV-negative group compared with 93% in the high-risk HPV-positive group. The presence of inguinal lymph node involvement is the most important prognostic factor reducing overall 5-year survival to ~50% with extension to pelvic nodes decreasing survival to ≪20%.[201] Approximately 20–25% of penile cancer patients initially diagnosed with node negative disease (cN0) will develop metastases.[202]

Chapter 57

FEMALE REPRODUCTIVE TRACT

Globally, breast cancer is the most common cancer and the leading cause of cancer-related deaths in women. Other less common tumors of the female reproductive tract include those of the uterus and ovary. Table 57.1 lists the strength of the human evidence (i.e., sufficient, limited) for carcinogenic agents and processes associated with female reproductive tract cancers based on evaluations by the International Agency for Research on Cancer (IARC). The carcinogenic potential of these agents/processes varies within their respective categories. The risks for a person are determined by individual risk factors (e.g., dose, exposure duration, host susceptibility, cocarcinogens).

FEMALE BREAST

The incidence of female breast cancer increases with age; between 2007–2017, the estimated global breast cancer incident rates increased by 4.5% (95% CI: 0.7–7.5).[2] In the United States, ~64,000 new breast cancer cases occur annually in US women, resulting in 1 in 8 US women developing breast cancer in their lifetime.[3] Overall, breast cancer is the second leading cause of cancer-related death in US women, accounting for ~40,000 deaths annually. For US women between 29–59 years of age, breast cancer is the leading cancer-related cause of death. From 1989–2012, US breast cancer mortality rates decreased by 36%. Although the overall breast cancer incidence is slightly greater in Caucasian than African-American women in the United States, breast cancer incidence is greater in African-American than Caucasian women of <45 years of age.[3] The overall incidence of triple-negative breast cancer is almost twice as high in black, non-Hispanic women than in Caucasian women at all ages, regardless of their socioeconomic group, and particularly in young black women. The hazard ratio for triple-negative breast cancer in black women compared with Caucasian women of <35 years of age in the Breast Cancer Surveillance Consortium cohort was 3.05 (95% CI: 2.52–3.70).[4] Prognosis of this histological subtype is much worse than the more common estrogen-receptor-positive subtypes (luminal A/B).[5] The breast cancer incidence rates vary by ~4-fold between countries worldwide, ranging from the lowest incidence rates in women from lower-income countries in Eastern Asia and Middle Africa (~27/100,000) to the highest rates (>100/100,000) in US white women living in Los Angeles and San Francisco.[6,7] About 2,500 cases of male breast cancer occur in the United States annually.[3]

CARCINOGENESIS

Several signaling pathways (Wnt/β-catenin, PI3K/ALT/mTOR) along with estrogen receptors and human epidermal growth factor receptor 2 gene, *HER2* (now known as erb-b2 receptor tyrosine kinase 2 gene, *ERBB2*), control normal breast development including stem-cell proliferation, cell differentiation, cell motility/adhesion, and cell death. PI3K/ALT/mTOR pathway activates critical downstream mediators (Akt, mTOR) that promote cell growth, cell-cycle progression,

TABLE 57.1. International Agency for Research on Cancer (IARC) classification of female reproductive tract cancer sites and associated carcinogens by sufficient and limited evidence of human carcinogenicity. (Adapted from International Agency for Research on Cancer, IARC).[1]

Anatomical Site	Carcinogens with *Sufficient* Human Evidence (Group 1)	Carcinogens with *Limited* Human Evidence (Groups 2A or 2B)
Breast	Alcoholic beverages, diethylstilbestrol, estrogen–progesterone contraceptives, estrogen–progesterone menopausal therapy, X- and γ-radiation	Dieldrin/aldrin metabolized to dieldrin, digoxin, estrogen postmenopausal therapy, ethylene oxide, night shiftwork (disruption in circadian rhythms), polychlorinated biphenyls, tobacco smoking
Vulva	Human papillomavirus type 16	Human immunodeficiency virus type 1 human papillomavirus types 18, 33
Vagina	Diethylstilbestrol (exposure *in utero*), human papillomavirus type 16	Human immunodeficiency virus type 1
Uterine cervix	Diethylstilbestrol (exposure *in utero*), estrogen–progestogen contraceptives, human immunodeficiency virus type 1, human papillomavirus types 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, tobacco smoking	Human papillomavirus types 26, 53, 66, 67, 68, 70, 73, 82
Endometrium	Estrogen menopausal therapy, estrogen–progestogen menopausal therapy, tamoxifen	Diethylstilbestrol
Ovary	Asbestos (all forms), estrogen menopausal therapy, tobacco smoking	Talc-based body powder (perineal use), X- and γ-ray radiation

anti-apoptosis, and translation. This signaling pathway is the most frequently enhanced oncogenic pathway in breast tumors, particularly in luminal type A and B breast tumors.[8] These oncogenic PI3K pathway mutations probably dedifferentiate luminal or basal mammary progenitor cells, resulting in multi-lineage potential.[9] Epigenetic regulators (e.g., DNA methylation) and noncoding RNA also promote estrogen signaling in luminal breast tumors, breast cancer proliferation, and metastasis, particularly in triple-negative (*BRCA1/2-*, *HER2-*) breast cancer.[10] BRCA1 promoter methylation downregulates the transcription of the *BRCA1* gene. About 25% of all triple-negative breast cancer patients have BRCA1 promoter methylation. In a genome-wide transcriptional survey of 995 breast tissue samples, breast tumors contained 215 aberrantly expressed long-noncoding RNA (lncRNAs).[11] Consistent with genomic instability present in triple-negative breast cancer tumors, the coding and noncoding mutation rates are higher in ER-negative/HER2-negative tumors than in other molecular breast cancer subtypes.[12]

Estrogen receptors (ERs) comprise membrane estrogen receptors (mostly G protein-coupled receptors) and nuclear estrogen receptors (ERα, ERβ). Approximately 70–75% of invasive breast tumor cells express ERα. The expression of this steroid hormone receptor and transcription factor activates oncogenic growth pathways in breast cancer cells. ERβ partially overlaps ERα in the tissue expression profile, declining as the tumor progresses.[13] *BRCA1* is a tumor suppressor gene that partially inhibits ERα signaling involved in complex biological and pathological processes (i.e., substantial cross-talk between multiple signaling pathways), including cell proliferation via activation of cyclin-dependent kinases (CDK4/6). Tamoxifen is an ERα antagonist. HER2 is a receptor tyrosine kinase affecting various pathways (e.g., mitogen-activated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. protein kinase, MAPK; phosphatidylinositol 4,5 bisphosphate 3-kinase, PI3K) involved with tumor-cell proliferation, cancer progression, and metastasis. The canonical Wnt/β-catenin signaling pathway produces proteins that affect embryonic induction, cell polarity, and cell differentiation. Downregulation of this pathway promotes triple-negative breast cancer and basal-like tumors targeting stem/progenitor cells and enhancing metastasis leading to poor prognoses.[14] Metastatic breast tumors are highly heterogeneous, with the most distant metastases acquiring driver mutations not seen in the primary breast tumor. In a meta-analysis of 48 mostly retrospective articles evaluating discordance in ER, PR, and HER2 status between primary and metastatic breast tumors, the discordance rates were 20% (95% CI: 16–35%, I^2 = 91%) for estrogen receptors, 33% (95% CI: 29–38%, I^2 = 79%) for progesterone receptors, and 8% (95% CI: 6–10%, I^2 = 77%) for human epidermal growth factor receptor 2.[15] The lack of similarity in discordance rates between these three tumor biomarkers suggests clonal genome evolution contributes to the differences as well as technical variation between studies.

EXPOSURE

Breast cancer is a biologically and molecularly heterogeneous disease involving many distinct histological types; multiple variables influence the occurrence of the tumor subtypes including lifestyle risk factors, reproductive cycle, breast density, family history, tissue origin (lobule, duct), and genetic predisposition (e.g., *BRCA1/BRCA2*, *TP53*).[16] Some risk factors are not amenable to modification, including family history, age, several reproductive factors, and breast density, whereas other risk factors of varying magnitude can be altered, including obesity in postmenopausal women, alcohol consumption, and combination menopausal hormone therapy. Some breast cancer risk factors reflect total lifetime exposure to bioavailable estrogens, including early menarche, late menopause, postmenopausal obesity, late conception of firstborn child, nulliparity, breastfeeding duration, and postmenopausal estrogen replacement therapy.[17] Age, menopausal status, and estrogen-receptor status interact to alter some strong risk factors (e.g., obesity, breast density).

Most information regarding risk factors is derived from self-reported questionnaires, usually obtained in retrospective case-control studies; consequently, recall and selection bias along with misclassification complicate the determination of precise risk estimates. The strength of these risk factors is relatively small including early menarche (<20%) and menarche ≥55 years (<12%), breastfeeding (<10%), and parity (<10–15%), depending on several factors including histological type and age. Lobular carcinomas are more variable and strongly associated with exposure to female hormones than ductal carcinomas; consequently, lobular carcinomas are more strongly associated with early menarche, later-stage first birth, and late menopause than ductal carcinomas.[18] In the 40–49-year-old age group, race and ethnicity are not risk factors for breast cancer using Caucasian women as the reference group.[19]

Using data from the first National Health and Nutrition Examination Survey (NHANES I) Epidemiologic Follow-up Study (NHEFS), a cohort of 7,508 women was surveyed in the early 1970s and followed through 1987.[20] Well-established risk factors accounted for ~47% (95% CI: 17–77%) of breast cancer cases in the NHEFS cohort and ~41% (95% CI: 2–80%) in the US population. Population attributable risk (PAR) estimates suggest these risk factors included later age at first birth and nulliparity (PAR = 29.5%, 95% CI: 5.6–53.3%), higher income (PAR = 18.9%, 95% CI: −4.3 to 42.1%), and family history of breast cancer (PAR = 9.1%, 95% CI: 3.0–15.2%).

Environment/Workplace

Data confirming a causal link between chemical exposures in the environment or workplace and breast cancer are limited with no definitive occupational or environmental breast carcinogens.[21] In a large prospective study of US adults, 1,780 cases of fatal breast cancer occurred in the cohort after a 9-year follow-up.[22] Little variability in breast cancer mortality by 14 broad occupational and 16 more narrowly defined occupational titles occurred based on self-reports on current and former job titles, including women working ≥10 years in their occupation.

Chemicals

In *in vitro* and experimental animal studies, some organochlorine compounds act as estrogen agonists or androgen antagonists leading to concern that these chemicals potentially could be cumulative environmental endocrine disrupters that produce increased breast cancer risks, particularly for early, high-dose exposures. Potential chemical breast carcinogens include chlorinated solvents,[23] chlorinated hydrocarbon pesticides,[24] and polychlorinated biphenyls because of their potential binding to hormonal receptors in breast tissue. The Malmö Diet and Cancer Study collected baseline information on 16,084 postmenopausal Swedish women, including work history, lifestyle, and reproductive factors. The Scandinavian job-exposure matrices were

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

used to estimate chemical exposures to 15 categories including organic solvents, aliphatic/alicyclic hydrocarbon solvents, aromatic hydrocarbon solvents, benzene, toluene, chlorinated hydrocarbon solvents, methylene chloride, 1,1,1-trichloroethane, other organic solvents, pesticides, fumes, polycyclic aromatic hydrocarbons, diesel exhaust, and oil mist.[25] The reported breast cancer risk was elevated in postmenopausal women with any chemical exposure (aHR = 1.26, 95% CI: 1.02–1.54) compared with no chemical exposure. The risk increased with duration of exposure ($P_{trend} = 0.01$); however, none of the breast cancer risks comparing the highest and lowest cumulative exposure groups in the 15 individual chemical categories reached statistical significance or demonstrated a significant trend between low and high cumulative exposure groups.

Organochlorines are a diverse group of synthetic chemicals that include polychlorinated biphenyls (PCBs), dioxins, and organochlorine pesticides (e.g., dichlorodiphenyl-trichloroethane, DDT, lindane, hexachlorobenzene). Although several cross-sectional[26] and nested case-control[27] studies reported statistically significant, albeit imprecise, associations between DDT, DDE, or chlordane concentrations and breast cancer incidence, most studies[28,29,30] found no clear causal association between these chemicals and breast cancer risks, including phenoxyl herbicides.[31,32]

A prospective case-control study of 148 women with breast cancer did not detect elevated DDE [1,1-dichloro-2,2-bis(*p*-chlorophenyl) ethene] concentration, the main DDT metabolite, or polychlorinated biphenyls (PCBs) in blood samples drawn within 6 months of breast cancer diagnosis.[33] A case-control study of 120 Mexican women with breast cancer and 126 controls from Mexico City reported a statistically significant increased adjusted odds ratio for breast cancer comparing the highest and lowest quartiles of serum DDE concentrations (OR = 3.81, 95% CI: 1.14–12.80, $P_{trend} = 0.02$); however, the adjusted odds ratios were wide and most of the confidence intervals contained one.[34] The breast cancer risk did not correlate with serum DDT concentrations. In a case-control study of 304 Connecticut women with breast cancer and 186 controls aged 40–79, there was no statistically significant association between breast cancer and the concentrations of any PCB congeners tested.[35] A 2004 meta-analysis[36] and an updated 2013 meta-analysis[37] concluded that the existing information does not support the hypothesis that exposure to DDT/DDE increases human breast cancer risks. The summary odds ratios were slightly elevated but not statistically significant in the latter meta-analysis for both DDE (summary OR = 1.05; 95% CI: 0.93–1.18) and DDT (summary OR = 1.02; 95% CI: 0.92–1.13).

The IARC classifies the epidemiological data for an association between breast cancer and dieldrin, polychlorinated biphenyls, and ethylene oxide as limited. A population-based case-control study of 646 breast cancer cases and 429 controls conducted in Long Island, New York, did not detect a substantial elevation of breast cancer comparing the highest and lowest quintiles for several chemicals, including chlordane (OR = 0.98, 95% CI: 0.62–1.55), dieldrin (OR = 1.37, 95% CI: 0.69–2.72), or 4 PCBs (OR = 0.83, 95% CI: 0.54–1.29).[32] No dose-response relationships were apparent between the chemicals and breast cancer risks. In a cohort of 7,576 women employed for at least 1 year and exposed an average of 10.7 years while working in commercial sterilization facilities, the standardized incidence ratio for breast cancer in the top quintile of cumulative ethylene oxide exposure with a 15-year lag was 1.27 (95% CI: 0.94–1.69, $P_{trend} = 0.002$).[38] A weight-of-evidence evaluation by the US EPA including epidemiological, laboratory animal, and mechanistic studies concluded ethylene oxide is carcinogenic in humans with the strongest human evidence for female breast and lymphoid cancers.[39] Little data support an association between male breast cancer and chemical exposures. A hypothesis-generating case-control study of male breast cancer, based on job-exposure matrices, detected elevated odds ratios for individuals working with motor vehicle manufacturing, blast furnaces, steel manufacturing, and rolling mills;[40] however, excesses of breast cancer following exposure to specific chemicals, including pesticides, organic solvents, and polycyclic aromatic hydrocarbons, were not identified.

Radiation

Breast cancer is a well-recognized complication of ionizing radiation exposure that varies with dose, age at exposure, and gender. The IARC lists X-ray and γ-radiation as human breast carcinogens (Group 1) based primarily on the Life Span Study of Japanese survivors of the Nagasaki and Hiroshima bombings, as well as early studies on intensive therapeutic radiation (e.g., scoliosis, tuberculosis), particularly in teenagers or young women with developing breasts.[41] Data from the Life Span Study of the Japanese atomic bomb survivors indicate exposure to local ionizing radiation of >200 mGy increases breast cancer risks.[42,43] A Finnish study attributed 1.7% of female breast cancer cases to occupation[44] compared with 4.6% of female breast cancer deaths in a British study primarily related to shift work and radiation.[45] Neither

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cosmic radiation nor circadian rhythm disruption explain the elevated breast cancer risk in female flight attendants. Using self-reported questionnaires and dividing the exposed group into low, medium, and high occupational ionizing radiation exposure groups, a Western Australian population-based case-control study of 1,205 incidence breast cancer cases and 1,789 controls detected a weak, statistically nonsignificant association between breast cancer and occupational exposure to ionizing radiation.[46] Compared with unexposed controls, the OR for all categories of ionizing radiation exposure was 1.16 (95% CI: 0.86–1.57, $P_{trend} = 0.18$) without evidence of a dose-response relationship. The odds ratio was higher for the few premenopausal women with human epidermal growth factor receptor 2-positive breast cancer (OR = 2.57, 95% CI: 1.09–6.03, $n = 8$). Studies of women undergoing fluoroscopy for tuberculosis or radiation treatment for postpartum mastitis during the 1950s and 1960s indicate an ~2-fold increase in breast cancer risks.[47,48] Breast cancer was more common in women irradiated under the age of 40 years than in older women. An incidence survey among atomic bomb survivors identified a strongly linear radiation dose-response in 807 breast cancer cases.[41] The highest dose-specific excess relative risk (ERR) occurred among survivors that were <20 years of age at the time of the bombings.[49] Among this subset of young survivors at the time of the bombing, there was a 13-fold ERR at 1 Sv for breast cancer occurring before age 35 years compared with a 2-fold excess for breast cancer appearing after age 35 years.

Electromagnetic Fields

Exposure to electromagnetic fields occurs in occupational settings, residences, and electric blanket use (i.e., primarily on the body). The association of electromagnetic fields with breast cancer has been studied since the 1980s, following postulation of the theory that magnetic fields suppress melatonin production similar to night-shift work, resulting in the inhibition of the protective property of melatonin on breast cancer.[50] Some early experimental and epidemiological studies provided some support for this hypothesis; however, these studies had limited design and/or statistical power, with most of the positive results confined to subgroups, particularly premenopausal women with ER-positive tumors.[51,52] A population-based case-control study, which enrolled 6,213 breast cancer cases and 7,390 age-matched controls, with an industrial hygienist classifying electromagnetic field (EMF) exposure as background, low, medium, or high. Compared with referents with background EMF exposure, the breast cancer risk in the highly exposed group was slightly elevated but statistically nonsignificant (OR = 1.16, 95% CI: 0.90–1.50).[53] Large epidemiological studies with improved design and statistical power have not confirmed the earlier studies. A World Health Organization risk assessment concluded the evidence from experimental and epidemiological studies was sufficient to confirm that extremely low-frequency magnetic fields (50–60 Hz) do not cause breast cancer.[54] A meta-analysis of 15 case-control studies including 24,338 cases and 60,628 controls demonstrated no significant association between ELF magnetic fields and breast cancer (summary OR = 0.988, 95% CI: 0.898–1.088, $I^2 = 75.8\%$) with substantial heterogeneity.[55] Subgroup analyses detected no significant effect of menopausal status or estrogen-receptor status on the effect of ELF exposure on breast cancer rates. A Chinese nested case-control study of 1,687 incident breast cancer cases and 4,702 controls from a cohort of 267,400 female textile workers demonstrated no significant association between cumulative ELF magnetic fields and overall breast cancer risk comparing the highest and lowest quartiles of cumulative exposure (HR = 1.03, 95% CI: 0.87–1.21).[56]

Reproductive Cycle

Reproductive risks modestly associated with increased breast cancer risks include early menarche (<12 years), late menopause (>55 years), late conception of the firstborn child (i.e., >30 years), and nulliparity, whereas multiple pregnancies and prolonged breastfeeding duration (>1–2 years) are associated with slight reductions in breast cancer risks.[19] Epidemiological studies do not consistently associate alterations in breastfeeding and parity with the risk of specific histological subtypes.[18] In addition to lengthening the duration of estrogen effects (e.g., early menarche, late menopause), analysis of data from 85 epidemiological studies indicates breast cancer risks increase more with estrogen-receptor-positive than estrogen-receptor-negative disease and more for invasive lobular than invasive ductal histological subtypes.[57] Substantial heterogeneity complicates the determination of precise breast cancer risks among these risk factors. In a meta-analysis of 42 case-control and 5 cohort studies, the overall breast cancer risk decreased modestly with increasing parity and breastfeeding duration.[58] Compared with controls, women with breast cancer had fewer births (2.2 vs. 2.6) and shorter breastfeeding duration (9.8 vs. 15.6 months). The summary breast cancer relative risk decreased by 7.0% (99% CI: 5.0–9.0; $P < 0.0001$) for each birth and 4.3% (99% CI: 2.9–5.8; $P < 0.0001$) for every 12 months

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of breastfeeding. The effects of parity and breastfeeding on breast cancer risks differ between mutation carriers of *BRCA1* and *BRCA2* genes. Analysis of data from a large international cohort of *BRCA1/2* carriers indicated *overall* parity was associated with increased breast cancer risk for *BRCA2* mutation carriers (HR = 1.33, 95% CI: 1.05–1.69) but not for *BRCA1* carriers (HR = 0.99, 95% CI: 0.83–1.18) compared with nulliparous women.[59] Compared with uniparous *BRCA1* carriers, multiparous *BRCA1* carriers had lower breast cancer risks (HR = 0.50, 95% CI 0.40–0.63, $n = \geq 4$ pregnancies, $P_{trend} < 0.0001$). Duration of breastfeeding was associated with reduced breast cancer risks in *BRCA1* mutation carriers ($HR_{>24\ months} = 0.66$, 95% CI: 0.50–0.87, $P_{trend} = 0.0003$) but marginally in *BRCA2* mutation carriers ($HR_{>24\ months} = 0.74$, 95% CI: 0.55–1.00, $P_{trend} = 0.01$).

The median age at menarche for 946 US girls enrolled at 6–8 years of age in a longitudinal observational study was 12.25 years.[60] Body mass index had a greater effect on age at menarche than did race or ethnicity. In a meta-analysis of primarily case-control studies using menarche at 13 years as the reference group for 40–49-year-old women, the risk ratio for menarche of ≥15 years was 0.87 (95% CI: 0.78–0.97, $I^2 = 0\%$, $n = 9$ studies).[19] Although substantial heterogeneity existed in the studies, the reported breast cancer risk for parous women in this age group using nulliparous women as the reference group was 1.16 (95% CI: 1.04–1.26, $I^2 = 80.3\%$, $n = 14$ case-control/3 cohort studies). Multiple births modestly decreased the breast cancer risk, whereas the age at first birth of ≥30 years modestly increased the risk.

Lifestyle

Alcohol

The IARC classifies alcohol use as a breast carcinogen (Group 1) with the risk depending on the amount of chronic use. Alcohol consumption is the most consistent dietary risk factor for breast cancer;[61] heavy alcohol consumption (≥3 drinks/day) is probably a risk factor for breast cancer with an increased risk up to ~40–60% in heavy drinkers.[42,62] In a collaborative reanalysis of 53 epidemiological studies on breast cancer, the pooled RR for breast cancer in women consuming ≥45 g ethanol/day or ≥3 drinks/day was 1.46 (95% CI: 1.33–1.61) compared with nondrinking controls.[63] Controversy remains regarding the presence of a threshold for ethanol consumption and breast cancer risks; however, the breast cancer risk for drinking one alcoholic drink daily is small. A meta-analysis of 113 papers on light ethanol drinking (≤1 drink/day) and breast cancer suggested a modest effect of ethanol on breast cancer rates (random effect summary RR = 1.04, 95% CI: 1.02–1.07, $I^2 = 64\%$) with moderate heterogeneity among studies.[64] The adjusted relative risk of breast cancer in women consuming 3–6 drinks/week in the Nurses' Health Study was 1.15 (95% CI: 1.06–1.24) compared with nondrinking women with higher risks in binge drinking than more frequent drinking.[61] The consumption of <3 drinks (0.1–4.9 g)/week was not associated with a statistically significant increase in breast cancer risk (RR = 1.06, 95% CI: 0.99–1.12). In a meta-analysis of 3 studies comparing 40–49-year-old women consuming ≥2 alcohol drinks daily with nondrinkers, the breast cancer risk was not statistically different between the two groups (RR = 1.24, 95% CI: 0.87–1.78, $I^2 = 38.5\%$).[19] The mechanism of ethanol-mediated breast cancer is unclear; however, the mechanism probably involves more than increased estrogen concentrations associated with chronic ethanol consumption (e.g., acetaldehyde genotoxicity, oxidative stress/DNA damage, epigenetic alteration of DNA expression). Chronic ethanol consumption increases the risk of excessive breast density. In a meta-analysis of three studies on the effect of alcohol on breast cancer risks that quantitated breast density, the random effects summary RR was 1.81 (95% CI: 1.07–3.04, $I^2 = 80.13\%$) with very substantial heterogeneity between the studies.[65]

Tobacco Smoke

Although tobacco smoke is a well-established carcinogen, tobacco smoking has a weak association with breast cancer risks.[66] In a meta-analysis of 1 cohort and 11 case-control studies comparing ever- and never-smokers in the 40–49-year-old age group, the breast cancer risk for smokers was 1.05 (95% CI: 0.98–1.13, $I^2 = 31\%$) with mild heterogeneity.[19] This study did not detect statistically significant breast cancer risks in former or current smokers using never-smokers as the reference group. In a prospective cohort study of 3,920 *BRCA1* and *BRCA2* mutation carriers evaluated biannually with questionnaires, the adjusted RR for comparing ever- and never-smokers was elevated but not statistically significant (aRR = 1.16, 95% CI: 0.96–1.41).[67] The breast cancer risk was significantly elevated in the highest cumulative smoking group compared with never-smokers (adjusted RR = 1.33, 95% CI: 1.02–1.75); however, the trend for the three cumulative smoking groups did not display a statistically significant dose-response ($P_{trend} = 0.08$). The association between tobacco smoking and breast cancer did not differ by age at diagnosis or specific *BRCA* subtype. Environmental tobacco smoke exposure also

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

adds little to breast cancer risks in nonsmoking women consistent with the minimal breast cancer risks from active tobacco smoking. In a meta-analysis of 47 mostly case-control studies comparing women with a spouse who is ever-smoking and a nonsmoking spouse, the estimated random-effects RR was weak but statistically significant (RR = 1.15, 95% CI: 1.07–1.23), with considerable evidence of heterogeneity.[68] However, the association between environmental tobacco smoke and breast cancer in prospective studies was statistically nonsignificant (RR = 1.003, 95% CI: 0.96–1.05) along with a lack of evidence of increased breast cancer risks for childhood or occupational environmental tobacco smoke exposures.

Obesity

The association between obesity and breast cancer risk is complex and inconsistent. Generally, breast cancer risk increases in overweight/obese postmenopausal women, whereas the risk is less in premenopausal overweight/obese women. Prior to menopause, the ovaries are the major estrogen source, whereas the fat tissues are the primary estrogen source postmenopause. Often, overweight premenopausal women have anovulatory cycles with reduced female hormone synthesis. Consequently, estrogen concentrations are higher in menopausal obese women and lower in premenopausal obese women than in less heavy women. Additionally, circulating metabolic and inflammatory factors (e.g., insulin, triglycerides, C-reactive protein, interleukin 6, leptin) are higher in obese postmenopausal women compared with normal-weight women.[69] In a meta-analysis of 9 case-control and 9 cohort studies using $<25\,kg/m^2$ ($\leq$ normal weight) as the reference group, the breast cancer risk decreased in overweight women aged 40–49 years (RR = 0.86, 95% CI: 0.82–0.90, $I^2 = 0.0\%$) and obese women (RR = 0.74, 95% CI: 0.68–0.81, $I^2 = 1.3\%$).[19] These values were consistent with their analysis of Breast Cancer Surveillance Consortium data with the exception that the latter data on breast cancer risk in obese women were not statistically significant (RR = 0.92, 95% CI: 0.84–1.01). BMI is positively associated with postmenopausal breast cancer with inconsistent results on the modification of this risk by using hormone replacement therapy. In the Women's Health Initiative, the hazard ratio of breast cancer for postmenopausal women with a BMI $\geq 35\,kg/m^2$ was 1.58 (95% CI: 1.40–1.79) compared with the reference group (BMI $< 25\,kg/m^2$).[70] The breast cancer risk for estrogen- and progesterone-receptor-positive tumors was higher (HR = 1.86, 95% CI: 1.60–2.17); however, the risk for estrogen-receptor-negative breast cancer was not statistically significant. Measures of central obesity (waist circumference, waist-to-hip ratio) did not modify the breast cancer risk factors. The inverse association between BMI and breast cancer risks in premenopausal women occurs primarily in hormone-receptor-positive rather than hormone-receptor-negative women; the greater magnitude of these effects appears in younger women.[71] The protective effect of higher BMI on premenopausal breast cancer occurs in the general population and *BRCA1/2* mutation carriers.[72]

Physical Activity

The association between breast cancer risk reduction and physical activity is relatively modest and inconsistent with negative and some positive studies, particularly in postmenopausal women;[73,74] however, the mechanism of action (e.g., altered sex hormones, insulin resistance, adipokines, inflammatory markers, body weight) is unclear. Recall bias, selection bias, and random errors are potential complications for determining the relationship between breast cancer risks and physical activity.[75] In a review of 10 studies using a variety of physical activity measures in women aged 40–49 years, none of the studies demonstrated a statistically significant difference in breast cancer risk among the physical activity groups; however, a meta-analysis was not possible because of the wide variation in techniques used to measure physical activity.[19] During 10 years of follow-up in the Nurses' Health Study II, 849 cases of premenopausal breast cancer occurred.[76] Comparing women in the self-reported high group ($\geq$27 metabolic equivalent (MET)-hours/week) with women reporting low physical activity (<3 MET-hours/week) as the reference group, the multivariate-adjusted breast cancer relative risk of the high-physical-activity group was 1.04 (95% CI: 0.82–1.33). In a review of 33 cohort and 40 case-control studies, null results were reported in 26%, 30% had borderline or statistically nonsignificant breast cancer risk reduction, 4% had an increased breast cancer risk, and 40% had a reduction in breast cancer risks.[77] The reduction in breast cancer risk was greater in case-control studies (30%) than cohort studies (20%), with the strongest reduction in postmenopausal women.

Diet

The effect of diet on breast cancer risks is very modest and somewhat inconsistent with the effect of dietary intake difficult to separate from the influence of body weight and other lifestyle and reproductive risk factors.[78] No conclusive evidence confirms an improved prognosis for early-stage breast cancer from changing dietary patterns after the diagnosis of breast cancer.[79]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Study size, measurement error (intake, outcome), variable human genetics, diverse lifestyle factors, and lack of diverse dietary habits limit the ability to measure the relatively small changes in breast cancer risks associated with diet.[80] Some epidemiological evidence suggests adherence to the Mediterranean diet excluding alcohol reduces breast cancer risks in postmenopausal women. In a cohort of 335,062 European women, 9,009 postmenopausal and 1,216 premenopausal primary incident invasive breast cancer tumors occurred during an 11-year follow-up. Using the lowest of three categories as the reference group and Cox proportional hazards regression models to adjust for breast cancer risk factors, the adjusted hazard ratio for breast cancer in the highest tertile of adapted relative Mediterranean diet scores of postmenopausal women was 0.93 (95% CI: 0.87–0.99, P_{trend} = 0.037).[81] The multivariate hazard ratio was not statistically significant in the middle tertile scores in postmenopausal women (HR = 0.98, 95% CI: 0.93–1.04) or in either tertile scores in premenopausal women. In the Women's Health Initiative dietary modification trial of 48,835 healthy postmenopausal women, a modest, statistically significant reduction in dietary fat intake was not associated with a statistically significant reduction in breast cancer (HR = 0.91, 95% CI: 0.83–1.01).[82] Similarly, another primary prevention trial of women of 30–65 years of age with mammographic density of >50% achieved a modest 1.6 kg average reduction in body weight after a mean 10-year follow-up without a statistically significant reduction in breast cancer risks (HR = 1.19, 95% CI: 0.91–1.55).[83]

Most studies on the consumption of vegetables, fruits, vitamins, and/or supplements demonstrate minimal or no reduction in breast cancer risks.[84,85] Some data suggest some subgroups of breast cancer (e.g., estrogen-receptor-negative) may benefit from dietary changes. In the European Prospective Investigation into Cancer and Nutrition (EPIC) cohort, comparison of the highest and lowest quintiles of vegetable intake demonstrated a reduced breast cancer risk (HR = 0.87, 95% CI: 0.80–0.94), mainly in total and hormone-receptor-negative breast cancer risk; however, overall intake of fruits and vegetables did not affect the overall breast cancer risk.[86] Pooled analysis of 993,466 women from 20 prospective, international cohort studies followed for >11–20 years reported a statistically significant reduction of breast cancer risks, comparing the highest and lowest quintiles of total vegetable consumption for ER− (multivariate RR = 0.82, 95% CI: 0.74–0.90, P_{trend} = <0.001, n = 917 cases), but not for estrogen-receptor positive cancer (multivariate RR = 1.04, 95% CI: 0.97–1.11, P_{trend} = 0.06, n = 4,217 cases) tumors.[87] The overall breast cancer risk comparing the highest and lowest quintiles of total fruit and vegetable consumption was not elevated (multivariate RR = 0.98, 95% CI: 0.93–1.02, P_{trend} 0.30, n = 6,981 cases). Total vegetable and fruit consumption also did not affect breast cancer risks. Although most prospective cohort studies on dietary fiber intake and breast cancer report statistically nonsignificant reductions in breast cancer, several meta-analyses suggest that increased self-reported dietary fiber intake modestly reduces breast cancer risk.[88] A meta-analysis of 20 cohort studies, mostly from developed countries, reported that increased dietary fiber content slightly reduced breast cancer risks.[89] The random-effects pooled risk estimate was 0.91 (95% CI: 0.87–0.95, I^2 = 19.6%, $P_{heterogeneity}$ = 0.210).

Medications

Cardiac glycosides are phytoestrogens that are associated with estrogen-sensitive cancers. A systematic review and meta-analysis of observational studies suggested an association between cardiac glycoside use and breast cancer (HR = 1.34, 95% CI: 1.25–1.44, I^2 = 16%, $P_{heterogeneity}$ = 0.30); however, the authors opined that confounding rather than a true causal effect may account for the association.[90] Multiple-subgroup analysis of cardiac glycoside use in a meta-analysis of 14 case-control studies and 15 cohort studies published between 1976 and 2016 indicated digoxin use was associated with an elevated risk in ER-positive breast cancer (RR = 1.332, 95% CI: 1.249–1.421) but not in ER-negative tumors (RR = 0.984, 95% CI: 0.611–1.584).[91] Experimental *in vitro* and *in vivo* studies suggest bisphosphonates can reduce tumor cell proliferation, adhesion, migration, invasion, and angiogenesis. A meta-analysis of four cohort and four case-control studies reported a reduced overall relative breast cancer risk for bisphosphonate use of 0.84 (95% CI: 0.77–0.90, I^2 = 52.1%, $P_{heterogeneity}$ = 0.041), with moderate heterogeneity between studies.[92] This reduction was greater for long-term use (>1 year) with an RR of 0.74 (95% CI: 0.66–0.83).

Menopausal Hormone Therapy

The IARC recognizes postmenopausal combined (estrogen–progesterone) hormone therapy as a human breast carcinogen (Group 1) based primarily on exogenous synthetic progestogen (progestin) use rather than endogenous progesterone. Limited studies on breast cancer risks and circulating progesterone concentrations among postmenopausal women are conflicting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(null to slightly positive).[93,94] For postmenopausal hormone therapy, breast cancer risks begin ~2 years after medication use begins and continue until several years after cessation of use. A register-based cohort study of menopausal combination therapy in 449,717 Norwegian women, aged 50–65 years using combined estrogen and progesterone therapy for >1 year, demonstrated an elevated breast cancer risk (HR = 2.06, 95% CI: 1.90–2.24, n = 744 cases).[95] Short-term estrogen use alone does not increase breast cancer risks, with limited evidence of increased breast cancer risks with prolonged therapy. The hazard ratio for women using only systemic estrogens in the Norwegian study was 1.03 (95% CI: 0.85–11.25, n = 106 cases). A pooled analysis of 51 studies from 21 countries demonstrated a mean risk of 1.35 (95% CI: 1.21–1.49) for women using hormone replacement therapy for 5 years.[96] The risk of breast cancer varied little with dose; the risk decreased 5 years after cessation of therapy.

In 2 randomized, placebo-controlled studies involving 27,347 postmenopausal women aged 50–79 years from the Women's Health Initiative Trials followed over a median of 20 years, the findings for breast cancer incidence and mortality were mixed.[97] For 10,739 women with a prior hysterectomy, the treatment group receiving 0.625-mg conjugated equine estrogen daily with no medroxyprogesterone had a statistically significant reduction in breast cancer incidence (HR = 0.78, 95% CI: 0.65–0.93, n = 238 treatment cases/296 placebo cases, $P = 0.005$) compared with the placebo group (no treatment). Breast cancer mortality was also modestly lower in the treatment group (HR = 0.60, 95% CI: 0.37–0.97, n = 30 treatment deaths/46 placebo deaths, $P = 0.04$). In contrast, breast cancer incidence in postmenopausal women with an intact uterus was higher in the conjugated equine estrogen plus medroxyprogesterone group (HR = 1.28, 95% CI: 1.13–1.45, n = 584 treatment cases/447 placebo cases, $P < 0.001$) compared with the placebo group. There was no statistically significant difference in breast cancer mortality between the estrogen plus progesterone and placebo groups. Subgroup analysis of breast tumor subtypes suggested lower breast cancer risks in the conjugated equine estrogen alone group without an intact uterus for estrogen-receptor-positive, progesterone-receptor-positive, and *HER2* (*ERBB2*)-negative tumors. Limitations of the study included suboptimal adherence to treatment regimens (i.e., 54% discontinuing conjugated equine estrogen alone, 42% discontinuing conjugated equine estrogen plus medroxyprogesterone during the trials).

A meta-analysis of 13 case-control and 9 cohort studies reported a stronger association with combined menopausal hormones (estrogen/progestin) than estrogen therapy and invasive lobular carcinomas than invasive ductal carcinomas. Using never-menopausal hormone therapy users as the reference group, the overall reported relative risk of invasive ductal carcinoma in current combined menopausal hormone therapy users was 1.5 (95% CI: 1.5–1.6) compared with 2.0 (95% CI: 1.9–2.1) for invasive lobular carcinoma in current menopausal hormone therapy users.[18] The overall breast cancer risks for invasive ductal carcinoma in current estrogen-only hormone therapy users were marginal (RR = 1.1, 95% CI: 1.0–1.1) and statistically significant for invasive lobular carcinoma (RR = 1.4, 95% CI: 1.3–1.5). The relative risks were not statistically significant in seven case-control studies on invasive ductal carcinoma subtypes and two on invasive lobular carcinoma.

Diethylstilbestrol

The IARC classifies diethylstilbestrol (DES) as a Group 1 (human) breast carcinogen as a result of epidemiological evidence from women administered DES for the prevention of miscarriages during the 1940s–1970s. Follow-up studies demonstrated slight increases in breast cancer risks among the women and their daughters.

Contraceptives

Compared with women never using oral contraceptives, women using estrogen–progesterone contraceptives have a slightly elevated breast cancer risk; however, the risk decreases to baseline 5 years after cessation of use. Elevated breast cancer risks from oral contraceptives are not associated with specific histological subtypes.[18] In a meta-analysis of 2 cohort and 10 case-control studies among women in their 40s with never-oral contraceptive users as controls, none of the studies demonstrated a statistically significant difference between groups including former, recent (i.e., within 5 years), and postmenopausal estrogen-only hormone therapy users.[19]

Mammographic Breast Density

Breast density on mammography is a measure of the amount of radiopaque fibroglandular tissue in the breast because breast epithelium and stroma are lighter in appearance than the darker-appearing fat on mammography. Breast density changes over time increasing with combined estrogen plus progestin therapy and decreasing with age, increasing body mass index (BMI),

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and tamoxifen use; physical activity does not directly affect the breast cancer risks associated with breast density.[98] Substantial heterogeneity occurs for breast cancer risks between studies depending on several factors including the study outcome (incidence vs. prevalence), measure of breast density (qualitative vs. quantitative), and population characteristics (symptomatic vs. asymptomatic). The relative (percent) and absolute areas of breast density are relatively strong breast cancer risk factors with 4- to 6-fold differences between the highest and lowest breast density categories;[99] however, these studies frequently do not have sufficient size and statistical power to separate the effect of other breast cancer risk factors from mammographic density (e.g., parity, breastfeeding in premenopausal women).[100,101] Epidemiological evidence suggests the increased risks of invasive breast cancer continue in women aged 65 years and older. In a meta-analysis of nine well-designed studies using pre-diagnostic mammograms with <5% radiodense fibroglandular breast tissue as controls, the estimated pooled relative breast cancer incidence ranged from 1.79 (5–24% density) to 4.64 (≥75% density), as displayed in Table 57.2. Postmenopausal women with extremely dense breast tissue probably have an increased risk of breast cancer, particularly women using combined estrogen/progestin therapy.

Analysis of Breast Imaging Reporting and Data System (BIRADS) breast density data on 14,090 breast cancer cases among 587,369 women undergoing 1,349,027 screening mammography examinations demonstrated overall elevated relative risks (RRs) for breast cancer in women with extremely dense breasts (BI-RADS-4).[102] Compared with women with average breast density (scattered fibroglandular densities, BI-RADS-2), the overall RR for BIRADS-4 was 2.04 (95% CI: 1.84–2.26) and 1.62 (95% CI: 1.51–1.75) for women with heterogeneously dense breasts (BI-RADS-3). Women with low-density, almost entirely fatty breasts (BI-RADS-1) had reduced breast cancer risks (RR = 0.46, 95% CI: 0.37–0.58). The strength of the association of extremely dense breast tissues (e.g., BI-RADS-4) with ER-positive tumors declines with age, whereas ER-negative cancer risks in these women remain relatively constant. Comparing women aged 35 years and 70 years in the community-based, geographically diverse US cohort of women undergoing mammography, the strength of the hazard ratio for ER-positive breast cancer declined with age, whereas the risk of ER-negative breast cancer did not significantly change between ages 35 and 70 years, as displayed in Table 57.3.

TABLE 57.2. Meta-analysis of nine well-designed studies comparing the combined relative risks of breast cancer in quintiles of breast density percentage groups. (Adapted from Kelsey).[17]

Breast Density (%)	Combined Relative Risk	95% Confidence Limit	Heterogeneity
<5 (referents)	1.0	—	—
5–24	1.79	1.48–2.16	$I^2 = 27\%$, $P = 0.22$
25–49	2.11	1.70–2.63	$I^2 = 46\%$, $P = 0.09$
50–74	2.92	2.49–3.42	$I^2 = 0\%$, $P = 0.63$
≥75	4.64	3.64–5.91	$I^2 = 0\%$, $P = 0.50$

TABLE 57.3. Effect of age and estrogen-receptor status on breast cancer risk as measured by hazard ratio using partly conditional Cox proportional hazards regression to facilitate risk prediction in the Breast Cancer Surveillance Consortium cohort. (Adapted from Kerlikowske et al.).[102]

Statistical Value	Breast Cancer Hazard Ratio	95% Confidence Limit	$P_{interaction}$
Reference Group (BI-RADS 2)	1.0	—	—
ER+ 35 years (BI-RADS 4)	2.13	1.89–2.40	
ER+ 70 years (BI-RADS 4)	1.35	1.20–1.53	<0.001
ER− 35 years (BI-RADS 4)	1.68	1.34–2.11	
ER− 70 years (BI-RADS 4)	1.76	1.36–2.27	0.34

Abbreviations: BI-RADS = Breast Imaging Reporting and Data System category 2 = scattered fibroglandular densities; category 4 = extremely dense; ER+ = estrogen-receptor-positive; ER− = estrogen-receptor-negative; $P_{interaction}$ = significance of interaction of age and ER status.

HISTOLOGY

Breast tumors are primarily carcinomas, whereas sarcomas (e.g., phyllodes tumors, angiosarcomas) account for <1% of mammary gland malignancies. Carcinomas develop in the epithelial cells that line the lobules and terminal ducts along with producing milk, whereas sarcomas are stromal breast components (blood vessels, myofibroblasts). Pathologically, breast cancers are divided into noninvasive (*in situ*), invasive, and metastatic breast tumors. Ductal carcinoma *in situ* (DCIS) develops inside preexisting normal ducts; however, these lesions often progress to invasive cancers. Infiltrating (invasive) breast cancer spreads outside the normal breast lobule or duct into stromal tissue. About 60–75% of women with breast cancer have invasive ductal carcinoma that includes several histological subtypes (cribriform, medullary, mucinous, papillary, tubular). Invasive lobular carcinomas are molecularly and genetically distinct from invasive ductal carcinomas, accounting for ~10–15% of breast cancers with a slightly later presentation (early 60s) than invasive ductal carcinomas (mid/late 50s). Compared with invasive ductal carcinomas, invasive lobular carcinomas are more strongly associated with prolonged estrogen/progesterone exposure (early menarche, delayed/low parity, late menopause).[18]

There are at least 20 histologically distinct female breast tumor types and 5 major molecular variations with each subtype differing in presentation and treatment response but not necessarily in a biologically significant way.[103] Beside substantial intertumor heterogeneity, intratumoral heterogeneity also occurs from the presence of multiple heterogeneous cell populations within the same (i.e., mixed) tumor. Heterogeneity involves molecular and clinical parameters (i.e., histological grade, tumor size, age, biomarker receptor status including HER2 (ERBB2 amplification), ER, and PR.[104,105] Gene expression profiling techniques allow classification of breast tumors into molecular subtypes, as listed in Table 57.4. Hormone-receptor-positive (HR+) and HER2-negative (HR+/HER2−) breast cancer occur in ~74% of US cases, whereas aggressive triple-negative breast cancer (ER−, PR−, HER2−) accounts for ~11% of cases.[106] Luminal A and B are estrogen-receptor-positive tumors. The prognosis for luminal A tumors is usually good, intermediate for luminal B, and worse for basal-like and triple-negative tumors. The vast majority of triple-negative tumors are high-grade, infiltrating basal-like ductal carcinomas exhibiting geographical necrosis.[107] The basal-like subtype is associated with inflammation, marked nuclear pleomorphism, necrosis, and high mitotic rates.[108] These tumors usually express genes present in normal breast myoepithelial cells (e.g., P-cadherin superfamily, *CK5*, *CD44*, *EGFR)* while often having triple-negative molecular biomarkers. Clinically, basal-like tumors present with large tumor sizes, high histological grades, and frequent lymph node invasion in young African-American women.[109]

The expression of genes activated by the estrogen-receptor positive (ER+) in the luminal epithelium lining

TABLE 57.4. Molecular breast cancer subtypes with biomarker receptor status characterized by molecular signatures, characteristic subtypes, common histology, and histological grade. Luminal A and B tumors are estrogen-receptor-positive (ER+) that may represent a continuum of the same subtype rather than a distinct subtype. Histological grade is a measure of differentiation (i.e., how similar are the tumor and normal breast tissue) evaluated as a summary score of epithelial tubule formation, nuclear pleomorphism, and proliferation (mitosis rate) with grade 1 being the most differentiated and grade 3 the least differentiated (i.e., most dysplastic). (Adapted from Eroles et al.).[104]

Subtype	Histology	Histological Grade	ER Status	HER2 Status	Ki67	Molecular Properties
Luminal A	Classical, lobular, tubular, cribriform	1–2	+	−	↓	Luminal CK+, E-cadherin +/−
Luminal B	Micropapillary	2–3	+/−	−/+	↑↑	Luminal CK+, p53 mutations
Basal-like	Medullary, metaplastic, adenoid cystic, secretory	3	−	−	↑↑	Basal CK+, p53 loss, *EGFR*+/− mutations
Molecular Apocrine	Apocrine, pleomorphic lobular	2–3	−	−/+	↑↑	Androgen gene receptor+
Claudin-low	Metaplastic	3	−	−	↑↑	Cancer-like stem cell, ↓E-cadherin

Abbreviations: CK = cytokeratins; *EGFR* = the epidermal growth factor receptor gene provides instructions for making a receptor protein called the epidermal growth factor receptor; ER = estrogen receptor; HER2 (human epithelial growth factor receptor 2), also known as ERBB2 or erb-b2 receptor tyrosine kinase 2, encodes a member of the epidermal growth factor (EGF) receptor family of receptor tyrosine kinases.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the mammary ducts along with low expression of cell proliferation genes characterizes luminal A tumors. The ER+, human epidermal growth factor receptor 2 negative (HER2−), and/or progesterone-receptor positive (PR+/−) luminal A breast tumors are low-histological grade, slow-proliferating (↓Ki67 expression), hormone-responsive (e.g., aromatase inhibitors) neoplasms accounting for most breast tumors. All lobular carcinomas *in situ* and most infiltrating lobular carcinomas are luminal A tumors.[18] The luminal B tumors are similar to luminal A with the exception of high Ki67 and cyclin B1 levels, HER2+/−, slightly more rapid growth, resulting in a relatively higher histological grade, a more aggressive phenotype, an increased proliferative index, and a worse prognosis compared with luminal A tumors. Overexpression of the *HER2* gene increases cell proliferation with an increased histological grade and worse prognosis. Triple-negative (HER2−, ER−/PR−) breast tumors are typically aggressive infiltrating ductal carcinomas with a worse prognosis than other breast cancer subtypes. About 1/8 of breast cancers are triple (receptor) negative. The claudin-low tumor is an uncommon subtype (12–14%) characterized by low expression of genes involved with intercellular adhesion (E-cadherin), tight junctions (e.g., cingulin, claudin-3/4/7, occludin), and overexpression of tumor immune system cells, resulting in a poor prognosis.[110,111]

HOST SUSCEPTIBILITY

Although only 5–10% of women with breast cancer have cancer susceptibility genes, up to 20–30% have a family history of at least one relative with previously diagnosed breast cancer.[112] Approximately 15% of female breast cancer patients have a close family member with breast cancer. A first-degree relative (mother, sister, daughter) with breast cancer increases the breast cancer risk of >50%, particularly if the relative developed breast cancer before the age of 50 years.[113] Two 1st degree relatives with breast cancer increase the risk almost 3-fold.[16] In a meta-analysis of 44 case-control and 8 cohort studies using women with no first-degree relatives with breast cancer, the estimated overall breast cancer risk ratio for a woman with one first-degree relative with breast cancer was 1.80 (99% CI: 1.69–1.91).[114] For two 1st-degree relatives with breast cancer, the risk ratio was 2.93 (99% CI: 2.36–3.64) and 3.90 (99% CI: 2.03–7.49) for ≥3 1st-degree relatives with breast cancer. The risks were greatest at younger ages, particularly when the relative developed breast cancer at an early age (<40 years), whereas the risks were lower in women with relatives presenting with breast cancer at >60 years of age.

Breast cancer susceptibility involves >90 genes or genetic loci.[115] Mutations in *BRCA1* and *BRCA2* genes are highly penetrant gene mutations with a wide spectrum of variants that increase breast cancer rates in women and men when compared with the general population.[116] A 2018 report by the Consortium of Investigators of Modifiers of *BRCA1/2* (CIMBA) identified 1,650 unique BRCA1 mutations in 26,861 *BRCA1* mutation carriers from 18,435 families with BRCA1 mutations and 1,731 unique BRCA2 mutations in 16,954 *BRCA2* mutation carriers from 11,351 families with BRCA2 mutations.[117] Several other rare inherited germline mutations are associated with elevated breast cancer risks, including ataxia-telangiectasia, Li–Fraumeni syndrome (*TP53*), Cowden syndrome (*PTEN*), Peutz–Jeghers syndrome (*STK11/LKB1*), and hereditary diffuse gastric cancer (*CDH1*). High-risk genes with relative risks of 5 to >20 (e.g., *BRCA1*, *BRCA2*, *TP53*) confer a lifetime breast cancer risk of 40–85%, with higher risks in younger adults, whereas moderate-risk genes with relative risks of 1.5 to <5 including the DNA repair genes (*PALB1*, *BRIP1*, *ATM*, *CHEK2*) confer a lifetime breast cancer risk of 20–40% with relatively low frequency.[118] More recent studies that enroll breast cancer patients with family histories or early-onset breast cancer have more central estimates of penetrance (i.e., ~60% for *BRCA1*, ~50% for *BRCA2*).[119,120] These high- and moderate-risk gene variants explain only ~½ of the inherited breast cancer, with low-penetrance polymorphisms (RR = <1.5) accounting for the rest of the variance.[121] Although pathogenic mutations in *BRCA1* and *BRCA2* display high penetrance, the frequency of these mutated genes in the general population is rare (i.e., ~0.4–0.6%). In non-Ashkenazi Jewish populations, the frequencies of these two germline pathologic variants are ≈0.1–0.2% and ≈0.3–0.4%, respectively. Please make the font consistent with the first line and ≈ set on the baseline. These genes normally repair DNA damage including double-stranded DNA breaks through homologous recombination and nucleotide excision repair along with helping regulate cell-cycle progression.[122] Up to 20% of women (i.e., ~7–10% *BRCA1*, ~10% *BRCA2*) with a family history of breast cancer harbor the breast cancer susceptibility (tumor suppressor, cell checkpoint control) genes, *BRCA1* and/or *BRCA2*. Women with the *BRCA1* germline pathogenic variant have an increased risk of triple-negative breast cancer and high-grade serous ovarian cancer whereas ER+ breast cancer is more common in women with *BRCA2* germline variant. These gene mutations are particularly common among Eastern European Ashkenazi Jews.[123] The estimated prevalence of gene mutations other than BRCA1/2 is ~4–6%.[124] The frequency of TP53 germline

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mutations in the general population is less common than BRCA1/2 mutations;[125] however, the cumulative breast cancer risk increases up to 85% by age 60 years.[126] These tumors usually occur at a young age with a median age at presentation of ~34 years.

A meta-analysis of 22 studies identified 289 BRCA1 and 221 BRCA2 germline mutation carriers from 6,965 female breast cancer cases, 176 male breast cancer cases, and 998 ovarian cancer cases.[127] Using a modified segregation analysis based on breast cancer incidence in relatives of mutation-carrying index case patients, the estimated average cumulative breast cancer risk in BRCA1 mutation carriers by age 70 was 65% (95% CI: 44–78%) and 45% (95% CI: 31–56%) for BRCA2 mutation carriers. The estimated average cumulative breast cancer risks by age 70 years in the prospective UK EMBRACE cohort study for 978 BRCA1 mutation carriers were 60% (95% CI: 44–75%) and 55% (95% CI: 41–70%) for 909 BRCA2 mutation carriers, similar to the meta-analysis.[128] The presence of these mutations increases the risk of contralateral breast tumors and early-onset breast cancer. In a meta-analysis of 16 studies on female breast cancer recurrence rates, the cumulative invasive breast cancer recurrence rates for ipsilateral primary tumors ranged from 1.9–11.1% with a median of 6.2% (median follow-up, 10.5 years); in 9 studies, the cumulative recurrence rates for invasive contralateral primary tumors ranged from 1.1–8.3%, with a median of 3.6% (median follow-up, 7.5 years).[129]

The cancer susceptibility breast cancer genes vary with histological type. Mutations in the *CDH1* gene that alter epithelial cadherin (E-cadherin) and cell–cell adhesion in breast tumors are associated exclusively with invasive lobular carcinomas. This gene produces a protein, called epithelial cadherin (E-cadherin), which is important for cell adhesion and the formation of organized tissues.[18] The common breast cancer susceptibility genes (e.g., *BRCA1*, *BRCA2*, *TP53*) are less commonly associated with lobular breast carcinomas than ductal carcinomas. BRCA1 mutation-associated breast tumors are more often HER2-negative and progesterone-receptor-negative compared with controls, whereas BRCA2 mutation-associated tumors are more commonly estrogen-receptor-positive.[115] In women carrying germline TP53 mutations, the tumors are usually ER+, PR+, and HER2+.[130]

CLINICAL FEATURES

The development of breast cancer in premenopausal women of <40 years is rare and more genetically dependent than postmenopausal breast cancer;[42] most breast cancer cases develop after age 50–55 years, with the peak occurrence of breast tumors occurring in women aged 55–64 years. The minimum latency period for breast cancer is 10–12 years and usually ~20 years.[131] Typically, few signs or symptoms occur early in the disease with a painless breast lump as the most common physical sign; clinical features of advanced breast cancer include swollen, enlarged lymph nodes and erythema/swelling of the breast with or without bloody nipple discharge, skin thickening (peau d'orange), or skin retraction.

Approximately ½ of breast cancers in the United States are discovered during screening mammograms.[132] Only 6% of 90% of women presenting with breast cancer have identifiable metastatic disease at initial presentation; however, breast cancer patients have an increased risk for distant metastases during their remaining lifetime that occasionally develop >10–15 years after initial diagnosis. Approximately 10–15% of women initially diagnosed with breast cancer will develop distant metastases within 3 years;[133] the risk of metastasis increases with histological tumor size and the number of involved axillary lymph nodes.[134] Metastatic sites include axillary nodes, bones, lung, liver, and brain. In a review of organ-specific dissemination of breast cancer, the estimated occurrences of metastasis at specific sites were the following: bone, 47–60%; lung, 16–34%; liver, 19–20%; and brain, 10–16%.[16] Survival rates depend on the tumor stage and tumor type. Overall, US survival rates are 89% at 5 years, 83% at 10 years, and 78% at 15 years. The ~20–30% of breast cancer patients with metastatic breast disease have a median survival of 2–4 years depending on tumor subtype. Luminal A tumors have a distinct metastatic pattern with a relatively high bone metastasis rate (~20%) and metastasis to other tissue sites (i.e., brain, liver, lung) representing <10%, whereas luminal B tumors have a higher liver metastatic rate (~14%) and a high metastatic bone rate.[104] BRCA status alone does not predict the prognosis of a specific breast tumor.[16]

UTERUS

CERVIX

Cervical cancers represent the vast majority of cancers developing between the uterine cervix and the external vulva. Persistent infections by high-risk human papillomavirus (HPV) genotypes (HPV-16, HPV-18, HPV-31, HPV-33, HPV-45) are associated with increased risks

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of cervical, vaginal, and vulvar cancers; however, these infections are not sufficient to produce these cancers. Carcinomas of the vagina and vulva are rare, accounting for 2% and 4% of gynecological malignancies, respectively. The IARC lists *in utero* diethylstilbestrol exposure and HPV-16 as recognized and HIV-1 as suspected human vaginal carcinogens, whereas HPV-16 is recognized and HPV-18, HPV-33, and HIV-1 are suspected human vulvar cancers. In a Spanish study, analysis of tissue from 1,709 vulvar and 408 vaginal cancer cases detected HPV DNA prevalence rates of 84.9% and 28.6%, respectively.[135] HPV is also associated with carcinomas of the anus, penis, oropharynx, and skin. This section focuses on the most common HPV-related cancer, cervical cancer. The US Food and Drug Administration approved primary HPV screening for cervical cancer in 2014 with implementation guidelines by multiple professional organizations published in 2015.[136]

Worldwide, cervical cancer is the fourth most common female malignancy with an estimated ~570,000 incident cases and ~310,000 cervical cancer-related deaths annually.[7] Incidence and mortality vary widely between different geographical regions and countries. Over 90% of these deaths occur in low- and middle-income countries, primarily Sub-Saharan Africa and South-Eastern Asia, whereas the cervical-related death rates are 7–10 times lower in North America, Australia, New Zealand, and Western Asia (Saudi Arabia, Iraq).[137] In the United States, the estimated number of new cervical cancer cases is ~13,000, with ~4,250 cervical cancer-related deaths annually.[3] For the last decade, the incidence of cervical cancer has decreased with the exception of the 30–34-year-old group; however, the data are unclear if detection bias with a stable disease occurrence accounts for the modest decrease (i.e., ~0.3 annual percentage change). Recent data suggest the decline in the incidence of cervical cancer has moderated.

CARCINOGENESIS

The heterogeneous papillomavirus family consists of >150–200 HPVs; these non-enveloped, double-stranded circular DNA viruses infect cutaneous and mucosal squamous epithelia through defects in the skin, oral cavity, and anogenital tract exclusively targeting the nucleus; ~40 HPVs infect the genital tract. These viruses encode viral regulatory proteins (E1, E2, E4, E5, E6, E7) involved with replication and two structural viral capsid proteins (L1, L2). HPV oncogenes include E5 (viral assembly, growth stimulation), E6 (destabilizes p53 and reduces apoptosis), and E7 (promotes malignant transformation by degrading retinoblastoma protein pRb). The latter disrupts the Rb/E2F complex, producing nitric oxide, causing DNA damage, activating inflammatory pathways (cyclooxygenase2/prostaglandin/PG G receptor), and promoting tumorigenesis.[138] E1 and E2 initiate replication, integrate viral DNA into the human genome, and express E6 and E7 oncoproteins. After replication, L1 and L2 form the viral capsid, with E4 proteins helping release the mature virus to infect other cells. The virus may remain non-detectable in a dormant state before reactivating years later.[139] Figure 57.1 displays the structure and functions of viral proteins in the highly oncogenic HPV-16 genotype.

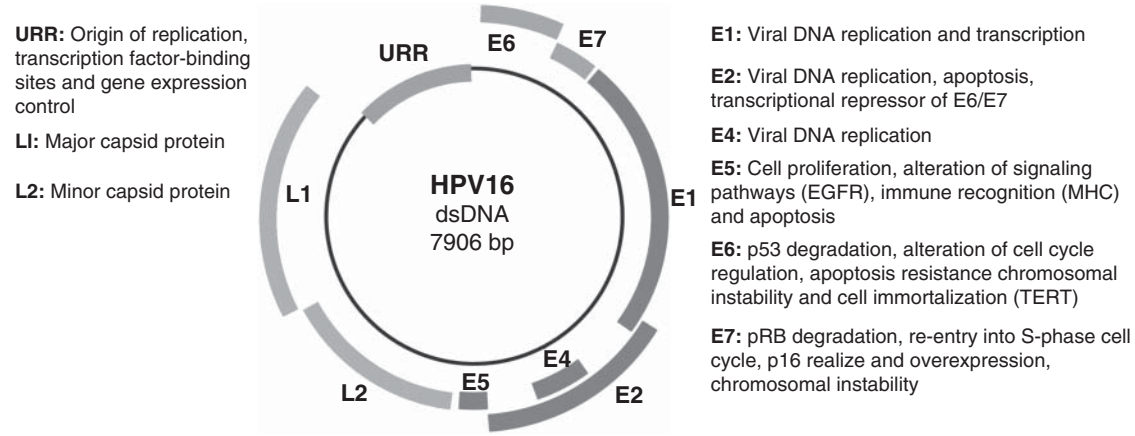

FIGURE 57.1. Human papillomavirus (HPV)-16 viral proteins, function, and structure. The early proteins (E) are necessary for initiating the viral life cycle and cell transformation. The late region (L) encodes the viral capsule and releases a mature virus capable of infecting another epithelial cell. E6 and E7 promote epithelial cell transformation by cell-cycle deregulation, telomerase activation, and enhancement of genomic instability. Over 60% of cervical cancers contain HPV-16 DNA. (Adapted from Eskander).[140]

High-risk HPVs account for ~70% of invasive cervical cancers worldwide, with HPV-16 and HPV-18 being the most virulent.[141] Most HPV infections are subclinical with ~60–70% clearing within 1 year and 91% within 2 years.[142,143,144] Almost every cervical cancer specimen is positive for a high-risk HPV type (i.e., >95%).[145] In a histological study of 8,977 invasive cervical cancer specimens, the most common HPV types were HPV-16, HPV-18, HPV-45, HPV-31, and HPV-33, as displayed in Table 57.5 by histological type; these HPV genotypes account for ~80% of squamous cell carcinomas and ~94% of adenocarcinomas.[146] HPV-16 is the most common genotype associated with squamous cell carcinomas (62%), adenocarcinomas (50%), and adenosquamous cell carcinomas (39%), based on a retrospective cross-sectional worldwide study of 22,661 paraffin-embedded, cervical tumor samples.[147]

The quadrivalent human papillomavirus (types 6, 11, 16, 18) vaccine effectively prevents infections and precancerous lesions caused by these four HPV types (Gardasil®, Merck & Co., Whitehouse Station, NJ).[148] Since 2006, the US Advisory Committee on Immunization Practices recommended routine use of the quadrivalent HPV vaccine for girls 11–12 years old and catch-up vaccination for girls and women 13–26 years old. Within 6 years of introducing the quadrivalent HPV vaccine, the prevalence of vaccine-type HPV strains decreased from 11.5 to 4.3% among adolescents of 14–19 years old and from 18.5 to 12.1% among women of 20–24 years old.[149] In 2014, the US FDA approved Gardasil 9® (Merck & Co., Whitehouse Station, NJ), which covers the same four HPV types as the quadrivalent HPV vaccine plus an additional five HPV types (types 31, 33, 45, 52, 58). Gardasil 9® is approved for use in males and females aged 9–45 years of age. Table 57.6 lists the carcinogenic categories of specific HPV genotypes along with the associated diseases.

Common genes mutated in cervical tumors include *EGFR*, *KRAS*, *PIK3CA*, *PTEN*, *TP53*, and *STK11*, as well as *EP300* (cell growth/differentiation), *FBXW7* (cell-cycle control by targeting cyclin E for ubiquitin-mediated degradation), *NFE2L2* (antioxidant response elements), and *ERBB2* (regulates outgrowth and stabilization of peripheral microtubules).[151] High-throughput genotyping platform analysis of 80 tumors (48 tumors validated, OncoMap platform, Dana-Farber Cancer Institute, Boston, Massachusetts) for 1,250 known mutations in 139 cancer genes identified PIK3CA mutations in 31% of the tumors.[152] The next highest mutation rates were reported in *KRAS* (~9%) and *EGFR* (~4%) genes. At least 14 long noncoding RNAs (lnc/RNAs) affect the development of cervical tumors, along with miRNAs and several proteins that produce posttranscriptional modifications of important signaling pathways. The HOTAIR lncRNAs silence some tumor

TABLE 57.5. The five most common human papillomavirus (HPV) genotypes in HPV DNA-positive tumors by histological type. The total number of specimens was 8,977 with 100 unclassified. (Adapted from de Sanjose et al.).[147]

	Total Number (% Total)	Squamous Cell Carcinoma (% Total)	Adenocarcinoma (% Total)	Adenosquamous Cell Carcinoma (% Total)
All specimens	8,977 (100%)	8,252 (92%)	470 (5%)	155 (2%)
HPV-16	5,439 (61%)	5,090 (62%)	235 (50%)	61 (39%)
HPV-18	918 (10%)	687 (8%)	152 (32%)	49 (32%)
HPV-45	528 (6%)	446 (5%)	56 (12%)	18 (12%)
HPV-31	335 (4%)	328 (4%)	3 (<1%)	3 (2%)
HPV-33	345 (4%)	338 (4%)	2 (<1%)	4 (3%)

TABLE 57.6. General carcinogenicity risks associated with specific human papillomavirus (HPV) genotypes along with associated diseases. (Adapted from de Sanjosé et al.).[150]

Characteristic Carcinogenicity	HPV Genotypes	Associated Disease
High-risk	16, 18, 31, 33, 35, 39, 45, 51, 52 56, 58, 59, 68, 69, 73, 82	Precursor lesions; cervical, anal, vulvar, vaginal, penile, oropharyngeal cancers
Low-risk	6, 11, 40, 42, 43, 44, 53, 54, 61, 72, 81	Genital warts, recurrent respiratory papillomatosis
Possible-risk	5, 8	Cutaneous squamous cell carcinoma in patients with epidermodysplasia verruciformis
Uncertain-risk	26, 30, 34, 53, 66, 67, 70, 73, 85, 97

suppressors (e.g., *HOXD10*, *PTEN*, *RBM38*) and activate some signaling pathways (PI3K/AKT, STAT3, Wnt/β-catenin) important in cervical tumor proliferation and progression.[153] DNA methylation and histone modifications are also epigenetic mechanisms that contribute to cervical tumor carcinogenesis. HPV-related promoter hypermethylation affects a variety of cellular processes including proliferation, differentiation, adhesion, and cell signaling. The principal targets of DNA promoter methylation and transcriptional repression include the tumor suppressor p16 protein along with cyclin A1 (cell-cycle control *CCNA1* gene), the antiapoptotic *DAPK1* gene, the tumor suppressor fragile histidine triad gene (*FHIT*), and *RAS*-associated domain family 1 isoform A (*RASSF1A* gene).[140]

EXPOSURE

Persistent HPV infection is a necessary but not sufficient factor for the progression of precancerous lesions to invasive cervical carcinomas.[154] In the National Health and Nutrition Examination Survey (NHANES), the overall HPV prevalence in US females aged 14–59 years was 26.8% (95% CI: 23.3–30.9%), with the highest HPV prevalence rate of 44.8% (95% CI: 36.3–55.3%) in women aged 20–24 years.[142] Chronic infection by high-risk human papillomavirus (HPV) genotypes accounts for almost all cervical cancers, with viral load and HPV genotype being the main determinants of progression from infection to cervical intraepithelial lesions and invasive cervical neoplasms. Therefore, the major risk factors for developing cervical cancer involve sexual behavior that increases the risk of HPV exposure and/or impairs immunity to HPV infection.[150] These cofactors include early age of initial sexual contact, multiple and/or high-risk sexual partners (e.g., prostitutes),[155] multiparity (≥5 pregnancies), tobacco smoking, lack of condom use, oral contraceptive use, immunosuppression (e.g., organ transplants), immunodeficiency disorders (e.g., HIV), sexually transmitted diseases, HPV-related vulvar or vaginal dysplasia, and inadequate HPV screening.[156,157] Oral contraceptive use for >5 years and hormone replacement therapy may upregulate HPV viral expression, whereas active tobacco smoking is a dependent cofactor for cervical cancer.

Diseases

HIV

The association between HIV and HPV-related cervical cancer results primarily from immunosuppression caused by active HIV infections rather than a direct effect of HIV; consequently, antiretroviral therapy probably significantly lowers HPV-related cancer risks in HIV+ patients.[150,158] Immunosuppression promotes persistent HPV infection with excess risk of cervical neoplasia occurring after human immunodeficiency virus (HIV) infection and subsequent immunosuppression, particularly with CD4 cell count <200 cells/μL. In a case-control study of 871 HIV-positive women and 439 HIV-negative women followed for a median of 2.5 years and 2.9 years, respectively, the relative risk of high-risk HPV infection comparing HIV+ and HIV− women was 1.8 (95% CI: 1.3–2.7), 2.1 (95% CI: 1.5–2.9) for intermediate-risk HPV, and 2.7 (95% CI: 2.0–3.6) for low-risk HPV genotype infections.[159]

Chlamydia trachomatis

Studies on the association between *C. trachomatis* and cervical cancer are inconsistent with both positive and negative studies. A nested case-control study using data from the Costa Rica HPV Natural History Study identified 182 women with prevalent and 132 women with incident cervical intraepithelial neoplasia grade 2(CIN2+) or higher including invasive cervical cancer; 995 women randomly selected from the cohort were controls.[160] *C. trachomatis* DNA-positive status at enrollment was associated with current and subsequent CIN+ status during follow-up (RR = 2.6, 95% CI: 1.6–4.2, n = 24 cases) compared with *C. trachomatis* DNA-negative controls. After restricting cases to *carcinogenic* HPV DNA-positive women, the association between *C. trachomatis* DNA (OR = 0.95, 95% CI: 0.44–2.04, n = 308) status and CIN2+ at follow-up was no longer statistically significant, indicating carcinogenic HPV status confounds the association between *C. trachomatis* status and high-grade intraepithelial neoplasia and invasive cervical cancer. The results using serum IgG as a surrogate for *C. trachomatis* were similar. In a meta-analysis of 22 studies (4,291 cases, 7,628 controls), the overall OR for cervical cancer comparing *C. trachomatis*-positive and *C. trachomatis*-negative patients was elevated in 3 prospective (OR = 2.21, 95% CI: 1.88–2.61, $I^2 = 46\%$, $P < 0.001$) and 22 retrospective (OR = 2.19, 95% CI: 1.74–2.74, $I^2 = 48\%$, $P < 0.001$) studies.[161] After multivariate logistic regression analysis adjusted for HPV and age in 11 studies, *C. trachomatis* was an independent risk factor in 11, but not all, studies (OR = 1.76, 95% CI: 1.03–3.01, $I^2 = 0\%$, $P = 0.04$).

Herpes Simplex

Studies on the association between *Herpes simplex type 2* (HSV2) and cervical cancer are more inconsistent

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and weaker than *C. trachomatis*-associated cervical carcinoma risks; the studies on the association with *Herpes simplex type 1* (HSV1) are mostly statistically nonsignificant. A study analyzing data from 8,184 women in the US NHANES database demonstrated seroprevalences of 60.73 ± 0.89 weighted percent for HSV1 and 25.02 ± 0.64 for HSV2.[162] The adjusted OR for cervical cancer associated with HSV2 seropositivity was elevated ($OR_{adjusted}$ = 1.72, 95% CI: 1.06–2.79). However, a meta-analysis of 20 studies (14 case-control and 6 longitudinal) involving 3,337 cases reported elevated pooled ORs for cervical cancer comparing HSV2-positive and HSV2-negative patients for case-control studies (OR = 1.37, 95% CI: 1.12–1.69) but not for prospective/nested case-control studies (pooled OR = 1.04, 95% CI: 0.82–1.31).[163] In the Nordic cohort of 550,000 women followed for an average of 5 years that identified 178 cervical carcinoma cases and 527 controls, HSV2 seropositivity did not significantly alter cervical cancer risks.[164] The adjusted relative risks of cervical cancer for this nested case-control study comparing HSV2-seropositive and -seronegative women were 1.0 (95% CI: 0.6–1.7) after adjusting for tobacco smoking and 0.7 (95% CI: 0.3–1.6) after adjusting for HPV-16, HPV-18, and HPV-33. A concurrent meta-analysis by the authors involving seven longitudinal studies (2,940,000 person-years of follow-up) reported an overall RR comparing HSV2-seropositive and HSV2-seronegative participants of 0.9 (95% CI: 0.6–1.3).

Occupation

Occupational exposures in women are not clearly associated with increased cervical cancer risks. The population-based Nordic study followed 15 million residents up to 45 years examining standardized cervical cancer incidence in 54 occupational categories. Beverage manufacturing workers had the highest cervical cancer risk (SIR = 2.01, 95% CI: 1.51–2.61), followed by "other construction workers" (SIR = 1.88, 95% CI: 1.30–2.63) and waiters (SIR = 1.64, 95% CI: 1.53–1.75).[165] The lowest cervical cancer risks occurred in dentists (SIR = 0.48, 95% CI: 0.30–0.74), physicians (SIR = 0.59, 95% CI: 0.41–0.83), and teachers (SIR = 0.59, 95% CI: 0.55–0.63). In a US mortality study of a cohort of 1,708 dry-cleaning workers with tetrachloroethylene exposure for >1 year based on retrospective analysis of union records, the national standardized mortality ratio for cervical cancer in tetrachloroethylene-exposed workers was marginally elevated (SMR = 195, 95% CI: 100–340, n = 12 cases). The study did not adjust for confounders or demonstrate sufficient dose-response data. In a pooled Northern European cohort study of 1,777 women with documented trichloroethylene exposure, the overall standardized incident ratio for cervical cancer was elevated (SIR = 2.31, 95% CI: 1.32–3.75, n = 16 cases); however, the SIR for cervical cancer in workers comparing the highest and lowest trichloroacetic acid ratios was not statistically significant ($HR_{adjusted}$ = 3.28, 95% CI: 0.73–14.91, P_{trend} = 0.08, n = 4 cases).[166] The estimated hazard ratios were imprecise due to small case numbers and limited statistical power; lifestyle factors potentially confounded the results. In a French case-control study of 67 cases (cervical dysplasia, cervical cancer) and 67 age-matched, clinic-based controls recruited by a local gynecologist, the adjusted OR for cervical dysplasia/cancer in ever-trichloroethylene-exposed workers was 1.51 (95% CI: 0.42–5.41, $n_{exposures}$ = 17 cases, 15 controls).[167] Cervical cancer rates did not correlate with cumulative dose, exposure time, or specific occupational sectors.

Lifestyle

Pregnancy

In the International Collaboration of Epidemiological Studies of Cervical Cancer on 11,161 women with invasive carcinoma and 33,542 women without cervical carcinoma from 25 epidemiological studies, the number of full-term pregnancies was associated with invasive cervical carcinoma risk. After controlling for age at first full-term pregnancy, the RR for invasive cervical carcinoma comparing women with ≥7 and 1–2 births was 1.76 (95% CI: 1.53–2.02).[168] Comparing invasive cervical carcinoma rates in the first full-term pregnancy at <17 years of age and ≥25 years of age, the RR was also elevated at 1.77 (95% CI: 1.42–2.23) after controlling for the number of full-term pregnancies. These values did not change significantly when restricted to HPV-positive women. A pooled analysis of 10 case-control studies (8 invasive cervical carcinomas, 2 carcinomas *in situ*) suggested histological differences in cervical cancer rates.[169] Compared with nulliparous women, the ORs for squamous cell carcinoma risks in women with ≥7 full-term pregnancies were 3.8 (95% CI: 2.7–5.5) and 2.3 (95% CI: 1.6–3.2) for women with 1–2 full-term pregnancies. Adenocarcinoma and adenosquamous carcinoma risks were not significantly associated with the number of full-term pregnancies. All participants were HPV-positive. In a 10-year prospective study of 1,812 oncogenic HPV-DNA-positive individuals, parity was not associated with increased risks of high-grade cervical neoplasia or invasive cervical cancer.[170]

Tobacco Smoking

Tobacco smoking is the most significant environmental risk for invasive cervical cancer. The IARC lists tobacco smoking as a cervical cancer risk factor with sufficient evidence of carcinogenicity in humans based primarily on retrospective case-control studies; most case-control and some prospective studies associate tobacco smoking with elevated invasive cervical cancer risks. The European Prospective Investigation into Cancer and Nutrition (EPIC) Study identified 261 invasive cervical cancers in a cohort of 308,036 women followed for a median of 9 years.[171] Using a nested case-control design with multivariate Cox regression models and never-smokers matched for HPV status as controls, the hazard ratio for invasive cervical carcinomas in self-reported current smokers was 1.9 (95% CI: 1.4–2.5, $n = 85$ cases) compared with 1.5 (95% CI: 1.1–2.1, $n = 66$ cases) for ever-smokers. Among ever-smokers, the trends for smoking duration ($P_{trend} = 0.08$), smoking intensity ($P_{trend} = 0.07$), and pack-years ($P_{trend} = 0.07$) were not statistically significant. Some evidence suggests cessation of tobacco smoking for ≥20 years reduced the invasive cervical carcinoma risks (HR = 0.4, 95% CI: 0.2–0.8, $P_{trend} = 0.02$, $n = 10$). The relative cervical cancer risk is probably higher in squamous cell cancers than in adenocarcinoma cervical cancers. Data from the 23 studies in the International Collaboration of Epidemiological Studies of Cervical Cancer suggest the risks associated with smoking and cervical cancer may be related to histological type. Using never-smokers as controls, the relative risk of cervical squamous cell carcinoma in current smokers was 1.60 (95% CI: 1.48–1.73, $P < 0.001$).[172] Although the relative risk was increased comparing former and never-smokers (RR = 1.12, 95% CI: 1.01–1.25), the trend for cervical squamous cell cancer and time since cessation was not statistically significant ($P_{trend} = 0.6$). The study reported no significant association between smoking and cervical adenocarcinoma in current or former smokers. In a pooled analysis of data from 10 case-control studies of HPV DNA-positive women, the excess cervical cancer risk for ever-smokers was 2.17 (95% CI: 1.46–3.22) using never-smokers as controls.[173] Analysis by histological type indicated an increased squamous cell carcinoma risk in current smokers (OR = 2.30, 95% CI: 1.31–4.04) and a statistically nonsignificant increase in ex-smokers (OR = 1.80, 95% CI: 0.95–3.44). The data did not demonstrate a clear association between adenocarcinomas and tobacco smoking.

The association of passive smoking with cervical cancer is difficult to separate from the effects of active smoking, with observational studies reporting inconsistent results. In a pooled analysis of 7 case-control studies enrolling 1,919 couples, invasive cervical cancer risks were elevated among couples with ever-smoking men and all women (OR = 1.57; 95% CI: 1.15–2.15), as well as couples with monogamous women (OR = 1.55; 95% CI: 1.07–2.23); however, the cervical cancer risk was not increased among lifetime nonsmoking monogamous women married to ever-smoking men.[174] The confounding of active smoking could not be separated from the effect of passive smoking on invasive cervical cancer risks. In a meta-analysis of 4 cohort and 10 case-control studies, the pooled OR for cervical cancer risk in participants exposed to passive smoke was 1.70 (95% CI: 1.40–2.07, $I^2 = 64.3\%$), with modest heterogeneity and evidence of publication bias (Egger's test, $P = 0.11$).[175] Subgroup analysis indicates substantially lower pooled odds ratios for cohort studies (OR = 1.37, 95% CI: 1.16–1.62, $I^2 = 0\%$) than case-control studies (OR = 2.09, 95% CI: 1.52–2.89, $I^2 = 76.6\%$).

Medications

Some studies suggest cervical cancer risks modestly increase with the duration of combined estrogen–progestogen oral contraceptive use, primarily ≥5 years;[176] however, the study results are conflicting. Rodent studies suggest progesterone and glucocorticoid response elements in HPV-16 and HPV-18 increase HPV E6 and E7 oncogene expression, providing a theoretical basis for an association between oral contraceptive use and invasive cervical cancer.[177] Analysis of pooled data from eight case-control studies and two studies of patients with carcinoma *in situ* suggested long-term oral contraceptive use increases cervical cancer risks. Compared with never-users, cervical cancer risks were not increased in women using oral contraceptives for <5 years (OR = 0.73, 95% CI: 0.52–1.03), whereas the odds ratio was increased for women using oral contraceptives for 5–9 years (OR = 2.82, 95% CI: 1.46–5.42) and >10 years (OR = 4.03, 95% CI: 2.09–8.02).[178] The imprecise OR suggests caution in interpreting the results. In the Nurses' Health Study cohort of 131,577 women followed for 36 years, ever-use of oral contraceptives did not increase cervical cancer-related mortality (HR = 1.04, 95% CI: 0.54–2.02, $n = 18$ deaths) using never-users as controls and adjusting for multiple risk factors.[179] In a systemic review of 5 cohort and 7 case-control studies, the overall pooled OR comparing ever-oral contraceptive users with never-users was 1.210 (95% CI: 0.911–1.607).[180] The quality ratings for these studies

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

were 5 good, 4 fair, and 4 poor. The review detected no time-dependent relationship between oral contraceptive use and cervical cancer ($OR_{>5\ years\ use}$ = 1.47, 95% CI: 0.91–2.38, $P_{heterogeneity}$ = 0.0033, n = 6 studies) with substantial heterogeneity. The difficulty of controlling all confounding factors (sexual behavior, current HPV infection, reproductive history, smoking) limits conclusions regarding whether the use of oral contraceptives increases invasive cervical carcinoma risks.

Epidemiological studies do not support an increase in cervical cancer risks among hormone replacement users. In an Italian case-control study using hospital-based controls, the multivariate odds ratio for ever-hormone replacement therapy users was 0.5 (95% CI: 0.3–0.8, n = 40 cases).[181] Duration of use was not associated with increasing cervical cancer risks. The study did not control for cervical cancer screening or treatment of early intraepithelial lesions.

HISTOLOGY

The transition between squamous and columnar cells (squamocolumnar junction) is the area of greatest risk of viral neoplastic transformation; ectocervical tumors are most often squamous cell carcinomas, whereas endocervical tumors are usually adenocarcinomas. The most common histological subtypes of cervical cancers are squamous cell carcinomas (~70%) and adenocarcinomas (~25%).[137] Cervical cancer has a long preinvasive phase; the progression from normal tissue to low-grade squamous intraepithelial lesions (CIN1), high-grade squamous intraepithelial lesions (CIN3), and invasive cervical cancer is relatively slow (i.e., 10–30 years with an average of 5–14 years).[182,183] In a review of the natural history of cervical intraepithelial neoplasms (CIN), estimated regression of CIN1 dysplasia was 60% with 30% persistence; progression to CIN3 10%, and progression to invasion 1%; the likelihood of CIN3 regressing was 33% and progressing to invasion was >12%.[184] Invasive cervical cancers do not spontaneously regress. The time from transformation to invasive cancer ranges from ~1–10 years.

HOST SUSCEPTIBILITY

Epidemiological evidence indicates some genetic predisposition to cervical cancer with a family history of cervical tumors in first-degree relatives because of the similar cervical cancer risk in siblings sharing a mother or father, which means the vertical transmission of HPV from mother to child is unlikely. In an analysis of data from the population-based Swedish national registers of all individuals born after 1940, the relative risk for cervical tumor cases was similar for half-sisters having a father (RR = 1.41, 95% CI: 1.22–1.62) or mother (RR = 1.49, 95% CI: 1.29–1.73) in common.[185] The relative risk of cervical tumors in biological full sisters was elevated (RR = 1.93, 95% CI: 1.85–2.01), whereas the RR of cervical tumors in adoptive sisters was not statistically different from unity (RR = 1.15, 95% CI: 0.82–1.57).

The development of cervical tumors depends on the interplay between the tumorigenic properties of the HPV and host factors that affect HPV exposure and immunity to infection [e.g., human leukocyte antigen (HLA) molecules that present antigens to the immune system, major histocompatibility complex (MHC) region]. A genome-wide association study of 731,422 single nucleotide polymorphisms (SNPs) in 1,075 cervical cancer cases and 4,014 controls identified *MICA* (polymorphic major histocompatibility complex class I chain-related protein A), *HLA-DPB1*, and *HLA-DPB2* as potential host-susceptibility genes that may cause impaired immune activation and increased cervical tumor risks.[186]

CLINICAL FEATURES

The median age at diagnosis of cervical cancer in the United States is 47 years, with many cases presenting at <35 years.[187] In a study of data from the US National Cancer Database on 69,739 initial primary invasive cervical cancers, the average age was ~50 years. Advanced clinical stages of cervical cancer tumors (Stage III/IV) extend to the lower 1/3 of the uterus and/or the pelvic wall and other organs; these tumors occur more often in older women (~42% in 70-year-old women) than women aged 12–34 years (~17%).[188] Early-stage cervical cancers are often asymptomatic and detected on routine screening or pelvic examination.[189] Clinical features may include postcoital or abnormal vaginal bleeding, whereas lower limb edema, sciatica, and flank pain suggest pelvic sidewall invasion. Prognosis closely relates to clinical stage with a 5-year relative survival rate of ~91% for patients with localized disease compared with ~58% for regional disease and 17% for distant disease.

EPITHELIAL ENDOMETRIUM

Worldwide, epithelial endometrial carcinoma is the second most frequent histological type of female genital

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 57.7. World Health Organization (WHO) classification of uterine corpus tumors. This classification also includes another malignant tumor category for neoplasms that do not fit into the major categories (metastatic, unclassifiable).

Histological Category	Cell Origin	Subtypes
Epithelial	Epithelial	Endometrioid, serous, clear cell, mucinous, squamous cell, transitional cell, small cell, undifferentiated
Mixed	Epithelial/ mesenchymal	Carcinosarcomas (Müllerian tumors)
Mesenchymal	Mesenchymal	Sarcomas (smooth-muscle, endometrial stroma, supporting tissues)
Gestational trophoblastic diseases	Trophoblast cells	Hydatidiform mole, choriocarcinomas, placental-site trophoblastic tumors, epithelioid trophoblastic tumors

tract cancer after cervical cancer; however, epithelial endometrial cancer is the most common female genital tract cancer in developed countries, with the highest incidence occurring in North America and western Europe. The worldwide cumulative risk of developing endometrial cancer by age 75 in women is ~1%, compared with a cumulative risk of ~0.2% for women dying from endometrial cancer by age 75 years.[7] Over 90% of uterine cancers arise from glandular epithelium lining the uterine cavity (i.e., epithelial endometrial carcinomas). The remaining types of uterine corpus (body) cancers include uterine sarcomas (~5%, endometrial stroma sarcoma, leiomyosarcomas, sarcomas of other supporting uterine fundus tissues), mixed tumors (carcinosarcomas or Müllerian, adenosarcomas), and secondary tumors (e.g., metastatic, unclassifiable), as displayed in Table 57.7. This section focuses on epithelial endometrial cancer (i.e., the vast majority of non-cervical uterine tumors).

In the United States, uterine cancer is the fourth most common cancer and the seventh most common cause of cancer-related deaths among women.[190] US annual uterine cancer incidence (~54,000 in 2016) and mortality (~11,000 in 2016) are some of the few US cancer rates increasing over the last several decades, averaging an annual increase of 0.7% and 1.1%, respectively, since 1999.[191] This pattern parallels the increase in the prevalence of the strongest risk factors for uterine cancer and obesity. Uterine cancer incidence is higher in US non-Hispanic black and Caucasian women (27 cases/100,000) than in other racial/ethnic groups (19–23 cases/100,000).

CARCINOGENESIS

Estrogen promotes glandular proliferation producing endometrial hyperplasia, whereas progestin secretion following ovulation causes glandular luteinization and the cessation of estrogen-induced stimulation. Unopposed estrogen stimulation is associated with increased endometrial cancer risks, particularly in postmenopausal women. The Bokhman clinicopathological classification of epithelial endometrial tumors divides these tumors into type I (endometrioid) and type II (non-endometrioid) tumors, as explained in the Histology Section. Endometrioid cancers usually display a high mutational load distributed throughout the genome. The major affected signaling pathways are PI3K/AKT/mTOR (regulation of cell growth/survival) and Wnt/β-catenin (regulation of gene transcription/development).[192] The *PTEN* tumor suppressor gene inhibits the PI3K/AKT/mTOR signaling pathway with loss from mutation occurring in a majority of endometrioid cancers (i.e., 52–78%).[193,194] These mutations are associated with deregulation of apoptosis and enhanced tumor survival. Alteration of the Wnt/β-catenin signaling pathway with loss of E-cadherin develops in up to 50% of endometrioid tumors, with the nuclear accumulation of β-catenin indicating activation of the Wnt/β-catenin signaling.[195] Alteration of cell adhesion and communication from β-catenin gene (*CTNNB1*, catenin beta 1) mutations occur in 14–44% of endometrioid tumors independent of microsatellite instability and mutations of other genes (*PTEN*, *KRAS*).[196,197]

Microsatellite instability involves the alteration of short repetitive nucleotide DNA sequences primarily as a result of *MLH1* (mutL homolog 1) gene promoter hypermethylation and the subsequent loss of function of the mismatch-repair protein during cell replication.[198] This process occurs in up to 1/3 of endometrial tumors due to DNA hypermethylation.[199] Promoter hypermethylation also produces underex-

TABLE 57.8. Comparison of estimated frequency of the six most common genetic alterations in Type I and II epithelial endometrial cancers. (Adapted from Murali et al.).[193]

Abnormality	Type I Tumors (%)	Type II Tumors (%)
PTEN mutation	52–78	1–11
PIK3CA mutation	36–52	24–42
Microsatellite instability	28–40	0–2
ARID1A mutation	25–48	6–11
PIK3R1 mutation	21–43	0–12
KRAS mutation	15–43	2–8
TP53 mutation	9–12	60–91
HER2 amplification	0	27–44
PPP2R1A mutation	5–7	15–43

Abbreviations: ARID1A = AT-rich interaction domain 1A that is part of the SWI/SNF complexes regulating chromatin remodeling; HER2 = a member of the epidermal growth factor (EGF) receptor family of receptor tyrosine kinases involved with cell surface receptor complexes and transcriptional regulation; KRAS = *KRAS* proto-oncogene that forms an oncogene via the action of GTPase on the RAS/MAPK pathway; PIK3R1 = phosphoinositide-3-kinase regulatory subunit 1 that affects signaling pathways for cell growth, division, migration, and survival; PPP2R1A = protein phosphatase 2 scaffold subunit A alpha of tumor suppressor PP2A complex; *PTEN* = phosphatase and tensin homolog tumor suppressor gene produces enzyme that affects cell division, adhesion, migration, and angiogenesis; TP53 = tumor suppressor protein p53 gene that helps control cell division.

pression of diverse genes involving PIK3 (*PIK3CA*, *PTEN*) and Wnt/β-catenin (*CTNNB1*, *APC*) signaling pathways in endometrioid tumors. Promoter hypermethylation is much less frequent in type II endometrial carcinomas.[200]

Mutation of the tumor suppressor gene *TP53* is the most common DNA abnormality in serous carcinomas present in ~90% of serous carcinomas compared with 30% of high-grade and 10% of low-grade endometrioid tumors.[193] In contrast to endometrioid tumors, type II (non-endometrioid) tumors also display frequent E-cadherin inactivation (80–90%), p16 tumor suppressor and cell-cycle regulator inactivation from CDKN2A (cyclin-dependent kinase inhibitor 2A) mutations (40%), c-erbB2 amplifications of epidermal growth factor receptor tyrosine kinases (30%), alterations of mitotic spindle checkpoint regulation genes (*STK15*), and chromosomal instability;[196,201] microsatellite instability is rare in serous tumors. Alterations of E-cadherin reduce cell adhesion and promote deep myometrial and vascular invasion as well as lymph node metastasis. Table 57.8 compares the percentages of the six most common genetic alterations in type I and II epithelial endometrial cancers.

EXPOSURE

The main risk factors for developing endometrial cancer include obesity, nulliparity, early menarche, late menopause, age ≥ 55 years, and tamoxifen use;[202] occupational and lifestyle factors contribute little to the overall endometrial cancer risk. Type I tumors (i.e., mainly endometrioid adenocarcinomas) are typically associated with unopposed estrogen stimulation, whereas less common and more clinically aggressive type II tumors (i.e., predominately serous carcinomas and mixed cell tumors) are estrogen independent. A large pooled analysis of 10 cohort and 14 case-control studies from the Epidemiology of Endometrial Cancer Consortium reported that endometrioid adenocarcinoma risk increases with BMI and diabetes, whereas the risk decreases with age at menarche, parity, oral contraceptive use, and cigarette smoking.[203] Endometrial cancer risk factors (i.e., ↑ parity, age at menarche, tobacco smoking) for heterogeneous, high-grade endometrioid tumors and type II tumors demonstrate similar reductions ($P_{trend} \leq 0.0006$), with the exception of clear-cell carcinomas. The latter tumors were not associated with age at menarche or parity. Although endometrial risk factors are similar between races, the prevalence of endometrial risk factors varies with race.[204]

Occupation

Increased endometrial cancer risks are not causally linked to any specific occupation. In the Nordic cohort study of 15 million people and 2.8 million incident cancer cases developing during follow-up in 1960–2005, analysis of the data demonstrated no clear pattern associating any of the 54 occupational categories with endometrial cancer risks.[165] A Chinese nested case-control study of textile workers suggested elevated age-adjusted hazard ratios for endometrial cancer in workers with ≥10 years in silk production (HR = 3.8, 95% CI: 1.2–11.8, $n = 4$ cases) and silica dust exposure (HR = 7.4, 95% CI: 1.4–39.7, $n = 2$ cases) using never-exposed textile workers as controls.[205] The imprecise hazard ratios, small number of incidence cases, and lack of a dose-response relationship indicate the results should be interpreted cautiously.

Lifestyle

Obesity

Obesity as measured by BMI and waist-to-hip ratio is the strongest risk factor for endometrial cancer, accounting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for ~40% of endometrial cancers in the developed world .[206,207] The vast majority of epidemiological studies report a statistically significant positive association between obesity and endometrial cancer risks. Obesity is associated with endometrial hyperplasia from excess estrogen production because of peripheral conversion of androgens (e.g., androstenedione) secreted from the adrenal gland and ovaries into estrone by aromatase in adipose tissues (e.g., adipocytes, preadipocytes, mesenchymal stem cells). Aromatase concentrations and activity increase with age and degree of adiposity.[208] Anovulation in obese women also produces continuous, unopposed estrogen stimulation because of the lack of a corpus luteum to produce progesterone. Additional potential mechanisms include increasing insulin resistance (↑ insulin-like growth factor-1) and inflammation (↑ tumor necrosis factor-α, leptin, interleukin-6, adipokines, C-reactive protein) leading to increased cell proliferation and decreased apoptosis.

In an analysis of data comparing obese (BMI 30–<35 kg/m^2) with normal-weight (BMI < 25 kg/m^2) women, the overall pooled risk estimate for endometrial cancer was 2.32 (95% CI: 2.08–2.58) in 28 case-control studies and 2.49 (95% CI: 2.28–2.73) in 25 cohort studies.[209] A large pooled study from the Endometrial Cancer Consortium reported an overall pooled estimate for endometrial cancer risks in obese women of 2.65 (95% CI: 2.43–2.90) using normal-weight women as controls.[203] Increasing obesity was associated with increased endometrial cancer risks. The OR per 2 kg/m^2 per increase in BMI was weaker for type II tumors (OR = 1.12, 95% CI: 1.09–1.14) than for estrogen-dependent type I tumors (OR = 1.20, 95% CI: 1.19–1.21) with substantial heterogeneity ($P_{heterogeneity}$ = <0.0001). Measures of central obesity (waist circumference, waist-to-hip ratio > 0.85) were also associated with elevated endometrial cancer risks. Studies on the effect of menopausal status on obesity and endometrial cancer risks are inconsistent.

Physical Activity

Observational studies suggest physical activity may reduce endometrial cancer risks; however, the data are inconclusive, in part because of the difficulty accounting for the confounding of obesity, potential recall bias, and misclassification. Most studies adjusting for obesity use BMI, which is an imperfect measure of obesity, as a measure of body fat and lean body mass. In multivariate models using data from the Nurses' Health Study cohort (71,570 women assessed every 2–4 years during 1986–2008), the endometrial cancer risk was reduced in women engaged in recent moderate recreational activity defined by 9 to <18 MET-hour/week (RR = 0.61, 95% CI: 0.48–0.78) and high recent recreational activity defined by ≥18 MET-hour/week (RR = 0.73, 95% CI: 0.58–0.92) compared with women expending <3 MET-hour/week, P_{trend} = 0.001).[210] However, these estimates became statistically nonsignificant after adjustment for body mass index suggesting the reduced risks reflected confounding by adiposity. In a meta-analysis of eight prospective cohort studies comparing the highest and lowest levels of recreational physical activity after adjustment for BMI, the estimated RR for endometrial cancer was reduced (pooled RR = 0.78, 95% CI: 0.63–0.95).[211] Four out of seven cohort studies reported a significant dose-response relationship. The trend for increasing endometrial cancer risk with increased sedentary time was positive for inactive women (P_{trend} = 0.04) but not for active women engaging in vigorous physical activity defined by >20 minutes 3 times/week (P_{trend} = 0.08). In a meta-analysis of 18 cohort, 1 nested case-control, and 14 case-control studies using mostly self-administered questionnaires or job titles, the summary relative risk for endometrial cancer comparing high and low recreational physical activity was 0.84 (95% CI: 0.78–0.91).[212] Analysis of activity by MET-hour in nine studies yielded a nonlinear inverse dose-response relationship for endometrial cancer risk. The inverse relationship with endometrial cancer was smaller in cohort (RR = 0.84, 95% CI: 0.78–0.91) than case-control (RR = 0.72, 95% CI: 0.64–0.80, $P_{difference}$ = 0.03) studies. The meta-analysis did not detect difference in endometrial cancer risks with menopausal status ($P_{difference}$ = 0.07) or adjusting for BMI ($P_{difference}$ = 0.39).

Alcohol

Alcohol consumption is probably not a strong risk factor for endometrial cancer. Most studies report null or statistically nonsignificant results; however, the data do not exclude slight risks in subgroups of epithelial endometrial cancers. Analysis of data from the NIH-AARP Diet and Health Cohort Study (114,414 US women, 1,491 incident endometrial cancer cases) demonstrated no significant trend (P_{trend} = 0.90) for increasing alcohol consumption and endometrial cancer risks.[213] Using Cox proportional hazards regression and nondrinkers as controls, the adjusted multivariate RR for endometrial cancer was not significantly elevated for daily alcohol consumption of 12 to <24 g (RR = 1.06, 95% CI: 0.87–1.31) or ≥24 g (RR = 0.93, 95% CI: 0.71–1.20). Analysis of alcohol intake data and endometrial cancer risk from the Nurses' Health Study using nondrinkers as

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

controls suggested a reduced endometrial cancer risk in women with light daily alcohol intake (<5 g, ~1/2 drink); the multivariable RR was 0.78 (95% CI: 0.66–0.94) with no increased risk for women consuming ≥2 drinks (multivariate RR = 0.78, 95% CI: 0.49–1.25).[214]

Tobacco Smoking

Cigarette smoking is associated with a reduced risk of endometrial cancer. Using never-smokers as controls in an analysis of pooled data from seven cohort and four case-control studies in the Epidemiology of Endometrial Cancer Consortium, endometrial cancer risks were decreased in current smokers in black (OR = 0.67, 95% CI: 0.47–0.95, $n = 58$ cases) and white (OR = 0.63, 95% CI: 0.56–0.72, $n = 406$ cases) women.[204] In the NIH-AARP Diet and Health Study of 110,304 US women (1,476 incident endometrial carcinomas) using never-smokers as controls, the endometrial carcinoma risk was marginally reduced in former smokers (RR = 0.89, 95% CI: 0.80–1.00) and reduced in current smokers (RR = 0.65, 95% CI: 0.55–0.78).[215] Smoking cessation within 1–4 years was associated with reduced risk (RR = 0.65, 95% CI: 0.48–0.89), but this reduction returned to baseline by 10 years post-cessation. Tumor characteristics did not substantially change the endometrial cancer risks.

Diet

Dietary factors are not clearly associated with endometrial cancer. Limited data suggest total fat and saturated fat are positively associated with endometrial cancer risk, but the epidemiology studies are inconclusive. In a meta-analysis of 5 cohort and 11 case-control studies, the pooled RR for endometrial cancer was reduced in the case-control studies comparing the highest and lowest categories of total dietary fat intake (pooled OR = 1.39, 95% CI: 1.10–1.76). However, the lower pooled RR in the cohort studies was not statistically significant (pooled RR = 0.91, 95% CI: 0.83–1.01).[216] The funnel plot and Egger test suggested significant publication bias ($P = 0.01$). Analysis of dietary saturated fat intake and endometrial cancer risk demonstrated similar risks. The pooled estimate of three cohort studies for monounsaturated fatty acids and endometrial cancer risks demonstrated an inverse association (pooled OR = 0.84, 95% CI: 0.73–0.98) but not case-control studies (pooled OR = 1.02, 95% CI: 0.85–1.22). The study reported no significant associations between monounsaturated fatty acids or linoleic acid and endometrial cancer risks.

Intrauterine Devices

Limited data suggest the use of nonhormonal intrauterine devices (IUDs) reduces endometrial cancer risks. A pooled analysis of data from 4 cohort and 14 case-control studies in the Epidemiology of Endometrial Cancer Consortium using multivariate logistic regression estimated a pooled OR of 0.81 (95% CI: 0.74–0.90) comparing endometrial cancer risks in ever- versus never-IUD users independent of known risk factors.[217] The estimates were significantly heterogeneous between studies (meta-OR = 0.83, 95% CI: 0.72–0.96, $I^2 = 68.6\%$, $P_{\text{heterogeneity}} \leq 0.0001$) and among case-control studies (meta-OR = 0.82, 95% CI: 0.69–0.98, $I^2 = 75.8\%$, $P_{\text{heterogeneity}} = <0.0001$) but not cohort studies (meta-OR = 0.86, 95% CI: 0.67–1.10, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.87$). The latter estimate was not statistically significant. The inverse association was strongest among inert IUDs and weaker among copper and hormone-releasing IUDs. Endometrioid (type I) tumors were inversely associated with ever-use of IUDs (pooled OR = 0.87, 95% CI: 0.79–0.95) but not non-endometrioid (type II) tumors (pooled OR = 1.05, 95% CI: 0.81–1.36). In a meta-analysis of 10 case-control studies, the pooled adjusted endometrial cancer risk for nonhormonal IUD users was 0.54 (95% CI: 0.47–0.63, $P_{\text{heterogeneity}} = 0.40$) with some evidence of a dose-response based on duration of use.[218] The biological mechanism for the inverse relationship between endometrial cancer risks and IUD use remains unclear.

Reproductive History

Parity is a strong risk factor for endometrial cancer. Approximately one-half of women of <45 years old diagnosed with endometrial carcinoma are nulliparous, frequently presenting with complex atypical hyperplasia.[219] Infertility related to anovulation and progesterone deficiencies rather than tubal factors increases endometrial cancer risks. Breastfeeding suppresses ovulation and maternal estrogen concentrations leading to reduced endometrial mitoses. A meta-analysis of 3 cohort and 14 case-control studies from the Epidemiology of Endometrial Cancer Consortium suggests breastfeeding modestly reduces endometrial cancer risks.[220] After excluding nulliparous women and using never-IUD users as controls, the pooled OR for endometrial cancer in self-reported ever-breastfeeding women was 0.89 (95% CI: 0.81–0.98, $I^2 = 45\%$, $P_{\text{heterogeneity}} = 0.02$) with moderate heterogeneity; however, the association with duration of IUD use was not clearly linear, particularly after 6–9 months. The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

inverse association did not vary substantially by recent BMI, parity, menopausal status, or tumor type (I vs. II).

Medications

Tamoxifen is associated with increased endometrial cancer in women treated for breast cancer, primarily low-grade endometrioid adenocarcinomas. Progestogens promote cellular differentiation, apoptosis, and cell-cycle arrest while inhibiting inflammation and invasion in endometrial tissue. Oral estrogen replacement therapy is associated with several-fold increased endometrial cancer risks, primarily low-grade endometrioid adenocarcinomas arising from complex atypical hyperplasia or endometrial intraepithelial neoplasia, whereas combined estrogen/progesterone therapy does not significantly increase endometrial cancer risks.[221] The use of oral contraceptives is associated with reduced endometrial cancer risks. In pooled data from seven cohort and four case-control studies from the Epidemiology of Endometrial Cancer Consortium using never-users as controls, the endometrial cancer risk was reduced in oral contraceptive users for ≥10 years in black (OR = 0.49, 95% CI: 0.27–0.88, $n = 29$ cases) and white (OR = 0.69, 95% CI: 0.58–0.83, $n = 389$ cases) women.[204] Observational studies on nonsteroidal anti-inflammatory drug (NSAID) and aspirin use on endometrial cancer are inconsistent. A systematic review and meta-analysis suggested a mild reduction in endometrial cancer risks; however, the pooled risk ratios were not statistically significant comparing regular use with nonusers.[222]

Diseases

Diabetes

The relationship between diabetes and endometrial cancer remains controversial. In a meta-analysis of mostly case-control studies (3 cohort, 13 case-control studies) including mostly type II diabetes, the summary relative risks for cohort studies were 1.62 (95% CI: 1.21–2.16, $I^2 = 0.0\%$, $P_{\text{heterogeneity}} = 0.60$, $n = 3$ studies) and 2.22 (95% CI: 1.80–2.74, $I^2 = 57.7\%$, $P_{\text{heterogeneity}} = 0.01$, $n = 13$ studies) respectively.[223] For the two studies controlling for physical inactivity and obesity, the summary RR was 2.47 (95% CI: 1.37–4.45, $I^2 = 48.8\%$, $P_{\text{heterogeneity}} = 0.16$, $n = 2$ studies) with moderate heterogeneity. For a meta-analysis of seven mostly prospective US and European cohorts involving mainly type II diabetics, the adjusted summary RR for endometrial cancer was 1.89 (95% CI: 1.46–2.45, $I^2 = 20.0\%$, $P_{\text{heterogeneity}} = 0.283$) using nondiabetics as controls.[224] Variation in study designs prohibited sensitivity and subgroup analyses; consequently, confounding by obesity and the effect of multiple comparisons were not excluded. In a review of four cohort studies adjusting for BMI, a Swedish study[225] reported a positive association between diabetes and endometrial cancer incidence and three US and Swedish studies did not.[226,227,228]

Polycystic Ovary Syndrome

Most observational studies indicate an increased risk of endometrial cancer in women with polycystic ovary syndrome (PCOS).[229] In a meta-analysis of five observational studies on women with PCOS, the risk of endometrial cancer was significantly increased when compared with controls without PCOS (OR = 2.79; 95% CI: 1.31–5.95, $P < 0.008$).[230] Exclusion of women >54 years of age increased endometrial cancer risks for PCOS (OR = 4.05, 95% CI: 2.42–6.76, $P < 0.00001$). The imprecise estimates of endometrial cancer risk suggest potential misclassification and selection bias. Analysis of data from the Danish National Patient Register identified 12,070 women with PCOS diagnosed between ages 9 and 49 years and followed during 1977–2012; the standardized incidence ratio (SIR) for endometrial cancer was 3.9 (95% CI: 2.2–6.3, $n = 16$ cases).[231]

HISTOLOGY

The vast majority (i.e., ~80%) of endometrial carcinomas are epithelial endometrial carcinomas, typically endometrial adenocarcinomas arising from glandular epithelium in areas of atypical hyperplasia.[232] Based on the clinical and epidemiological characteristics of Russian women in the former Soviet Union, Bokhman developed a dualistic clinicopathological classification that divides epithelial endometrial cancer into the following two major classifications: type I (low-grade, diploid, endometrioid, hormone-receptor-positive tumors with a good prognosis) and type II (high-grade, aneuploid, non-endometrioid, hormone-receptor-negative tumors with TP53 mutations, frequent metastatic lesions, and a poor prognosis).[233] Type I tumors are associated with obesity, excess estrogen stimulation, endometrial hyperplasia, and moderate-to-high differentiation; these tumors range widely from well-to-poorly differentiated (i.e., low- to high-grade) tumors. Low-grade endometrioid carcinomas usually occur in premenopausal women in association with endometrial hyperplasia. Type II epithelial endometrial tumors typically develop in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nonobese women with absent metabolic/endocrine abnormalities, atrophic endometrium, and poorly differentiated tumors. Occasionally, these tumors arise from precancerous lesions in atrophic endometrium or endometrial polyps. Serous tumors usually develop in postmenopausal women with atrophic endometrium and aggressive features; however, overlap between types I and II tumors as well as heterogeneity within tumor subtypes occur. Some non-endometrioid carcinomas probably arise from preexisting endometrioid carcinomas by tumor progression.[196] Although the Bokhman model fits low-grade endometrioid and serous tumors well, many endometrioid tumors do not share all the characteristics of the type I classification, particularly molecular markers and prognosis.[193] Approximately 10–19% of endometrioid carcinomas are high grade, with characteristics being intermediate between types I–II or more similar to type II tumors (e.g., no endometrial hyperplasia, poor prognosis). Additionally, substantial overlap occurs between tumor subtypes and molecular markers, as displayed in Table 57.9. The depth of myometrial invasion correlates with lymph node spread.

The Cancer Genome Atlas (TCGA)/research network published a new molecular classification of epithelial endometrial tumors based on genomic analysis of endometrial tumors. This classification contains the following four subgroups: 1) POLE ultramutated tumors that can encode the central catalytic subunit of the polymerase epsilon involved with DNA repair; 2) hypermutated, microsatellite-unstable tumors with reduced *MLH1* gene expression from promoter DNA hypermethylation; 3) copy number-low, microsatellite-stable endometrioid tumors; and 4) copy number-high, serous-like tumors representing almost all serous carcinomas, some high-grade endometrioid carcinomas, a few low-grade endometrioid carcinomas, and most mixed histology tumors.[234,235]

HOST SUSCEPTIBILITY

Most endometrial cancers arise sporadically with only a small fraction attributable to inherited genetic susceptibility. Studies on the endometrial cancer risk in women with first-degree relatives with endometrial cancer are inconsistent. A systematic review and meta-analysis of four clinic-based case-control, six population-based case-control, and six cohort studies reported an ~2-fold increased endometrial cancer risk comparing women with and without self-reported first-degree relatives with endometrial cancer.[236] A majority of these studies adjusted for multiple endometrial risk factors. Using a fixed-effects model, the overall RR was 1.82 (95% CI: 1.65–1.98, I^2 = 29.6%, $P_{\text{heterogeneity}}$ = 0.402). Three studies estimated the relative risk of endometrial cancer by excluding Lynch syndrome families based on tumor microsatellite instability (OR = 1.3, 95% CI: 0.8–2.4),[237] mismatch-repair gene mutations ($HR_{\text{age 70 years for 1 first or second-degree relative}}$ = 3.40, 95% CI:

TABLE 57.9. Molecular and clinicopathological characteristics of type I (endometrioid) and type II (high-grade non-endometrioid) tumors. Serous and clear-cell tumors often present at advanced stages (International Federation of Gynecology and Obstetrics grade 3), whereas low-grade endometrioid tumors present at early stages. Prognosis is better at an early stage of presentation for clear cell than for serous tumors. (Adapted from Murali et al.).[193]

Characteristic	Endometrioid	Endometrioid	Serous	Clear Cell
Histological grade	Low	High	High	High
ER/PR expression	+	+/−	−/+	−
PTEN expression	−/+	−/+	+	+
DNA MMR loss	−/+	−/+	−	−/+
TP53 mutation	−	−/+	+	−/+
Ki67/*MIB-1*	Low	High	High	Low/High
Metastatic potential	Uncommon	Lymph nodes, distant organs	Lymph nodes, distant organs, peritoneal	Lymph nodes, −/+ peritoneal
Prognosis	Favorable	Poor	Poor	Poor

Abbreviations: + = present/high; −/+ = occasional; +/− = frequent; − = absent/low; ER = estrogen receptor; Ki67 = an antigen exclusively associated with cell proliferation; *MIB-1* = mindbomb E3 ubiquitin protein ligase 1 gene that promotes TNF-induced apoptosis; MMR = mismatch repair; PR = progesterone receptor; *PTEN* = phosphatase and tensin homolog tumor suppressor gene produces enzyme that affects cell division, adhesion, migration, and angiogenesis; *TP53* = tumor suppressor protein p53 gene that helps control cell division.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. 2.32–4.66),[238] and clinical criteria (SIR ≅ 2).[239] These findings suggest familial endometrial cancer risks involve mutations other than mismatch DNA repair genes. *BRCA* gene carriers do not have an increased risk of endometrial cancer unless they receive tamoxifen.[206]

The most common genetic disease associated with endometrial cancer is hereditary nonpolyposis colon cancer (Lynch syndrome) that affects 2–3% of endometrial cancer patients; endometrial cancer is the second most common cancer occurring in patients with this syndrome.[240] This autosomal-dominant disorder results from DNA replication errors causing germline-inactivating DNA mismatch-repair mutations from several genes, including *MLH14* (mutL homolog 1), *MSH2* (mutShomolog 2), *MSH6* (mutShomolog 6), and *PMS2* (PMS1 homolog 2A). Approximately 75% of these patients with endometrial cancer have microsatellite instability. Most tumors in these patients display pure or mixed endometrioid features, with only ~15% demonstrating non-endometrioid histology.[241] In a study of 76 women with mutation-proven Lynch syndrome and pathology-confirmed endometrial cancer, 76% of these women had low-grade endometrioid carcinomas with the remaining being high-grade tumors (serous, clear-cell, mixed/other carcinomas, dedifferentiated carcinomas).[242] The approximate mix of common mutations involved *MSH2* (66%), *MLH1* (24%), and *MSH6* (10%) DNA repair genes. Rare causes of hereditary endometrial cancer include Cowden syndrome (PTEN mutations)[243] and Peutz–Jeghers syndrome (STK11 mutations).[244]

CLINICAL FEATURES

The vast majority of women with endometrial cancer present in the sixth and seventh decades of life with abnormal vaginal bleeding with or without vaginal discharge and pyometra; the bleeding involves postcoital or persistent inter-cyclic bleeding in premenopausal women or postmenopausal bleeding beginning 1 year after menopause.[245] Approximately 10% of women with postmenopausal bleeding have endometrial cancer.[206] Pelvic pain is a much less common feature of endometrial cancer; however, patients with advanced disease may complain of abdominal or pelvic pain and abdominal distension. Endometrial cancer is an age-related disease, with only ~14% developing in premenopausal women and ~5% in women of <40 years of age; the mean age for the most common endometrial cancer (i.e., endometrioid adenocarcinoma) is 61 years.[246,247] Endometrial cancer is usually primary with rare cases of metastatic disease from other organs (e.g., breast, ovary, lung, colorectal); the lungs are the most common site of distant metastasis.[206]

The annual mortality/incidence ratio for endometrial cancer is lower (0.24) than for breast (0.32), uterine cervical (0.55), or ovarian cancers (0.63).[248] Survival rates vary with clinical staging (International Federation of Gynecology and Obstetrics, FIGO) and histology as well as with age, comorbidities, and tumor size. Most endometrial cancers (i.e., ~75%) are diagnosed at an early stage (FIGO Stage I or II) with an overall survival rate of 74–91% in women without metastatic disease. The overall survival rate for FIGO Stage II is 57–66% with the rate decreasing to 20–26% for FIGO Stage IV.[3] The 5-year recurrence-free survival rates for endometrioid carcinomas range from 68–83%, with lower survival for high-grade endometrioid tumors.[249] Analysis of SEER data on 4,180 women with endometrial cancer, grade 3 endometrioid tumors, accounted for 15% of the endometrial tumors and 27% of endometrial cancer-related deaths, whereas grade 1/2 (low-grade) tumors represented 72% of the diagnoses and 26% of the endometrial cancer-related deaths.[250] Five-year survival rates for serous carcinomas range from 20–55% compared with ~40–50% for clear-cell carcinomas.[251]

OVARY

Ovarian cancer is the second most common gynecological cancer in the United States, with an annual incidence of ~22,000 cases and annual ovarian cancer-related deaths of ~14,000.[252] The average lifetime ovarian cancer risk in US women is ~1.3% (i.e., 1/78 women), with rates ~30% higher in non-Hispanic white women than African-American or Asian women and 12% higher than Hispanic women.[253] Ovarian cancer ranks first in overall mortality from gynecological cancers because the diagnosis of most ovarian cancers occurs in postmenopausal women of ≥50 years of age with advanced disease and widespread metastasis.[254] Worldwide, ovarian cancer is the eighth most common cancer and cancer-related cause of mortality among women.[7] The reported ovarian cancer incidence is highest in Northern, Central, and Eastern Europe; intermediate in Western Europe, North America, and Australia; and lowest in Asia and Africa.

The US ovarian cancer incidence decreased beginning in the mid-1980s, resulting in an overall reduction of 29% between 1985 (16.6/100,000) and 2014 (11.8/100,000).[252] Ovarian cancer-related deaths decreased by 33% between 1976 (10.0/100,000) and 2015 (6.7/100,000). Currently, there are no clearly

effective ovarian cancer screening methods for the general population with benefits that outweigh potential risks.[255]

CARCINOGENESIS

Although several carcinogenic mechanisms have been proposed for ovarian cancer tumorigenesis, including hormonal (gonadotropin) stimulation, incessant ovulation, and chronic inflammation,[256] the etiology of ovarian cancer remains unclear. Ovarian cancer is a heterogeneous group of neoplasms of histological and clinicopathological subtypes that vary in risk factors, etiology, molecular biology, cellular origin, prognosis, and treatment. Low-grade serous, endometrioid, clear-cell, and mucinous epithelial tumors probably arise from inclusion cysts or extraovarian benign lesions that migrate to the ovary and undergo mutations of multiple genes (e.g., *BRAF*, *KRAS*, *PTEN*) to form a malignant neoplasm.[257] Extraovarian sources for ovarian tumors include benign deposits of fallopian tube epithelium (endosalpingiosis) for low-grade serous carcinomas, benign foci of endometrial tissue in the ovary (endometriosis) for endometrioid and clear-cell carcinomas, and benign foci of transitional epithelium from the tuboperitoneal junction for mucinous carcinomas.

EXPOSURE

Factors associated with an increased risk for invasive epithelial ovarian cancer include age, race, nulliparity, family history of breast or ovarian cancer, endometriosis, and prior history of breast or endometrial cancer.[258,259] Inherited genetic variants (e.g., BRCA1/2) account for up to about 25% of ovarian cancers. Higher androstenedione and dehydroepiandrosterone (DHEA) concentrations are associated with dose-related, increased ovarian cancer risks,[260] whereas multiparity, lactation, oral contraceptive use, and tubal ligation/hysterectomy are inversely related to ovarian cancer risks.[261,262] The cumulative risk of developing ovarian cancer by age 65 ranges from 0.3% for white women who had ≥3 pregnancies and ≥4 years of oral contraceptive use to 1.6% for nulliparous white women with no oral contraceptive use.[263] There is no clear, consistently strong association between ovarian cancer and smoking, coffee, alcohol consumption, or physical activity.[264,265] Dietary factors (e.g., fat, protein, calorie intake) are potential risk factors, but few data identify specific dietary factors with clinically significant increased ovarian cancer risks.[266]

The heterogeneity of ovarian tumors and differences in potency between histological subtypes complicate the evaluation of specific risk factors.[267] Most ovarian cancer risk data focus on invasive epithelial ovarian cancer.[268] Each subtype has a unique combination of risk factors, with the strongest associations with endometrioid and clear-cell tumors. The latter two subtypes share similar risk factors. Moderate-to-poorly differentiated serous cancers have distinctly different risk patterns, whereas well-differentiated serous carcinomas demonstrate risk patterns similar to endometrioid carcinomas. Most reproductive and hormonal risk factors are more strongly associated with endometrioid and clear-cell carcinomas than other subtypes. Serous and poorly differentiated carcinomas are the common aggressive subtypes, with the strongest association being with family history of ovarian cancer and modest associations with other common risk factors (e.g., menopausal hormone therapy, parity, oral contraceptive use). Table 57.10 summarizes the major risk factors associated with overall invasive epithelial ovarian cancer and, when sufficient data exist, with histological subtypes.

Occupation

Asbestos and asbestos-contaminated talc (hydrous magnesium silicates) are the two main industrial chemicals most often associated with ovarian cancer. No other single, non-asbestos-related occupation is an established ovarian carcinogen. Many occupational studies on ovarian cancer are ecological or lack adjustment for well-established risk factors and potential misclassification due to difficulty distinguishing peritoneal mesotheliomas from ovarian cancers.

Job Category

A hypothesis-generating case-control study of ovarian cancer suggests the following possible associations based on reported job titles: aromatic hydrocarbon solvents (SIR = 1.3, 95% CI: 1.0–1.7), leather dust (SIR = 1.4, 95% CI: 0.7–2.7), man-made vitreous fibers (SIR = 1.3, 95% CI: 0.9–1.8), high asbestos concentrations (SIR = 1.3, 95% CI: 0.9–1.8), and engine exhaust.[269] None of these associations reached statistical significance, although the trends for increasing exposure to chlorinated hydrocarbon solvents, man-made vitreous fibers, and chromium were statistically significant. The relatively low SIR suggests the possibility of confounding or misclassification. A population-based case-control study using self-administered questionnaires and adjusting for potential confounders suggests excess ovarian cancer risks for teachers, bookkeepers/accounting clerks, retail store employees, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 57.10. Summary of epithelial ovarian cancer risks and protective factors. Unless otherwise stated, the ovarian cancer risk refers to the overall epithelial ovarian cancer risk. (Adapted from Webb and Jordan).[253]

Association Strength	Increased Ovarian Cancer Risk	Primary Carcinoma Subtype	Reduced Ovarian Cancer Risk
Established	Ovarian cancer family history Tobacco smoking Obesity Endometriosis Estrogen-only hormone therapy	Mucinous Non-high-grade serous cancers Endometrioid, clear cell	Pregnancy (lasting >6 months) Oral contraceptives Tubal ligation
Probable	Delayed menopause		Breastfeeding
Possible	Early menarche Combined menopausal hormone therapy Pelvic inflammatory disease Diabetes mellitus Genital talc use Asbestos	Borderline tumors	Older first birth Aspirin Vitamin D
Unlikely or insufficient	Diet, physical activity, alcohol use, infertility treatment, hysterectomy without oophorectomy, polycystic ovarian syndrome, fibroids, ovarian cysts		

noninstitutional health services.[270] The lack of specific exposure information, low response rates for controls, failure to establish biological plausibility for increased risks in multiple job types, and multiple comparisons limit any conclusions about causality.

An Italian case-control, hospital-based study of women with definite exposure to triazine herbicides suggests the possibility of an increased ovarian cancer risk (OR = 2.8, 90% CI: 0.9–8.4, $n = 7$ cases) compared with 7 unexposed controls;[271,272] however, the results were not statistically significant with wide confidence intervals and no quantitation of triazine exposure. A population-based, case-control study of epithelial ovarian cancer in Central California did not detect a statistically significant increase in ovarian cancer risks between ever- and never-occupational triazine herbicide exposures (adjusted OR = 1.34, 95% CI: 0.77–2.33).[273] There was no dose-response relationship between triazine herbicide exposure and ovarian cancer ($P_{trend} = 0.22$).

Asbestos

The IARC lists asbestos as a human carcinogen causing ovarian cancer, with sufficient human evidence of carcinogenicity; however, this classification remains controversial because of methodological issues including failure to adjust for known risk factors, inappropriate comparison populations, and tumor misclassification. A meta-analysis of ovarian cancer and occupational exposure to asbestos, primarily from European studies, demonstrated an overall pooled standardized mortality ratio (SMR) of 1.77 (95% CI: 1.37–2.28, $I^2 = 35.3\%$, $P_{heterogeneity} = 0.061$) when compared with the general population SMR.[274] There was slight to moderate evidence of heterogeneity among the studies, with higher SMRs in European studies and cohorts compensated for asbestosis, whereas three US and Australian cohort studies of occupational asbestos exposure reported no increased ovarian cancer risks. Most of the positive studies used death certificates to validate the outcome of asbestos-related ovarian deaths. In a pooled Italian cohort of 5,741 female asbestos workers followed over 40 years, the SMR for ovarian cancer was borderline (SMR = 1.38, 95% CI: 1.00–1.87, $n = 43$ deaths).[275] A meta-analysis of 14 cohort and 2 case-control studies mostly in Europe reported an increased overall ovarian cancer effect size (SMR = 1.75, 95% CI: 1.45–2.10, $I^2 = 16.2\%$, $P_{heterogeneity} = 0.268$); however, sensitivity analysis indicated the effect size became statistically nonsignificant when analyzing only studies using pathologically confirmed ovarian cancers.[276] The analysis of four studies examining cancer incidence did not demonstrate a statistically significant effect. The authors recommended cautious interpretation of the data because of potential disease misclassification.

Reproductive History

Epidemiological studies indicate hormonal and reproductive factors influence ovarian cancer risks consistent

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with incessant ovulation and gonadotropin stimulation hypotheses; nulliparity is the strongest hormonal risk factor for ovarian cancer. Parous women have a dose-related reduction in ovarian cancer risk (i.e., 30–60%) compared with nulliparous women, particularly endometrioid and clear-cell carcinomas. Although age at first birth was not independently associated with ovarian cancer risk in the large prospective Nurses' Health Study of 121,700 female registered nurses aged 30–55 years, the age-adjusted, overall relative risk of epithelial ovarian cancer comparing parous (mean = 3.1 births) with nulliparous women was 0.55 (95% CI: 0.38–0.80).[277] The relative risk per birth was 0.84 (95% CI: 0.77–0.91, $P_{\text{trend for each birth}} = <0.001$). Analysis of data from the Ovarian Cancer Cohort Consortium indicates that the reduction in ovarian cancer with higher parity was most strongly associated with endometrioid (RR/birth = 0.78, 95% CI: 0.74–0.83) and clear-cell (RR/birth = 0.68, 95% CI: 0.61–0.76, $P_{\text{heterogeneity}} = <0.001$) histological subtypes.[268] The reduction in ovarian cancer with parity also occurs in carriers of the mutated *BRCA1* gene. In a matched case-control study of *BRCA* mutation carriers with (1,329 cases) and without (5,267 controls) ovarian cancer, increasing parity was associated with a significant inverse trend among *BRCA1* mutation carriers (age-adjusted OR = 0.87, 95% CI: 0.79–0.96; $P_{\text{trend}} = 0.005$) but not *BRCA2* mutation carriers (age-adjusted OR = 0.98, 95% CI: 0.81–1.19, $P_{\text{trend}} = 0.85$).[278] The association between ovarian cancer and older age at first or last birth is inconsistent based on limited evidence. Most studies indicate pregnancies of <6 months duration (e.g., abortions, ectopic pregnancies, miscarriages) do not significantly reduce the risk of ovarian cancer.[279] The influence of infertility is difficult to determine because of confounding associated with problems separating various causes of infertility that affect ovarian cancer risks; consequently, evidence from these studies is inconsistent.[265]

Menstruation

The quantitative associations between ovarian cancer and age at menarche or menopause remain uncertain, with stronger evidence for the latter. A meta-analysis of 22 case-control and 5 cohort studies using random-effects models comparing the oldest and youngest categories of age at menarche reported a summary relative risk of 0.85 (95% CI: 0.75–0.97, $P_{\text{effect}} = 0.016$, $I^2 = 42.2\%$) with slight to moderate heterogeneity and no indication of publication bias.[280] The summary relative risk for the five cohort studies was not statistically significant (RR = 0.89, 95% CI: 0.76–1.03, $I^2 = 0\%$). Analysis of data from the Ovarian Cancer Cohort Consortium did not confirm the reduced ovarian cancer risk with increasing age at menarche.[268] The overall invasive epithelial ovarian cancer risk per 1-year increase in menarche using the youngest age group (≤11 years) as referents was 0.99 (0.97–1.00), with no statistically significant difference between histological types except clear-cell tumors (RR = 0.92, 95% CI: 0.85–0.99). For age at menopause, a relatively small increase in overall ovarian cancer risks per 5-year increase in menopause using >50–55 years at menopause as referents (RR = 1.06, 95% CI: 1.02–1.10) was reported. The study reported marked heterogeneity ($P_{\text{heterogeneity}} = 0.009$) between histological subtypes and increased ovarian cancer risks per 5-year increase in age at menopause, particularly for clear-cell (RR = 1.37, 95% CI: 1.15–1.64) and endometrioid (RR = 1.19, 95% CI: 1.05–1.34) cancers.

In an analysis of data from the large prospective Nurses' Health Study categorizing menarche in 1-year groups <12–≥16 years, age at menarche did not significantly influence multivariate relative risks of ovarian cancer ($P_{\text{trend}} = 0.33$) using the <12-year group as referents.[277] Categorizing age at menopause in groups of <45, 45–49 (referents), 50–52, and ≥53 years, age at menopause also did not significantly influence multivariant relative risks of ovarian cancer ($P_{\text{trend}} = 0.43$).

Breastfeeding

Lactation suppresses pituitary gonadotropin secretion, resulting in anovulation, particularly in the initial postpartum period. Several meta-analyses and pooled analyses suggest breastfeeding reduces invasive and epithelial ovarian cancer risks by 25–30% comparing ever- with never-breastfeeding, consistent with lactation-induced anovulation from lower gonadotropin concentrations. However, the biological mechanism for a reduction in ovarian cancer risks with breastfeeding is not well defined. Overall, the evidence of an association is limited and inconsistent with the risks depending on lactation duration and histological subtype.[281] A metanalysis of 5 cohort and 35 case-control studies (12,765 parous, 4,374 nulliparous women) published through 2012 reported a pooled RR of 0.70 (95% CI: 0.64–0.76, $I^2 = 76.29\%$, $P_{\text{heterogeneity}} = 0$) comparing ever- versus never-breastfeeding using in-person interviews and questionnaires.[282] Subgroup analysis indicated the RR for case-control studies was statistically significant (RR = 0.67, 95% CI: 0.61–0.74, $I^2 = 77.4\%$, $P_{\text{heterogeneity}} = 0$), whereas the RR for cohort studies was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

weaker and marginally significant (RR = 0.89, 95% CI: 0.78–1.01, $I^2 = 0$, $P_{\text{heterogeneity}} = 0.96$). Meta-regression analysis indicated an increasing inverse linear trend for increased duration of breastfeeding and ovarian cancer. However, only analysis of North American studies demonstrated a statistically significant reduction in epithelial ovarian cancer with longer breastfeeding. In a pooled analysis of 13 case-control studies participating in the Ovarian Cancer Association Consortium of 7,991 parous women with invasive ovarian cancer and parous controls, the pooled odds ratio of invasive ovarian cancer was reduced in breastfeeding women (OR = 0.76, 95% CI: 0.71–0.80), particularly for high-grade serous subtype.[283] Compared with 4,426 never-breastfeeding parous women, the OR for invasive ovarian cancer in breastfeeding women ranged from 0.82 (95% CI: 0.76–0.88, $n = 1{,}879$) for reported breastfeeding for <3 months to 0.66 (95% CI: 0.58–0.75, $n = 400$) for breastfeeding for >12 months ($P_{\text{trend}} = 0.001$).

Longer durations of breastfeeding may account for some of the heterogeneity and inconsistency associated with studies on ovarian cancer risks comparing breastfeeding among parous women. An Australian population-based, case-control study of epithelial ovarian cancer (Australian Ovarian Cancer Study) reported an inverse association between breastfeeding duration (all episodes combined) and ovarian cancer incidence (OR = 0.986, 95% CI: 0.978–0.994) independent of parity;[284] however, extending breastfeeding beyond 12 months postpartum did not further reduce ovarian cancer incidence. Most benefits appear in the first 5–6 months of breastfeeding.

Analysis of data from the Ovarian Cancer Cohort Consortium demonstrated no statistically significant increase in overall invasive epithelial ovarian cancer risk (adjusted RR = 0.96, 95% CI: 0.89–1.03) per year of breastfeeding.[268] Similarly, no statistically significant differences appeared in the risk of developing any of the common histological subtypes ($P_{\text{heterogeneity between histological types}} = 0.64$). The rarity of most ovarian cancer histological subtypes limits the evaluation of the effect of breastfeeding on the risk of developing a specific ovarian cancer subtype. Although the Australian Ovarian Cancer Study did not detect statistically significant differences between ovarian cancer types (serous invasive, serous borderline, endometrioid, clear cell, mucinous) and duration of breastfeeding per month, the strongest association occurred with endometrioid (adjusted OR = 0.981, 95% CI: 0.962–1.001, $n = 102$ cases). The authors recommended caution when interpreting the importance of these values because of limited power in the study resulting from too few cases.

Lifestyle

Although vigorous physical activity potentially may reduce ovarian cancer risks by reducing inflammatory biomarkers and producing anovulation/amenorrhea, few data support a significant association between physical exercise and ovarian cancer. Leisure-time physical activity probably does not affect ovarian cancer risks,[285] whereas studies on increased ovarian cancer risk from sedentary lifestyles are limited and inconsistent.[286] The presence of selection and recall biases limits definite conclusions regarding a positive association between diet and ovarian cancer; however, current evidence provides little support for an association between ovarian cancer and overall dietary fat intake or consumption of micronutrients (vitamins A, C, E, folate), fruits, or vegetables, with the possible exception of vitamin D.

Tobacco Smoke

Most early studies of cigarette smoking and ovarian cancer reported null values; however, more recent studies suggest a positive association only between smoking and invasive mucinous ovarian cancer. In a meta-analysis of 51 observational studies using never-smokers as controls, the overall ovarian cancer risk was slightly increased but varied with study type and histological subtype ($P_{\text{heterogeneity}} = <0.0001$).[287] For 19 prospective studies, the overall adjusted RR for ovarian cancer in current smokers was 1.06 (95% CI: 1.01–1.11). The adjusted summary RR for ovarian cancer was elevated in current smokers (summary RR = 1.08, 95% CI: 1.03–1.14) in 21 population-based case-control studies (summary RR = 1.08, 95% CI: 1.03–1.14) and reduced in 11 hospital-based case-control studies (summary RR = 0.81, 95% CI: 0.75–0.89). The mucinous ovarian cancer risk was elevated in current smokers compared with never-smokers (RR = 1.79, 95% CI: 1.60–2.00), primarily from borderline malignant mucinous tumors, whereas current smokers had reduced risks of endometrioid (RR = 0.81, 95% CI: 0.72–0.92) and clear-cell (RR = 0.80, 95% CI: 0.65–0.97) epithelial ovarian cancers. Similarly, in a prospective study of 300,398 Norwegian women aged 19–67 years at enrollment in national registries and followed for a median of 19 years, the hazard ratio for invasive mucinous cancer in current smokers using never-smokers as controls was 1.78 (95% CI: 1.20–2.64, $P_{\text{heterogeneity}} = 0.34$) and 2.26 (95% CI: 1.71–2.97) for borderline mucinous ovarian cancer.[288] Smoking was not associated with serous or endometrioid ovarian cancers. In a prospective study of 100 incident ovarian cancer cases in *BRCA* mutation carriers followed for 15,720

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

person-years, the adjusted hazard ratio was not statistically different when comparing ever- and never-smokers (RR = 1.45, 95% CI: 0.96–2.19, n = 51 ever-smokers/49 never-smokers) or current and never-smokers (adjusted HR = 1.25, 95% CI: 0.73–2.12).[67] Ovarian cancer risks did not differ by BRCA mutation type or age at cancer diagnosis.

Alcohol

Large-scale pooled analyses indicate alcohol consumption is not a significant risk factor for overall ovarian cancer risks, with most studies reporting null or decreased risks.[265] A large, US population-based case-control study reported no significant association of ovarian cancer with increasing alcohol consumption during ages 20–30 years (P_{trend} = 0.42) or the recent past (P_{trend} = 0.83).[289] The type of beverage did not affect ovarian cancer risks with the exception of beer consumption of ≥1 beer daily; a significant positive association was limited to serous tumors (OR = 1.52, 95% CI: 1.01–2.30) with relatively sparse data on other histological subtypes. A pooled analysis of 10 cohort studies comprising 529,638 women with 2,001 incident epithelial ovarian cases did not support an association between moderate alcohol intake and ovarian cancer risk.[290] Using random effects models, the pooled multivariate RR comparing daily consumption of ≥30 g alcohol with nondrinkers was 1.12 (95% CI: 0.86–1.44). The ovarian cancer risk did not vary significantly with the type of beverage (i.e., wine, beer, spirits).

Obesity

The association between obesity and ovarian cancer is inconsistent with high heterogeneity between studies, depending on the outcome measure (BMI, waist-to-hip ratio, waist circumference), menopausal status (pre- vs. postmenopausal), and ovarian cancer histological subtypes (serous vs. non-serous, low- vs. high-grade). In general, ovarian cancer risks are greater in premenopausal than postmenopausal women and strongest in non-serous and low-grade serous subtypes. Secondary analyses stratified by behavior/subtype on data from 39 studies in the Ovarian Cancer Association Consortium suggested the strongest ovarian cancer risks occurred in invasive low-grade/borderline serous cancers (OR = 1.93, 95% CI: 1.33–2.81, n = 1,411 cases) consistent with observational data.[291] A meta-analysis of 13 case-control and 13 cohort studies using normal weight (18.5–24.9 kg/m^2) as the reference group reported elevated ovarian cancer risks for overweight (pooled RR = 1.07, 95% CI: 1.02–1.12, I^2 = 11.2%, $P_{heterogeneity}$ = 0.302) and obese women (pooled RR = 1.28, 95% CI: 1.16–1.41, I^2 = 54.2%, $P_{heterogeneity}$ = 0.001).[292] However, subgroup analysis indicated no increased ovarian cancer risks in overweight (pooled RR = 0.97, 95% CI: 0.76–1.24, I^2 = 64.1%, $P_{heterogeneity}$ = 0.016, n = 6 studies) or obese (pooled RR = 0.93, 95% CI: 0.61–1.42, I^2 = 77.6%, $P_{heterogeneity}$ = 0, n = 6 studies) postmenopausal women with substantial heterogeneity between studies. A meta-analysis of 12 primarily US prospective studies reported increased ovarian cancer risks in obese premenopausal women (multivariate RR = 1.72, 95% CI: 1.02–2.89) but not in postmenopausal women (multivariate RR = 1.07, 95% CI: 0.87–1.33).[293] Analysis of data from the Ovarian Cancer Cohort Consortium did not detect a statistically significant increase in overall ovarian cancer risk or any subtype risk with increasing BMI using 20–<25 kg/m^2 as the reference group ($P_{heterogeneity\ between\ histological\ types}$ = 0.10).[268]

Talc

Talc is a magnesium silicate similar to asbestos, with a particular lamellar (sheet-like) structure. Although the IARC classified asbestos as a human ovarian cancer carcinogen, the association remains controversial because of limited studies, weak dose-response data (frequency/duration of talc use), potential recall bias of self-reports, and the common misclassification of peritoneal mesothelioma as an asbestos-related disease. Studies on the association between cosmetic talc use and ovarian cancer risks are conflicting. Although animal, pathological, and mechanistic studies generally do not support the carcinogenicity of talc on the ovarian epithelium with no clear evidence of genotoxicity or a dose-response relationship,[294] earlier studies suggested an ~20–35% (i.e., summary RR ≅ 1.2–1.5) increased ovarian cancer risk with talc use.[295] Some US and European baby powders manufactured in the 1970s contained small amounts of tremolite or quartz silica;[296,297] however, cosmetic talcum powder has reportedly not contained detectable asbestos concentrations for several decades.[298,299] Ovarian cancer subtypes most closely associated with talc include invasive serous and endometrioid tumors along with borderline serous and mucinous tumors. The potential risk factor associated with talc use is not a major contributor to the etiology of ovarian cancer because of the limited number (i.e., 14%) of women using talc in many of these studies.[300]

Several case-control studies reported increased ovarian cancer risks with relatively small effect sizes in talc users. A case-control study of 450 patients with ovarian

cancer demonstrated a statistically significant association between the cosmetic use of talc and ovarian cancer risk (OR = 1.42, 95% CI: 1.08–1.86).[301] The relationship between increased ovarian cancer risk and duration of talc use was marginal, with no significant relationship to the frequency of talc use. A retrospective case-control study reported elevated ovarian cancer risks among talc users (OR = 1.33, 95% CI: 1.16–1.52), particularly for serous and endometrioid cancers in premenopausal and postmenopausal women using hormonal therapy.[302] A case-control study of 499 patients with epithelial ovarian cancer did not demonstrate an increased ovarian cancer risk with talc use when compared with a control population of 755 women after adjustment for known risk factors.[303] There was also no association with the duration of talc use for >20 years (OR = 0.9, 95% CI: 0.6–1.2).

Recent meta-analyses have not demonstrated consistent, statistically significant associations between talc powder use in the genital area and ovarian cancer risks, particularly in cohort studies. In a meta-analysis of 24 case-control studies (13,421 cases) and 3 cohort studies (890 cases totaling 181,860 person-years) using never-talc users as controls, any talc use was associated with a statistically significant risk of ovarian cancer in the 24 case-control studies (OR = 1.35, 95% CI: 1.27–1.43) but not in the 3 cohort studies (OR = 1.06, 95% CI: 0.90–1.25).[304] Subgroup analysis suggested an increased risk of serous ovarian cancer in the cohort studies (OR = 1.25, 95% CI: 1.01–1.55) but not clear-cell or mucinous subtypes. Most of the studies used self-reported talc use among ovarian cancer patients. In a pooled analysis of 4 large, US-based cohorts (252,745 women) followed for a median of 11.2 years, 38% reported ever-use of genital talc powder (10% long-term, 22% frequent use) and 2,168 women developed ovarian cancer. The pooled estimate of the adjusted hazard ratio for ovarian cancer in ever-users was 1.08 (95% CI: 0.99–1.17, $P_{\text{heterogeneity}} = 0.81$). Similarly, the estimate of the adjusted HR for ovarian cancer was statistically nonsignificant in long-term users (adjusted HR = 1.01, 95% CI: 0.82–1.25, $P_{\text{heterogeneity}} = 0.90$, $P_{\text{trend}} = 0.49$) and frequent users (adjusted $\text{HR}_{\geq 1/\text{week}} = 1.09$, 95% CI: 0.97–1.23, $P_{\text{heterogeneity}} = 0.65$, $P_{\text{trend}} = 0.20$). None of the hazard ratios for ovarian cancer histological subtypes reached statistical significance, including ever-use of talc in serous ovarian cancer cases (HR = 1.10, 95% CI: 0.97–1.25, n = 1,038 cases, $P_{\text{heterogeneity}} = 0.86$). Among 61,576 postmenopausal women in the Women's Health Initiative Observational Study cohort followed for a mean of 12.4 years, 52.6% reported ever-using perineal powder; the hazard ratio for ovarian cancer in ever-use was 1.06 (95% CI: 0.87–1.28) compared with never-use.[305] The ovarian cancer risks were not affected by the duration or location of talc use.

Medications

Several prospective and case-control studies suggest an inverse association between aspirin or nonsteroidal anti-inflammatory drugs and ovarian cancer incidence;[306] however, the relationship is inconsistent and not clearly dose-related, with no clinical trials to support efficacy.

Menopausal Hormone Therapy

Most initial studies on unopposed estrogen therapy in postmenopausal women did not demonstrate an association between duration of use and increased ovarian cancer risks.[307] More recent studies indicate increased ovarian cancer risks in ever-users of hormonal replacement therapy with increasing risk for longer use. In the prospective observational Nurses' Health Study of 82,905 postmenopausal women using never-users as the reference group, the ovarian cancer risks were elevated for current users with ≥5 years of use (RR = 1.41, 95% CI: 1.07–1.86) and former users with ≥5 years of use (RR = 1.52, 95% CI: 1.01–2.27).[308] However, hormonal therapy use for <5 years was not associated with increased ovarian cancer risks in current (RR = 1.01, 95% CI: 0.70–1.44) or former users (RR = 0.88, 95% CI: 0.64–1.19). Pooled data from 52 epidemiology studies comparing current users with <5 years of use with never-users demonstrated an RR of 1.43 (95% CI: 1.31–1.56, $P < 0{\cdot}0001$).[309] The addition of progestin to estrogen therapy mitigates the positive association between estrogen use and ovarian cancer. Most, but not all, observational studies report no or a weak positive association between estrogen plus progestin use and ovarian cancer risks.[265,310,311] The ovarian cancer risks are stronger for endometrial and serous subtypes and statistically nonsignificant for mucinous and clear-cell subtypes.[268,309]

Oral Contraceptives

Observational studies indicate oral contraceptive use reduces ovarian cancer risks regardless of the oral contraceptive formulation in gravid, but not nulligravid, women.[312] Although data are limited, similar reductions in ovarian cancer risks with other types of contraception including vasectomy suggest mechanisms other than hormonal or ovulation contribute to reduced ovarian

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancer risks. The protection against ovarian cancer is similar for many subtypes (serous, endometrioid, clear cell) except for mucinous cancers in some studies.[265,268] In the large prospective Nurses' Health Study, oral contraceptive use reduced the relative risk of ovarian cancer by 30–60%, depending on the duration of use.[277] The relative risk decreased by ~11% per year of use, but there was little protective effect beyond 6 years of use. Analysis of pooled data for 23,257 women with ovarian cancer (cases) and 87,303 without ovarian cancer (controls) from 45 epidemiological studies in 21 countries indicated an ~30% reduction in overall ovarian cancer risk comparing ever-oral contraceptive users with never-users.[313] Longer use was associated with greater risk reduction ($P < 0.0001$) with effects persisting for >30 years; however, the effect attenuated over time.

Diseases

Most epidemiological studies on the inverse relationship between tubal ligation and ovarian cancer report reductions in the range of 20–30%, including *BRCA* mutation carriers with stronger effects for endometrioid and clear cell than invasive serous cancer risks.[253] The reductions persist at least 30 years after surgery, regardless of age when the procedure was performed.[314] Although the human papilloma virus occurs commonly in patients with ovarian cancer (i.e., 15–20%), evidence of a statistically significant positive association is inconclusive.[315]

Endometriosis

Endometriosis is a common estrogen-dependent inflammatory disease present in ~5–10% of reproductive-age women. Case-control[316] and cohort[268] studies suggest endometriosis substantially increases type I ovarian cancer (endometrioid, clear-cell carcinoma) risks. Analysis of pooled data from 13 ovarian cancer case-control studies in the Ovarian Cancer Association Consortium demonstrated elevated risks in self-reported endometriosis cases for clear-cell (OR = 3.05, 95% CI: 2.43–3.84, $P < 0{\cdot}0001$), low-grade serous (OR = 2.11, 95% CI: 1.39–3.20, $P < 0.0001$), and endometrioid (OR = 2.04, 95% CI: 1.67–2.48, $P < 0.0001$) invasive ovarian cancers when compared with controls (no reported endometriosis).[316] Endometriosis was not associated with statistically significant elevations in the risk of mucinous, high-grade serous, or borderline tumors of either subtype of invasive ovarian cancer.

Pelvic Inflammatory Disease

Although pelvic inflammatory disease (PID) is a potential risk factor for ovarian cancer because of the plausible biological mechanism of chronic inflammation (↑ cytokines, chemokines) and increased repair processes, studies on the overall association are inconsistent and relatively weak with limited statistical power and short follow-up periods and complicated by the heterogeneity of ovarian tumors. In an analysis of pooled data from 13 case-control studies involving 9,162 cases of ovarian cancer, 2,354 women with borderline tumors, and 14,736 controls from the Ovarian Cancer Association Consortium, the adjusted overall ovarian cancer risk was not associated with self-reported PID status (pooled OR = 0.99, 95% CI: 0.83–1.19, $I^2 = 36.8\%$, $P_{\text{heterogeneity}} = 0.09$) compared with controls (no history PID).[317] Subgroup analysis suggested a history of PID was associated with an increased risk of borderline ovarian tumors (adjusted OR = 1.32, 95% CI: 1.10–1.58, $I^2 = 0$, $P_{\text{heterogeneity}} = 0.85$, $n = 49$ cases), comparing participants with and without a history of PID, particularly serous and mucinous borderline tumors. However, the adjusted OR for these latter two borderline tumors did not reach statistical significance. In a meta-analysis of six cohort and seven case-control studies, the overall ovarian cancer risk comparing participants with and without a history of PID based on self-reporting (case-control studies) or hospital records (cohort studies) was elevated (summary RR = 1.24, 95% CI: 1.06–1.44, $I^2 = 58.8\%$, $P_{\text{heterogeneity}} = 0.003$) with moderate heterogeneity.[318] Subgroup analysis indicated significantly different results between Asian and Caucasian studies ($P_{\text{between-group heterogeneity}} = 0.054$), with the former studies demonstrating a statistically significant increased ovarian cancer risk. The authors recommended a cautious interpretation of the results.

Diabetes Mellitus

A meta-analysis of 14 cohorts suggested a modest increase in overall ovarian cancer risk in diabetic women (summary RR = 1.19; 95% CI: 1.06–1.34, $I^2 = 43.8\%$, $P_{\text{heterogeneity}} = 0.040$, $n = 5{,}534$ ovarian cancer cases) compared with nondiabetic women (diabetic type and metformin use not available).[319] A population-based cohort study of women with type 2 diabetes ($n = 319{,}310$) and age-matched, nondiabetic controls ($n = 319{,}308$) did not support an association between ovarian cancer and diabetes type II (covariate-adjusted HR = 1.06, 95% CI: 0.92–1.22).[320]

HISTOLOGY

Epithelial ovarian cancers represent 90% of malignant ovarian cancer[321] comprising five major histotypes of invasive disease, including high- and low-grade serous (52%), endometrioid (10%), mucinous (6%), and clear cell (6%); two histotypes of borderline disease (serous, mucinous); and the remaining rare/unspecified.[322,323] Nonepithelial ovarian cancers are usually less aggressive tumors (e.g., germ cell tumors, 3%; sex cord–stromal tumors, 2–6%).[324] The rare ovarian germ cell tumors mostly affect children and young women consistent with their embryological origin.[325]

Clinicopathological classification of epithelial ovarian cancers involves low-grade type I neoplasms (unilateral, large, cystic tumors with indolent behavior) and genetically unstable, high-grade type II neoplasms (bilateral aggressive ovarian tumors with advanced stage and poor prognosis).[326] The latter tumors primarily consist of high-grade serous carcinomas and less often carcinosarcomas and undifferentiated carcinomas; high-grade serous carcinomas account for ~2/3 of epithelial ovarian cancer deaths.[327] Type I tumors include endometrioid, mucinous, clear-cell, and well-differentiated serous carcinomas that probably arise from ovarian epithelium or inclusions of germ cell layers from the Müllerian system;[257] type I tumors are typically associated with mutations in *KRAS*, *BRAF*, *PTEN*, *PIK3CA*, *CTNNB1*, *ARID1A*, and *PPP2R1A* genes, whereas TP53 mutations are rare.[328] Type II ovarian neoplasms probably arise from the fallopian tubular epithelium associated with TP53 mutations.

HOST SUSCEPTIBILITY

Heredity accounts for ~18–24% of ovarian carcinomas.[328] The strongest overall risk factor for ovarian cancer is a family history of ovarian or breast cancer with a family history of ≥3 first- or second-degree relatives, suggesting the presence of a significant genetic predisposition to ovarian cancer.[329] Twin studies indicate most of the familial ovarian cancer risk results from inherited genetic factors rather than environmental or lifestyle factors common to family members.[330] A woman with a first-degree relative diagnosed with ovarian cancer has an ~50% increased ovarian cancer risk, whereas a first-degree relative with breast cancer increases a woman's ovarian cancer risk by ~10%.[268] A past history of breast cancer was reported in 4.6% of 138 Italian women with ovarian cancer compared with 23.6% of women with ovarian cancer who had a history of familial ovarian cancer.[331] Approximately 2% of Ashkenazi (Eastern European) Jewish women have the BRCA1/2 mutations compared with <1% of women in the general population.[332]

Although the BRCA1/2 mutations are relatively rare in the non-Ashkenazi population, inherited mutations account for an estimated 14–18% of epithelial ovarian cancers, primarily high-grade serous carcinomas in patients with mutations in *BRCA1* and/or *BRCA2* genes.[327,333] These two mutations are high-penetrance mutations accounting for ~40% of ovarian cancer cases in women with a family history of ovarian cancer.[334,335] By age 80, an estimated 44% of women with BRCA1 mutations and 17% with BRCA2 mutations will develop ovarian cancer based on family studies; these risks are somewhat lower in population-based studies (e.g., 39% and 11%, respectively).[127,336] For women with BRCA1/2 mutations, bilateral salpingo-oophorectomy decreases ovarian cancer risks by ~80%.[337] Whole-exome sequencing indicates mutations in mismatch repair *MSH6* (genomic stability) as well as *RAD51C*, *TP53*, and *ATM* (cell-cycle regulation, serine/threonine kinase) genes contribute to ovarian cancer susceptibility.[338] Rare epithelial ovarian cancer mutations in genes with moderate penetrance include the homologous DNA recombination and repair genes *BRIP1* (BRCA1-interacting protein C-terminal helicase 1)[339] and the *RAD51C/D* recombinase genes.[340]

Lynch syndrome (hereditary nonpolyposis colon cancer) is a rare, autosomal-dominant hereditary condition associated with an ~11-fold increased cumulative ovarian cancer risk (i.e., 6–12%) by age 70 years compared with the general population; these tumors are primarily type I, non-serous epithelial tumors (endometrioid, clear-cell carcinomas) as well as cancers at other sites (e.g., colorectal, endometrial).[252] The main germline mutations involve DNA mismatch-repair genes, including *PMS1* (PMS homolog 1), *MLH1* (mutL homolog 1), *MSH2* (mutS homolog 2), and *MSH6* (mutS homolog 6).[341] In a systematic review of 747 patients with Lynch syndrome and ovarian cancer, the most frequent mutations were in *MSH2* (47%) and *MLH1* (38%) genes; 31% ($n = 136$) of these patients presented with mixed histological types (mucinous/endometrioid/clear-cell carcinomas).[342] The mean age at presentation was 45.3 years (range, 19–82 years). Other rare hereditary syndromes associated with increased ovarian cancer risks include Peutz–Jeghers and Li–Fraumeni syndromes.[327]

CLINICAL FEATURES

The median age for patients diagnosed with ovarian cancer is about 63 years. Ovarian cancer is rare before

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. age 40, primarily involving germ cell tumors, whereas over the age of 40, the vast majority are epithelial ovarian cancers with the incidence increasing sharply until a peak at ~65–75 years of age. Serous tumors usually occur in women between 40 and 60 years of age, typically in an advanced stage at presentation. Patients with the BRCA1 and BRCA2 mutations usually present earlier (i.e., ~10 years) than other ovarian cancer patients.[128] In an analysis of data from an international registry containing 5,689 women with 195 incident cases of ovarian and fallopian tube cancer followed for a mean of 4.7 years (range, 0–22.6 years), the mean age at diagnosis was 51.3 years (range, 33–84 years) among *BRCA1* mutation carriers and 61.4 years (range, 44–80 years) among *BRCA2* mutation carriers.[343]

Early stages of ovarian cancer often do not display obvious symptoms. The most common feature of advanced disease is ascites; however, some women experience nonspecific symptoms during the months prior to diagnosis including abdominal distension, pain (back, abdomen, pelvis), anorexia, indigestion, early satiety, vomiting, altered bowel habits, and/or urinary frequency.[344]

The prognosis for ovarian tumors depends primarily on histological stage and tumor type. A majority of women present with advanced disease associated with many episodes of recurrent disease and progressively shorter disease-free intervals ultimately ending in bowel obstruction.[345] The overall median 10-year survival at major treatment centers is ~40–50%. The prognosis is progressively worse as the stage at diagnosis increases, as reflected by the following 10-year survival rates: Stage I, 73–92% (limited to ovary or fallopian tube); Stage II, 45–55% (spread to pelvis); Stage III, 21% (spread to lymph nodes and/or beyond pelvis); and Stage IV, <6% (spread to organs outside the abdomen). Most serous carcinomas are high-grade epithelial tumors that present in Stage III (~50%) or Stage IV (~30%), whereas most (i.e., 58–64%) endometrioid, clear-cell, and mucinous carcinomas present in Stage I.[252] The 5-year survival rate for Stage III serous carcinomas is ~42%, with the rate declining to 29% for Stage IV serous carcinomas. Analysis of US mortality data from the SEER*Stat database from the National Center for Health Statistics indicates the overall 5-year, cause-specific survival rate is 82% for endometrioid carcinomas compared with 66% for clear-cell carcinomas and 71% for mucinous carcinomas. The use of PARP inhibitors substantially improves 5-year survival (i.e., about 70%) in advanced-stage ovarian cancers with BRCA genetic variants.

Chapter 58

CENTRAL NERVOUS SYSTEM

Central nervous system (CNS) tumors most commonly involve primary brain tumors, intracerebral metastases from primary extracranial tumors, extracerebral intracranial tumors (e.g., meningiomas), and meningeal carcinomatosis (invasions of meninges by a primary extracranial tumor, most commonly primary melanoma, breast, lung, or gastrointestinal cancer). Less frequent CNS tumors capable of compressing, invading, or spreading in the central or peripheral nervous systems include neoplasms in structures around the brain (e.g., dura, base of the skull, cavities in the skull) or tissue and skin around the skull or neck.[1] Brain tumors are a complex, heterogeneous group of rare pathological neoplasms that display different clinical, histological, and prognostic features. These tumors account for ~2% and 1.4% of all cancer mortality in men and women, respectively, with the incidence varying with sex, age, ethnic origin, location, and histological type. Based on cancer registry data, neuroepithelial tumors predominate in men, whereas meningiomas are more common in women.[2] The incidence of brain tumors ranges from 8.5/100,000 in Estonia to 21.4/100,000 in the United States.[3,4]

Brain tumors are the most common solid tumor in children of <14 years of age in the United States, with ~3,400 new cases annually; these tumors are also the leading cause of solid cancer-related deaths in this age group.[5] Before age 30 years, neuroepithelial tumor incidence is ~3/100,000 rising to 5/100,000 by age 50 years; the incidence peaks at 20/10,000 near age 70 years and decreases slightly thereafter. In most developing countries, epidemiological data suggest brain cancer incidence and mortality have increased slowly since the 1940s, particularly in elderly patients.[6,7] Overall, brain cancer incidence is relatively stable to decreasing in adults and stable to increasing in children.[8] Although improvements in diagnostic technology (e.g., CT, MRI), demographic variation, and classification changes account for part of the apparent changes in incidence, some histological types of brain tumors are probably increasing, including malignant astrocytomas in the elderly, intracranial lymphomas in HIV/AIDS patients, ependymomas in adults, nerve sheath tumors in males, and pituitary tumors in females.[9] Most intracranial tumors develop in older adults, particularly malignant astrocytomas in men of >60 years of age.[10,11] Although CNS tumors are rare, significant morbidity and mortality from brain tumors occur in children and young adults, with these tumors accounting for 30% and 20%, respectively, of cancer-related mortality in these age groups.[12] The incidence of nonmalignant brain tumors is more than twice as common as malignant tumors in adolescents and young adults (15–39 years of age).[13] Meningiomas are the most common brain tumors.

CRANIAL TUMORS

EXPOSURE

Most patients with brain tumors lack an identifiable risk factor. Aside from ionizing radiation and rare genetic causes,[14,15] there are no well-established environmental

TABLE 58.1. International Agency for Research on Cancer (IARC) classification of brain and central nervous system cancer sites by strength of evidence categories. (Adapted from IARC).[17]

Anatomical Site	Carcinogens with *Sufficient* Human Evidence (Group 1)	Carcinogens with *Limited* Human Evidence (Groups 2A or 2B)
Eye	Human immunodeficiency virus type 1, ultraviolet-emitting tanning devices, ultraviolet emissions from welding	Solar radiation
Central nervous system	X-ray and γ-radiation	Radiofrequency electromagnetic fields (gliomas, acoustic neuromas, or vestibular schwannomas)

or lifestyle risk factors clearly associated with brain tumors including cell phone use.[16] The IARC lists only X-ray and γ-radiation as carcinogens with sufficient human evidence; radiofrequency electromagnetic fields including wireless phones are classified as carcinogens with limited human evidence (Group 2B) for gliomas and benign vestibular schwannomas (acoustic neuromas), as displayed in Table 58.1.[17] The latter remains particularly controversial because of the presence of multiple issues in case-control studies including recall bias, selection bias between studies, difficulty obtaining accurate cell phone long-term exposure data, and rapidly changing cell phone use and electromagnetic fields with continuing upgrades of cell phone transmission technology. Current data associating cell phone use with increased meningioma and glioma risks in adults are insufficient, whereas the data on vestibular schwannomas (acoustic neuromas) and gliomas are limited.[18,19]

Although some studies demonstrate a positive correlation between brain tumors and certain risk factors (nitrosamines, intracranial infections, radon, electromagnetic radiation, head trauma,[20,21] vinyl chloride,[22] pesticides[23]), overall the data are inconclusive, particularly with electromagnetic fields and childhood radon exposure.[24] Some reviews and meta-analyses suggest the presence of allergic conditions (e.g., asthma, eczema, hay fever, food allergies) has an inverse association with brain cancer incidence (e.g., meningioma, glioma, vestibular schwannoma);[25,26] however, the presence of substantial heterogeneity and limited exposure data produce inconsistent results regarding causation.[27] A death certificate-based case-control study associated socioeconomic status with increasing brain cancer risks, particularly for engineers.[28] The incidence of brain tumors after irradiation or chemotherapy for a previous malignancy is relatively small.

Occupation

Job Title

Although a number of occupations (agriculture, rubber and plastic manufacturing, electronics) have been associated with increased brain cancer risks, these associations are inconsistent and none of the associations are conclusive, including pesticides, herbicides, solvents, fertilizers, and infectious agents. Hypothesis-generating studies of patients with brain tumors suggest that white-collar workers (i.e., engineers, teachers, lawyers, physicians, accountants, judges) as well as foundry/smelter workers, petroleum/gas workers, and painters are at increased risk of developing brain tumors compared with the general population.[29,30] Among workers with potential exposure to carcinogens, mortality studies suggest an increased incidence of brain tumors in workers from the rubber industry, petroleum petrochemical and pharmaceutical production, farming, electrical industries, and polyvinyl chloride production.[6] However, the etiology of the increased risk is obscured by the small sample size, potential for misclassification of nonexposed workers, lack of confirmation of histological type of brain tumor, and inadequate exposure data. No consistent chemical exposure(s) accounts for the increased risk detected in these occupations. Using mailed questionnaires to assess occupational exposure history, a Canadian population-based case-control study of 1,009 brain cancer cases and 5,039 controls evaluated 18 chemicals and >100 occupations.[31] The results suggested potential associations between usual occupation and multivariate-adjusted brain cancer risks for protective services (OR = 1.67, 95% CI: 1.08–2.56, $n = 31$ cases), teaching (OR = 1.38, 95% CI: 1.02–1.87, $n = 57$ cases), knitting in textile processing (OR = 12.42, 95% CI: 2.00–77.1, $n = 3$ cases), construction trades (OR = 1.00–1.79, $n = 71$ cases), and transport equipment operation (OR = 1.43, 95% CI: 1.02–2.02, $n = 49$ cases). Brain cancer risks in the other over 100 occupations were statistically nonsignificant, including farmers (OR = 0.88, 95% CI: 0.56–1.38, $n = 24$ cases). Of the 18 chemicals evaluated, brain cancer risks were elevated only for asphalt (multivariant adjusted OR = 1.29, 95% CI: 1.02–1.62, $n = 120$ cases). Exposure duration also was not associated with brain cancer risks for any of the 18 chemicals, except asphalt ($P_{\text{trend}} = 0.033$, adjusted $\text{OR}_{\geq 10 \text{ years exposure}} = 1.39$, 95% CI: 0.97–1.99,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. $n = 43$ cases). The multiple comparisons and relatively weak results limit any causal conclusions regarding brain cancer risks and these occupations.

A retrospective cohort study from 1944–1952 of white male workers aged 25–64 years in four Ohio tire building and curing companies suggested a higher mortality rate due to tumors of the central nervous system in these workers compared with local residents (observed deaths = 77/expected deaths = 53.8).[32] A follow-up study of American rubber workers did not demonstrate an elevated risk of brain tumors after 1963; this study suggested that the excess of brain malignancies before 1963 resulted from high chemical exposure in earlier manufacturing processes.[33]

Extremely Low Electromagnetic Fields

Some, but not most, studies[34] of occupations with exposure to high levels of electric or magnetic fields suggest an increased risk of developing gliomas and benign vestibular schwannomas (acoustic neuromas); however, the studies are inconsistent and usually do not indicate elevated meningioma risks.[35,36,37] Based on mortality studies using job titles, the occupations at greatest risk of developing brain tumors are electrical engineers and technicians (OR = 2.7), telephone workers (OR = 1.6), electric power workers (OR = 1.7), and electrical workers in manufacturing industries (OR = 2.1).[38] Exposure to electromagnetic fields in these studies was based on job title rather than an estimation of actual exposure. A study of the Swedish Cancer-Environment Registry for the period 1961–1979 did not demonstrate an elevated incidence of gliomas in electrical occupations.[39] Similarly, a cohort of electric occupations followed for 18 years did not demonstrate an increased incidence of brain tumors overall, but an increased risk was detected for radio/TV assembly and repairmen.[40] In these jobs, the SMR for overall brain tumors was 290 (95% CI: 120–590), with particularly elevated risks for glioblastomas (SMR = 340, 95% CI: 110–800). Even though these studies suggest the need for further evaluation of the association between electromagnetic fields and brain cancer, especially in terms of documentation of exposure and histological type, the studies to date have not demonstrated a consistently strong relationship. The risk of developing brain cancer in a population-based study of eight Canadian provinces was not statistically different (OR = 1.33; 95% CI: 0.75–2.36) for men, with average magnetic field exposure of >0.6 μT compared with men exposed to <0.3 μT.[41] The more pronounced risk (OR = 5.36; 95% CI: 1.16–24.78) occurred in the subset of cases with more malignant gliomas (glioblastoma multiforme). Exposure to magnetic fields was not associated with an increased incidence of astrocytoma or other brain cancers. In a hospital-based case-control study of 489 glioma cases, 197 meningioma cases, and 799 controls using job-specific quantitative estimates of ELF–EMF, the study evaluated glioma, meningioma, and vesicular schwannoma risks associated with four exposure indices (maximum exposure, total exposure years of <1.5 mG, cumulative lifetime exposure, average lifetime exposure).[42] The age-, sex-, and location-adjusted odds ratios demonstrated no statistically significant elevations or trends across exposure categories for the four different exposure metrics and three tumor types. A case-control study of 1,346 gliomas investigated three categories of ELF–EMF exposure (cumulative, average, maximum) using a job-exposure matrix to compare the highest and lowest quintiles of exposure.[43] Generally, the odds ratios were weak and statistically nonsignificant, particularly for cumulative and maximum exposures except for astrocytoma grade IV (glioblastoma multiforme). For cumulative exposure of <15 years, the OR for the highest exposure category (2.75 μT-years) compared with the lowest (<0.91 μT-years) was 1.9 (95% CI: 1.4–2.6, $n = 89$ cases, $P_{\text{trend}} = <0.001$); however, the odds ratio for the highest cumulative exposure (≥15 μT-years) was not statistically significant ($P_{\text{trend}} = 0.44$), indicating the lack of a dose-response relationship.

Ionizing Radiation

Previously, human CNS tissue was considered relatively resistant to ionizing radiation-induced carcinogenesis; consequently, relatively high X-ray doses from diagnostic examinations and radiotherapy were relatively common. Ionizing radiation is now a well-established risk factor for cancer in previous cohorts receiving moderate- to high-dose radiation (atomic bomb survivors, prophylactic cranial irradiation, *Tinea capitis*, and adenoid hypertrophy radiation therapy).[12] Although a variety of rare CNS tumors (e.g., embryonal tumors, lymphomas, hemangioblastomas) developed in these cohorts, the most common radiation-induced CNS tumors were meningiomas, gliomas, and benign vestibular schwannomas.[44,45] The highest radiation-induced cancer risks occur in patients exposed as infants to particularly high radiation doses, with the risk decreasing as the time since radiation exposure increases. In a systematic review of eight cohorts receiving intracranial radiation with the average age at exposure ranging from 8 months (Pooled Skin Hemangioma cohorts) to 26 years (Japanese Life Span Study), mean brain radiation dose ranged from 0.07 Gy (Pooled Skin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Hemangioma cohorts) to 10 Gy (US Childhood Cancer Survivor Study, British Childhood Cancer Survivor Study).[46] Phantom studies analyzing the irradiation for *Tinea capitis* treatment in Israeli children during the 1950s, using the most popular radiation protocol (Adamson–Keinbock technique), demonstrated a scalp surface radiation dose of 5–8 Gy and a brain surface radiation dose of 1.4–1.5 Gy.[47]

Generally, ionizing radiation-induced excess relative risks appeared higher for meningiomas than gliomas. The former displayed no effect modifications (i.e., sex, age at exposure, time since exposure, attained age), whereas glioma risks appeared stronger for younger than older age at exposure. Although all the studies reported elevated CNS cancer risks, substantial variation occurred across studies ($I^2 = 74.7\%$, $P_{\text{heterogeneity}} = 0.003$), and no summary excess relative risk was calculated.

Lifestyle

Conventional lifestyle factors (smoking, excessive alcohol consumption, diet) are not important risk factors for brain cancer risks.[48] Although a case-control study reported a weak association (RR = 1.44) between smoking and brain tumors,[49] other studies have not confirmed this link.[30,50,51]

Medications

Some case-control studies suggest self-reported hormone replacement therapy in postmenopausal women and oral contraceptive use reduce glioma risk, whereas delayed menarche or late menopause increase glioma risk; however, most studies do not demonstrate statistically significant alterations in risk or a dose-response relationship.[52] Generally, the results are heterogeneous, with limited power and relatively weak associations. There is no clear association between meningioma risks and oral contraceptives, pregnancy, parity, or breastfeeding. Some cohort studies on hormone replacement therapy and meningioma risks in postmenopausal women suggest an increased risk based on statistically significant increases in current users, primarily estrogen-only;[53,54] however, the studies are also conflicting and report no associations with past users or a dose-response relationship.

HISTOLOGY

Central nervous system (CNS) tumors are a heterogeneous group of tumors arising from cells within the CNS. The Central Brain Registry of the United States (CBRUS) lists over 100 histologically separate CNS tumors based on the World Health Organization (WHO) Classification of Tumors of the Central Nervous System using ICD-0-3 codes and the International Classification of Childhood Cancer (ICCC) grouping system for pediatric cancers with distinct clinical features and outcomes.[5] The incidence of CNS tumors varies with age and sex; the most common childhood brain tumor types are pilocytic astrocytomas, embryonal tumors, or malignant gliomas, whereas meningiomas, pituitary tumors, and malignant gliomas are the most frequent adult brain tumors.[5] About one-half of malignant brain tumors in adults are glioblastomas and 30% are diffusely infiltrating lower-grade gliomas. Most histological brain tumors are confirmed by microscopic techniques, with the exception of meningiomas and benign vestibular schwannomas (acoustic neuromas) that are established by radiography. Table 58.2 lists the frequency of CNS tumors based on a 5-year increment in age at diagnosis. The incidence rates for most CNS tumor histological types except for meningiomas are usually higher in men than women.

CNS tumors vary by location (Figure 58.1) and histology (Figure 58.2). Based on Central Brain Registry

TABLE 58.2. Common histological types of central nervous system tumors in the United States by age group. The age-adjusted incidence rates for adult CNS tumors increase from 10.55/100,000 (30% malignant, 70% nonmalignant) at age 20–34 years to 83.75/100,000 (24% malignant, 76% nonmalignant) at age 85 years and older. (Adapted from Ostrom et al.).[5]

Age (Years)	Most Common Tumor	Second Most Common Tumor	Third Most Common Tumor
0–4	Embryonal tumors	Pilocytic astrocytoma	Malignant glioma
5–9	Pilocytic astrocytoma	Malignant glioma	Embryonal tumors
10–14	Pilocytic astrocytoma	Pituitary tumors	Malignant glioma
15–19	Pituitary tumors	Pilocytic astrocytoma	Neuronal and mixed neuronal-glial tumors
20–34	Pituitary tumors	Meningioma	Nerve sheath tumors (e.g., vestibular schwannomas)
35–44	Meningioma	Pituitary tumors	Nerve sheath tumors (e.g., vestibular schwannomas)
45–54	Meningioma	Pituitary tumors	Glioblastoma
55–85+	Meningioma	Glioblastoma	Pituitary tumors

of the United States (CBRUS) data, the estimated most frequent overall tumor sites were the meninges (36%), brain (frontal, 8%; temporal, 6%; parietal, 3.5%; occipital, 1%), and pituitary/craniopharyngeal duct (17.5%). The most common malignant tumor locations are frontal (24%), temporal (17.5%), parietal (10%), and occipital (3%), whereas the most common nonmalignant tumor sites involve the meninges (53%), pituitary (24%), and nerve sheaths (12%). The estimated most frequent overall histological tumor types were meningioma (37%), pituitary (16.5%), and glioblastoma (15%). The most common malignant tumor was glioblastoma (48%), whereas the most common nonmalignant tumor type was meningioma (53%). The vast majority of nerve sheath tumors are benign vestibular schwannomas (formerly acoustic neuromas).

Approximately one-half of brain tumors in infants and children are gliomas (e.g., pilocytic astrocytoma, other low-grade gliomas), whereas embryonal tumors (e.g., medulloblastomas, primitive neuroectodermal tumors) account for ~15%; the latter tumors are the most common childhood malignant brain tumors.[12] Medulloblastomas develop in the posterior fossa; primitive neuroectodermal neoplasms are supratentorial tumors.

HOST SUSCEPTIBILITY

Adults with malignant brain tumors rarely have a family history of brain tumors, and almost all brain tumors are sporadic; however, several familial syndromes are associated with increased brain cancer risks. Neurofibromatosis type I (NF1) is the most common familial syndrome associated with brain tumors occurring as an autosomal dominant inherited syndrome in ~1/3,000 live births.[55] In a British study of 448 NF1 patients (221 male and 227 female), followed for a median of 13.6 years, the cumulative malignancy risk by age 50 years was 20% (95% CI: 14–29%) with the incidence of brain and connective tissue tumors significantly increased.[56] The hallmark brain tumors were optic pathway, hemispheric, and brainstem gliomas. Neurofibromatosis type II (NF2) is a less frequent inherited syndrome (i.e., with an occurrence of ~1/40,000 live births). The most common brain tumors in patients with NF2 are vestibular schwannomas and multiple meningiomas.[57] Table 58.3 lists genetic syndromes commonly associated with CNS and other tumors.

CLINICAL FEATURES

The median age at diagnosis of CNS tumors varies with age, as outlined in Table 58.4. Pilocytic astrocytomas

TABLE 58.3. Association of the central nervous system and other tumors with most common genetic syndromes. (Adapted from Hottinger and Khakoo).[57]

Syndrome	CNS Tumor	Chromosome	Gene	Associated Tumors
Cowden disease	Dysplastic cerebellar gangliocytoma	10q23	*PTEN*	Colon polyps, breast and thyroid carcinomas
Li–Fraumeni syndrome	Gliomas, primitive neuroectodermal tumors/medulloblastoma, choroid plexus carcinoma	17p13.1	*TP53*	Breast carcinoma, sarcomas, leukemia, adrenocortical carcinoma
Neurofibromatosis type I (von Recklinghausen disease)	Optic pathway gliomas, astrocytomas, vestibular schwannoma, ependymomas, neurilemmomas, meningiomas, neurofibromas	17q11.2	*NF1*	Pheochromocytoma, gastrointestinal stromal tumors, juvenile chronic myelogenous leukemia, rhabdomyosarcoma
Neurofibromatosis type II (central neurofibromatosis)	Vestibular schwannoma, spinal ependymoma, astrocytomas, meningioma	22q12	*NF2*	None
Tuberous sclerosis	Giant cell astrocytoma	9q34.14, 16p13.3	*TSC1, TSC2*	Multisystem nonmalignant tumors
Von Hippel–Lindau	Cerebellar hemangioblastoma, retinal angiomatosis	3p25	*VHL*	Renal cell carcinomas, pheochromocytomas, endolymphatic sac tumors

Abbreviation: NF1 = neurofibromin 1; *NF2* = neurofibromin 2; *PTEN* = phosphatase and tensin homolog; *TP53* = tumor protein p53; *TSC* = TSC complex subunit 1; *VHL* = von Hippel–Lindau tumor suppressor.

TABLE 58.4. Median age at diagnosis for specific histological type based on data from Central Brain Tumor Registry of the United States (CBTRUS). (Data adapted from Ostrom et al.).[5]

Histological Type	Origin	Median Age at Diagnosis (Years)
Astrocytoma, anaplastic	Neuroepithelial	53
Astrocytoma, diffuse	Neuroepithelial	48
Astrocytoma, pilocytic	Neuroepithelial	13
Ependymal tumors	Neuroepithelial	44
Glioblastoma	Neuroepithelial	64
Glioneuronal tumors, mixed	Neuroepithelial	27
Oligodendroglioma	Neuroepithelial	43
Oligodendroglioma, anaplastic	Neuroepithelial	49
Choroid plexus tumors	Non-neuroepithelial	19
Craniopharyngioma	Non-neuroepithelial	42
Embryonal tumors	Non-neuroepithelial	9
Germ cell tumors	Non-neuroepithelial	17
Lymphoma	Non-neuroepithelial	65
Meningioma	Non-neuroepithelial	65
Pineal tumors	Non-neuroepithelial	33
Pituitary tumors	Non-neuroepithelial	51

(grade I) occur primarily in children and young adults compared with the third to fourth decade for oligodendrogliomas (grade II) and the sixth to seventh decade for malignant gliomas.

Patients with primary brain tumors present with focal (i.e., related to specific location of tumor) or generalized symptoms (e.g., seizures) over days to years depending on the proliferation rate and tumor location.[58] About 50% of patients with malignant brain tumors present with headache and may have new neurological signs (e.g., seizures, neurocognitive impairment, focal neurological signs) depending on location. Frontal lobe tumors are associated with weakness or dysphasia, whereas parietal tumors cause hemineglect, spatial disorientation, and numbness. Visual field defects may result from occipital, parietal, or temporal neoplasms. Prefrontal lobe, temporal lobe, or carpus callosum lesions may produce cognitive impairment, memory loss, personality changes, and mood disorders. Infratentorial tumors are associated with cranial-nerve palsies, cerebellar dysfunction, and long-tract signs. Progressive headaches worse at night, early morning nausea and vomiting, drowsiness, blurred vision, diplopia, and seizures may indicate increased intracranial pressure.

The overall 1-year survival rate for nonmalignant CNS tumors in the United States is ~94–96% compared with 91–95% for 5-year survival, whereas the overall 1-year survival rate for malignant CNS tumors is ~57% and 32–34% for 5-year survival.[5,59] In Europe, the 5-year survival rate varies substantially between countries and histological types, with an overall average of 85% for benign and ~20% for malignant tumors.[60]

MENINGIOMAS

Meningiomas are the most common adult brain tumor accounting for ~50% of the total number based on data from the Central Brain Tumor Registry of the United States (CBTRUS), with ~24,000 new cases annually.[5] Figure 58.2 displays the distribution of the most common primary brain and other CNS tumors based on their histological type and malignant potential. The estimated incidence of meningiomas is 7.6 cases/100,000 with the incidence ~2- to 3-fold higher in women than men and ~20% higher in African-Americans than Caucasians;[61] however, the exact incidence is difficult to calculate because these neoplasms are often asymptomatic, benign, and discovered incidentally. Worldwide, the age-standardized cerebral meningioma incidence ranges from 1.28–7.80/100,000 inhabitants.[62]

CARCINOGENESIS

Meningiomas arise from arachnoid cap cells within the arachnoid layer of the arachnoid villi lining the skull vault, skull base, and spinal cord. Although most meningiomas (i.e., ~95%) are benign, encapsulated tumors with few genetic aberrations, serious, potentially lethal effects may result from the growth of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

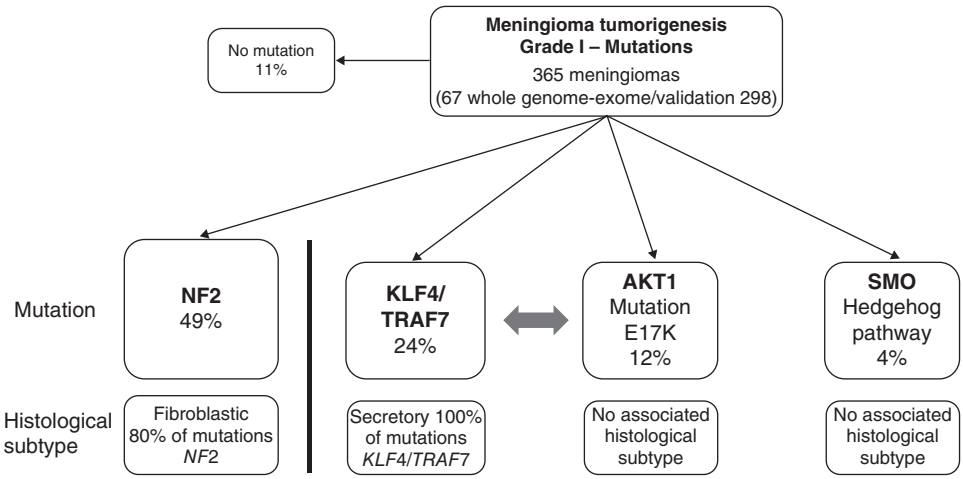

FIGURE 58.3. Benign meningioma molecular genetics and associated histological subtypes. Inactivation of *NF2* (neurofibromin 2) and chromosome 22 loss occur in ~50% of meningiomas. *NF2* expresses the merlin protein involved with cell shape, growth, adhesion, and tumor suppression. Among *NF2*-independent meningiomas, relatively frequent activation mutations include *AKT1* (AKT1 kinase) involved with cell proliferation, differentiation, apoptosis, *SMO* (G protein-coupled receptor for hedgehog proteins in Sonic Hedgehog pathway), and *KLF4/TRAF7*. The latter (Kruppel-like factor 4) modulates differentiation through transcriptional regulation of pluripotent stem cells, whereas tumor necrosis factor receptor-associated factor 7 is a proapoptotic protein and signal transducer for members of the TNF receptor superfamily. (Adapted from Peyre and Kalamarides).[65]

these tumors in certain intracranial locations. The long latency of meningiomas (i.e., 20–30 years post-ionizing radiation), difficult exposure ascertainment from recall bias, substantial subclinical disease in the general population, and detection bias complicate the determination of mechanisms and risk factors. The complexity of genetic aberrations increases with tumor grade. Sporadic meningiomas typically result from ≥1 focal chromosomal deletion commonly involving deletion and inactivation of *NF2* tumor suppressor gene on chromosomal locus 22q12 along with biallelic deletions.[63] Approximately 50% of meningiomas have an inactivation of *NF2*/chromosome 22 loss. *NF2* expresses the merlin protein; this tumor suppressor helps regulate cell adhesion, cell proliferation via induced senescence, and cell size.[64] Figure 58.3 displays the molecular genetics of benign meningiomas along with associated histological subtypes. This gene probably participates in tumor initiation rather than tumor promotion. Among NF2 mutation-negative meningiomas, relatively frequent activation mutations involve *AKT1* (AKT1 kinase) (involved with cell proliferation, differentiation, apoptosis), *SMO* (G protein-coupled receptor for hedgehog proteins in Sonic Hedgehog pathway), and *KLF4/TRAF7* genes. Kruppel-like factor 4 affects cell differentiation via transcriptional regulation of pluripotent stem cells, whereas tumor necrosis factor receptor-associated factor 7 is a proapoptotic protein and signal transducer for members of the TNF receptor superfamily.[65] Progression of benign meningiomas to grade II/III tumors results from activation of oncogenes, inactivation of tumor suppressor genes, and alteration of several molecular pathways (Hedgehog, Wnt, Notch, transforming growth factor β, and insulin receptor singling pathways).[66] Progression also involves: 1) altered DNA methylation of transcription-regulating genes; 2) epigenetic (posttranscriptional) changes including abnormal miRNA expression involving post-transcriptional regulation of gene expression, mRNA translation, and mRNA degradation; and 3) mutant epigenetic modifiers.[67]

EXPOSURE

Current weight of the evidence does not conclusively support increased meningioma risks from cell phone use, organic solvent exposure, or head trauma.[68] The association with the latter is inconsistent, probably from the influence of recall and detection bias. In a case-control study of 105 meningioma cases (mean age = 52 years) and age-matched neighborhood controls, self-reported serious head trauma (i.e., loss of consciousness, dizziness, medical consultation) was associated with meningiomas (OR = 1.9, $n = 39$ cases).[37] A population-based, case-control study of 200 meningiomas and 400 controls reported increased

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

meningioma risks in cases with a self-reported history of head trauma (OR = 1.83, 95% CI: 1.28–2.62), particularly head trauma occurring 10–19 years prior to the reference date. The number, but not severity, of head traumas is correlated to meningioma risks. Other studies failed to detect increased meningioma risks in follow-up studies of head trauma patients. Analysis of data from 2,953 patients followed for 29,859 person-years demonstrated a relative meningioma risk of 1.6 (95% CI: 0.3–4.7, $n = 3$ meningiomas) using age-specific incidence rates for meningiomas.[69] Severity and location of head injuries were not related to tumor occurrence. In a Danish cohort of 228,055 residents hospitalized for head trauma (e.g., concussion, fractured skull) and followed up to 17 years (mean = 8 years), the standardized incidence ratio for meningioma after the first year was statistically nonsignificant (SIR = 1.2, 95% CI: 0.8–1.7).[70]

Ionizing Radiation

High-dose ionizing radiation is the established risk factor for meningiomas based on atomic bomb survivors and the 1950s *Tinea Capitis* cohort of Israeli children (~10-fold increase).[71] The follow-up cohort study of Israeli children irradiated for *Tinea capitis* indicated a stronger mean risk for the development of meningiomas (RR = 9.5) compared with gliomas (RR = 2.6).[72] The studies on dental X-rays are relatively weak and inconsistent. The ionizing radiation exposure for atomic bomb survivors in the Life Span Study was relatively low compared with the cohort of *Tinea capitis* radiotherapy. Over 50% of the Japanese cohort were ≥20 years of age at the time of the exposure, with the estimated brain radiation dose exceeding 1 Sv in only 3% of the cohort.[73] The distribution of brain tumor types in the Life Span Study cohort was similar to Japanese population data, with meningioma being the most common tumor type. Of the 88 meningiomas diagnosed from 1958–1995, three were malignant; however, the estimated dose did not correlate to malignancy (two of the three patients had no significant ionizing radiation from the atomic explosion). A Los Angeles-based retrospective case-control study of 101 cases in women and 101 neighbors matched for sex, age within 5 years, and race suggested an association between meningiomas and the frequency of full-mouth dental X-rays in early childhood based on self-reported questionnaires.[37] For the first full-mouth dental X-ray series before 20 years of age, the OR was 4.0 ($P = <0.01$) with no reported confidence limits. The odds ratio for a reported history of >10 full-mouth dental X-rays was 4.9 with $P_{trend} = 0.01$. The supratentorial and infratentorial locations of the meningiomas were similar between cases and controls. The study also reported positive associations for meningiomas with self-reported histories of head trauma (OR = 2.0, $P = 0.01$) and high-nitrite meats (OR = 2.8, $P = <0.01$). In a US population-based case-control study of 1,433 patients with intracranial meningiomas diagnosed at 20–79 years (mean = 57.3 years), neither the association between age at exposure nor the frequency of full-mouth X-rays was statistically significant.[74] However, the study reported elevated odds ratios for ever having a bitewing examination (OR = 2.0, 95% CI: 1.4–2.9) and for more frequent bitewing X-rays in adults, but not in children of <10 years of age. Cosmic radiation is not consistently associated with elevated CNS tumor risks including meningiomas using airline crew as surrogates for increased cosmic radiation exposures.[75,76] In a European and North American mortality study of ~94,000 airline crew members, the mortality rates were statistically similar to the general population for male cockpit crew (SMR = 1.14, 95% CI: 0.83–1.54, $n = 59$ cases), male cabin crew (SMR = 1.25, 95% CI: 0.64–2.18, $n = 16$), and female cabin crew (SMR = 0.95, 95% CI: 0.59–1.46, $n = 29$).[77] A US mortality study of ~6,000 former commercial airline cockpit crew members reported no statistically significant increased CNS tumor mortality (SMR = 1.39, 95% CI: 0.95–1.96, $n = 32$ cases) and a marginally increased standardized rate ratio comparing the highest (≥43.7 mSv) and lowest (<18.1 mSv) cumulative exposure categories (SRR = 3.84, 95% CI: 1.00–14.74, $n = 9$ cases) with a 10-year lag.[78] The CNS tumor risk was not associated with the duration of employment.

Occupation

No specific occupational substances are clearly associated with increased meningioma risks. The INTEROCC study of 1,906 meningioma cases and 5,565 population-based controls from European, Canadian, and New Zealand workers used job-exposure matrices based on interviews to evaluate three exposure indices (ever vs. never; lifetime cumulative exposure; total exposure duration) for 12 chemical substances.[79] This multinational case-control study reported little evidence of associations between meningioma and most of the 12 chemical exposures, including asbestos, animal dust, quartz, wood dust, benzo(a)pyrene, bitumen, diesel/gasoline engine exhaust, polycyclic aromatic hydrocarbons, and sulfur dioxide. The exception was oil mist; for ever-exposure to oil mists, the OR was elevated (OR = 1.57, 95% CI: 1.10–2.22, $n = 51$ exposed

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cases) with statistically significant exposure-response relationships for cumulative exposure ($P_{difference} = 0.01$) and duration of exposure ($P_{difference} = 0.04$). Among women in the highest exposure categories, the data suggested some indication of an exposure-response for asbestos and excess risks for formaldehyde-associated meningioma; however, the associations remain unconfirmed. Although several studies suggest an excess brain cancer incidence in farmers, the studies are inconsistent and primarily involve gliomas; the limited studies and lack of accurate exposure data among the many agricultural products limit conclusions. In a French population-based case-control study of 67 incident meningiomas and 77 matched, unexposed controls, the adjusted OR for the highest quartile of pesticide exposure was 0.65 (95% CI: 0.16–2.55, $n = 9$ cases).[80] Power analysis indicated the study design would identify a detectable meningioma risk of 2.6. The overall adjusted OR for ever- versus never-pesticide exposure was also statistically nonsignificant (adjusted OR = 1.26, 95% CI: 0.61–2.64, $n = 37$ exposed cases), with a detectable overall risk of 1.6 for all brain tumors.

Lifestyle

Although case-control studies on the association between cell phone use and gliomas are conflicting, the results on meningiomas are generally negative.[62] Interpretation of studies associating diet with meningiomas is complicated by the difficulty in obtaining accurate estimation of dietary components (e.g., *N*-nitroso compounds in smoked meats) and analysis of histological types. Currently, no evidence clearly supports an association between diet and meningiomas. The association between smoking and meningioma risks is weak and relatively small, with some studies suggesting a modestly increased risk in men but not women. In a meta-analysis of seven case-control and two cohort studies, the overall pooled estimated meningioma risk comparing ever- and never-smokers was not elevated (RR = 0.95, 95% CI: 0.87–1.05, $P_{difference} = 0.32$, $I^2 = 31.5\%$, $P_{heterogeneity} = 0.177$).[81] Pooled estimates comparing meningiomas in ever- and never-smokers were also statistically nonsignificant for case-control (pooled RR = 1.02, 95% CI: 0.85–1.21, $I^2 = 39.2\%$, $P_{heterogeneity} = 0.144$) and cohort (pooled RR = 0.93, 95% CI: 0.83–1.04, $I^2 = 18.2\%$, $P_{heterogeneity} = 0.269$) studies. Subgroup analyses suggested an increased meningioma risk in men (pooled RR = 1.49, 95% CI: 1.06–2.09, $P_{difference} = 0.02$, $I^2 = 33.6\%$, $P_{heterogeneity} = 0.210$) but not women (pooled RR = 0.86, 95% CI: 0.65–1.13, $I^2 = 66.2\%$, $P_{heterogeneity} = 0.019$). Current and past smoking did not correlate to meningioma risks with substantial heterogeneity.

Medications

The high incidence of meningiomas in women and the presence of hormone receptors (estrogen, progesterone, androgen) in some meningiomas suggest an etiological role for hormones. The most consistent results associate an increased meningioma risk with hormonal replacement treatment in postmenopausal women. There is little statistical evidence of an increased meningioma risk in women using oral contraceptives.[52] Additionally, limited evidence supports an association with parity, breastfeeding, or age at menarche. In a case-control study of 1,127 women of 29–79 years of age with intracranial meningioma and 1,092 age- and location-matched controls, the meningioma risk among premenopausal women was elevated with current use of oral contraceptives (OR = 1.8, 95% CI: 1.1–2.9).[82] Current use of hormone replacement therapy among postmenopausal women was not associated with a significantly increased meningioma risk (OR = 1.1, 95% CI: 0.74–1.67). In a nested case-control analysis using unconditional logistic regression, the study identified 741 meningioma cases aged 12–89 years from the Health Improvement Network UK primary care database along with 10,000 age- and sex-matched controls.[83] Compared with nonusers, meningioma risks were not elevated in women using oral contraceptives (OR = 1.15, 95% CI: 0.67–1.98) or hormone replacement therapy (OR = 0.99, 95% CI: 0.73–1.35). In a Finnish case-control study of 264 meningioma cases in women aged 20–69 years and 505 population-based controls, immunohistological analysis yielded 86.3% progesterone-receptor-positive results in successfully stained specimens and 50% for estrogen receptors.[84] Meningioma risks were not associated with postmenopausal hormonal treatment use (OR = 1.13, 95% CI: 0.76–1.67, $n = 50$ cases) or ever- versus never-contraceptive users (OR = 1.33, 95% CI: 0.94–1.89, $n = 182$ cases).

Diseases

In general, the effect of allergy on brain tumors remains controversial, with the evidence less consistent for meningiomas than gliomas. In a meta-analysis of three case-control and two cohort studies, the pooled RR for an association between self-reported atopy (allergy, asthma, eczema) and meningiomas was not statistically significant (pooled RR = 0.93, 95% CI:

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

0.72–1.19, $n = 1{,}070$ cases, $P = 0.57$) with moderate heterogeneity.[85] A meta-analysis of 5 case-control and 2 cohort studies, including 54,391 participants and 2,656 meningiomas, reported a statistically nonsignificant odds ratio comparing meningioma patients with and without allergic conditions (summary OR = 0.91, 95% CI: 0.79–1.04, $P = 0.163$, $I^2 = 31.3\%$).[86] Subanalysis suggested an inverse association between eczema and self-reported allergy (summary OR = 0.75, 95% CI: 0.65–0.87, $P < 0.05$, $I^2 = 0.0\%$). A US population-based case-control consortium study of 1,065 surgically resected meningiomas reported an increased self-reported history of physician-diagnosed allergy (OR = 0.64, 95% CI: 0.51–0.80) compared with controls.[87] The serum IgE concentrations were also lower in cases than in controls. In a German population-based case-control study involving 381 meningioma cases and 1,494 controls, the odds ratio for self-reported allergies (asthma, eczema, hay fever) in meningioma patients was statistically nonsignificant (OR = 0.87, 95% CI: 0.66–1.14).[88]

HISTOLOGY

Approximately 95% of meningiomas are benign encapsulated tumors (grade I) with limited genetic aberrations; only ~1–3% progress to malignant (grade III) tumors.[12] Unlike most cancer histological types, brain tumors are not classically categorized by stages. Table 58.5 lists the central nervous system tumors of meningeal origin. Most meningiomas have mixed histology, with classification depending on the dominant part.

HOST SUSCEPTIBILITY

Genetic studies on factors associated with increased meningioma risk are limited. A meta-analysis of case-control studies using Mantel–Haenszel statistics reported statistical evidence for increased meningioma susceptibility for genetic variants of *MLLT10* (MLLT10 histone lysine methyltransferase DOT1L cofactor), *MTRR* (5-methyltetrahydrofolate-homocysteine methyltransferase reductase), and *MTHFR* (methylenetetrahydrofolate reductase) genes.[90]

Although most meningiomas are sporadic, having a first-degree relative with a meningioma increases the risk of developing this tumor. In a study of data from the Swedish Cancer Registry, the incidence of meningiomas was increased in patients with first-degree relatives with meningiomas (SIR = 2.17, 95% CI: 1.44–3.14, $n = 28$ cases), particularly in patients of <50 years of age at presentation.[91] Using data from the nationwide Swedish and Norwegian databases on familial cancer to calculate standardized incidence ratios, histology-specific population-based familial risks for meningioma were increased for offspring of affected parents (SIR = 1.6, 95% CI: 1.3–2.0).[92] People with certain mutations of the neurofibromatosis gene (*NF2* on chromosome 22) have a significantly increased risk for meningiomas; however, other genes are probably involved in other areas of the chromosomes, including 18q, 10q, 14q, 1p, and 6q.[93]

CLINICAL FEATURES

The most common symptoms associated with meningiomas include headache, sensorimotor impairment, and convulsions. Other symptoms include behavioral disorders and cognitive impairments with sensory changes, particularly common in patients of >70 years of age.[94] The incidence of meningiomas increases steadily with age, as noted in Table 58.4. As a result of their long latency time (i.e., 10–20 years) and subclinical presentation, these tumors are frequently discovered incidentally during imaging for other conditions.[95] The median interval between radiation and diagnosis ranged somewhat longer for meningiomas (17–23 years) than gliomas (9–18 years).[12] The mean latency period for the occurrence of meningiomas in Israeli children irradiated for *Tinea capitis* was ~36 years.[72,96] Table 58.6 displays average latency periods for meningioma patients receiving low, moderate, and high ionizing radiation doses based on a 1991 study by Harrison et al.[97] The latency period is significantly shorter in children irradiated at ≤5 years of age than in adults. Although the latency period tends to decrease with higher ionizing radiation doses, published studies have limited power to detect a statistically significant difference between high- and low-dose radiation and latency.

The clinical severity of these tumors depends primarily on their location.[98] The relatively rare malignant transformation of meningeal neoplasms (i.e., grade I to grade III) produces little mortality except for skull-based tumors. The overall 5-year survival rate of meningiomas is age-dependent, with an average of <70% decreasing with age.[99] Complete resection of meningiomas occurs in <50% of patients, with tumor recurrence developing in ~20% of benign meningiomas.[100] Malignant meningiomas are associated with significant morbidity and mortality because of their high recurrence rates and median disease-free interval of 2 years.

[a] Morphology code of the International Classification of Diseases for Oncology (ICD-0) and Systematized Nomenclature of Medicine: 0 = benign tumor, 1 = low or uncertain malignant potential, 2 = *in situ* lesions, 3 = malignant tumor.

TABLE 58.6. Summary of latency periods for meningioma based on a case series and published cases identified by a literature review by Harrison et al.[97]

Radiation Dose	Latency Average (Range in Years, Cases)	Patient Age at Exposure (Years, Cases)
Low (<10 Gy)	35.2 (12–58, $n = 120$)	44.5 (22–63, $n = 118$)
Moderate (10–20 Gy)	26.1 (2–63, $n = 11$)	32.3 (5–75, $n = 11$)
High (>20 Gy)	19.5 (4–50, $n = 31$)	34.2 (8–63, $n = 30$)

GLIOMAS

Gliomas represent ~80% of malignant brain tumors, with glioblastomas and WHO grade IV astrocytomas accounting for >50% of malignant brain tumors. Figure 58.2 displays the distribution of the most common primary brain and other CNS tumors based on histological type and malignant potential. Overall, gliomas account for ~24% of adult brain tumors, with ~20,000 new cases annually in the United States. The overall glioma incidence rate is modestly lower in women than men, except for pilocytic astrocytomas (i.e., similar rates). Glioblastoma multiforme is the most frequent and lethal primary malignant CNS tumor in adults, with a US age-adjusted incidence rate of 3.97/100,000 in men and 2.53/10,000 in women.[5] The prevalence rate of glioblastomas is usually higher in whites than in other racial groups.[101] Overall, glioma incidence generally varies little between countries or various ethnic groups in the same country;[16] however, non-Hispanic whites have the highest glioma incidence rate in the United States.[99] The overall age-adjusted incidence of gliomas ranges from ~4.5–6/100,000, whereas the rate for glioblastoma is ~0.6–3.7/100,000.[102] Recent overall glioma rates are relatively stable.

CARCINOGENESIS

The vast majority of glioblastomas (>90%) arise *de novo* (i.e., ~90%), whereas ~5% are secondary glioblastomas progressing from lower-grade astrocytomas.[103] These tumors are molecularly heterogeneous and rapidly infiltrate local brain tissue; the overexpression and downregulation of a wide variety of miRNAs and lncRNAs contribute to tumor proliferation, cell migration, invasion, and neovascularization.[104] For glioblastomas, studies indicate recurrent alteration in several core pathways including: 1) retinoblastoma (RB) signaling involving RB mutation, CD4/CD6 amplification, and CDKN2A/CDKN2A deletion (cyclin-dependent kinase inhibitor 2A/2C); 2) TP53 protein signaling involving CDKN2A deletion, MDM1/MDM4 amplification; and 3) activation of the receptor tyrosine kinase signaling pathway and EGFR/PDGFRA amplification.[105] Molecular markers vary with histological subtypes. EGFR alterations and homozygous CDKN2A deletion characterize the classical glioblastoma subtype, whereas concomitant chromosomal loss of 1q/19q is associated with oligodendromas and improved survival.[106] Mutations of the *TP53* gene are often associated with WHO grade I–II astrocytomas that ultimately develop into secondary glioblastomas and primary glioblastomas *IDH1/2* wildtype.[107] Alteration of telomere maintenance mechanisms also occurs in some gliomas. Point mutations in the telomerase reverse transcriptase (*TERT*) gene promoter occur in ~75% of oligodendrogliomas and primary glioblastomas, resulting in increased telomerase activity. Alternately, ~75% of WHO grade II–III astrocytomas and secondary glioblastomas lengthen telomere by activating telomerase-independent telomere maintenance pathway (telomere binding protein ATRX mutations).[108] Epigenetic events (e.g., CpG island methylation) silence downstream genes. Glioblastomas frequently (i.e., ~40%) hyper-methylate the *MGMT* gene promoter (O^6-methylguanine-DNA methyltransferase) that codes the enzyme responsible for restoring guanine from *O*-6-methylguanine.[104]

At least 25 genomic variants are associated with increased glioma risk. Examination of nine gliomas arising 5–23 years after intracranial radiation indicates significant genetic deviation from spontaneous gliomas based on sequencing of *EGFR* (epidermal growth factor receptor), *K-RAS*, *MTAP*, p16 protein (*MTS1/CDKN2*), *TP53*, and *PTEN* genes.[109] Radiation-induced gliomas differ from spontaneous tumors in several features including higher grades, younger ages, and atypical sites (e.g., cerebellum, suprasellar region). Gene expression is more homogeneous in radiation-induced pediatric tumors than spontaneous glioblastomas, with greater overlap in pilocytic astrocytomas than glioblastomas.[110] Western blot analyses indicated much greater expression of ErbB3, SOX10, and platelet-derived growth factor receptor-alpha proteins in radiation-induced glioblastomas than pediatric glioblastomas.

EXPOSURE

Ionizing Radiation

Ionizing radiation is a well-established risk factor for gliomas in previous cohorts receiving high-dose radiation (atomic bomb survivors, prophylactic cranial irradiation, *Tinea capitis*, and scalp hemangioma radiotherapy). These studies indicate high therapeutic radiation doses are associated with increased CNS cancer risks, particularly gliomas, in children exposed at <5 years of age.[111] A retrospective analysis of 10,834 Israeli children treated with low-dose radiation (mean = 1.5 Gy, range, 0.98–6.0 Gy) reported 21 malignant gliomas in the irradiated group compared with 12 in the sibling/population control group after a 40-year follow-up with increased risk in younger children.[96] The excessive relative risk/Gy decreased

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from 3.56 in children of <5 years of age to 0.47 at the age of ≥10 years ($P_{trend} = 0.037$). The Swedish study of infants of <18 months of age treated with lower mean absorbed intracranial radiation doses (mean = 0.07 Gy, range, 0–11.5 Gy) for scalp hemangiomas also reported increased CNS tumor risks.[112] The standardized incidence ratio (SIR) was 1.42 (95% CI: 1.13–1.75) with an excess relative risk (ERR/Gy) of 2.7 (95% CI: 1.0–5.6). In the Life Span Study of atomic bomb survivors, glioblastomas accounted for 13 cases and anaplastic astrocytoma for 11 cases of the 44 total cases of neuroepithelial tumors;[73] 23% of these tumors were diagnosed postmortem. The age-adjusted incidence rate for gliomas in men was 3.5 compared with 2.0 in women. Several studies of survivors of childhood cancers treated with high-dose radiation reported increased glioma risks, particularly in children of <5 years of age at radiation exposure. In a retrospective cohort (Childhood Cancer Survivor Study) of 14,361 5-year survivors of childhood cancers, the odds ratio for glioma in irradiated children was markedly elevated (OR = 6.78, 95% CI: 1.54–29.7, $n = 40$ gliomas) compared with 160 age-, sex-, and time since original cancer diagnosis-matched controls.[113] The wide confidence limits suggest imprecise odds ratios. After adjustment for radiation dose, glioma risks were not associated with the original cancer diagnosis or chemotherapy. A national, population-based, UK cohort study (British Childhood Cancer Survivor Study) of 17,980 individuals surviving at least 5 years after diagnosis of childhood cancer also reported increased glioma risks.[114] The standardized incidence ratio for gliomas was 10.8 (95% CI: 8.5–13.6). Data associating gliomas with medical radiation exposure from diagnostic head CT scans remain inconclusive, with recent questionnaire-based case-control studies suggesting an inverse association, whereas most nested case-control and cohort studies report no association.[115]

Occupation

Detecting elevated glioma risks from occupational exposures is limited by the rarity of this cancer and methodological difficulties in estimating individual exposures retrospectively. Evidence for an association between occupational exposures and glioma incidence is generally weak and inconsistent.

Job Categories

Studies on glioma risks and job titles or specific chemical exposure have not demonstrated a clear association between glioma incidence and any occupational title or chemical. In the Upper Midwest Health Study using the longest employment duration for 780 cases and 1,156 controls, the engineer/architect group was the only occupational category with a statistically significant age/sex/education-adjusted odds ratio (OR = 2.5, 95% CI: 1.12–5.60, $n = 16$ cases, 10 controls).[116] The OR for food processing workers (e.g., butchers, meat cutters) was statistically marginally significant (adjusted OR = 1.78, 95% CI: 0.99–3.18, $n = 27$ cases, 21 controls), whereas the study did not support elevated glioma risks in farmers, electrical workers (polychlorinated biphenyls), or rubber workers (*N*-nitroso compounds). A subanalysis of 228 primary intracranial glioma cases (50% proxy respondents) in farm pesticide applicators and 417 population-based controls demonstrated no significant positive associations with cumulative years or estimated lifetime cumulative exposure to farm pesticides based on questionnaire responses evaluated by an industrial hygienist.[117] The odds ratio for nonfarm pesticide application was inversely related to glioma risk (adjusted OR = 0.79, 95% CI: 0.52–0.99, $n = 65$ cases, 48% proxy respondents). In the 15 million member Nordic cohort evaluating occupation and cancer, the highest glioma risks among male work categories were other health workers (SIR = 1.30, 95% CI: 1.02–1.64) and military personnel (SIR = 1.24, 1.06–1.44), whereas the SIR was below unity for forestry workers (SIR = 0.78, 95% CI: 0.70–0.88), fishermen (SIR = 0.81, 95% CI: 0.68–0.96), and seamen (SIR = 0.82, 95% CI: 0.71–0.96).[118] For women, the highest SIR was among physicians (SIR = 1.55, 95% CI: 1.02–2.25) with no SIR below unity.

Most studies on pesticide exposures and glioma risk have not observed a positive association, except for a population-based case-control study in southwestern France.[80] In this French study based on an expert review of job titles, the glioma risk in the highest quartile of cumulative pesticide exposure was elevated (OR = 3.21, 95% CI: 1.13–9.11, $n = 11$ cases) compared with unexposed controls, whereas the overall glioma risk was not significantly increased (OR = 1.47, 95% CI: 0.81–2.66, $n = 31$ cases). The Upper Midwest Health Study did not observe a positive association between cumulative pesticide use and glioma risk.[116] The INTEROCC study of 1,800 glioma cases and 5,160 population-based controls from European, Canadian, and New Zealand workers used job-exposure matrices based on interviews to evaluate three exposure indices (ever vs. never; lifetime cumulative exposure; total exposure duration).[119] None of the 10 agents displayed a statistically significant increase in OR or dose-response relationship between glioma risks and cumulative or exposure duration. The substances included asbestos, diesel/gasoline exhaust, formaldehyde, metals, and solvents. A mortality study of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

vinyl chloride polymerization workers reported a SMR of 329 for brain tumors, primarily glioblastomas multiforme.[120] A similar mortality study of workers exposed to vinyl chloride monomer in Great Britain did not detect an increased mortality from brain tumors compared with the general population.[121] Formaldehyde was implicated as a potential source of elevated brain tumor risks in pathologists[122] and embalmers[123] by mortality studies; however, the contribution of formaldehyde to the overall incidence of brain tumors remains unclear.

Electromagnetic Fields

A substantial number of studies explored the incidence of brain tumor/gliomas and a variety of extremely low-frequency magnetic fields (ELFs) exposure markers, including self-reported exposure, measured and modeled estimates, job-exposure matrices, and expert assessments with mixed results. The small study sizes, poor occupational history, and rarity/heterogeneity of glioma subtypes complicate the interpretation of these studies. A meta-analysis of 22 studies reported a small but statistically significant increase in glioma risk in workers exposed to ELFs (estimated pooled RR = 1.18, 95% CI: 1.1–1.26, $n = 22$ studies). The cumulative meta-plot demonstrated no clear exposure-response. In the INTEROCC study of 1,939 glioma cases and 5,404 population controls, glioma risk was not associated with average, maximum, or lifetime cumulative ELF exposure as measured by job-exposure matrix. The odds ratio for the highest cumulative ELF exposure group of ≥7.5 μT-years was 0.80 (95% CI: 0.63–1.00, $P_{\text{trend}} = 0.08$).[124] Although the glioma risk for the highest cumulative exposure group in the most recent duration category (1–4 years) was statistically significant (OR = 1.67, 95% CI: 1.36–2.07, $P_{\text{trend}} = <0.0001$), the longer ELF exposure groups did not demonstrate elevated glioma risks. In a retrospective US study of 489 glioma cases and 799 hospital-based controls using a job-exposure matrix supplemented with job-specific questionnaires, glioma risks were not associated with peak exposure ($P_{\text{trend}} = 0.19$), duration ($P_{\text{trend}} = 0.32$), lifetime average ($P_{\text{trend}} = 0.68$), or cumulative ($P_{\text{trend}} = 0.23$) exposures. None of the trends suggest a dose-response relationship.[42]

Lifestyle

Smoking

Most studies on brain cancer and smoking analyze glioma risks. In a meta-analysis of 6 cohort and 11 case-control studies using multivariate-adjusted risk estimates comparing ever- versus never-smokers, the overall odds ratio was 1.06 (95% CI: 0.97–1.15). For cohort studies, the OR was 1.10 (95% CI: 1.01–1.20) and 1.00 (95% CI: 0.88–1.15) for case-control studies.[125] The limited number of studies indicates no dose-response relationship between smoking and glioma risks. A meta-analysis of seven case-control studies demonstrated no significant association between smoking and glioma risks (OR = 0.96, 95% CI: 0.86–1.07, $P_{\text{difference}} > 0.05$, $I^2 = 48.0\%$, $P_{\text{heterogeneity}} = 0.073$).[126]

Mobile Phone Use

The IARC lists radiofrequency electromagnetic fields, including exposure from wireless phones as a suspected carcinogen with limited human evidence (Group 2B), primarily involving gliomas and, to a lesser extent, benign vestibular schwannomas (acoustic neuromas). Several,[19] but not all,[127] case-control studies, biological data, animal experiments, brain tumor incidence trends, and reviews suggest that 10–15 years of mobile phone use have not significantly increased glioma risks for regular cell phone users, particularly for fast-growing tumors (e.g., malignant glioma). A European study reported no clear trend indicating a change in the annual age-standardized glioma incidence rates from 1979–2008 in adults from Nordic countries.[128] In simulations, the observed time trends were incompatible with relative risks for all users of 2.0 for an induction of ≤15 years, 1.5 for <10 years, and 1.2 for <5 years. The trends were also incompatible with a relative risk of 2.0 among heavy cell phone users over <5 years. Another study estimated the projected glioma incidence rates using the combined relative risks reported in the 2010 Interphone study and the 2011 Hardell et al. Swedish study[129] with US incidence rates adjusted for age, registry, sex; mobile phone use; and latency periods.[130] The latter study was used by the IARC to reclassify mobile phone exposure. Similar to the previous study, the elevated glioma risks associated with mobile phone use reported by the Swedish study were 40% higher than the observed US incidence rates; however, US data could be consistent with the modest excess glioma risks reported in the Interphone study.

Current evidence has not supported a dose-response relationship between long-term cell phone use and gliomas, particularly when successive rollouts of cell phone technologies have reduced ELF and radiofrequency exposures. In a UK prospective cohort (Million Women Study) of cancer in 791,710 middle-aged women comparing long-term cell phone use (>10 years) with never-cell phone users as controls, the estimated glioma risk for the long-term users was not elevated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(RR = 0.78, 95% CI: 0.55–1.10, $P_{\text{difference}} = 0.16$).[131] Furthermore, time trends in glioma incidence are not compatible with the estimated risks in positive case-control studies. An Israeli study of low-grade glioma incidence reported a statistically significant decrease in glioma risks during the 30 years after the introduction of cell phone technology in 1980.[132] The relative short observation period for slow-growing tumors (e.g., meningiomas, vestibular schwannomas) limits definitive conclusions regarding the causal connection between these tumors and long-term cell phone use including cell phone use in childhood. (See Mobile Phone section under Carcinogenesis in the Nonionizing Radiation – Radiofrequencies chapter for a detailed discussion.)

Reproductive Factors

Reproductive factors are not consistently associated with increased glioma risks. Although the NIH-AARP Diet and Health Study reported that older age at menarche (≥ 15 years) was associated with increased glioma risk (HR = 1.67, 95% CI: 1.03–2.69, $n = 23$ glioma cases), other reproductive factors demonstrated no association with glioma risks, including age at first live birth, parity, age at menopause, or ever-oral contraceptive use (adjusted HR = 0.74, 95% CI: 0.53–1.05, $n = 53$).[133] The European Prospective Investigation into Cancer and Nutrition (EPIC) study reported glioma risks were not associated with reproductive factors (age at menarche, parity, age at first birth, menopausal status, or age at menopause).[134] There were no exposure-response relationships for any of these risk factors.

Medications

Several studies suggest a reduced glioma risk with hormone replacement therapy and oral contraceptive use, along with an increased risk with later menarche and menopause;[52] however, the risk estimates from these studies usually do not reach statistical significance, particularly the higher-quality studies (nested case-control, cohort). Examination of data from the NIH-AARP Diet and Health Study on 225,355 women aged 50–71 years identified 174 cases of primary gliomas during a median follow-up of 7.5 years.[133] The reported hazard ratio comparing ever- versus never-use of menopausal hormone replacement therapy was 0.99 (95% CI: 0.63–1.56, $n = 61$ glioma cases) based on baseline questionnaires. Duration of use did not display an exposure-response relationship for oral contraceptives ($P_{\text{trend}} = 0.22$) or hormone replacement therapy ($P_{\text{trend}} = 0.22$). The European Prospective Investigation into Cancer and Nutrition (EPIC) study identified 193 glioma cases during a mean follow-up time of 8.4 years.[134] Current oral contraceptive use was not associated with increased glioma risks (adjusted HR = 0.76, 95% CI: 0.49–1.19, $n = 34$ glioma cases) using never-users as referents. Glioma risks in current postmenopausal hormone replacement therapy users were also not statistically different from those in never-use referents (adjusted HR = 1.23, 95% CI: 0.53–2.83, $n = 8$ glioma cases). There were no exposure-response relationships for these risk factors. In the San Francisco Bay Area Adult Glioma Study of 619 women with gliomas and 650 population-based controls using never-users as referents, glioma risks were inversely associated with self-reported ever-use of oral contraceptives (adjusted OR = 0.72, 95% CI: 0.53–0.99, $n = 405$ glioma cases) and postmenopausal hormone therapy (adjusted OR = 0.50, 95% CI: 0.25–0.98, $n = 47$ glioma cases).[135] A nested case-control study using data from population-based Danish registries on women aged 55–84 years identified 658 glioma cases and 4,350 controls.[136] Using never-users as referents, the glioma risk for ever-hormone replacement therapy was not elevated (adjusted OR = 0.9, 95% CI: 0.8–1.1, $n = 247$ cases). Glioma risks were also not statistically different than referents for overall long-term use (≥10 years), hormone replacement use (adjusted OR = 1.1, 95% CI: 0.7–1.7, $n = 26$ cases), estrogen-only use (adjusted OR = 1.6, 95% CI: 0.9–2.6, $n = 25$ cases), or progestogen use (adjusted OR = 2.2, 95% CI: 0.9–5.5, $n = 8$). None of the trends for cumulative exposure were statistically significant.

Diseases

Allergies

Although most studies suggest a modestly inverse glioma risk (i.e., ~40%) with self-reported allergies (asthma, eczema, food allergies, hay fever), these studies do not consistently report a dose-response relationship with duration, timing, antihistamine use, or allergy biomarkers.[102] Imprecise risk estimates, heterogenous allergy descriptions, self-reported histories, and varying outcome measures complicate the interpretation of positive studies. Several case-control studies report a modest inverse relationship between glioma risks and self-reported allergies, frequently with substantial proxy respondents. Using controls with no allergies, analysis of data from five INTERPHONE study countries (Australia, Canada, France, Israel, New Zealand) demonstrated an inverse association between any allergy and high-grade glioma risk (adjusted OR = 0.69, 95% CI: 0.55–0.87, $n = 123$

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cases, 17% proxy respondents). The inverse relationship with low-grade gliomas was not statistically significant (adjusted OR = 0.77, 95% CI: 0.57–1.04, $n = 72$ cases).[137] The exposure-response relationship for duration of allergy was stronger for hay fever than eczema or asthma. In a German population-based case-control study of 366 glioma cases and 1,494 nonallergic controls, the odds ratio between glioma risks and self-reported allergies was not statistically significant (OR = 0.92, 95% CI: 0.70–1.22, 3% proxy respondents).[88] Glioma risks were stronger, albeit statistically nonsignificant, for self-reported asthma (adjusted OR = 0.65, 95% CI: 0.36–1.1, $n = 15$ cases) than other allergic conditions. In a meta-analysis of eight observational (six case-control, two cohort) studies, the pooled glioma relative risk comparing an allergy history with nonallergic controls was inverse (adjusted RR = 0.61 (95% CI: 0.55–0.67, $P_{\text{difference}} < 0.001$, $P_{\text{heterogeneity}} = 0.51$).[85] The relationship between asthma and eczema was similarly inverse. The proxy response rate ranged from 2–34%.

Diabetes

The results of studies on the relationship between diabetes and glioma risks are highly variable, with risks including inverse, null, and positive results In a pooled analysis of US and Chinese data from 5 nested case-control and 2 case-control studies involving glioma cases and 2,195 controls, a self-reported diabetes history (type I/II) was inversely associated with glioma risk (adjusted OR = 0.58, 95% CI: 0.40–0.84) compared with nondiabetic controls.[138] The relationship was stronger for participants with BMI $< 25\,kg/m^2$. The relationship was no longer inverse in obese participants with BMI $\geq 30\,kg/m^2$ (OR = 1.16; 95% CI: 0.61–2.20). A cross-sectional case-control study of 1,144 glioblastoma cases and 969 age- and sex-matched controls assessed the association between diabetes type II, hyperlipidemia, and obesity with glioblastoma incidence.[139] Glioblastoma risks were not associated with diabetes type II (adjusted HR = 0.9, 95% CI: 0.7–1.2), hyperlipidemia, or obesity $\geq 30\,kg/m^2$ (adjusted OR = 0.7, 95% CI: 0.5–1.0, $P_{\text{difference}} = 0.72$).

HISTOLOGY

The origin of gliomas remains unclear. These tumors are highly heterogeneous, suggesting different molecular subtypes may arise from different cellular origins or develop distinct molecular alterations during carcinogenesis.[140] Some experimental evidence suggests adult neural stem and progenitor cells located in the subventricular zone, subcortical white matter, and dentate gyrus of the hippocampus are potential sites of origin for glioblastomas.[141] The most frequent locations for gliomas are the frontal (~26%), temporal (~20%), and parietal (~12%) lobes, whereas these tumors are rare in the spinal cord (~4%), brainstem (~4%), occipital lobe (~3%), and cerebellum (~3%).[142] The World Health Organization (WHO) restructured the classification of diffuse gliomas, medulloblastomas, and other embryonal tumors to incorporate new entities defined by histology and molecular features in 2016. Previously, histological classification depended on hematoxylin and eosin-stained microscopic features, ultrastructural characterization, and immunohistochemical expression of lineage-associated proteins.[143] The use of molecular markers improves the separation of biologically distinguishable groups with different clinical outcomes. In the case of discordant results, genotype has precedence over histological phenotype.[144] Table 58.7 displays the updated WHO classification of neuroepithelial CNS tumors (gliomas) with the morphology codes.

The most frequent histological types of adult gliomas are astrocytomas (grades I–IV), oligodendrocytic mixed, and oligoastrocytomas (grades II–III). Malignant gliomas arise from neuroepithelial tissue in the interstitium of the central nervous system. Tumors of neuroepithelial origin from glial or precursor cells include astrocytomas, glioblastoma multiforme, ependymoma, oligodendroglioma, astroblastoma, oligoastrocytoma, choroid plexus tumors, neuroblastomas, pineal tumors, and medulloblastomas (see Table 58.2).[145] The latest WHO histological classification combines phenotypic and genotypic categories by integrating the histopathological name followed by genetic features (e.g., glioblastoma, *IDH*-wildtype). Glioma histology ranges from benign and surgically curable pilocytic astrocytoma tumors (circumscribed gliomas, grade I) to highly aggressive diffusely infiltrating gliomas (glioblastomas, grade IV). Gliomas are separated into circumscribed gliomas (pilocytic astrocytomas, pleomorphic xanthoastrocytomas; WHO grade I) and diffusely infiltrating gliomas (astrocytic or oligodendroglial; WHO grades II–IV) based on growth patterns and IDH (isocitrate dehydrogenase) status. Diffuse gliomas range from low-grade astrocytomas (WHO grade II) to glioblastomas (WHO grade IV). Gliomas account for ~75 of malignant brain tumors with ~1/2 of these being glioblastomas.[5]

Glioblastoma multiforme (astrocytoma grades III and IV) accounts for the majority of malignant tumors in older age groups. The incidence of other gliomas decreases with age. Endothelial proliferation and necrosis characterize the histology of glioblastomas, resulting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 58.7. Central nervous system (CNS) tumors of neuroepithelial origin based on the 2016 World Health Organization (WHO) CNS classification upgraded with 2021 WHO changes. This 5th edition of WHO CNS tumor classifications introduces major changes based on histology, immunohistochemistry, and some novel molecular diagnostic technologies (e.g., DNA methylome profiling). The three tumors with a superscripted "a" are provisional classifications requiring more evidence to be accepted as distinct disease entities. (Adapted from Louis et al.).[143]

Gliomas, glioneuronal tumors, and neuronal tumors
Adult-type diffuse gliomas
Astrocytoma, IDH-mutant
Glioblastoma, IDH-wildtype
Oligodendroglioma, IDH-mutant, and 1p/19q-codeleted
Pediatric-type diffuse low-grade gliomas
Diffuse astrocytoma, *MYB*- or *MYBL1*-altered
Angiocentric glioma
Polymorphous low-grade neuroepithelial tumor of the young
Diffuse low-grade glioma, MAPK pathway-altered
Pediatric-type diffuse high-grade gliomas
Diffuse midline glioma, H3 K27-altered
Diffuse pediatric-type high-grade glioma, H3-wildtype and IDH-wildtype
Diffuse hemispheric glioma, H3 G34-mutant
Infant-type hemispheric glioma
Circumscribed astrocytic gliomas
Pilocytic astrocytoma
High-grade astrocytoma with piloid features
Pleomorphic xanthoastrocytoma
Subependymal giant cell astrocytoma
Chordoid glioma
Astroblastoma, *MN1*-altered
Glioneuronal and neuronal tumors
Ganglioglioma
Desmoplastic infantile ganglioglioma / desmoplastic infantile astrocytoma
Dysembryoplastic neuroepithelial tumor
Diffuse glioneuronal tumor with oligodendroglioma-like features and nuclear clusters[a]
Papillary glioneuronal tumor
Rosette-forming glioneuronal tumor
Myxoid glioneuronal tumor
Diffuse leptomeningeal glioneuronal tumor
Gangliocytoma
Multinodular and vacuolating neuronal tumor
Dysplastic cerebellar gangliocytoma (Lhermitte-Duclos disease)
Central neurocytoma
Extraventricular neurocytoma
Cerebellar liponeurocytoma

[a] Provisional classification.

in grade IV classification. Glioblastomas typically infiltrate more than one lobe with both multifocal (multiple areas with a clear path of spread from one lesion to another, up to ~30%) and multicentric (multiple lesions with no clear path of spread, ~5%) lesions.[146]

HOST SUSCEPTIBILITY

Family history of brain cancer is not an important factor in the vast majority of brain tumors.[147] The incidence of glioma in patients with first-degree relatives is only slightly elevated, with glioma being sporadic as most gliomas occur in families without a known predisposing hereditary disease.[148] A Swedish population-based study of all astrocytomas occurring from 1985–1993, demonstrated an ~3-fold increased incidence in patients with first-degree relatives with astrocytomas, primarily in the younger cohort.[149] A Swedish population-based study using segregation analysis of 807 first-, second-, and third-degree relatives of glioma patients estimated familial gliomas occur in ~5% of glioma cases, with 1% possibly having an autosomal dominant inheritance.[150] Mendelian disorders include neurofibromatosis, Li–Fraumeni syndrome, and tuberous sclerosis.

Genome-wide association studies identify seven common heritable risk alleles associated with increased glioma risks. Four of these variant genes (*EGFR*, *TERT*, *RTEL1*, *TP53*) contribute to the development of all glioma grades and histological types, including oligodendroglial tumors, whereas other variant genes (*CCDC26*, *CDKN2B*, *PHLDB1*) affect specific grades, histology, and molecular subtypes.[151] Table 58.8 displays the seven common heritable gene variants associated with increased glioma risks.

CLINICAL FEATURES

The median interval between radiation exposure and diagnosis ranged from 9–18 years for gliomas in children

Gene	Gene Function	Chromosome Location	Associated Glioma Subtype
CCDC26	Modulated cell differentiation/death	8q24.21	Oligodendromas, astrocytomas IDH-mutant
CDKN2B	Encodes cyclin-dependent kinase inhibitor	9q21.3	Astrocytomas WHO II-IV
EGFR	Produces transmembrane receptor	7p11.2	All
PHLDB1	Produces protein	11q23.3	IDH-mutant gliomas
RTEL1	Maintains stability/length telomeres	20q13.33	All
TERT	Maintains telomere ends	5p15.33	All
TP53	Encodes tumor suppressor protein	17p13.1	All

Abbreviations: CCDC26 = coiled-coil domain containing 26; *CDKN2B* = cyclin-dependent kinase inhibitor 2B; *EGFR* = epidermal growth factor receptor; IDH = isocitrate dehydrogenase; *PHLDB1* = Pleckstrin Homology Like Domain Family B Member 1; *RTEL1* = regulator of telomere elongation helicase; *TERT* = telomerase reverse transcriptase; *TP53* = tumor protein p53.

irradiated with relatively high ionizing radiation during radiotherapy.[12] The clinical course depends on tumor location and the extent of infiltration into brain tissue along with the amount of edema and tissue destruction. Seizures are a common feature of glioblastomas as a presenting symptom and during the disease course. Headaches occur in <1/3 of glioblastoma patients, typically occurring at night or early in the morning as a dull pain.[152] Increased intracranial pressure may cause nonspecific symptoms (e.g., nausea, vomiting, fatigue, dizziness, cognitive impairment). Painful nerve root compression and myelitis may result from leptomeningeal dissemination.[141] Most (i.e., 75–90%) recurrences of glioblastomas occur within 2–4 cm of the original border.[153] These tumors rarely metastasize, with the most common sites being the lung, pleura, lymph nodes, liver, and bone.

For prognostic purposes, gliomas frequently are divided into the following three categories based on median survival rates: 1) low-grade astrocytoma (5–8 years), 2) anaplastic astrocytoma (1.5–2.5 years), and 3) glioblastoma multiforme (1 year).[154,155] Survival depends on the histological type and grade ranging from 90%, 10-year survival for pilocytic astrocytomas to <5%, 5-year survival rate for glioblastomas; the latter tumor has one of the worst survival rates of all human cancers (i.e., 37% 1-year survival).[59] In a systematic review of 162 glioblastoma cases published from 1950–2014, the 10-year survival rate was 0.71% with a median age at diagnosis of 31.1 ± 11.1 years.[156] Several genetic and epigenetic markers affect survival, most commonly isocitrate dehydrogenase 1/2, 1p19q codeletion, *O*-6-methylguanine-DNA methyltransferase (*MGMT*) methylation, and glioma-CpG island methylator (G-CIMP) phenotype.[27] Substantial differences in glioblastoma patient survival and incidence exist between sexes. The survival is shorter and the incidence higher (male/female ≅ 1.6) in men than women. These differences occur across all age groups suggesting sex hormones alone are not entirely responsible for the difference. Glioblastoma transcriptome and outcome data suggest that these differences result at least in part from differences in tumor signaling pathway abnormalities (cell cycle in men vs. integrin signaling in women).[157]

PITUITARY TUMORS

Pituitary tumors account for ~15% of adult CNS tumors, with an estimated 11,000 new tumors annually (i.e., ~3.8/100,000); overall, pituitary tumors are more common in women than men.[5] Nonfunctioning pituitary adenomas account for 14–54% of pituitary adenomas, with a prevalence of 7–41/100,000 population.[158] The standardized annual incidence rate ranges from 0.6–2.3/100,000, with peak occurrence in the fourth to eighth decade. Many of these tumors are incidental with no obvious clinical impact. Pituitary incidentalomas represent mostly nonfunctioning pituitary adenomas discovered incidentally during radiological imaging or autopsy; the prevalence of these tumors ranges from 9–21% of nonfunctioning pituitary adenomas.[158] The relatively higher incidence of pituitary adenomas in autopsy series than in cancer registries suggests these tumors may be under-reported in the clinical literature.[159]

CARCINOGENESIS

The anterior pituitary gland is the master endocrine gland that regulates multiple target glands by synthesizing and secreting multiple hormones into the blood, including prolactin, adrenocorticotropic (ACTH), growth (GH), thyroid-stimulating (TSH), follicle-stimulating (FSH), and luteinizing hormones. Pituitary tumors are monoclonal, mostly benign adenomas that arise from differentiated hormone-expressing cells and display features of premature proliferative arrest.[160] These tumors are often non-secreting benign neoplasms (nonfunctioning pituitary adenomas, NFPAs). However, adenomas may secrete one or more hormones (ACTH, GH, TSH, glycoprotein gonadotroph subunits) producing symptoms specific to the combination of one to three hypersecreted hormones.

Early events involve chromosome instability, multiple molecular alterations, epigenetic changes (p16 promoter methylation), and aneuploidy.[161] Gene mutations in sporadic pituitary tumors are not well defined. *PTTG* (pituitary tumor-transforming gene) overexpression occurs in a variety of tumors, including breast, colon, esophagus, ovary, prostate, and thyroid, as well as the central nervous system. *PTTG* gene inhibits sister chromatid separation as well as expression and secretion of angiogenic and metastatic factors, resulting in cell proliferation, chromosomal destabilization, and cell transformation.[162] Oncogene activation, tumor suppressor gene silencing, and epigenetic changes (hypermethylation-mediated DNA promoter silencing, miRNA-induced histone modification) produce a variety of changes in gene expression including: 1) alteration of cell-cycle gene expression (e.g., cyclin-dependent kinases, CDKs; retinoblastoma-associated protein, RB); 2) activation of specific pituitary oncoproteins; 3) loss of pituitary suppressor factors including CDK inhibitors *INK4a/ARG* (p15, p16, p18) and CIP/KIP inhibitors (p21, p27, p57); and 4) defective signaling transduction pathways (e.g., *GNAS* gene encoding G protein α subunit).[163,164] The rare mutations in cyclins and cyclin-dependent kinase inhibitors in human pituitary tumors suggest compromise of the cell-cycle regulatory protein expression and stability occurs upstream in signaling pathways.

Gene expression differs dramatically between pituitary adenomas and carcinomas. In a study of gene expression in an ACTH pituitary carcinoma metastatic to the liver and four pituitary adenomas using Affymetrix GeneChip HGU-133A-oligonucleotide arrays, the adenomas overexpressed 2,057 genes and underexpressed 2,241 genes compared with the carcinoma.[165] Common cancer-associated oncogene (*TP53*, *RB1*) and tumor suppressor (RAS-family) mutations are unusual during the unique indolent growth of pituitary adenomas. Mutations of the *HRAS* genes are reported rarely in invasive prolactinomas, whereas distant metastatic pituitary carcinomas typically overexpress p53 protein compared with adenomas.[166,167] Table 58.9 displays some of the genetic alterations present in pituitary tumors along with their function, type of action, and common tumor type. The most important oncogene in sporadic pituitary tumors is the GNAS (GNAS complex locus) gene mutation that normally encodes a stimulatory guanine-binding protein subunit (G protein$_{\alpha}$). The mutation dysregulates hypothalamic GH-releasing hormone in 40% of somatotrophinomas. Mechanisms associated with cessation of cell proliferation include G1 cell-cycle arrest with DNA damage and p53-induction of CDK inhibitor p21 that stops RB phosphorylation. Premature growth arrest (cell senescence) occurs in the early development of malignant tumors or slowly proliferating benign neoplasms but not in malignant or late-stage benign tumors.[168]

EXPOSURE

Few data are available linking environmental exposures with human pituitary adenomas. AIP (aryl hydrocarbon receptor-interacting protein) is a molecular chaperone to the dioxin receptor with multiple functions, including modulation of the transcriptional activity of the aryl hydrocarbon receptor that mediates the toxicological properties of dioxin. An ecological Italian study examined the incidence of pituitary tumors in the Seveso population exposed to 2,3,7,8-tetrachlorodibenzo-*para*-dioxin following an industrial accident in 1976.[169] The area was subdivided based on soil dioxin concentrations into the following three contamination zones: high (median = 447 ppt, $n = 804$ subjects, $n = 1$ prolactinoma), intermediate (median = 94 ppt, $n = 5{,}941$ subjects, $n = 2$ nonfunctioning pituitary tumors), and low (median = 48 ppt, $n = 38{,}624$ subjects, $n = 3$ prolactinomas and 2 nonfunctioning pituitary adenomas). The surrounding noncontaminated area contained the referents ($n = 232{,}745$ subjects, $n = 42$ pituitary adenomas). Based on the hospital discharge registration system of the Lombardy region and using the noncontaminated area for referents, the rate ratio for the high contamination area was 6.2 (95% CI: 0.9–45.5, $P_{\text{difference}} = 0.07$) and 1.9 (95% CI: 0.5–7.7, $P_{\text{difference}} = 0.39$) for the intermediate contamination area. None of these rate ratios were statistically significant, including the low contamination

TABLE 58.9. Some of the complex genetic alterations occurring in pituitary adenomas. Transcriptional regulators (e.g., *HMGA2* gene, *PLADL1* expression of zinc finger protein) and miRNAs are also involved in pituitary adenoma proliferation; however, their roles are currently not well defined. (Adapted from Melmed).[160]

Gene	Function	Mode of Action	Tumor Type
GNAS	Oncogene	Activating, imprinting	Nonfamilial, syndromic, or sporadic
CREB	Transcription factor	Constitutive phosphorylation	Sporadic
AIP	Tumor suppressor	Inactivating	Familial, syndromic
MEN1	Tumor suppressor	Inactivating	Familial, syndromic
PRKAR1A	Tumor suppressor	Inactivating	Familial, syndromic
H-RAS	Oncogene	Activating	Invasive or malignant
CCNB2	Cyclin	Induced by HMGA	Sporadic
CCND1	Oncogene	Overexpression	Sporadic
CDKNIB	CDK inhibitor	Inactivating	Sporadic, syndromic
HMGA2	Oncogene	Overexpression	Sporadic
FGFR4	Oncogene	Alternative transcription	Sporadic
PTTG	Securin	Overexpression	Sporadic
RB	Tumor suppressor	Epigenetic silencing	Sporadic
CDKN2A	Cyclin-dependent kinase inhibitor	Epigenetic silencing	Sporadic
BRG1	Tumor suppressor	Glucocorticoid receptor function	Sporadic
GADD45G	Proliferation inhibitor	Epigenetic silencing	Sporadic
MEG3	Proliferation inhibitor	Epigenetic silencing	Sporadic

area (RR = 0.7; 95% CI: 0.3–1.8, $P_{\text{difference}} = 0.48$). The wide confidence limits for the more contaminated areas suggest imprecise risk estimates.

HISTOLOGY

Pituitary adenomas are heterogeneous tumors with a single tumor often containing multiple hyperplastic areas and numerous monoclonal tumors with different growth patterns, pathological features, and apoptotic rates. The most common pituitary adenomas are prolactinomas (~50%), followed by nonfunctioning pituitary adenomas (~30%), somatotrophinomas (~15–20%), corticotroph adenomas (~5–10%), and thyrotroph adenomas (<1%).[159,170] Metastatic tumors from other primary tumor sites account for ~1% of pituitary tumors. Pituitary carcinomas represent <0.2% of pituitary tumors. Typically, these tumors secrete ≥1 hormone, mostly ACTH and prolactin. Distant metastatic sites (e.g., brain, spinal cord, bones, lymph nodes, liver, lungs, ovary, heart) define these malignant pituitary tumors rather than immunohistological stains or specific genetic markers.

The 2017 WHO classification of pituitary tumors categorizes pituitary histological variants by hormone content, specific histological and immunohistochemical features (e.g., pituitary transcription factor 1, PIT-1), and proliferation potential (e.g., mitotic count, Ki67 index).[171] Table 58.10 displays the classification of pituitary adenomas, the most common pituitary tumor. Other much less common pituitary tumors include pituitary carcinomas, pituitary blastomas, and posterior pituitary tumors (pituicytoma, granular cell tumor of neurohypophysis, spindle cell oncocytoma, and sellar ependymoma).

Nonfunctioning pituitary adenomas represent a heterogenous group of pituitary tumors characterized by an absence of endocrine features associated with hypersecretion of adenohypophyseal hormones. About one-third of pituitary neuroendocrine tumors are nonfunctioning depending on the type of study (clinical registry vs. autopsy series).[172] These silent tumors typically present as macroadenomas invading the cavernous sinus or less often as incidentalomas. The histopathological types of nonfunctioning and functioning pituitary adenomas are similar based on the expression of adenohypophyseal hormones (e.g., gonadotroph, corticotroph) and pituitary-specific transcription factors (e.g., PIT-1, T-PIT).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 58.10. 2017 World Health Organization (WHO) pathological classification of pituitary adenomas. These adenomas are also separated by transcription and other cofactors (e.g., PIT-1). The null cell adenoma is negative for pituitary transcription factors and hormones. Plurihormonal adenomas (formerly known as silent subtype III adenoma) contain various combinations of the three hormones and are PIT-1-positive. (Adapted from Mete and Lopes).[171]

Adenoma Type	Morphological Variant	Pituitary Hormones
Somatotroph	Densely granulated	Growth hormone, α-subunit
	Sparsely granulated	Growth hormone
	Mammosomatotroph	Growth hormone/prolactin ± α-subunit[a]
	Mixed somatotroph-lactotroph	Growth hormone/prolactin ± α-subunit[a]
Lactotroph	Densely granulated	Prolactin
	Sparsely granulated	Prolactin
	Acidophil stem cell	Growth hormone/prolactin
Thyrotroph		β-thyroid-stimulating hormone, α-subunit
Corticotroph	Densely granulated	Adrenocorticotropic hormone
	Sparsely granulated	Adrenocorticotropic hormone
	Crooke's cell	Adrenocorticotropic hormone
Gonadotroph		β-follicle-stimulating hormone, α-subunit,[a] β-luteinizing hormone, α-subunit[a]
Null cell		None
Plurihormonal		β-thyroid-stimulating hormone ± α-subunit,[a] growth hormone/prolactin ± α-subunit[a]

[a] The mammosomatotroph adenoma has the two hormones in the same cell, whereas the mixed somatotroph-lactotroph adenoma has this combination in different cells. Gonadotroph adenomas contain various combinations of their two hormones. The plurihormonal adenoma contains various combinations of the three hormones.

HOST SUSCEPTIBILITY

Although most pituitary tumors are sporadic, ~5% belong to 1 of the 4 most common familial tumor syndromes, including multiple endocrine neoplasia type 1 (MEN1), MEN1-like multiple endocrine neoplasia type 4 (MEN4), Carney complex syndrome (CNC), and familial isolated pituitary adenoma (PIPA).[173] MEN1 causes selective development of neuroendocrine tumors in the anterior pituitary (prolactinomas, GH/ACTH-secreting adenomas), pancreatic, and parathyroid glands. Angiofibromas, collagenomas, and lipomas are also common in this syndrome. The *MEN1* gene produces the transcriptional regulatory protein menin involved with transcription of endocrine gene promoters. About 2.7% of pituitary adenomas are autosomal dominant MEN type 1.[174] MEN4 is a rare syndrome involving acromegaly and Cushing disease as part of a multiple endocrine neoplasia type 4 syndrome unrelated to the *MEN1* gene. The primary gene mutation occurs in the *CDKN1B* (cyclin-dependent kinase inhibitor 1B) gene that encodes $p27^{kip1}$. Carney complex syndrome (CNC) results from mutation of the tumor suppressor *PRKAR1A* (protein kinase cAMP-dependent type I regulatory subunit α) gene. This syndrome is associated with myxomas, testicular, adrenal, and/or pituitary hyperplasia or adenomas. About 70% of CNC cases are familial with the syndrome occurring in all racial groups and demonstrating a slight female predominance.[175] FIPA is associated with several pituitary types including acromegaly/gigantism. The tumors in family members can be the same (homogeneous) or different (heterogeneous). Mutations of the *AIP* (aryl hydrocarbon receptor-interacting protein) gene occur commonly in somatotrophinomas and prolactinomas associated with this syndrome, particularly in young men diagnosed with acromegaly and gigantism.[176] The genes associated with the familial tumor syndromes are not usually mutated in sporadic pituitary tumors. In a prospective cohort study of 443 patients with *sporadic* pituitary adenomas of all histotypes, 16 of these patients (3.6%) had AIP mutations.[177] For 148 patients with acromegaly, 6 (4.1%) had the AIP mutation compared with 5 (4.5%) of 132 prolactinoma patients and 3 (6.8%) of 44 corticotropic adenoma patients. None of the thyrotropic adenoma patients and only 1 (0.9%) of the 113 patients with nonfunctioning pituitary adenomas had the AIP mutation.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. CLINICAL FEATURES

Most of these tumors are benign and often asymptomatic, with many pituitary tumors diagnosed incidentally (e.g., pituitary incidentalomas). The overall incidence of adult pituitary tumors increases with age peaking in the seventh decade, whereas pituitary tumors occur rarely in childhood or adolescence (i.e., 1–10% of brain tumors).[178] Incidence also varies with histological type. Prolactinomas most frequently develop during the second to fourth decades, while nonfunctioning pituitary adenomas are the most common pituitary tumor after 40 years of age.[179] The clinical features of hormone-secreting tumors reflect mass effects and the monoclonal cell of origin. Prolactinomas secrete prolactin, resulting in galactorrhea and hypogonadism, whereas GH-secreting somatotrophinomas cause acromegaly and gigantism, TSH-secreting thyrotroph tumors produce hyperthyroidism, and ACTH-secreting tumors cause Cushing disease. Symptoms associated with pituitary adenomas range widely from asymptomatic to manifestations of pituitary hormone hypersecretion or hypothalamic/pituitary dysfunction and/or local space-occupying effect (e.g., cranial nerve, visual field impairment). Headaches are common and present in up to 75% of patients with pituitary tumors. The acute onset of severe headache may occur with sudden vascular-induced expansion of tumor volume (apoplexy).[180] Visual field defects typically involve bitemporal hemianopia; however, the defects vary widely from asymmetric unilateral to whole central hemifield visual loss. Expansion of the tumor into the cavernous sinus produces highly variable clinical ocular abnormalities depending on the compromised nerve (e.g., ophthalmoplegia from pressure on the abducens or oculomotor nerves). Invasion of the dura and adjacent brain may produce temporal lobe epilepsy. Hypopituitarism often develops slowly with subtle signs of visual impairment. Pituitary microadenomas are typically <1 cm inside small intrasellar lesions, whereas macroadenomas are ≥1 cm localized within an enlarged sella turcica. Macroadenomas represent ~40% of pituitary tumors. Complications from these tumors result from pressure on the optic chiasm/pituitary stalk and local invasion of the suprasellar area, sphenoid sinus, and/or cavernous sinus. Very large macroadenomas may obstruct the foramen of Monro, resulting in hydrocephalus and intracranial hypertension.

Morbidity and mortality depend primarily on location, function, and progression. Mortality from pituitary adenomas can result from surgical complications, pituitary dysfunction, tumor recurrence, and tumor progression with local invasion. In a nationwide, population-based Swedish study of 2,795 patients with nonfunctioning pituitary adenomas followed for a mean of 7 years (range, 0–25 years), the SMR was significant for women (SMR = 1.29, 95% CI: 1.11–1.48, $n = 192$ deaths), but not for men (SMR = 1.00, 95% CI: 0.88–1.12, $n = 278$ deaths).[181] Some evidence suggested the diagnosis of a nonfunctioning pituitary adenoma at ≤40 years increased mortality (SMR = 2.68, 95% CI: 1.23–5.09, $n = 9$ deaths, $P_{\text{difference}} = 0.015$). A study using Swedish Cancer Registry data from the era before personalized chemotherapy (1958–1991) reported an elevated overall SMR of 2.0 (95% CI: 1.9–2.2) with a significantly higher SMR for women than men ($P_{\text{difference}} < 0.01$). However, the median survival was 25 years for women and 18 years for men. In a Danish study of 160 patients undergoing pituitary surgery for a nonfunctioning suprasellar pituitary adenoma, subsequent mortality was higher in women compared with the general population (SMR = 1.97, 95% CI: 1.20–3.21), but not in men (SMR = 0.83, 95% CI: 0.55–1.26).[182]

EYE

Ocular melanoma is a rare human malignancy accounting for <0.5% of human neoplasms.[183] After the skin, the eye is the most common location for primary melanomas. There are five types of primary ocular melanomas with the most common being uveal melanomas; choroid, ciliary body, iris, and conjunctival melanomas are much less common. The overall mean US age-adjusted annual incidence of uveal melanoma is ~5.1 cases/10^6,[184] whereas the standardized European incidence rates for uveal melanoma demonstrate a north-to-south decreasing incidence rate with a range of 1.3–8.6 cases/10^6.[185] Of all extracutaneous melanoma sites, ocular melanomas have the highest incidence and best survival rates with no recent statistically significant change in European incidence rates.[186] The epidemiological pattern of cutaneous and ocular melanomas differs. Conjunctival melanoma is almost exclusively a Caucasian disease. The incidence is increasing similar to cutaneous melanoma, whereas intraocular and mucosal melanoma incidence rates remain relatively stable.[187,188] The reported incidence rates of uveal melanoma are much lower in Africa and Asia (0.2–0.3 cases/10^6).

CARCINOGENESIS

Table 58.11 displays the most frequently known genetic mutations in uveal melanoma and their chromosome

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 58.11. Commonly recognized gene mutations in uveal melanoma with the approximate percentage of mutations in evaluated tumors. (Adapted from Kaur et al.).[192]

Gene	Chromosome	Uveal Melanoma (%)
HDM2 (MDM2)	12q15	97
GNAQ/GNA11	9p21	83
CCND1	11q13	65
NBS1	8q21	50
BRAF	3p21	48
BAP1	7q34	44
MYC	8q24	43

Abbreviations: BAP1 = BRCA1-associated protein 1. BAP1 protein is a deubiquitinase that helps to regulate the function of many proteins involved in diverse cellular processes; *BRAF* = *BRAF* proto-oncogene, serine/threonine kinase. The BRAF protein is involved in the RAS/MAPK pathway that helps regulate cell proliferation, differentiation, migration, and apoptosis. *CCND1* = cyclin D1. The encoded protein functions as a regulatory subunit of CDK4 or CDK6 and helps to regulate cell-cycle G_1/S transition; *GNAQ*/*GNA11* = G protein subunit alpha q/G protein subunit alpha 11. These encode G proteins that trigger a complex network of transduction signaling pathways that influence many cell functions. *HDM2* (*MDM2*) = *MDM2* proto-oncogene. These genes encode a nuclear-localized E3 ubiquitin ligase that promotes tumor formation by degrading tumor suppressor proteins (e.g., p53). *NBS1* = Nijmegen breakage syndrome (*NBN*) gene. The encoded protein (nibrin) recognizes broken strands of DNA and helps coordinate double-strand DNA break repair (RAD50 double-strand break repair protein).

locations. Somatic oncogenic GNAQ (heterotrimeric G protein α-subunit q) and GNA11 (G protein subunit alpha 11) mutations are much more frequent in uveal melanomas than in other melanomas. These mutations affect multiple downstream signaling pathways, including MEK, PI3K/AKT, protein kinase C, and YAP. The presence of GNAQ and GNA11 gene mutations in 80% of uveal melanomas suggests these mutations, rather than mutations of *BAF*, *NRS*, or *KIT* genes, initiate malignant transformation and activate these oncogenic pathways.[186,189] Cell-cycle deregulation by CCND1 mutations helps overcome the G1/S checkpoint, resulting in cell proliferation and cytogenetic instability (e.g., 1p, 6q, and 8p losses; monosomy 3; 6p and 8q gains). The *KIT* gene encodes a receptor tyrosine kinase involved with cell growth and survival, whereas the *NRAS* gene is a member of the *RAS* family that encodes GTPases involved with cell growth. Although mutations of *BAF*, *NRAS*, and *KIT* genes are associated with highly activated mitogen-activated protein/extracellular signal-regulated kinase/(MEK/MAPK) and mitogen-activated protein kinase (PI3K/AKT) pathways in some uveal melanoma tumors, these oncogenes are much less common in uveal than cutaneous melanomas.[190,191]

Conjunctival melanomas share more common mutations with cutaneous than uveal melanomas, particularly the mitogen-activated protein kinase (MAPK) signaling transduction pathway; ~50% of primary conjunctival melanoma tumors contain mutations of the *BRAF V600E* gene.[193] The *BRAF* gene encodes a protein that transmits chemical signals from the cytoplasm to the nucleus as part of the RAS/MAPK pathway. In contrast to uveal melanomas, fewer mutations of the *KIT* and *NRAS* genes occur in conjunctival melanoma mutations than uveal melanoma mutations. The role of oncogenic transformation of *NRS* and *KIT* genes in conjunctival melanomas remains unclear. Sporadic mutations of the tumor suppressor *RB1* (RB transcriptional corepressor 1) gene cause most retinoblastomas in children; however, germline mutations account for ~1/3 of these tumors. The *RB1* gene encodes the RB protein that prevents replication of damaged DNA by deacetylating chromatin and stopping the progression from G1 to the S phase. This protein inhibits transcription factors of the E2F family preventing entry of the cell into the S phase.[192]

EXPOSURE

Risk factors for ocular melanoma include light eye color, fair skin, propensity to sunburn, ocular or oculodermal melanocytosis, and atypical nevi (choroid, cutaneous skin, iris). In contrast to cutaneous melanoma risk factors (e.g., excessive sunlight exposure, hair/eye color, abundance of atypical skin nevi), intraocular melanomas have few strong environmental or occupational risk factors.[194] Most ocular cancers are uveal melanomas that preferentially affect the choroid of fair-skinned, light-eyed Europeans and their descendants. A systematic review of four meta-analyses suggests several *potential* risk factors for ocular melanoma (welding, occupational cooking, fair skin, light eye color, common

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cutaneous nevi count, sunburn propensity, iris nevi, cutaneous freckles) with odds ratios varying in order from atypical cutaneous neve (OR = 2.82, 95% CI: 1.10–7.26) to cutaneous freckles (OR = 1.27, 95% CI: 1.09–1.49).[195] All the studies were case-control designs of moderate quality, limited adjustment for potential cofounders, and wide confidence limits (e.g., atypical nevi). Factors without statistically significant positive associations with ocular melanomas include hair color, outdoor leisure activity, birth latitude, and occupational sunlight exposure. In a meta-analysis of 10 observational studies (1,732 cases) using random effects models, the uveal melanoma risk for blue-/gray-eyed cases was statistically different than brown-eyed cases (summary OR = 1.75, 95% CI: 1.31–2.34, $P_{\text{heterogeneity}} = 0.006$) with significant heterogeneity. For propensity to sunburn using a fixed model and an assessment of multiple previous sun exposures or general tanning ability, the summary uveal melanoma risk was 1.64 (95% CI: 1.29–2.09, $n = 1{,}021$ cases, $P_{\text{heterogeneity}} = 0.53$) compared with good tanning ability. The summary OR for uveal melanoma in fair-skinned cases was 1.80 (95% CI: 1.31–2.47, $n = 586$ cases, $P_{\text{heterogeneity}} = 0.50$) compared with dark-skinned cases, whereas the summary odds ratio was not statistically significant for the comparison of blond-/red-haired and dark-haired cases (OR = 1.02, 95% CI: 0.82–1.26, $n = 1{,}012$, $P_{\text{heterogeneity}} = 0.11$).

Atypical Nevi

The association between atypical (dysplastic) nevi and uveal melanoma is inconsistent. In a case-control study of patients with dysplastic nevi and volunteer controls, the relative risk for uveal melanoma was 4.36 (95% CI: 1.84–10.36). The wide confidence limit suggests imprecise RR estimates.[196] In a case-control study of 211 unselected ocular melanoma patients attending a UK oncology clinic and 416 hospital controls, the relative risk for ocular melanoma increased with the number of atypical nevi and common nevi; however, the two groups were not comparable.[197] Nine percent of cases and 1% of controls had the Atypical Mole Syndrome (AMS) phenotype, whereas six cases had concurrent primary cutaneous melanoma. A cross-sectional study of 65 consecutive patients diagnosed with posterior uveal melanoma and 218 consecutive controls referred for general retinal evaluation reported no association between posterior uveal melanoma and the presence of iris (4 cases, 6.2%; 9 controls, 4.1%; $P_{\text{difference}} = 0.955$) or choroidal (12 cases/18.5%; 38 controls, 17.4%; $P_{\text{difference}} = 0.815$) nevi.[198]

Choroidal nevi are the most common intraocular lesions; ~5% of the US Caucasian population has these nevi compared with 0.6% in blacks.[199] The annual malignant transformation rate for choroidal nevi is age-related, ranging from ~1/270,000 in 15–19-year-old adolescents to ~1/3,700 in 80–84-year-olds. Factors associated with increased transformation to melanoma include a thickness of >2 mm, symptoms, subretinal fluid, orange pigment, margin near disc, lack of halo, and ultrasonographic hollowness.[200] In a retrospective and comparative case series of 1,611 patients referred to an ocular oncology center with iris nevi, Kaplan–Meier estimates calculated the cumulative transformation to melanoma at <1% in 1 year, 3% in 5 years, 4% in 10 years, 8% in 15 years, and 11% in 20 years.[201]

UV Light

The evidence associating UV radiation with the development of intraocular melanoma is equivocal, without a strong correlation between high-UV occupational radiation exposure and intraocular melanomas. Little solar UVA and UVB radiation reach the pigmented layer of the uveal tract, including the ciliary body and choroidal melanocytes.[202] Dosimetry studies indicate <1–2% of UVB (280–315 nm) radiation at the exterior of the eye reaches the posterior portions of the eye.[203] Some case-control studies with retrospective analysis of UV exposure suggest the relative risk of ocular melanoma increases by ~1.5–3 with high sun exposure[204] or light complexion (blue, gray, hazel, or green eyes, red or blonde hair);[205,206,207] however, other studies report the absence of a significant relationship between chronic UV exposure and intraocular melanoma.[208,209] A meta-analysis of 10 case-control and 2 cohort studies reported inconsistent findings on the effect of ultraviolet light on uveal melanoma risks.[210] Comparing the highest and lowest scores for occupational sunlight exposure and fixed-effects models, the summary odds ratio for chronic ultraviolet exposure and uveal melanoma risk was nonsignificant (OR = 1.37, 95% CI: 0.96–1.96, $n = 4$ studies/572 cases) with substantial heterogeneity ($P_{\text{heterogeneity}} = 0.56$). A German case-control study compared 459 incident uveal melanoma cases and 3 control groups (827 population controls, 180 ophthalmologist controls, and 187 sibling controls).[211] The odds ratio for uveal melanoma in cases with >15 years of total lifetime occupational sun exposure was significant in ophthalmologist controls (OR = 2.8, 95% CI: 1.1–7.0), but not in population (OR = 1.1, 95% CI: 0.8–1.7) or sibling (OR = 1.6, 95% CI: 0.7–3.7) controls. The wide confidence limits suggest imprecise estimates.

An analysis of UV exposure based on the job-exposure matrix demonstrated a significantly increased ocular melanoma risk in occupational groups exposed to artificial ultraviolet radiation but not in outdoor occupational groups exposed to sunlight. Based on geographical tumor mapping of 92 ocular melanomas, there was no significant correlation between tumor location in the choroid and the estimated UV radiation dose. Although choroidal melanomas are common ocular melanomas, significant doses of UVC (100–280 nm) and UVB radiation do not reach the choroid.[212] The cornea and lens filter UVA (315–400 nm) radiation.

Occupation

Using population controls, the relative risk of developing uveal melanoma after occupational exposure to sunlight was not statistically significant (RR = 1.24, 95% CI: 0.88–1.74). There was an excess risk of uveal melanoma in French welders but not in welders from eight other European countries. A French population-based case-control study of 50 incident cases of uveal melanoma diagnosed during 1995–1996 suggests an increased risk in male welders (odds ratio = 7.3, 95% CI: 2.6–20.1).[213] Although the study reported a dose-response relationship with job duration based on self-reported work history, the wide confidence limits indicate imprecise risk estimates. A European population-based, case-control study of uveal melanoma diagnosed during 1995–1997 did not detect an association between occupational sunlight exposure and the risk of uveal melanoma using a job-exposure matrix.[214] Using population controls and comparing ever with never occupationally exposed, occupational sunlight exposure was not associated with a statistically significant increased uveal melanoma risk (RR = 1.24, 95% CI = 0.88–1.74). A meta-analysis of 5 case-control studies involving 1,199 uveal melanoma cases and 6,927 controls suggests an increased uveal melanoma risk in occupational cooks (OR = 1.81, 95% CI: 1.33–2.46, $P_{\text{difference}} < 0.001$, $I^2 = 27.7\%$) with slight heterogeneity.[215]

HISTOLOGY

Melanomas arise from neural crest-derived dendritic melanocytes located in various anatomical locations, most commonly in skin, mucous membranes, or the eye. Conjunctival melanoma usually arises from primary acquired melanosis with atypia (~50–75%) and less frequently from conjunctival nevi (~5%) or sporadically (18–30%).[216] Analyses of the US National Cancer Database containing 84,836 melanoma cases diagnosed from 1985–1994 indicate cutaneous melanomas accounted for ~91% of the total compared with ~3–5% for the eye, ~2% for unknown primary melanomas, and ~1% for mucosal melanomas (nasal, oropharyngeal, pulmonary gastrointestinal, anorectal, vaginal, urinary tract).[217] The reported anatomical locations of ocular melanomas in this database primarily involve the uvea (~80–85%) and less commonly the conjunctiva (~1–5%) and other sites (~10%; eyelid, lacrimal gland, orbit, retina). Uveal melanomas are much more common in the posterior tract (choroid, ciliary body) than in the anterior tract (iris). A retrospective medical records review of 8,033 uveal melanoma cases indicates the vast majority of these tumors occurred in the choroid (90%), whereas the ciliary body accounted for 6% and the iris for 4%.

HOST SUSCEPTIBILITY

There is an absence of strong familial clustering in cases of uveal melanoma including choroidal melanomas. Mutations of the *BAP1* (BRCA1-associated protein 1) tumor suppressor gene are associated with increased uveal melanoma risks; the BAP1 hereditary cancer predisposition syndrome increases the risk of uveal melanoma as well as malignant mesothelioma, basal cell carcinoma, cutaneous melanomas, and renal cell carcinoma.[218] The BAP1 protein is a deubiquitinase that promotes the degradation of proteins tagged with ubiquitin; this protein is involved in numerous pathways ranging from DNA repair to cell differentiation. Mutations of the *BAP1* gene in uveal melanoma can be either germline (BAP1 hereditary cancer predisposition syndrome) or sporadic. In a retrospective cohort study of 507 patients at an academic ophthalmology referral center, analysis of blood samples indicated 5% (25 patients) had the BAP1 mutation with nine of the mutations being novel.[219]

Oculodermal melanocytosis is a congenital pigmentary abnormality involving slate-gray pigmentation at multiple sites in the head (sclera, uvea, periocular skin, orbit, palate, tympanic membrane, meninges), typically resulting in a unilateral reduction in pigmentation. In a retrospective chart review of 7,872 patients with uveal melanoma treated at a US eye institute, melanocytosis involved the sclera (92%), iris (17%), choroid (12%), eyelid (8%), and temporal fossa (1%) of the cases.[220] Approximately 1.4–3% of uveal melanoma cases have this pigmentation abnormality; the lifetime uveal melanoma risk in a Caucasian patient with ocular/oculodermal melanocytosis is 1/400.[221]

CLINICAL FEATURES

Analysis of the US Surveillance Epidemiology and End Results (SEER) database revealed 7,069 ocular melanoma cases from 1988–2010, representing ~3% of all melanomas with a median age of 63 years (IQR = 52–73 years, male/female ratio = 1.1).[222] The incidence of this disease is much higher in white than black races (15–50:1).[223] The clinical course of ocular melanoma is difficult to predict because of the early hematogenous spread of micrometastases and the occurrence of metastatic disease after a prolonged disease-free interval. Clinical features of ocular melanoma associated with a poor prognosis include advanced age and stage (large size, diffuse configuration, extraocular invasion).[224,225] Metastasis and prognosis correlate to aberrations in 1, 3, 6, and 8 chromosomes, particularly monosomy 3. Conjunctival and cutaneous melanomas spread locally to lymph nodes via lymphatics and by hematogenous spread, whereas uveal melanoma usually metastasizes to the liver via hematological spread.[226] In the US SEER registry, the 5-year survival rate for ocular melanoma was 78.4% (95% CI: 76.9–79.8%) compared with 89.0% (95% CI: 88.7–89.2%) for cutaneous melanoma.[222] Metastatic melanoma to the eye is rare, with the orbit and retina being the most frequent metastatic sites.

Conjunctival

Conjunctival melanomas are typically present as asymptomatic light to dark brown macules or elevated pigmented plaques/tumors in the bulbar conjunctiva near the limbus.[227] Systemic disease in patients with conjunctival melanoma usually involves the lungs, liver, brain, bones, and gastrointestinal tract. The 5-year metastasis rate is ~16% (74–86% survival rate) and ~26% after 10 years (41–78% survival rate).[187]

Uvea

The uvea consists of three layers beneath the sclera including: 1) the iris, 2) the ciliary body that secretes the vitreous, and 3) the choroid that contains the connective tissue and vessels between the sclera and retina. Most cases of uveal melanoma occur after 50 years of age; the peak age is ~70 years, with a plateau after 75 years of age; children seldom develop uveal melanoma (e.g., <15% below 11 years of age).[223] The age-adjusted uveal melanoma incidence is higher in men (5.8 cases/10^6) than women (4.4 cases/10^6), primarily as a result of the increased uveal melanoma incidence in men of ≥65 years of age.[184]

A retrospective case series of 500 uveal melanoma cases reported monosomy 3 in 25%, partial monosomy 3 in 27%, and disomy 3 in 48%; the cumulative 3-year metastatic rates were 24% in monosomy 3 compared with 3% for disomy 3 and 5% for partial monosomy 3.[228] Univariate Cox analysis of whole-genome single-nucleotide polymorphism arrays from 320 uveal melanomas associated poor prognosis with chromosome losses in 3, 1p, 6q, and 8p and gain of function in 8q; sex, tumor basal height/diameter, and ciliary body involvement also affect the prognosis.[229] Using multivariate analysis of the joint effects of six chromosomal regional aberrations, the hazard ratios ranged from 7.90–37.25. Size of the uveal melanoma correlates to metastatic liver risks with metastasis 5 years after diagnosis being uncommon (i.e., <5%) when the tumor thickness and diameter are <3 mm and <10 mm, respectively, at the time of discovery.[230] The average survival after discovery of metastatic uveal melanoma is <6 months.[231]

Iris

The incidence of melanoma is much lower in the iris than in the uvea; iris melanoma is usually diagnosed 10–20 years earlier than ciliary body or choroidal melanomas.[223] The classic presentation of diffuse iris melanoma includes ipsilateral glaucoma, unilateral cataract, prominent episcleral (sentinel) vessels, anterior chamber inflammation, and acquired hyperchromic heterochromia iridis.[232] The prognosis is much better (5–10 times lower mortality rates) for iris than choroidal or ciliary body melanomas consistent with earlier presentation and smaller tumor size. In a case series of 317 iris melanoma patients, metastasis occurred in 4% with 2% dying during a mean follow-up of 4.5 years.[233]

Choroid/Ciliary Body

Choroidal melanomas usually present as a dome-shaped mass, whereas ciliary body melanomas are often diagnosed late because the lesion remains asymptomatic behind the iris. The most common clinical features include blurred vision, photopsia, and less often floaters, visual field loss, pain, and metamorphopsia.[234] About 30% of choroidal and ciliary body (posterior uveal) melanomas present without ocular symptoms. Posterior uveal melanoma has a relatively high metastatic rate. A Finnish cohort of 289 choroidal and ciliary body

melanomas in the European Collaborative Ocular Melanoma Study was followed for a median of 28 years (50 survivors).[235] The Kaplan–Meier estimates of metastasis were 32% by 5 years, 50% by 15 years, 56% by 25 years, and 62% by 35 years. In the prospective, longitudinal follow-up study from the Collaborative Ocular Melanoma Study Group involving 739 choroidal melanoma cases with at least 1 metastatic site, the most common metastatic sites were liver (89%) followed by lung (29%), bone (17%), subcutaneous skin (12%), and lymph nodes (11%).[236] Ciliary body melanomas typically are more aggressive than choroid or iris melanomas, reflecting delayed detection, larger tumor size, and rich blood supply.[237]

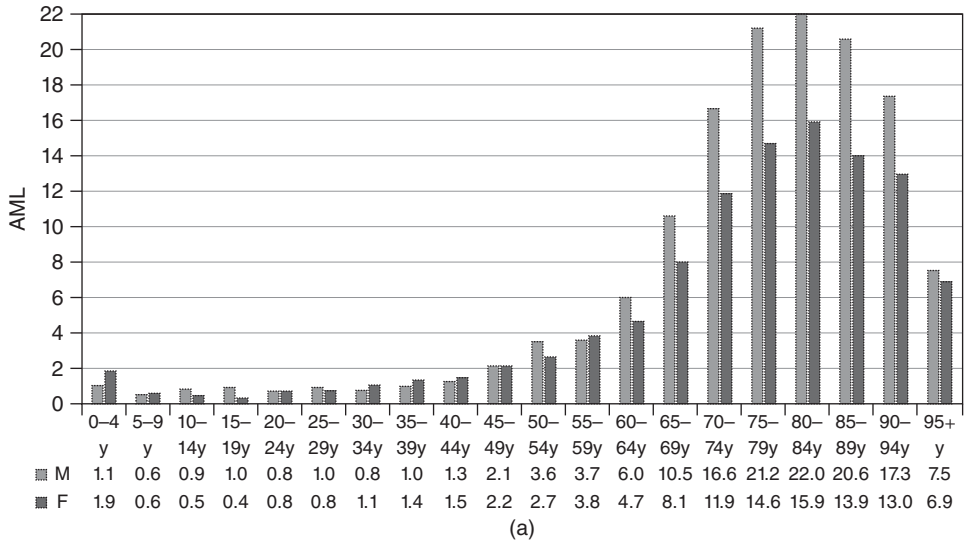
Chapter 59

LEUKEMIA

Leukemia is the common name for neoplasms presenting with increased abnormal or immature peripheral white blood cells derived from leukemogenic processes in the bone marrow; ultimately, this disease leads to bone marrow failure. Leukemias evolve from lymphoid and myeloid cells depending on the subtype, whereas lymphomas result from malignant transformation of B, T, or natural killer cells originating in the lymphoid stem cell lineage. The predominant leukemia cell typically consists of either mature cells (e.g., chronic lymphocytic leukemia, CLL), precursor cells of various lineages (e.g., acute myelocytic leukemia, AML; acute lymphoblastic leukemia, ALL), or both precursor and mature cells (e.g., chronic myelocytic leukemia, CML). Leukemias present at all ages, from newborns to the elderly; however, the distribution of major leukemia groups changes with age (e.g., ALL in children, CLL in the elderly), as displayed in Figure 59.1. Leukemia is the most common cancer in children, representing 20–30% of childhood cases.[1]

Overall, adult leukemia incidence declined after substantial increases during 1950–1985, with a slight male predominance, particularly in Caucasians.[3,4] Currently, ~62,000 new leukemia cases occur annually in the United States, with a male/female ratio of ~1.4/1.[5] Leukemias are the ninth most common cancer site accounting for ~4% of all cancers in men and the sixth most common cause of cancer-related deaths (~4% of all cancer deaths). In women, leukemias are the 10th most common cancer accounting for ~3% of new cancer cases and the 8th most common cause of cancer-related deaths (~3% of all cancer-related deaths). Worldwide, reported leukemia incidence rates trend lower in less socioeconomically developed countries than in more developed countries. Childhood leukemia increased by ~0.7% annually for the last several decades in higher socioeconomically developed countries, particularly for ALL (CD19/20+ B cell cALL) in 2–6-year-olds.[5,6] Similar peaks have not been reported in Africa and India, where overall incidence rates are lower. The incident rates also vary with race; higher childhood leukemia rates occur in Hispanics and whites with lower rates in blacks.[7,8]

CLASSIFICATION



Historically, presumed cell lineage and clinical criteria separated leukemias into four major groups, including acute myeloid leukemia (AML), chronic myeloid leukemia (CML), acute lymphoblastic leukemia (ALL), and chronic lymphocytic leukemia (CLL). In 2008, the third edition of the International Classification of Disease for Oncology implemented the World Health Organization's recommendations for the classification of hematopoietic malignancies based on cytogenetic, morphological, and molecular criteria. Published in 2016, the fourth edition revised the 2008 classification by incorporating new clinical morphological, immunophenotypic, prognostic, and genetic data rather than creating a new classification scheme as listed in Table 59.1.[9]

IMMUNITY

The basic organs of the immune system include: 1) bone marrow – repository of stem cells capable of forming all immune cells and blood types; 2) lymph system, including lymph nodes and spleen, that contains B and T cells, filter debris/antigens, and enhance contact between the immune system and foreign antigens; and 3) thymus gland – contains maturing T cells capable of remembering and recognizing host and foreign tissues.[10] The immune system responds to pathogenic foreign material by developing two types of responses (innate and adaptive immunity). Innate immunity is a rapid, nonspecific response without a prior memory of a similar exposure (e.g., macrophage engulfing a microbe); cells of innate immunity include neutrophils, eosinophils, basophils, natural killer cells, and mast cells. Adaptive immunity is a slower, more specific immune

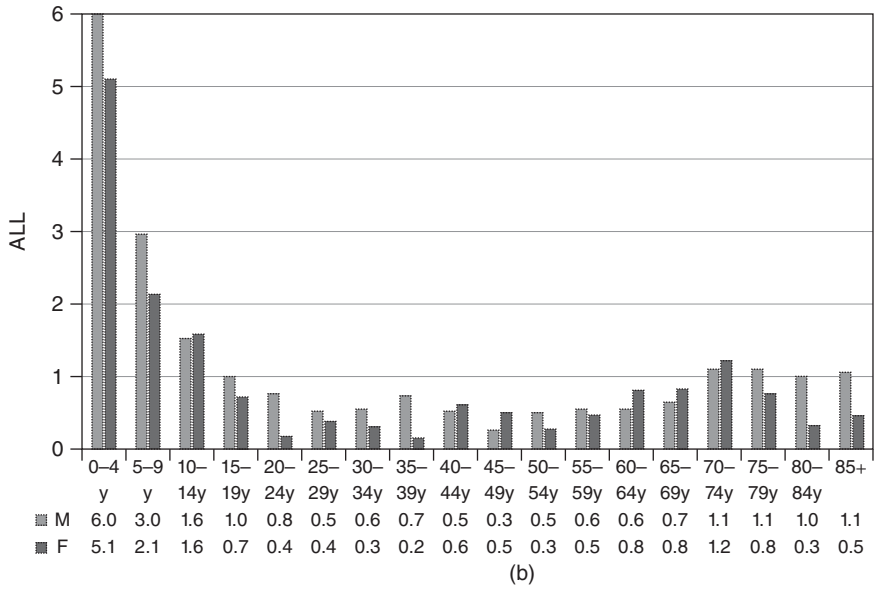

FIGURE 59.1. Age distribution of acute myelocytic leukemia (AML, a), acute lymphoblastic leukemia (ALL, b), and chronic myelocytic leukemia (CML, c) diagnosed in Sweden during 1997–2013 (AML), 2005–2014 (ALL), and 2005–2014 (CML) by 5-year increments (Adapted from Juliusson and Hough).[2] *Abbreviations:* F = annual incidence of leukemia type in females/100,000 Swedish inhabitants; M = annual incidence of leukemia type in males/100,000 Swedish inhabitants.

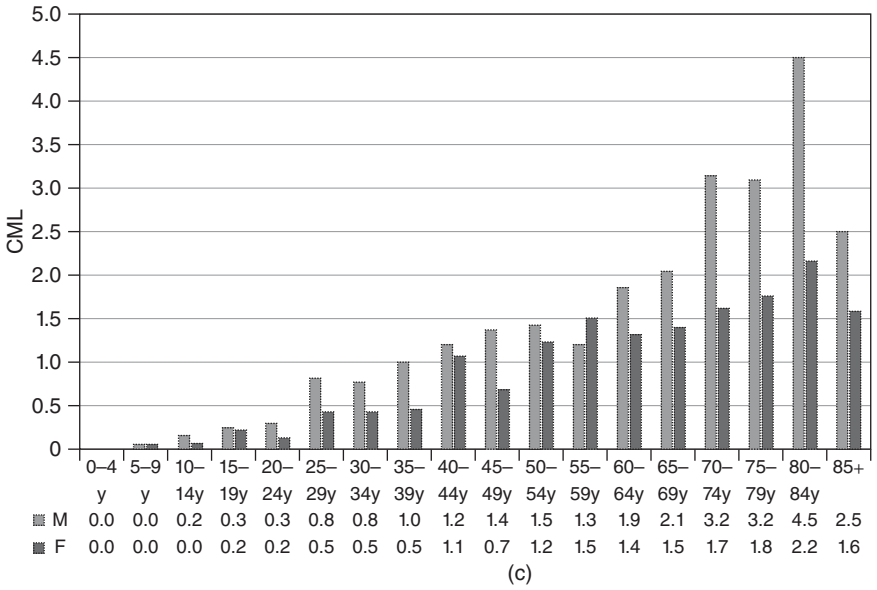

FIGURE 59.1. (*Continued*)

response with a past memory capable of distinguishing self from foreign antigens (e.g., response to measles virus in a vaccinated person); cells in the adaptive immune system include natural killer T cells, other T cells, and antibody-producing B cells. Figure 59.2 displays normal hematopoiesis that begins with a small population of multipotential hematopoietic stem cells in the bone marrow. These self-renewing stem cells produce self-renewing myeloid and lymphoid stem cells that subsequently produce committed progenitor cells. The latter cells begin the process of differentiation into mature leukocytes, erythrocytes, and platelets in the peripheral blood.

CARCINOGENESIS

Leukemia probably results from sequential accumulation of mutations in multiple oncogenes and tumor suppressor genes altering stem cell development. Many childhood leukemia subtypes develop from a series of genetic events within a previously initiated cell; the initiation may occur *in utero*. Myelodysplastic syndromes (MDSs) are a group of heterogeneous, premalignant bone marrow tumors characterized by ineffective hematopoiesis, peripheral cytopenias, and morphologically dysplastic hematopoietic cells. Analysis of MDS patients indicates the presence of multiple mutations of genes in 80–90% of these patients, with frequent mutations involving DNA repair (*ATM*, *BRCC3*, *DLRE1C*, *FANCL*), signal transduction/kinases (*FLT3*, *JAK2*), RAS pathway (*CBL*, *KRAS*, *NF1*, *NRAS*, *PTPN11*), cohesin complex (*CTCF*, *RAD21*, *SMC1A*, *STAG2*), RNA-splicing machinery (*SF3B1*, *SRSF2*, *U2AF1*, *U2AF2*, *ZRSR2*), transcription factors (*RUNX1*, *TP53*), DNA methylation (*DNMT3A*, *IDH1/2*, *TET2*), and chromatin modification (*ASXL1*, *EZH2*) genes.[11] Normal B cell maturation occurs in two phases: 1) "foreign antigen-independent" B cells existing primarily in fetal liver or bone marrow; and 2) "primarily foreign antigen-dependent" B cells developing in lymph nodes and spleen. Leukemias are a diverse group of malignancies that are clonal expansions of single cells at different stages of hematopoiesis. These transformed cells undergo uncontrolled proliferation, failing to differentiate into functionally mature cells.

Leukemia cells exhibit far fewer genetic aberrations compared with solid tumors, which require many genetic mutations to develop metastatic capabilities.[12] Common genetic mutations in childhood leukemia that form during the fetal period include t(12;21)TEL-AML1 and t(8:21)AML1-ETO; the former is the most frequent translocation in AML and the latter is the most common translocation in ALL. The inv(16)CBFB-MYH11 translocation in AML is also prenatal. The MLL (MLLT11 transcription factor 7 cofactor) translocation is prenatal in infants with ALL and postnatal in children of >2 years of age.[13] A significant portion (i.e., >1%) of normally born children have these translocations; however, the vast majority of these preleukemic clones are self-limiting and do not produce disease. Hence, mutations associated with leukemia are insufficient to produce disease without further gene mutations.[14] MLL

TABLE 59.1. 2022 World Health Organization (WHO) classification of myeloid and histiocytic/dendritic neoplasms. The myelodysplastic/myeloproliferative neoplasm category was introduced in the 3rd edition to provide a classification for myeloid tumors that overlap myelodysplastic syndrome and myeloproliferative neoplasms. Classification is based on cell lineage from benign to malignant and divided into category, family, type (disease/tumor), and subtype. The arrangement of these tumors integrates cytology, histology, and immunophenotyping along with molecular and cytogenetic data. See reference 9 for details on complete diagnostic criteria.[9]

Myeloproliferative neoplasms
Chronic myeloid leukemia
Polycythemia vera
Essential thrombocythemia
Primary myelofibrosis
Chronic neutrophilic leukemia
Chronic eosinophilic leukemia
Juvenile myelomonocytic leukemia
Myeloproliferative neoplasm, NOS
Cutaneous mastocytosis
Urticaria pigmentosa/Maculopapular cutaneous mastocytosis
Monomorphic
Polymorphic
Diffuse cutaneous mastocytosis
Cutaneous mastocytoma
Isolated mastocytoma
Multilocalized mastocytoma
Systemic mastocytosis
Bone marrow mastocytosis
Indolent systemic mastocytosis
Smoldering systemic mastocytosis
Aggressive systemic mastocytosis
Systemic mastocytosis with an associated hematologic neoplasm
Mast cell leukemia
Mast cell sarcoma
Mast cell sarcoma
Myelodysplastic neoplasms with defining genetic abnormalities
Myelodysplastic neoplasms with low blasts and isolated 5q deletion
Myelodysplastic neoplasms with low blasts and SF3B1mutation
Myelodysplastic neoplasms with biallelic *TP53* inactivation
Myelodysplastic neoplasms, morphologically defined
Myelodysplastic neoplasms with low blasts
Myelodysplastic neoplasms, hypoplastic
Myelodysplastic neoplasms with increased blasts
Myelodysplastic neoplasms-IB1
Myelodysplastic neoplasms-IB2
Myelodysplastic neoplasms with fibrosis
Childhood myelodysplastic neoplasms (MDS)
Childhood MDS with low blasts
Hypocellular
Not otherwise specified
Childhood MDS with increased blasts

TABLE 59.1. (Continued)

Myelodysplastic/myeloproliferative neoplasms
Chronic myelomonocytic leukemia
Myelodysplastic/myeloproliferative neoplasm with neutrophilia
Myelodysplastic/myeloproliferative neoplasm with SF3B1 mutation and thrombocytosis
Myelodysplastic/myeloproliferative neoplasm, NOS
Acute myeloid leukemia
Acute myeloid leukemia with defining genetic abnormalities
Acute promyelocytic leukemia with *PML::RARA* fusion
Acute myeloid leukemia with *RUNX1::RUNX1T1* fusion
Acute myeloid leukemia with *CBFB::MYH11* fusion
Acute myeloid leukemia with *DEK::NUP214* fusion
Acute myeloid leukemia with *RBM15::MRTFA* fusion
Acute myeloid leukemia with *BCR::ABL1* fusion
Acute myeloid leukemia with *KMT2A* rearrangement
Acute myeloid leukemia with *MECOM* rearrangement
Acute myeloid leukemia with *NUP98* rearrangement
Acute myeloid leukemia with *NPM1* mutation
Acute myeloid leukemia with *CEBPA* mutation
Acute myeloid leukemia, myelodysplasia-related
Acute myeloid leukemia with other defined genetic alterations
Acute myeloid leukemia, defined by differentiation
Acute myeloid leukemia with minimal differentiation
Acute myeloid leukemia without maturation
Acute myeloid leukemia with maturation
Acute basophilic leukemia
Acute myelomonocytic leukemia
Acute monocytic leukemia
Acute erythroid leukemia
Acute megakaryoblastic leukemia
Myeloid neoplasms associated with germline predisposition
Myeloid neoplasms with germline predisposition without a preexisting platelet disorder or organ dysfunction
Germline CEBPA P/LP variant (CEBPA-associated familial AML)
Germline DDX41 P/LP variant[a]
Germline TP53 P/LP variant[a] (Li-Fraumeni syndrome)
Myeloid neoplasms with germline predisposition and pre-existing platelet disorder
Germline RUNX1 P/LP variant[a] (familial platelet disorder with associated myeloid malignancy, FPD-MM)
Germline ANKRD26 P/LP variant[a] (Thrombocytopenia 2)
Germline ETV6 P/LP variant[a] (Thrombocytopenia 5)
Myeloid neoplasms with germline predisposition and potential organ dysfunction
Germline GATA2 P/LP variant (GATA2-deficiency)
Bone marrow failure syndromes

TABLE 59.1. (Continued)

Severe congenital neutropenia
Shwachman-Diamond syndrome
Fanconi anemia
Telomere biology disorders
RASopathies (Neurofibromatosis type 1, CBL syndrome, Noonan syndrome or Noonan syndrome-like disorders[a])
Down syndrome[a]
Germline SAMD9 P/LP variant (MIRAGE Syndrome)
Germline SAMD9L P/LP variant (SAMD9L-related Ataxia Pancytopenia Syndrome)
Biallelic germline BLM P/LP variant (Bloom syndrome)
Acute leukemias of ambiguous lineage
Acute leukemia of ambiguous lineage with defining genetic abnormalities
Mixed-phenotype acute leukemia with BCR::ABL1 fusion
Mixed-phenotype acute leukemia with KMT2A rearrangement
Acute leukemia of ambiguous lineage with other defined genetic alterations
Mixed-phenotype acute leukemia with ZNF384 rearrangement
Acute leukemia of ambiguous lineage with BCL11B rearrangement
Acute leukemia of ambiguous lineage, immunophenotypically defined
Mixed-phenotype acute leukemia, B/myeloid
Mixed-phenotype acute leukemia, T/myeloid
Mixed-phenotype acute leukemia, rare types
Acute leukemia of ambiguous lineage, NOS
Acute undifferentiated leukemia
Dendritic cell and histiocytic neoplasms
Plasmacytoid dendritic cell neoplasms
Mature plasmacytoid dendritic cell proliferation associated with myeloid neoplasm
Blastic plasmacytoid dendritic cell neoplasm
Langerhans cell and other dendritic cell neoplasms
Langerhans cells neoplasms
Langerhans cell histiocytosis
Langerhans cell sarcoma
Other dendritic cell neoplasms
Indeterminate dendritic cell tumor
Interdigitating dendritic cell sarcoma
Histiocytic neoplasms
Juvenile xanthogranuloma
Erdheim-Chester disease
Rosai-Dorfman disease
ALK-positive histiocytosis
Histiocytic sarcoma

Abbreviations: CML = chronic myeloid leukemia; CMML = chronic myelomonocytic leukemia; CNL = chronic neutrophilic leukemia; NOS = not otherwise specified.

[a] Lymphoid neoplasms can also occur as well as the footnoted entities.

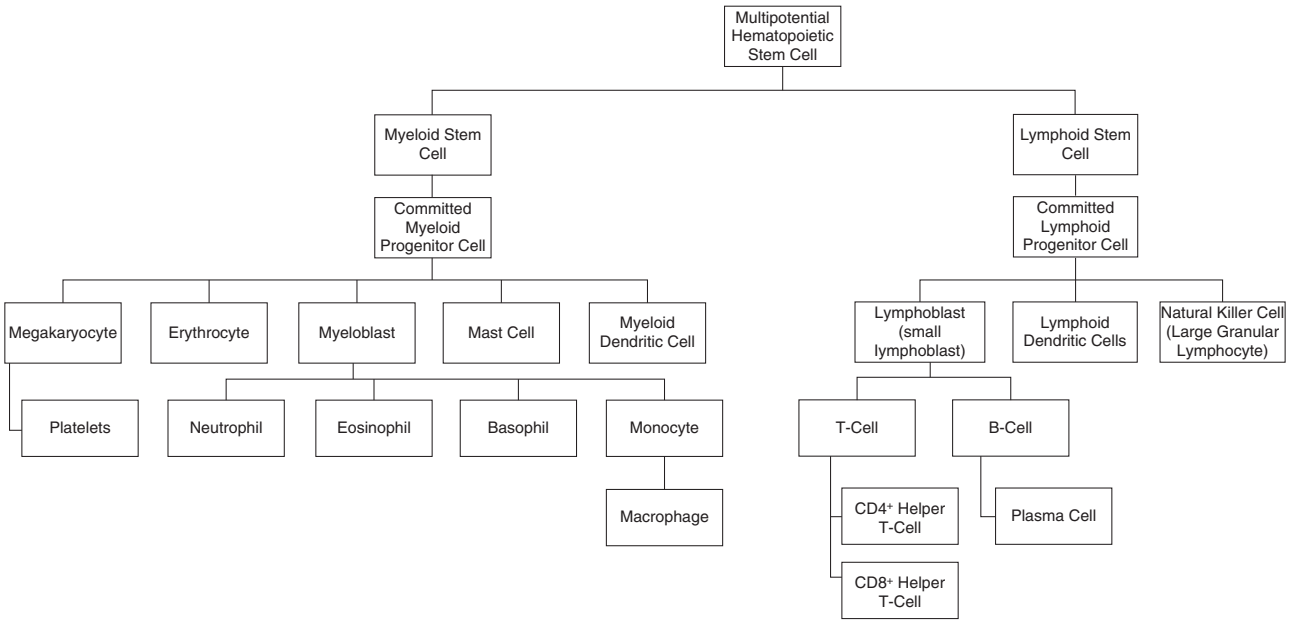

FIGURE 59.2. Normal hematopoiesis differentiation pathway. The multipotential hematopoietic stem cells produce self-renewing myeloid and lymphoid stem cells in bone marrow. Differentiation begins following the formation of committed myeloid and lymphoid progenitor cells from myeloid and lymphoid stem cells. These stem cells undergo self-renewal to maintain an adequate supply of stem cells for continued production of leukocytes. Ultimately, mature leukocytes (i.e., neutrophils, basophils, eosinophils, B cells, T cells, natural killer cells) appear in the peripheral blood along with erythrocytes and platelets. With an immature, B cell receptor, competent B cells migrate from the bone marrow to the spleen where they form a primary follicle with T cells and follicular dendritic cells with the B cell zone surrounding the T cell zone. Naïve follicular B cells that survive become fully mature B cells capable of participating in immune responses; these mature B cells subsequently circulate through all lymphoid tissues (spleen, lymph nodes, lymphoid-associated tissue) while being exposed to antigens. From the germinal center or the memory B cell population, antigen-specific B cells proliferate into plasma cells in the presence of the appropriate antigen. Plasma cells in the spleen or lymph nodes produce antibodies only for limited periods of time, whereas plasma cells that migrate to bone marrow are long-lived secreting antibodies into the blood for extended periods of time. T cells undergo further differentiation into CD4+ and CD8+ helper T cells in the thymus; these cells remain immunologically naïve until antigenic stimulation at sites of inflammation induces differentiation into effector cells capable of interacting with the antigens.

translocations are also complications of radiotherapy and chemotherapeutic drugs (e.g., topoisomerase II inhibitors, alkylating agents).[15] Figure 59.3 displays the probable cells of origin for AML, ALL, cALL (common acute lymphoblastic leukemia), and CML along with common translocations. Myeloid progenitor-derived leukemias are involved with innate rather than adaptive immunity that is important to monitoring native cellular processes. Alterations in immune surveillance may enhance the development of childhood leukemia. Immune stimulation from vaccinations and the normal course of childhood infections appears protective when some potentially childhood leukemia patients develop susceptibility to leukemia *in utero* from overactive immune responses.[12]

Adult leukemogenesis is a complex process involving multiple DNA mutations and structural changes; small, nonprotein-coding micro-RNAs (miRNAs) and long, nonprotein-coding RNAs (lncRNAs) also influence leukemogenesis by acting epigenetically to interact with signaling pathways that dysregulate gene expression in the nuclear compartment and cytoplasm. Numerous miRNAs and lncRNAs suppress or promote neoplasms by affecting tumor angiogenesis, growth, immune response, and metastasis.[16,17] These ncRNAs are potential biomarkers for determining the diagnosis and prognosis of leukemia subtypes (e.g., AML, CML, T-ALL).[18] Epigenetic functions include promoter-specific gene regulation, control of chromatin, structural maintenance of nuclear bodies, genomic imprinting/silencing, and X-chromosome inactivation.[19] Recent data suggest ~20,000 lncRNAs exist that potentially can interact with the human genome including a subset of lncRNAs capable of impeding miRNAs

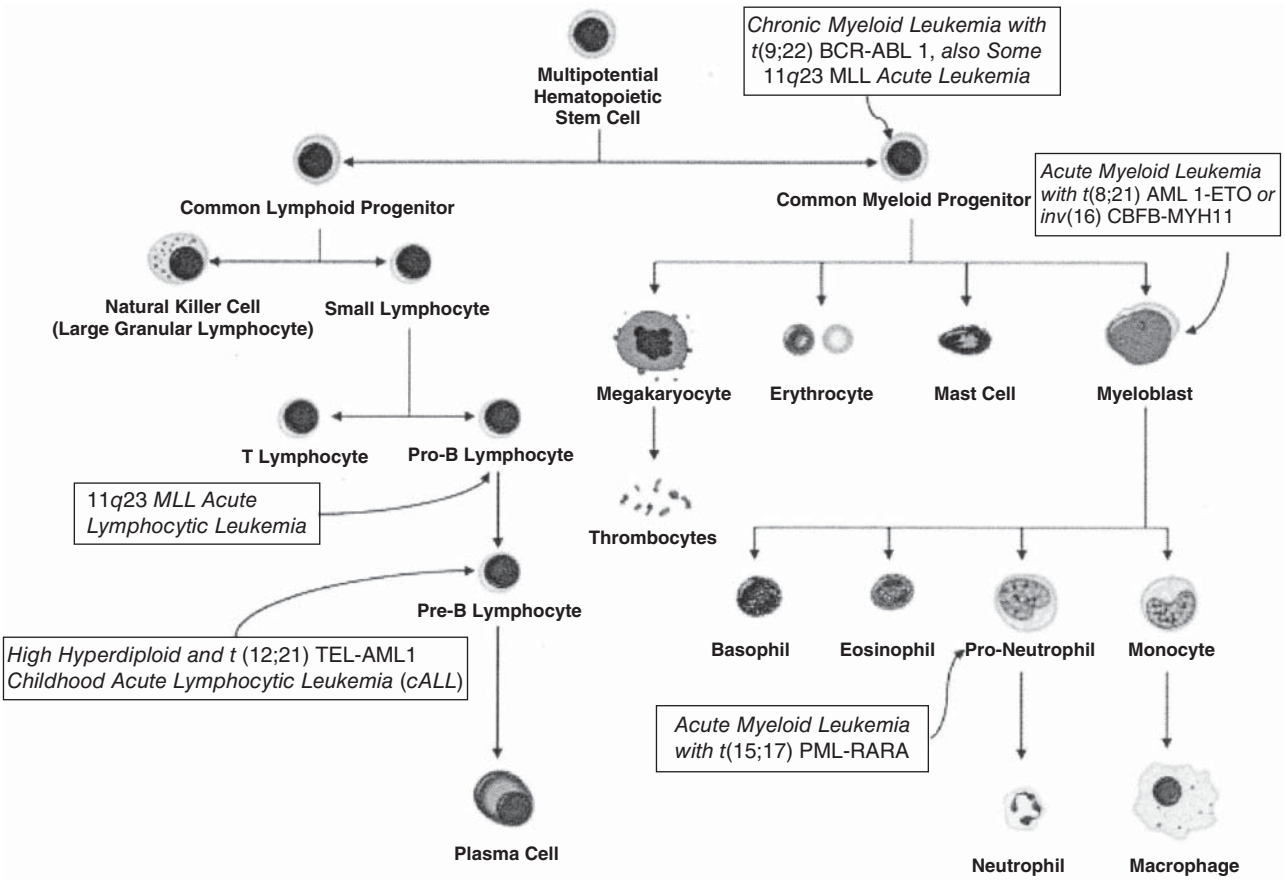

FIGURE 59.3. Cellular origin of common leukemias with the most frequent translocations. Most hematopoietic precursor cells have neoplastic counterparts that share similar morphological features with the original cell. (Adapted from Wiemels).[12]

and increasing mRNA expression.[20] Noncoding RNAs display significant tissue specificity functioning as transcriptional activators or cofactors as well as competing with endogenous RNAs, resulting in specific ncRNA expression patterns for leukemia subtypes. The *NOTCH1* gene has diverse functions (e.g., proliferation, differentiation, apoptosis) that allow the gene to function as an oncogene or a tumor suppressor. Aberrant expression of the oncogenic lncRNA, IGF1R activator RNA 1, enhances malignant T cell transformation during the development of *NOTCH1*-driven T cell acute lymphoblastic leukemia.[21]

EXPOSURE

Most leukemia cases are sporadic with no recognized risk factors; only an estimated 10% of childhood leukemias are associated with recognized risk factors (age, sex, race, ionizing radiation, certain congenital diseases).[22] Both childhood and adult leukemias are heterogeneous diseases with multiple subtypes and potentially different risk factors from variations in chromosomal translocations, fusion genes, and gene deletions/duplications. Hence, no single cause accounts for all leukemias or leukemia subtypes. Some leukemia subtypes (e.g., AML), but not all leukemia subgroups (e.g., CLL), have been causally linked with exposure to ionizing radiation, high-dose benzene exposures, some viruses, or chemotherapeutic agents.[23] Table 59.2 lists the strength of the human evidence (sufficient, limited) for carcinogenic agents and processes associated with hematopoietic cancers based on evaluations by the International Agency for Research on Cancer.[24,25] Some childhood leukemias are associated with congenital genetic syndromes (e.g., Down syndrome, neurofibromatosis, Fanconi's anemia); however, these disorders are uncommon (i.e., <5–10% of childhood cases). Pesticides are suspected agents associated with some adult lymphoproliferative cancers and childhood leukemias based almost

TABLE 59.2. International Agency for Research on Cancer (IARC) classification of cancer sites by sufficient and limited evidence of human carcinogenicity in leukemias, lymphomas, and multiple myeloma. (Adapted from Cogliano et al.).[24]

Cancer Type	Carcinogens with *Sufficient* Human Evidence (Group 1)	Carcinogens with *Limited* Human Evidence (Groups 2A or 2B)
	Childhood leukemia	
Acute lymphocytic		Tobacco smoking (parents)
Acute myeloid		Benzene, teniposide, tobacco smoking (parents)
All childhood leukemias combined	Fission products including ^{90}Sr, ^{232}Th, x- and γ-radiation	Chloramphenicol, extremely low frequency magnetic fields, painter (mother), radioiodines including ^{131}I, tobacco smoking (parents)
	Adult leukemia	
Acute myeloid	Benzene, busulfan, chlorambucil, cyclophosphamide, etoposide with cisplatin and bleomycin, formaldehyde, melphalan, MOPP, and other combination chemotherapy including alkylating agents, ^{32}P as phosphorus, semustine, ^{232}Th and decay products, tobacco smoking, treosulfan, x- and γ-radiation	Bischloroethyl nitrosourea, etoposide, mitoxantrone, teniposide
Other acute non-lymphocytic	Benzene, formaldehyde, ^{32}P as phosphorus, ^{232}Th and decay products, tobacco smoking, x- and γ-radiation	Bischloroethyl nitrosourea
Chronic myeloid	Formaldehyde, ^{232}Th and decay products, tobacco smoking, x- and γ-ray radiation	Benzene
Acute lymphocytic	^{32}P as phosphorus, ^{232}Th and decay products, x- and γ-radiation	
Chronic lymphocytic		Benzene, ethylene oxide
Adult T cell leukemia/ lymphoma (ATLL)	Human T cell lymphotropic virus type 1, ^{232}Th and decay products, x- and γ-radiation	
All leukemias combined	1,3-Butaiene, fission products including ^{90}Sr, rubber manufacturing industry, thiotepa	Chloramphenicol, diazinon, nitrogen mustard, petroleum refining occupation, radioiodines including ^{131}I, ^{222}Ra and decay products, styrene
	Lymphoma	
Hodgkin	Epstein–Barr virus, human immunodeficiency virus type 1 infection	
Primary effusion	Kaposi sarcoma herpesvirus	
Non-Hodgkin: immunosuppression-related	Epstein–Barr virus	
Non-Hodgkin: Burkitt	Epstein–Barr virus	Malaria caused by endemic *Plasmodium falciparum* infection
Non-Hodgkin: NK/T cell (nasal type)	Epstein–Barr virus	
Non-Hodgkin: low-grade B cell mucosa associated lymphoid tissue (MALT gastric)	*Helicobacter pylori* infection	
Non-Hodgkin: combined	Azathioprine, cyclosporine, chronic hepatitis C virus infection, human immunodeficiency virus type 1 infection, lindane, pentachlorophenol	Benzene, chlorophenoxy herbicides, DDT, diazinon, dichloromethane (methylene chloride), ethylene oxide, firefighters (occupation), glyphosate, hepatitis B virus chronic infection, malathion, polychlorinated biphenyls, polychlorophenols, and sodium salts, 2,3,7,8-tetrachorodibenzo-*para*-dioxin, trichloroethylene, x- and γ-radiation
Multicentric Castleman disease		Kaposi sarcoma herpesvirus
Lymphoma: combined	1,3-Butadiene, rubber manufacturing industry	Styrene
	Multiple myeloma	
Multiple myeloma	1,3-Butadiene, pentachlorophenol	Benzene, ethylene oxide, styrene, 1,1,1-trichloroethane, x- and γ-ray radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. exclusively on unvalidated self-reports in case-control studies.[26,27] Inconsistent findings, imprecise exposure assessments (time/intensity), lack of exposure-response relationships, complex/changing lymphoma classifications/exposure misclassification, small sample sizes, long latency, and confounding factors limit definitive conclusions on causation.[28] The IARC lists diazinon as a carcinogen with limited human evidence. The prospective Agricultural Health Study of 23,106 eligible pesticide applicators (21.5% participation rate) identified 32 leukemia cases classified by ICD9 codes 204–208.[29] Using lifetime exposure days as a measure of cumulative diazinon exposure based on self-reported, take-home questionnaires, the adjusted relative risk of the highest tertile compared with no exposure was elevated, but imprecise (aRR = 3.36, 95% CI: 1.08–10.49, $n = 4$ cases, $P_{\text{trend}} = 0.026$). The aRR for leukemia in the highest tertile using intensity-weighted exposure days was statistically nonsignificant and imprecise (aRR = 2.88, 95% CI: 0.92–9.03, $n = 4$, $P_{\text{trend}} = 0.053$).

Other potential leukemogenic substances include some chemicals, electromagnetic fields, and lifestyle factors (e.g., smoking, alcohol consumption); however, none of these agents are proven risk factors for leukemia. Background ionizing radiation (e.g., radon) does not account for most leukemia cases based on case-control studies including childhood leukemias. In a German study of 82 childhood leukemia cases and 209 population-matched controls, indoor radon concentrations were not associated with childhood leukemia using a prespecified cutpoint of 70 Bq m^3 (OR = 1.30, 95% CI: 0.32–5.33).[30] The mean indoor radon concentration of 27 Bq m^3 was relatively low compared with other studies.

Ionizing Radiation

The IARC lists x-radiation, γ-radiation, and several isotopes as human carcinogens that increase leukemia risks, including ^{90}strontium and other fission products, ^{32}phosphorus, and ^{232}thorium and its decay products. Isotopes associated with limited human evidence for increasing leukemia risks include radioiodine (e.g., ^{131}iodine) and ^{222}radon and its decay products. Leukemia was the first cancer detected in atomic bomb survivors from Hiroshima and Nagasaki.[31] Significant dose-related elevated risks occurred for CML, AML, and ALL; however, no increased risk of CLL was observed. The incidence of CLL is much lower in Japan than in the United States or Europe. Although significant publication bias exists for the exclusion of CLL from outcome measures of radiation-induced epidemiology studies, most lymphoma/leukemia studies with >15 years of follow-up report odds ratios above 1, albeit without statistical significance, whereas results from occupational cohorts are more varied.[32] Significant excess relative risks (ERRs) of leukemia-associated mortality from non-CLL leukemias occurred in a cohort receiving radiotherapy for ankylosing spondylitis (ERR = 3.11, 95% CI: 2.37–4.07, $n = 53$, $P_{\text{trend decreasing with time}} = <0.001$).[33] In the Israeli *Tinea capitis* study using age- and sex-matched population controls, the relative risk of leukemia-related death was statistically marginally significant (RR = 2.3, 95% CI: 1.0–5.6, $n = 14$ cases).[34] The ERR/Gy was 2.22 (95% CI: 0.6–4.8/Gy).

The association between parental occupational sources and childhood leukemia is relatively weak and inconsistent. Most case-control studies do not report a statistically significant increase in leukemia risk. In a German study of 1,184 leukemia cases and 2,588 age-matched controls, preconception paternal occupation in the nuclear industry undergoing dosimetric surveillance was not associated with a statistically significant increase in childhood leukemia (OR = 1.80, 95% CI: 0.71–4.58). The radiation doses of these fathers were mostly below detection or unknown, with no radiation dose exceeding 30 mSv. A systematic review of nine case-control studies published from 1990–2006 did not detect an association between prenatal diagnostic X-rays and leukemia (pooled random effects OR = 0.99, 95% CI: 0.87–1.13, $n = 433$ cases/4,459 nonexposed controls, $I^2 = 0\%$).[35]

Electromagnetic Fields

Adults

The association between electromagnetic field exposure and adult leukemia is weak and inconsistent.[36] Occupations potentially at risk from electromagnetic fields include telephone and power linemen electrical and electronics technicians, radio operators, and radio and television repairmen.[37] In a California study of 2,355 men with leukemia working in occupations associated with electric field exposures and 65,792 controls with other non-CNS cancers, the OR for all leukemias comparing the highest (>20 V/m) and lowest (<10 V/m) estimated mean electrical field exposure was 1.15 (95% CI: 0.78–1.72, $n = 31$ cases/793 controls).[38] Calculation of electric fields was based on task-weighted exposure estimates for each job title reflecting exposure over the preceding 15–20 years. The results indicate no clear

evidence of an exposure-response relationship between electric field estimates and leukemia. A case-control study of military personnel detected a borderline significant elevation (RR = 2.4, 95% CI: 1.0–5.0, $n = 7$ cases) of increased leukemia risks only in electrical mates exposed to 60 Hz electromagnetic fields.[39] Overall the standardized incidence ratio for leukemia in all US Navy occupations in the study was 0.9 (95% CI: 0.8–1.1, $n = 102$ cases) using Surveillance, Epidemiology, and End Results (SEER) data from the general US population. A population-based New Zealand study of 110 incident acute leukemia cases and 199 age-matched controls reported a marginally statistically significant increased acute leukemia risk comparing ever- and never-electrical workers (adjusted OR = 1.9, 95% CI: 1.0–3.8, $n = 26$ cases/27 controls) based on telephone interviews.[40] The strongest association occurred in telephone line workers and welders, with no statistically significant increased acute leukemia risks reported in occupations with the highest potential electric field exposures (e.g., electric vehicle operators, electricians, electrical power line/cable workers, electrical fitters).

Epidemiology studies suggest a weak positive association between occupational ELF-MF exposures and some leukemia subtypes, primarily myeloid types; however, the studies are inconsistent between the subtypes. In a UK study of 73,051 electrical workers employed for at least 6 months, overall leukemia risks were close to unity for all exposure categories without evidence of increased risks in the highest cumulative magnetic field exposure categories.[41] ALL risks demonstrated a significant positive trend based primarily on unusually low ALL risks in the lowest exposure category, whereas risks for AML, CML, and CLL showed no definite positive trend. In contrast, the prospective Netherlands Cohort Study reported an elevated AML risk for ever high-ELF-MF exposed category of the Dutch general population (HR = 2.15, 95% CI: 1.06–4.35), but no increased risks for ALL, CLL, or CML.[42] Analysis of data from the Nordic Occupational Cancer cohort on 5,409 adult AML cases and 27,045 age-, sex-, and country-matched controls did not demonstrate an association between high levels of ELF-MF exposure and AML (HR = 0.88, 95% CI: 0.77–1.01).[43] In the Swiss National Cohort, overall hemato-lymphopoietic cancer mortality was not associated with ELF-MR exposures, with the exception of increased myeloid leukemias (HR = 1.31, 95% CI: 1.02–1.97, $n = 70$ cases).[44] Their meta-analysis of occupational ELF-MF exposures and AML risks based on job-exposure matrices yielded a summary RR of 1.21 (95% CI: 1.08–1.37, $I^2 = 73.2\%$) with high heterogeneity.

The weaknesses of these studies include lack of control over confounding variables (benzene, ionizing radiation) and inadequate measurements of electromagnetic field exposures. Measuring residential fields is logistically difficult and expensive. Therefore, surrogates (e.g., wire-code classifications) are frequently used to estimate exposure. The wiring code correlates with factors other than residential magnetic fields, including age of house, housing density, and traffic density.[45]

Children

Childhood leukemia has been associated with electromagnetic field exposures in environmental settings in several different countries; however, no clear, plausible biological mechanism or experimental research supports a causal relationship.[46,47] The IARC considers ELF electromagnetic fields a possible childhood carcinogen (Group 2B) based on limited epidemiological evidence for an association with childhood leukemia, primarily in the top percentiles of extremely low frequency magnetic field exposure (>0.3–0.4 μT). The observational studies involve small case numbers and imprecise risk estimates.[48] This association was weaker in a pooled analysis of more recently conducted studies on childhood leukemia without a clear dose-response relationship.[49] Compared with the lowest tertile (≤0.1 μT), the childhood leukemia risk for the upper tertile (≥0.3 μT) was not statistically significant (OR = 1.44, 95% CI: 0.88–2.36).

Although some case-control studies suggest a positive correlation between exposure to electromagnetic waves and childhood leukemia, most cohort studies do not support a causal association between electromagnetic fields and leukemia. An approximate 1.5-fold excess of childhood leukemia is associated with living in a house belonging to the high wire-code category;[45] however, these studies have not demonstrated a dose-response relationship between exposure to electromagnetic fields and the risk of developing leukemia. Follow-up studies have not detected excess magnetic field exposures in children developing leukemia. A recently updated case-control study of 53,515 UK children from the National Registry of Childhood tumors reported a reduction in childhood leukemia risks for offspring of mothers residing within 199 m of overhead high-voltage powerlines (132–400 kV) at the time of birth when compared with controls (>1,000 m from powerlines).[50] For all voltages, the relative risks decreased from 4.50 (95% CI: 0.97–20.83) in the 1960s to 0.71 (95% CI: 0.49–1.03) in the 2000s. The aggregate over the entire

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

time period was 1.12 (95% CI: 0.90–1.38). Positive values for childhood leukemia risks did not extend beyond 600 m.

Occupation

The IARC lists occupational exposures to several chemicals as human carcinogens that increase leukemia risks including 1,3-butadiene, formaldehyde, pentachlorophenol, and work in the rubber production industry. Agricultural and other occupational exposures associated with limited evidence of increasing leukemia risks include benzene, busulfan, chlorambucil, cyclophosphamide, diazinon, ethylene oxide, formaldehyde, melphalan, MOPP therapy, petroleum refining, ^{32}P as phosphorus, semustine, styrene, tobacco smoking, treosulfan, and x- and γ-radiation. In addition, the IARC classifies childhood leukemia from maternal exposure to painting occupations as limited human evidence of leukemia risks.

A New Zealand cancer registry study of 225 leukemia cases and 471 controls used unconditional regression to compare ever- versus never-employed workers in specific occupations based on information obtained from face-to-face interviews.[51] Statistically significant elevated leukemia risks occurred in the agricultural sector, including horticulture/fruit growing (OR = 2.62, 95% CI: 1.51–4.55, $n = 32$ cases/32 controls), plant nurseries (OR = 7.51, 95% CI: 1.85–30.38, $n = 8$ cases/3 controls), and vegetable growing (OR = 3.14, 95% CI: 1.18–8.41, $n = 10$ cases/8 controls); the elevated risks occurred in women only. Using semi-Bayes adjustment (gender, age, smoking history, occupational status) to compensate for multiple comparisons, statistically significant elevated leukemia risks appeared in physical science and engineering associated professionals (OR = 1.74, 95% CI: 1.03–2.94, $n = 29$ cases/27 controls). For industries, suggestive increased leukemia risks occurred in personal and household goods retailing (OR = 1.85, 95% CI: 1.25–2.75, $n = 63$ cases/94 controls). Poor participation rates (57% cases/48% controls), age differences (56.2 years cases/59.2 years controls), small numbers, imprecise exposure estimates, and potential misclassification limit conclusions regarding causation. An analysis of data from the Nordic Occupational Cancer Study estimated standardized incidence ratios for AML, CLL, and other leukemias in workers from over 300 occupational categories.[52] The study reported modestly elevated AML risks in drivers (SIR = 1.16, 95% CI: 1.07–1.26, $n = 555$ cases) and food workers (SIR = 1.13, 95% CI: 1.01–1.27, $n = 287$ cases), whereas CLL risks were modestly increased in clerical workers (SIR = 1.07, 95% CI: 1.01–1.14, $n = 1{,}086$ cases) and farmers (SIR = 1.09, 95% CI: 1.04–1.14, $n = 1{,}746$ cases). For other leukemias, the risks were increased in sales agents (SIR = 1.15, 95% CI: 1.06–1.25, $n = 562$ cases) and seamen (SIR = 1.24, 95% CI: 1.04–1.49, $n = 118$ cases). Five occupations had reduced SIRs including forestry workers and seamen for AML, seamen for CLL, and other health workers and fishermen for other leukemias. The study did not adjust for multiple comparisons.

Benzene and the Petroleum Industry

The association between high benzene exposures in industrial settings and acute myeloid leukemia is consistently strong and exposure-response related. The association with relatively low benzene concentrations (i.e., <1 ppm) or other lymphohematopoietic cancers is weaker, particularly with changes in refining processes and recent reductions in the benzene content in transportation fuels. A nested case-control study of 69 leukemia cases and 284 age-matched, unexposed company controls did not detect a clear association between work in refining division and leukemia based on job classifications and death certificates (OR = 0.85, 95% CI: 0.46–1.5, $n = 19$ deaths);[53] however, the study did suggest the possibility of an association between production and maintenance workers in oil and gas industries and myelogenous leukemia (adjusted OR = 3.2, 95% CI: 1.1–9.2, $n = 9$ deaths). In a pooled analysis of three nested case-control studies of Australian, Canadian, and UK petroleum distribution workers with 370 case subjects and 1,587 controls, data analysis suggests a dose-response relationship between myelodysplastic syndrome (MDS) and cumulative benzene exposure; the odds ratio of MDS comparing the highest (>2.93 ppm-years) and lowest tertile (≤0.348 ppm-years) of benzene exposure was 4.33 (95% CI: 1.31–14.3, 15 cases/39 controls, $P = 0.03$).[54] The study reported little evidence of exposure-response relationships between cumulative benzene exposure and AML, CLL, CML, or myeloproliferative disease. The large confidence intervals indicate imprecise OR estimates from small case numbers. A review of historical cohort studies of petroleum refinery and chemical manufacturing workers in Texas did not reveal any statistically significant increase in SMR for the 20 types of cancers studied including leukemia (SMR = 112, 95% CI: 94–130).[55] Some epidemiological evidence suggests benzene exposure increases leukemia risks other than AML, but the associations are relatively weak and varied based on mortality studies.[56,57] Most studies do not associate benzene exposure with non-Hodgkin lymphoma or multiple myeloma.[58,59]

Smoking does not appear to increase the risk of developing leukemia following occupational benzene exposure,[60] despite cigarettes being a relatively high benzene source (30–73 μg benzene/*cigarette*).[61,62] In comparison to cigarette smoke, the benzene content of cigar and pipe smoke is higher (85–207 and 250–470 μg benzene/g tobacco, respectively).[63]

Gasoline

The presence of benzene in gasoline creates a potential leukemia risk, particularly for acute myelogenous leukemia; the epidemiological evidence for an association with other leukemia subtypes is weaker.[64,65] The mean benzene concentration averaged 0.8–3.18% from 1972–1991, with European gasoline typically containing <2%; however, the benzene concentration is significantly lower in gasoline vapor than liquid.[66,67] Control systems and refinery procedures have reduced benzene exposure from gasoline for most refinery and distribution workers to relatively low concentrations (e.g., <1 mg/m^3).[68] An evidence-based analysis ranked 54 epidemiology studies on occupational gasoline exposure and lymphatic/hematopoietic cancer risks; the 30 highest-ranked studies were divided into three tiers based on strength, specificity, consistency, temporality, dose-response trends, and coherence.[69] None of the meta-relative risks for total leukemias or leukemia subgroups in tier 1 (highest) or tier 2 (intermediate) studies were statistically significant, including the meta-RR for acute myelogenous leukemia (ICD 205.0) using fixed effects models (e.g., meta-$RR_{tier\,1} = 1.00$, 95% CI: 0.993–0.1007). The meta-RR for ALL in tier 3 (lowest category), but not tier 2 (intermediate), was statistically significant (meta-$RR_{tier\,3} = 1.92$, 95% CI: 1.05–2.79, $n = 3$ studies) using a fixed effects model. Subanalysis of the data reported elevated hematopoietic cancer risks in US refinery cohorts occurred primarily in workers hired before 1950, consistent with more recent studies.[70]

1,3-Butadiene and Styrene–Butadiene Rubber Industry

Epidemiological research on 1,3-butadiene focuses primarily on two cohorts: North American styrene–butadiene synthetic rubber production and the US butadiene monomer industry. The IARC considers 1,3-butadiene a human carcinogen associated with lymphohematopoietic cancers via a direct-acting genotoxic mechanism involving the formation of reactive epoxides and DNA damage. The epidemiological evidence for an association with hemolymphatic cancers is strongest for leukemias based on the styrene–butadiene synthetic rubber production cohort. The association with leukemia subtypes is weaker, in part, because of low case numbers and imprecise risk estimates. Furthermore, the evolving, multifaceted classifications and diagnostic criteria of hematopoietic and lymphatic tumors complicate the interpretation of results from these cohorts.

Mortality data from 17,924 men employed in the North American styrene–butadiene rubber cohort followed from 1943–1998 demonstrate elevated leukemia risks based on evaluations of work histories, standardized mortality ratios (SMRs), and procedures to determine the International Classification of Diseases (ICD) codes for decedents;[71] the monomer industry study was less conclusive. The SMR for overall leukemia in the whole cohort was positive, but not statistically significant (SMR = 116, 95% CI: 91–147, $n = 71$ cases). Subgroup analysis indicated statistically significant increased leukemia risks were concentrated in hourly employees employed for ≥10 years and 20–29 years since hire (SMR = 258, $n = 19$ cases), polymerization workers (SMR = 204, $n = 18$ cases), maintenance workers (SMR = 326, $n = 15$ cases), and laboratory operators (SMR = 326, $n = 14$ cases). For leukemia subgroups in the last 30 years of the cohort, data were difficult to interpret because the case numbers were small and the estimates imprecise. The authors opined that CML and CLL accounted for most of the overall increased leukemia SMR noted above in the hourly employees employed for ≥10 years and 20–29 years since hire. The data did not support an elevated risk of Hodgkin lymphoma, non-Hodgkin lymphoma, or multiple myeloma. Analysis of data on 4,863 female styrene–butadiene rubber plant workers did not support excess deaths for leukemia, Hodgkin lymphoma, multiple myeloma, or non-Hodgkin lymphoma.[72] Analysis of exposure-response relationships indicates average butadiene intensity and peaks (>100 ppm) were associated with leukemia mortality.[73] Some uncertainty about the strength of the results remained because the specific carcinogenic agent was not identified and cofounding was not excluded.

Leukemia mortality in the butadiene monomer industry is not clearly associated with butadiene exposure based on pre-2008 WHO leukemia classifications.[74] In a Texas study of 614 operations, shipping, laboratory, and maintenance workers at the Deer Park refinery with at least 5 years of employment while exposed to butadiene monomer, the SMR from 1948–1998 for these workers was 1.06 (95% CI: 0.22–3.11, $n = 3$ cases) based on death certificates.[75] There were no leukemia-related deaths. Random sampling indicates the mean 8-hour

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

time-weighted average butadiene concentration was <1.75 ppm, except for shipping workers (i.e., ~10 ppm). The overall cancer standardized mortality rate was 0.55 (95% CI: 0.42–0.70, $n = 61$ deaths), whereas the 56-year mortality study of 10,621 male refinery workers at the Deer Park petroleum and chemical plant (mean = 34 years of follow-up) with ≥10 years of employment did not detect an elevated SMR for overall lymphatic and hemopoietic cancers.[76] The SMR was 1.04 (95% CI: 0.81–1.30, $n = 74$ deaths) with no increased SMR in any major lymphatic or hemopoietic subgroups (i.e., AML, ALL, CML, CLL). Although data analysis from 16,579 synthetic rubber industry workers followed from 1943–1998 suggests CML and, to a lesser extent, CLL mortality were elevated, the more commonly occurring, chemically induced leukemia subtype, AML, was not.[77] Exposure-response modeling of data from the styrene–butadiene synthetic rubber industry using cumulative 1,3-butadiene ppm-years as the predictor variable indicates the slope for lymphoid, but not myeloid (i.e., CML, AML), neoplasms is statistically significantly greater than zero.[78] *In vitro* studies indicate 1,3-butadiene can induce the pathological t(9:222) translocations (Philadelphia chromosome); however, the frequency of the translocations is much lower for butadiene than ionizing radiation.[79]

Formaldehyde

Although large positive cohort studies suggest an association between occupational formaldehyde exposure and lymphohematopoietic neoplasms, the ability of formaldehyde to cause leukemia or lymphomas remains controversial, particularly among specific leukemia and lymphoma subtypes including myeloid leukemia.[80] The IARC lists formaldehyde as a human (Group 1) carcinogen, with sufficient evidence of increased myeloid leukemia risks based on epidemiological studies of formaldehyde-exposed workers and moderate evidence of formaldehyde-induced cytotoxicity/genotoxicity in Chinese workers. However, a substantial minority of the working group considers the epidemiological evidence for formaldehyde-induced carcinogenicity limited.[81] After the IARC determined formaldehyde was a human carcinogen, the USEPA reviewed the carcinogenicity issue based on recommendations from a National Academy of Science Committee.[82] This review included several critical reviews and extended analyses of epidemiological studies, recent updates of earlier occupational cohort studies, mouse studies in a sensitive strain, and mechanistic studies on exogenous versus endogenous effects of formaldehyde on bone marrow. The review concluded, "with few exceptions, new findings are consistently negative, and integration of all available evidence challenges the earlier conclusions that formaldehyde causes leukemia."

Formaldehyde-exposed workers include anatomists, embalmers, and formaldehyde industrial workers; studies of these cohorts are inconsistent with the strongest evidence for combined myeloid leukemia.[83] Meta-analyses on formaldehyde exposure and leukemia risks demonstrated mixed results, with some analyses failing to support the association.[84] In a meta-analysis of four cohort studies of formaldehyde-exposed industrial workers, the meta-SMR for leukemia deaths was not elevated (meta-SMR = 0.90, 95% CI: 0.75–1.97, $n = 122$ deaths, $P_{\text{heterogeneity}} = 0.53$).[85] The meta-SMR for leukemia deaths in five cohorts of professionals (e.g., anatomists, embalmers) was increased (meta-SMR = 1.36, 95% CI: 1.03–1.79, $n = 51$ deaths, $P_{\text{heterogeneity}} = 0.84$). A meta-analysis of 15 studies focusing on the highest exposure groups in each study reported an elevated meta-relative risk for leukemia deaths (summary-RR = 1.54, 95% CI: 1.18–2.00, $P_{\text{heterogeneity}} = 0.11$) using fixed effects models with Shore adjustment.[86] The summary relative risk for myeloid leukemia was 1.90 (95% CI: 1.31–2.76, $n = 36$ deaths, $P_{\text{heterogeneity}} = 0.15$). A meta-analysis of cohort and case-control studies on formaldehyde and leukemia reported little support for a causal relationship between formaldehyde exposure and leukemia including leukemia subtypes.[87] For cohort studies, the summary relative risk was 1.05 (95% CI: 0.93–1.20) and 0.99 (95% CI: 0.71–1.37) for case-control studies. The analysis detected no evidence of serious heterogeneity or publication bias.

The association of formaldehyde with leukemia is weaker for industry than for professional workers. In the National Cancer Institute's (NCI) cohort of 25,619 workers in formaldehyde industries comparing the highest (≥4 ppm) and lowest (>0–<2 ppm) peak exposure categories, the relative risk of death was elevated for all lymphohematopoietic malignancies (RR = 1.37, 95% CI: 1.03–1.81, $n = 108$ deaths, $P_{\text{trend}} = 0.2$) and Hodgkin lymphoma (RR = 3.96, 95% CI: 1.31–12.02, $n = 11$ deaths, $P_{\text{trend}} = 0.01$) based on death certificates and ICD-8 codes.[88] The positive associations were reported as statistically nonsignificant for multiple myeloma (RR = 2.04, 95% CI: 1.01–4.12, $n = 21$ deaths, $P_{\text{trend}} = 0.08$) and myeloid leukemia (RR = 1.78, 95% CI: 0.87–3.64, $n = 19$ deaths, $P_{\text{trend}} = 0.13$). AML and CML were not separated despite genetically different mutations (e.g., Philadel-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

phia chromosome in CML) and substantially different risk factors. The study reported little evidence of associations between these neoplasms and cumulative or average intensity formaldehyde exposures. Analysis of mortality data from the US National Cancer Institute cohort did not support increased mortality from AML (SMR = 0.80, 95% CI: 0.56–1.14, $n = 30$ deaths) or CML (SMR = 0.97, 95% CI: 0.56–1.67, $n = 13$ deaths).[89]

The cohort mortality study of 11,043 formaldehyde garment workers provided limited evidence of an association between formaldehyde exposure and leukemia.[90] Compared with the US population, the SMR for myeloid leukemia was modestly elevated, but statistically nonsignificant (SMR = 1.28, 95% CI: 0.79–1.96, $n = 21$ deaths). Similarly, the SMR for AML, CML, Hodgkin/non-Hodgkin lymphoma, and multiple myeloma were elevated without statistical significance. In a US study of 168 deceased funeral directors and embalmers from lymphohematopoietic tumors and 265 unexposed deceased funeral industry controls, myeloid leukemia mortality significantly increased with duration of embalming compared with the lowest category of embalming (<500 lifetime); the odds ratio for the highest category of >34 years was 3.9 (95% CI: 1.2–12.5, $n = 14$ deaths, $P_{trend} = 0.020$).[91] The odds ratio for AML in this exposure category was not statistically significant (OR = 3.1, 95% CI: 0.7–13.7, $n = 8$ deaths, $P_{trend} = 0.63$) based on death certificates and ICD-8 codes; however, a considerable amount of missing data required the use of estimated exposures (i.e., imputation). The imprecise estimates reflect the use of next-of-kin interviews as the information source for formaldehyde exposure.

Most epidemiology studies have not reported significantly increased Hodgkin or non-Hodgkin lymphoma risks in formaldehyde-exposed workers. An Italian cohort study of 2,750 laminated plastic factory workers with at least 6 months of formaldehyde exposure reported a nonsignificant reduction in lymphohematopoietic cancer deaths (SMR = 68.6, 95% CI: 31.4–131.3, $n = 9$ deaths).[92] The SMR was unrelated to the likelihood of formaldehyde exposure with no increased deaths among blue-collar workers. No quantitative exposure measurements for formaldehyde were available. A nested case-control study from a cohort of 14,008 UK chemical workers reported no statistically significant elevation of overall myeloid leukemia deaths (SMR = 1.20, 95% CI: 0.84–1.66, $n = 36$ deaths) or deaths in the highest formaldehyde exposure category defined by >2 ppm for ≥1 year (SMR = 0.93, 95% CI: 0.40–1.82, $n = 8$ deaths).[93]

Ethylene Oxide

Ethylene oxide is a highly reactive epoxide that is a direct-acting alkylating agent and mutagen, producing ethylene oxide-derived hemoglobin and DNA adducts as well as chromosomal aberrations, sister chromatid exchanges, and micronucleus formation. The IARC upgraded this chemical to a human carcinogen based on genotoxic mechanistic data, sufficient evidence in animals, and limited evidence in humans.[94] Epidemiological data do not provide consistent and convincing evidence associating ethylene oxide exposure with increased leukemia or non-Hodgkin lymphoma risks.[95] A previous analysis of 10 studies on leukemia in workers exposed to ethylene oxide demonstrated a combined SMR of 1.06 (95% CI: 0.73–1.48).[96] Historical inconsistencies in the histopathological classification of leukemia and lymphomas complicate the interpretation of these studies. In a Swedish study of 733 ethylene oxide workers, the SMR was elevated (SMR = 9.21, 95% CI: 3.51–18.03, $n = 8$ leukemia cases); however, small sample size, imprecise SMR estimates, and poor control of confounding variables limit definitive conclusions on a causal association.[97] The estimated average airborne ethylene 8-hour time-weighted average for earlier workers was 5–8 ppm compared with 0.4–1.6 ppm for later workers.

The US NIOSH ethylene oxide cohort study of 18,254 ethylene oxide-exposed workers at 14 plants producing sterilized medical supplies and spices exposed them for an average of 4.9 years and followed them for 16 years.[98] The recent 8-hour time-weighted adjusted ethylene oxide exposure averaged 4.3 ppm for sterilizer operators and 2.0 ppm for other workers, with the authors opining that earlier ethylene oxide exposures were several times higher. Overall, the study demonstrated no significant increase in mortality from any cause, including an SMR of 0.97 for leukemia (95% CI: 0.52–1.67; $n = 13$ deaths) and 1.0 for non-Hodgkin lymphoma (95% CI: 0.57–2.37, $n = 8$ deaths). Although mortality was greatest in the highest cumulative ethylene oxide exposure category of >8,500 ppm-days (SMR = 1.24, 95% CI: 0.66–2.13, $n = 13$ deaths), the trend was weak ($P_{trend} = 0.32$) and statistically nonsignificant.[99] An additional follow-up period of 11 years revealed no overall excess of hematopoietic cancers combined or non-Hodgkin lymphoma.[100] In an internal analysis, log-cumulative ethylene oxide exposure was associated with lymphatic and hematopoietic cancers that lagged 15 years in men ($P_{trend} = 0.02$), but not in women. The combined lymphoid-cell cancer SMR (non-Hodgkin, myeloma, lymphocytic leukemia) for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ethylene oxide workers was statistically significant but imprecise and lacked a dose-response relationship (SMR = 3.76, 95% CI: 1.03–13.64, $P_{trend} = 0.13$). Duration, average/cumulative exposure, and peak exposure were not correlated to lymphatic or hematopoietic cancer risks.

A study of 2,063 ethylene oxide-production workers in West Virginia exposed from 1940–1988 and followed through 2003 did not demonstrate any excess cancer deaths or dose-response relationships from lymphohematopoietic malignancies.[101] The hazard ratios comparing the highest (>65 ppm-year) and lowest (≤15 ppm-years) tertiles were 0.332 (95% CI: 0.044–2.496, $n = 11$ deaths) for leukemia mortality and 0.41 (95% CI: 0.128–2.276, $n = 17$ deaths) for lymphoid tumor mortality. In a meta-analysis of 10 cohort studies on ethylene oxide-exposed workers, the heterogeneity-adjusted meta-SMR for leukemia was 1.08 (95% CI: 0.61–1.93, $n = 35$ deaths), whereas the meta-SMR for non-Hodgkin lymphoma was 1.34 (95% CI: 0.96–1.89, $n = 33$ deaths).[102] There were no statistically significant positive trends in duration, intensity, or latency. In a Swedish study of 2,171 ethylene oxide sterilant workers employed for at least 1 year and followed up to 34 years, the median cumulative ethylene oxide exposure was 0.13 ppm-years.[103] The SIR for leukemia was 1.40 (95% CI: 0.45–3.26, $n = 5$ cases) and remained statistically nonsignificant with a 15-year lag (SIR = 1.15, 95% CI: 0.25–3.37, $n = 3$ cases). Using the bottom tertile as a referent, the SIR for lymphohematopoietic cancer in the top tertile (≥0.22 ppm-years) was 1.08 (95% CI: 0.35–2.54, $n = 5$ cases).

Lifestyle

Few lifestyle risk factors are causally associated with elevated adult or childhood leukemia risks. Although the IARC considers the evidence for environmental benzene exposure (e.g., parental smoking) and childhood leukemia stronger for AML than ALL, the reported risks are mostly statistically nonsignificant with bias, chance, and/or confounding potential alternate explanations of the results.[104]

Tobacco

The IARC lists tobacco smoking as a human carcinogen associated with at least nine cancers including acute myeloid leukemia, whereas limited human evidence associates childhood leukemia with maternal smoking and extremely low frequency magnetic fields.[105]

Adult Smoking

Epidemiology studies on overall leukemia incidence rates and tobacco smoking are mixed, with similar numbers of cohort and case-control studies reporting positive and null results.[106] The results are much stronger for myeloid than lymphoid leukemia, with most studies reporting positive results for myeloid leukemia in cigarette smokers,[107] particularly AML subtypes M2 and t(8:21) translocation,[108] whereas most,[109,110] but not all, studies on overall lymphoid leukemia incidence rates report null results.[111] Small case numbers and imprecise risk estimates complicate the interpretation of the rarer lymphoid leukemia subtypes in adults. In the Swedish prospective cohort study of 334,957 construction workers followed for 10 years, the AML incidence rate ratio adjusted for age and BMI in current smokers was 1.50 (95% CI: 1.06–2.11, $n = 92$ cases) and 0.94 (95% CI: 0.60–1.48, $n = 30$) in ex-smokers using never-tobacco users as referents.[112] The study reported no association between smoking and ALL ($n = 47$ cases). The Three Mile Island Cohort Study reported a marginally elevated adult AML risk in current smokers using never-smokers as referents (RR = 3.47, 95% CI: 1.002–11.99, $n = 9$ cases) after adjustment for age, gender, education level, race, and occupational/background radiation.[113] Examination of smoking intensity (daily cigarettes, smoking duration, pack-years) yielded no statistically significant trend using $P = 0.05$ as the cutoff. The overall leukemia risk in current smokers was not statistically different from that in referents (adjusted RR = 1.39, 95% CI: 0.69–2.82, $n = 17$ cases, $P_{trend} = 0.57$). In a population-based sample of 1,068 incident adult leukemia cases and 5,039 healthy controls with similar age and sex distribution, the association between the highest tertile of lifetime environmental tobacco smoke (ETS) exposure in never-smokers with overall leukemia (>123 smoker-years) was positive, but not statistically significant (adjusted OR = 1.46, 95% CI: 0.97–2.18, $n = 112$ cases, $P_{trend} = 0.001$) using healthy never-smokers as referents.[114] Analysis of leukemia subgroups yielded no association of lifetime ETS smoke with most leukemia subtypes, except CLL. The highest tertile of lifetime ETS exposure (>123 smoker-years) for CLL in nonsmoking adults was 2.31 (95% CI: 1.16–4.59, $n = 53$ cases, $P_{trend} = 0.001$). Smoker-years represent the lifetime sum of exposure to the number of smokers at work and home.

Parental Smoking

The evidence for parental smoking causing substantially increased overall childhood leukemia risks is relatively weak, with varied results complicating the interpretation of contradictory conclusions.[115] Most studies on self-reported maternal smoking and childhood leukemia do not report a significant positive association either before or during pregnancy with some studies reporting an inverse association.[116,117] In contrast to maternal smoking, studies on paternal smoking and childhood leukemia report more positive studies, albeit less than a majority for smoking before, but not during pregnancy. The positive studies more often associated smoking with ALL than with AML.[118] Leukemia subtype risks may vary with exposure time (e.g., prenatal, postnatal, conception) and cytogenetic subtype reflecting the time of genetic mutations in fetal development [e.g., t(2/21)/ETV6-RUNX1)], postnatal (e.g., t(1;19)E2A-PBX1), or possibly both time periods (e.g., MLL fusion).[119] Small case numbers typically generate imprecise risk estimates. The Northern California Childhood Leukemia Study examined self-reported smoking information in 767 ALL/135 AML cases and 1,139 randomly selected controls matched to date of birth, sex, Hispanic ethnicity, and maternal race.[120] Multivariable regression analyses demonstrated no definite overall association between parental prenatal active smoking and the child's passive exposure. A history of paternal prenatal active smoking combined with the child's postnatal exposure to passive residential smoking increased ALL risks (OR = 1.5, 95% CI: 1.01–2.23, $n = 115$ cases/88 controls, $P_{\text{interaction}} = 0.02$). The magnitude of the association was strongest for B cell precursor ALL harboring t(12;21) translocation (OR = 2.08, 95% CI: 1.04–4.16, $n = 26$ cases, $P_{\text{interaction}} = 0.01$). Associations with other leukemia subtypes (e.g., AML) did not reach statistical significance. A meta-analysis of epidemiology studies on self-reported maternal smoking during pregnancy (any vs. none) involving 9,167 ALL and 1,925 AML incident childhood cases and 25,221 nonsmoking controls detected no significant deviation of AML/ALL risks from the null.[121] The pooled odds ratio estimate for AML was 0.99 (95% CI: 0.90–1.09, $n = 1$ cohort/14 case-control studies, $I^2 = 28.6\%$, random effects models) and 1.03 for ALL (95% CI: 0.95–1.12, $n = 1$ cohort/19 case-control studies, $I^2 = 49.21\%$, fixed effects models) with moderate heterogeneity.

A Canadian case-control study on self-reported smoking before and during pregnancy reported odd ratios mostly of >1 for maternal and paternal smoking; however, the odds ratios and exposure-response relationships (P_{trend}) were all statistically nonsignificant using nonsmokers as referents. Comparing the highest smoking tertile (≥20 cigarettes daily) with controls, the OR for maternal smoking during pregnancy was 0.98 (95% CI: 0.50–1.89, $n = 22$ cases/218 controls, $P_{\text{trend}} = 0.373$) for ALL and 0.40 (95% CI: 0.04–3.80, $n = 2$ cases/18 controls, $P_{\text{trend}} = 0.287$) for AML.[122] For paternal smoking before pregnancy, the odds ratio for ALL was 1.15 (95% CI: 0.79–1.67, $n = 95$ cases/179 controls, $P_{\text{trend}} = 0.399$) and 0.90 (95% CI: 0.34–2.38, $n = 11$ cases/19 controls, $P_{\text{trend}} = 0.736$) for AML. In the French ESTELLE study of 636 ALL cases (503 B cell precursors, 95 T cell precursors, 26 Burkitt's ALL, 12 unspecified/unable to complete study), 100 AML cases, and 1,421 population-based controls, preconception paternal smoking within 3 months of conception (ever vs. never) was associated marginally with ALL (OR = 1.2, 95% CI: 1.0–1.5, $n = 297$ cases/319 controls, $P_{\text{trend}} = 0.13$) and AML (OR = 1.5, 95% CI: 1.0–2.3, $n = 51$ cases/48 controls, $P_{\text{trend}} = 0.03$).[123] ALL and AML risks in children born to mothers who smoked before or during pregnancy did not deviate from the null.

Alcohol

The potential association between self-reported maternal alcohol consumption during pregnancy and ALL remains unclear with both positive and negative studies and studies demonstrating an inverse relationship; limited data on AML are also inconclusive. A Ukrainian nested case-control study of 137 leukemia cases and 873 controls in the male Chernobyl cleanup cohort reported no significant association between leukemia and alcohol consumption after adjustment for radiation doses; exposure was based on personal questionnaires and models of radiation dosage.[124] In the Canadian childhood leukemia study, consumption of >2 alcoholic drinks weekly was not associated with a statistically significant increased ALL risk (adjusted OR = 0.88, 95% CI: 0.46–1.67, $n = 21$ cases/220 nondrinking controls, $P_{\text{trend}} = 0.229$).[122] An Australian study of 388 ALL case families and 1,396 control families reported no evidence of maternal alcohol use before or during pregnancy and increased ALL risks.[125] Compared with nondrinkers, the adjusted odds ratio for ALL in children from mothers drinking >2 days weekly was reduced (adjusted OR = 0.56, 95% CI: 0.37–0.86, $n = 33$ cases/112 controls), with evidence of a dose-response relationship between wine consumption and reduced ALL risks.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

In a French study of 472 ALL cases and 567 population-based controls, consumption of >1 glass of alcohol daily during pregnancy was associated with a statistically significant increase in ALL risk (OR = 2.8, 95% CI: 1.3–5.9, $n = 23$ cases/344 controls).[126] The odds ratio was not calculated for AML because there was an insufficient number of smokers among the 62 AML cases. Using never-drinkers as controls, the French ESTELLE case-control study reported a positive, statistically significant AML risk for maternal alcohol consumption of >2 alcoholic drinks weekly during pregnancy (OR = 2.8, 95% CI: 1.2–6.7, $n = 7$ cases/69 nondrinking controls, $P_{trend} = 0.02$), but not for ALL (OR = 0.7, 95% CI: 0.4–1.5, $n = 10$ cases/495 nondrinking controls, $P_{trend} = 0.38$).[123] A meta-analysis of 21 case-control studies reported a much stronger association between maternal alcohol consumption during pregnancy and AML than ALL.[127] No cohort studies were available. Comparing yes versus no alcohol consumption during pregnancy, based mostly on interviews and self-administered questionnaires, the meta-OR for AML was statistically significant (OR = 1.56, 95% CI: 1.13–2.15, $n = 9$ studies/731 cases, $I^2 = 52.5\%$, $P_{heterogeneity} = 0.032$); for ALL, the meta-OR was statistically nonsignificant (OR = 1.10, 95% CI: 0.93–1.29, $n = 11$ studies/5,198 cases, $I^2 = 66\%$, $P_{heterogeneity} = 0.001$). Heterogeneity was moderate between studies.

Obesity

Recent epidemiology studies suggest a modestly positive association between leukemia risks and obesity, but not with subjects overweight in the several years before diagnosis based on self-reported height and weight. In general, leukemia risks are higher in men than women and stronger for AML than other leukemia subtypes. In a meta-analysis of 16 primarily American and European prospective studies (20,813 incidence leukemia cases) comparing obese (BMI $\geq 30\,kg/m^2$) participants with normal-weight controls (BMI: 18.5–24.9 kg/m^2), the overall maximumly adjusted RR for leukemia in obese men and women was 1.26 (95% CI: 1.17–1.37, $p < 0.001$, $I^2 = 43\%$).[128] The RR for overall leukemia was statistically significant in obese men (RR = 1.40, 95% CI: 1.24–1.57, $p < 0.001$, $I^2 = 33\%$) as well as the four common leukemia subtypes. For women, the adjusted RR was statistically significant for overall leukemia (RR = 1.20, 95% CI: 1.07–1.35, $P = 0.002$, $I^2 = 29\%$), marginally significant for AML and CML, and nonsignificant for CLL and ALL. Meta-regression revealed a significant association for leukemia incidence per kg/m^2 in obese men ($p = <0.001$), but not obese women ($p = 0.11$). The adjusted RR for overweight men and women was not statistically significant for overall leukemia or any subtype. Meta-analysis results were not adjusted for all potential confounders (e.g., smoking, alcohol intake, diet). The biological mechanism linking leukemias to obesity remains unclear.

Tea

Few studies analyze the effects of tea or coffee consumption on leukemia risks; many of the studies are population-based, case-control studies that report mixed results. A meta-analysis of 95 myeloid leukemias and 279 population-based controls suggests high-intensity tea consumption reduces the frequency of myeloid leukemias.[129] Compared with no tea consumption, the adjusted meta-OR for myeloid neoplasms in the highest category of tea consumption was significantly reduced statistically (adjusted meta-OR = 0.4, 95% CI: 0.2–0.9, $n = 10$ cases, $P_{trend} = 0.017$). None of the other adjusted meta-ORs for tea or coffee consumption indicate a statistically significant reduction or dose-response relationship. The authors opined that the reduced meta-OR for high tea consumption and myeloid leukemia should be interpreted cautiously because of the small case numbers. In a meta-analysis of six case-control and one cohort studies from the United States and China, the overall leukemia risk in the highest tertile using the lowest tertile/non-tea drinkers as referents was significantly reduced (meta-RR = 0.57, 95% CI: 0.41–0.78, $n = 700$ cases, $P_{heterogeneity} = 0.11$, $I^2 = 40.5\%$); statistical analysis indicated the presence of moderate heterogeneity and evidence of publication bias ($P_{Egger's\ test} = 0.01$).[130] In the French ESTELLE study, the acute leukemia risk (ALL/AML) for mothers drinking tea during their pregnancy did not deviate significantly from the null (OR = 0.9, 95% CI: 0.8–1.1), with no evidence of a dose-response relationship compared with nondrinkers.[123]

Coffee

A meta-analysis of 12 case-control studies involving 3,649 cases and 5,705 controls reported positive, but statistically nonsignificant, associations for ever-maternal coffee drinking during pregnancy and acute childhood leukemia (OR = 1.14, 95% CI: 0.95–1.37, $n = 7$ studies, $I^2 = 53.7\%$, $P_{heterogeneity} = 0.044$); the risk for ALL was also nonsignificant (OR = 1.10, 95% CI: 0.99–1.22, $n = 8$ studies, $I^2 = 0.0\%$, $P_{heterogeneity} = 0.434$).[131] The estimate for AML was statistically significant (OR = 1.44, 95% 1.01–2.04, $n = 6$ studies, $I^2 = 39.8\%$, $P_{heterogeneity} = 0.140$). The analysis associated high

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

but not low-to-moderate maternal coffee consumption during pregnancy with childhood leukemia. Exploring exposure-response relationships by comparing high versus never/lowest coffee consumption, the risks were statistically significant for acute leukemia (OR = 1.57, 95% CI: 1.16–2.11, $n = 6$ studies, $I^2 = 55.2\%$, $P_{\text{heterogeneity}} = 0.048$) and ALL (OR = 1.43, 95% CI: 1.22–1.68, $n = 8$ studies, $I^2 = 0.0\%$, $P_{\text{heterogeneity}} = 0.464$), but statistically nonsignificant for AML (OR = 1.81, 95% CI: 0.93–3.53, $n = 6$ studies, $I^2 = 53.7\%$, $P_{\text{heterogeneity}} = 0.056$). Moderate heterogeneity occurred between studies suggesting limited control of confounding including the interaction of smoking and coffee.

In the French ESTELLE study, the association between ALL and maternal consumption of >2 cups of coffee daily during pregnancy was marginally significant (OR = 1.3, 95% CI: 1.0–1.8).[123] Similarly, analysis of pooled data from the Childhood Leukemia International Consortium suggested that high maternal coffee intake during pregnancy may increase childhood ALL risks.[132] The pooled OR for > 2 cups daily was 1.27 (95% CI: 1.09–1.43, $P_{\text{trend}} = 0.005$) using non-coffee drinkers as referents. Using multivariate unconditional logistic regression in an Italian study of 651 leukemia cases and 1,771 population-based controls, the lower leukemia risks in regular coffee users were not confirmed based on dietary questionnaires.[133] The odds ratio for myeloid leukemia in regular coffee consumers drinking >4 cups of coffee daily was 0.82 (95% CI: 0.50–1.3, $n = 28$ cases, $P_{\text{trend}} = 0.212$).

Medications

The IARC lists lindane and multiple chemotherapeutic and immunosuppressive agents as human carcinogens increasing leukemia risks, including busulfan, chlorambucil, chloramphenicol cyclophosphamide, cyclosporine, etoposide with cisplatin/bleomycin, melphalan, MOPP (vincristine-prednisone-nitrogen mustard-procarbazine mixture), semustine (methyl-CCNU), thiotepa, and treosulfan. Therapeutic agents associated with limited human evidence of increased leukemia risks include chloramphenicol agents, including bischloroethyl nitrosourea (BCNU), etoposide, mitoxantrone, nitrogen mustard, and teniposide.

Diseases

The IARC lists multiple infectious agents as human carcinogens that increase leukemia risks, including Epstein–Barr virus, *Helicobacter pylori*, hepatitis C virus, human immunodeficiency virus type 1 (HIV1), human T cell lymphotropic virus type 1, and human herpesvirus-8 (HHV-8, Kaposi sarcoma herpes virus) but only one (human T cell lymphotropic virus type 1) as a cause of adult T cell leukemia/lymphoma.

HISTOLOGY

Adult leukemia accounts for 90% of all leukemias with the remainder being childhood leukemias. These two leukemia classifications differ in several respects. The most common adult leukemia is CLL, whereas CLL does not usually occur in childhood.[134] Adults display a wider range of leukemia subtypes with a much higher incidence of CML, AML, and myelodysplastic/myeloproliferative syndromes; the incidence of B and T cell ALL is lower in adults than children. For childhood leukemia, ALL accounts for ~80% of the cases in children of <16 years of age, with AML representing 15–17%, CML 2%, and rare subtypes (e.g., CLL) accounting for the remainder.[106]

HOST SUSCEPTIBILITY

Somatic and germline mutations drive the development of hematological malignancies. All human cells inherit germline mutations that are shared with multiple family members, whereas somatic mutations occur only in specific cells that drive malignant transformation and acquisition of subsequent mutations.[135] The absence of characteristic features or a positive family history does not exclude the presence of germline mutations. Phenotypic expression of germline mutations is highly variable among affected family members as a result of variable penetrance that silences or attenuates expression of the germline mutations. Consequently, cancer predisposition syndromes present a variety of clinical features including hemolymphatic malignancies, myelodysplastic syndrome, bone marrow failure, and systemic symptoms. In a case series of 71 pediatric and young adult patients diagnosed with idiopathic bone marrow failure or myelodysplastic syndrome after standard genetic testing based on a clinical evaluation, eight had serious germline mutations in multiple genes (i.e., *DKC1*, *GATA2*, *LIG4*, *RUNX1*).[136]

Few childhood leukemias have underlying hereditary genetic abnormalities. About 2–3% of children with leukemia have recognized genetic conditions that predispose them to developing leukemia, primarily Down syndrome, as demonstrated in Table 59.3.

TABLE 59.3. Hemolymphatic neoplasms are commonly associated with cancer predisposition syndromes. Most of these syndromes have multiple gene mutations with only the predominate gene mutation listed when present. Formation of hematological neoplasm genes may occur somatically in hematopoietic cells or constitutionally in germline cells (e.g., *CEBPα*, *GATA2*, *RUNX1*, *TP53*, *RAS* genes). (Adapted from Furutani and Shimamura).[135]

Abbreviations: ALL = acute lymphoblastic leukemia; AML = acute myeloid leukemia; BMF = bone marrow failure; MDS = myelodysplastic syndrome.

CLINICAL FEATURES

Acquired genetic defects in early hematopoietic progenitors produce a much more rapid progression (i.e., 2–4 weeks) to bone marrow failure in untreated acute than chronic leukemias, with bone marrow failure in the former occurring in weeks to months. Clinical features result from bone marrow failure (lethargy/anemia, anorexia, bruising, bleeding, infection, fever related to leukemia) and organ infiltration (bone pain, pathological fractures, limping, hepatomegaly, splenomegaly, lymphadenopathy, headache, seizures). Hyperviscosity (dyspnea, confusion, impaired hearing/vision) or superior vena caval syndrome (stridor, cough, orthopnea) may complicate the course of leukemia. The differential diagnosis of leukemia includes bone marrow infiltration from other tumors (e.g., neuroblastoma) and aplastic anemia.

The occurrence of leukemia increases steadily with age in the major leukemia subgroups, with the exception of ALL; this leukemia peaks in early childhood before declining with age. Among atomic bomb survivors in the Life Span Study, the risk and dose-response of the major leukemia subgroups vary with age at exposure, temporal risk pattern, and gender. CML risk declines over time with a relationship to time of exposure, whereas adult AML risk rises with increasing attained age. As the incidence of leukemia increases with age, excess leukemia risks generally decline with attained age or time since exposure.[137] Excess incidence of radiation-induced leukemias begins ~2 years after radiation exposure, with peak excess in ~7–8 years. Radiation-associated excess non-CLL leukemia risks persisted in the Life Span Study cohort throughout the 55-year follow-up after the bombings, particularly for acute myeloid leukemia; however, the increased leukemia risk very significantly decreased after 20 years.[138] The benzene-induced leukemia risk also decreases with time since exposure ceased; leukemia risk is small 10–15 years after exposure ceases.[139] The AML dose-response relationship is nonlinear; other subgroups also do not display a linear dose response. Figure 59.1 compares the age-related incidences of AML, ALL, and CML based on Swedish

data; CLL is a lymphoid disease primarily of the elderly.

The cure rates for childhood leukemia have improved dramatically because of improved chemotherapy, better risk stratification, and improved supportive care. Prognosis depends on multiple factors including age, leukocyte count, circulating blasts, molecular mutations, cytogenetic abnormalities, metastatic (i.e., extramedullary) disease, stage, initial therapeutic response, and presence of secondary leukemia. While >80% of childhood ALL resolves with chemotherapy, successful responses to chemotherapy for adult ALL remain below 30%. The prognosis for childhood AML also remains poor and variable depending on multiple factors.[140]

ACUTE MYELOGENOUS LEUKEMIA (AML)

Although AML is the most common adult leukemia in Western countries representing ~25% of all leukemias, it is a relatively rare disease accounting for ~1.3% of annual US cancer cases.[141] The adult incidence varies slightly between races and genders.[4,106] Geographically, reported AML incidence is higher in Western countries (United States, Australia, Western Europe) than Asian countries and Asian/Pacific Islanders, typically with a slight male predominance. AML incidence is increasing, in part, due to the occurrence of more common risk factors including complications of previous hematological malignancy (e.g., myelodysplastic syndromes/myeloproliferative neoplasms) and previous cancer-related therapy from medications associated with AML (e.g., alkylating agents, topoisomerase II inhibitors, radiotherapy).

The two peaks in AML incidence occur in early childhood and later in adulthood; AML incidence peaks occur during the first two years of life and decreases afterward until slowly increasing in adolescence. In childhood, AML incidence is much less common (i.e., 5-fold) than ALL. The variation in childhood AML between racial/ethnic groups is relatively small. The possible exception is the slightly increased risk of the AML subtype, acute promyelocytic leukemia in Asian/Pacific Islanders and Hispanics compared with Caucasians and African Americans.[6] Substantial geographical differences in childhood AML rates exist between Western and less developed countries, at least partly due to differences in ascertainment methods between registries. Juvenile myelomonocytic leukemia is a myelodysplastic/myeloproliferative disorder subtype unique to children.

CARCINOGENESIS

AML is a genetically and molecularly complex disease with at least 11 distinct subgroups containing many recurrent mutations in many genes (e.g., core-binding factor, *BCR-ABL1*, *CEBPA*, *FLT3*, *KIT*, *KMT2A*, *NPM1*, *RUNX1*); consequently, no singular pathogenic model accounts for all AML tumors.[142] The most favored pathogenetic model involves a group of mutations in genes that activate signal transduction pathways (e.g., *FLT3*, *KIT*, *PTPN11*, *RAS*) resulting in proliferation and enhanced survival of hematopoietic cells and a second group of mutations in genes that later alter transcription factors inhibiting cell differentiation and apoptosis (e.g., *CEBPA*, *RUNX1*). Compared with most cancers, the number of recurrent mutations is relatively small. The vast majority of AML tumors contain at least two driver gene mutations (median = 3, range 2–9).[143,144] Additionally, individual tumors usually contain subclones with substantial mutational diversity resulting in a genetically unique neoplasm. Table 59.4 displays the diverse mutation spectrum of adult AML.[145] The most frequent mutations occur in signaling pathway components, tumor suppressors, epigenetic (histone) modifiers, and cohesin complex members.

Genetic

The critical initial pathogenic event in most AML tumors involves translocation or inversion events that produce chimeric fusion genes in hematopoietic stem and progenitor cells. The gain in stem cell-like self-renewal properties is sufficient to maintain malignant transformation and clonal expansion.[146] The Philadelphia chromosome occurs in <1% of *de novo* adult AML patients. In elderly patients, the genetic landscape of AML resembles secondary AML associated with myelodysplastic syndrome rather than AML in adult patients of <60 years of age.[147] Approximately 50–60% of AML patients have chromosomal abnormalities; these changes help predict prognosis and relapse.[148] Different AML subtypes express diverse miRNAs. A novel chimeric fusion gene involving the core-binding factor complex results from t(8;21) and inv (16) chromosomal aberrations; this abnormality disrupts normal hematopoiesis leading to core-binding factor acute myeloid leukemia (CBF-AML).

TABLE 59.4. Frequent mutations in adult (<60 years of age) acute myeloid leukemia (AML) based on analysis of cytogenetic and molecular features in large patient cohorts. These mutations reflect the genetic heterogeneity of AML involving multiple functional categories including signaling pathway components, tumor suppressors, cohesion complex members, transcription factors, epigenetic modifiers (DNA methylation, chromatin regulators, spliceosome complex components). The mutations in *FLT3* tyrosine kinase receptor gene increase cell proliferation through activation of signaling pathways (JAK-STAT, P13K-AKT, RAS-RAF), whereas myeloid transcription factor mutations (*RUNX* gene) impair hematopoietic differentiation. Mutations in the nucleophosmin gene (*NPM1*) disrupt multifunctional chemical signaling that controls the shuttling of proteins between the nucleus and cytoplasm, whereas mutations in the tumor suppressor gene (*TP53*) deregulate transcription and inhibit apoptosis. Deregulation of RNA processing results from mutations in the spliceosome-complex genes (*SRSF2*, *SF3B1*, *U2AF1*, *ZRSR2*), whereas mutations in the genes affecting epigenetic cell homeostasis include chromatin modification deregulation (ASXL1, EZH2) and impairment of DNA methylation (DNMT3A, IDH1/2, KMT2A-MLLT3 gene fusion, TET2). (Adapted from Grimwade et al.).[145]

Function	Genes Mutated	Expressed Protein	Frequency (%)
Activate signaling	*FLT3-ITD*	FMS-related tyrosine kinase 3-internal tandem duplication	27
	FLT3-TKD	FMS-related tyrosine 3-kinase domain	11

	MLL-PTD	MLLT11 transcription factor 7 cofactor-partial tandem duplications	5
	KMT2A	Lysine methyltransferase 2A	5
	PHF6	PHD finger protein 6	3
	BCOR	BCL6 corepressor	1
	EZH2	Enhancer of zeste 2 polycomb repressive complex 2 subunit	1
Splicing factors	*SF3B1*	Splicing factor 3b subunit 1	3
	SRSF2	Serine and arginine-rich splicing factor 2	2
	U2AF1	U2 small nuclear RNA auxiliary factor 1	2

In AML, the genes most commonly involved in signaling pathway mutations include *FLT3-ITD*/*TKD*, *NRAS*/*KRAS*, *PTPN11*, and *KIT*; however, ~40% of AML tumors lack gene mutations encoding classical signaling pathway components.[149] The FLT3 protein is a receptor tyrosine kinase that transmits signals from the cell surface into the cell (signal transduction). Subsequently, this protein activates a series of intracellular processes involved with cell proliferation and survival, particularly in hematopoietic progenitor cells.[150] *NRAS* and *KRAS* genes belong to the *Ras* family of proto-oncogenes. The *NRAS* proto-oncogene

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

expresses the GTPase protein, N-RAS, primarily involved with cell division, whereas the K-RAS protein is a GTPase that is part of the RAS/MAPK signaling pathway involved with cell division, differentiation, and apoptosis. Activation of proto-oncogenes enhances cell proliferation and tumor formation. The *PTPN11* (protein tyrosine phosphatase, non-receptor type 11) gene encodes the SHP-2 protein. This protein helps regulate the RAS/MAPK pathway and several other important cellular processes (e.g., cell differentiation, migration, apoptosis) during the embryonic development of blood cells and bones. The *KIT* (*KIT* proto-oncogene receptor tyrosine kinase) gene expresses a receptor tyrosine kinase protein involved with transduction of extracellular signals; stem cell factor activates this proto-oncogene resulting in the phosphorylation and activation of multiple intracellular signaling pathways regulating cell proliferation, survival, and migration in germ cells and hematopoietic stem cells.

The most common tumor suppressor mutations in AML tumors involve *NPM1* and *TP53* genes. The *NPM1* gene encodes the intranucleolar protein, nucleophosmin, which protects the tumor suppressor *ARF* gene from degradation.[151] Nucleophosmin travels between the nucleolus and cytoplasm while participating in multiple cellular processes (e.g., cell-cycle progression, DNA replication, protein formation). The tumor protein p53 is a tumor suppressor (i.e., guardian of the genome) essential for regulation of cell division and prevention of tumor formation; this protein plays a critical role in determining whether damaged DNA will undergo repair or will self-destruct (apoptosis).

Common mutated myeloid transcription factor mutations that involve AML include *RUNX1* and *CEBPA* genes.[152] The RUNX1 protein is a transcription factor that interacts with core-binding factor β to form a core-binding factor complex. The complex helps control the proliferation and differentiation of hematopoietic stem cells.[153] The *CEBPA* (CCAAT enhancer-binding protein alpha) gene encodes the transcription factor and tumor suppressor CCAAT enhancer-binding protein α that binds DNA regions controlling the expression of specific genes involved with blood cell differentiation.

The chromosome cohesion complex, cohesin, forms a large proteinaceous ring that traps sister chromatids during prophase and prometaphase. In anaphase, the complex dissociates from chromatin, resulting in segregation of sister chromatids. *STAG1/2* (stromal antigen 1/2) gene expresses intranuclear members of the SCC3 family of proteins that form a component of the cohesin complex. SMC1 and SMC3 proteins produced by these genes also help regulate chromosomal structure and organization as components of the cohesin complex.[154] The latter proteins stabilize the chromosomes by repairing damaged DNA and activating genes essential for normal development. The protein expressed by the *RAD21* gene is also part of the cohesin complex that holds the sister chromatids together during early cell division. Mutations of these genes disrupt chromosomal DNA causing translocations and deletions.

Epigenetic

Some AML tumors contain hematopoietic stem and progenitor cells with epigenetic-modifying gene mutations and normal multipotent differentiation characteristics. Clonal evolution studies suggest this epigenetic dysregulation in preleukemic hematopoietic stem cells occurs early in AML tumorigenesis prior to malignant transformation. Epigenetic modifiers in AML primarily involve DNA methylation with gene silencing (e.g., *DNMT3A*, *IDH1/2*, *TET2*, *WTI*) and chromatin regulation (e.g., *ASX1*); mutations of these genes are not unique to AML.[155,156] Mutations in *DNMT3A*, *NPM1*, and *FLT3-ITD* often co-segregate, suggesting interaction in developing AML. Although these mutations precede overt leukemia, some preleukemic mutations in genes (e.g., *DNMT3A*, *TET2*, *ASXL1*) are biomarkers of a poor prognosis.[145] DNA methyltransferase 3α promotes differentiation of stem cells into mature blood cell types. The role of *TET2* gene is not well defined; however, the enzyme produced by *TET2* probably helps regulate the initial step in DNA demethylation.[145] Hypothesized effects include tumor suppression and differentiation of hematopoietic cells into mature blood cells. *IDH1* and *IDH2* genes encode the enzymes, isocitrate dehydrogenase 1 and 2; these enzymes catalyze the cellular process that produces energy from fat-forming NADPH and protect the cell from reactive oxygen species. The WT1 protein is a transcription factor that helps regulate differentiation and apoptosis.

In AML neoplasms, the most frequent mutations involved with chromatin regulation include *ASXL12*, *MLL-PTD*, *KMT2A*, *PHF6*, *BCOR*, and *EZH2* genes.[157] The *ASXL1* (ASXL transcriptional regulator 1) gene encodes a transcriptional regulator involved with chromatin remodeling and probably gene silencing via DNA methylation. The *MLL-PTD* (mixed lineage leukemia-partial tandem duplications) gene helps regulate development in all leukemic cell lines. Also known as the *KMT2A* (lysine methyltransferase 2A) gene,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

this gene encodes a transcriptional coactivator (histone methyltransferase) essential in regulating gene expression during early development and hematopoiesis. The *BCOR* (BCL6 corepressor) gene encodes the BCL6 corepressor protein that interacts with the DNA-binding protein produced from the *BCL6* gene. The *BCL6* gene enhances the function and survival of certain immune system cells. The *EZH2* (enhancer of zeste 2 polycomb repressive complex 2 subunit) gene produces a histone methyltransferase that binds to DNA and modifies chromosome shape; the resulting changes can suppress gene activity during normal development.

Spliceosomes are relatively large RNA–protein complexes that remove noncoding segments (introns) from premessenger RNAs; this process is critical to the accurate reproduction of mRNA and subsequent protein translation by the ribosome. Mutations of several genes occur in AML tumors that change the spliceosomes including *SF3B1*, *SRSF2*, and *U2AF1* genes. These mutations alter the spliceosomes by modifying subunit 1 of the splicing factor 3b protein complex (SF3B1) or pre-mRNA splicing factors (SRSF2); mutations of *U2AF1* (U2 small nuclear RNA auxiliary factor 1) gene disrupt the interaction between *U2AF2* and the enhancer complex. SF3B1 mutations correlate to the presence of ring sideroblasts, whereas SRSF2 mutations are also prominent in chronic myelomonocytic leukemia. These splicing factor gene mutations are part of a hallmark panel of mutations pathognomonic of AML arising from myelodysplasia syndrome.[147]

MiRNAs control the expression of numerous genes involved in normal cell processes, including proliferation, differentiation, and apoptosis. In AML, the failure of hematopoietic stem cells and myeloid precursor cells to undergo terminal differentiation causes tumorigenesis. These small, noncoding RNAs interact with multiple genes rather than a single gene target to determine their effect on gene expression; multiple miRNAs may be upregulated or downregulated depending on the specific genomics of the AML subtype.[158] MiRNA-expression profiling can distinguish myeloid leukemia from lymphoid leukemia as well as various AML subtypes using the upregulation and downregulation of specific miRNAs.[159] Specific miRNAs involved with the progression of AML include miRNA-29, miRNA-125, miRNA-142, miRNA-146, and miRNA-155, with the presence of miRNA-20a, miRNA-25, miRNA-191, miRNA-199a, and miRNA-199b adversely affecting overall survival.[160]

EXPOSURE

Recognized risk factors for adult AML include age, gender, ionizing radiation exposure, certain prior hematological disorders, some chemotherapy drugs, germline genetic abnormalities, benzene, and cigarette smoking; however, these risk factors are relatively modest accounting for a small portion of AML cases.[161] Most AML cases are sporadic (i.e., *de novo*). In a large, population-based study of 3,363 AML patients in the Swedish Acute Leukemia Registry, 12% had previous myelodysplasia, 8% had therapy-related disease (chemotherapy, radiotherapy), and 6% had previous myeloproliferative disease.[162]

Few risk factors have been identified for childhood AML as a result of small sample sizes and the frequent inclusion of childhood AML with the more common ALL. *In utero* ionizing radiation is the only well-established *de novo* childhood AML risk factor other than advanced maternal age. In a US case-control study using pooled population-based data, AML risks increased slightly with advancing maternal age (OR = 1.08, 95% CI: 1.01–1.16, $n = 804$ cases).[163] Although paternal age is not typically associated with AML risks, the estimated odds ratio for AML became statistically nonsignificant after adjustment for paternal age (OR = 1.06, 95% CI: 0.96–1.17, $n = 722$ cases).

Ionizing Radiation

Adults

AML is a heterogeneous disease with multiple subtypes and variations in risk factors. Increased AML incidence occurred in groups receiving high-ionizing radiation doses (e.g., Japanese atomic bomb survivors,[164] medical radiation for ankylosing spondylitis, and Hodgkin disease[33]). Dose-related excess AML developed in these cohorts with the relative AML risk decreasing with increased time since radiation exposure. A California study of 412 matched case-control pairs reported no statistically significant association between *diagnostic* X-rays and AML or AML subtypes based on interviews and medical records using the older French–American–British classification of AML subtypes.[165] In a risk analysis of total estimated bone marrow dose of >2,000 mGy from diagnostic imaging procedures in the 2–10 years preceding diagnosis, the AML odds ratio was 1.6 (95% CI: 0.8–3.2, $n = 23$ cases/13 controls, $P_{trend} = 0.28$) using medical records and 2.5 (95% CI: 1.0–6.0, $n = 18$ cases/8 controls, $P_{trend} = 0.70$) using interviews.

Children

In utero ionizing radiation is a recognized cause of childhood AML based on older studies of mothers receiving relatively high radiation doses from diagnostic abdominal X-rays during pregnancy. Case-control studies of these offspring suggest relative risks in the range of 1.3–1.5 for studies published before 1980.[166] The Oxford Survey of Childhood Cancers identified 866 childhood deaths during 1953–1967 from myeloid leukemia (AML/CML) in children of ≤14 years of age receiving *in utero* exposure. Compared with healthy age/sex/residence-matched controls, the RR was 1.47 (95% CI: 1.20–1.81, $n = 120$ cases/80 controls).[167] In a US study of 116 AML cases aged ≤14 years diagnosed from 1995–2008 and age/sex/race-matched controls, *in utero* diagnostic X-rays were not associated with increased childhood AML risks (OR = 0.85, 95% CI: 0.26–2.78, $n = 111$ cases).[168]

A pooled analysis of nine historical cohort studies supported increased AML risks in children receiving postnatal cumulative bone marrow doses of ≤100 mSv; the dose responses remained significant for doses of ≤50 mSv.[169] The fitted RR for acute myeloid leukemia at a cumulative bone marrow dose of 100 mSv was 2.56 (95% CI: 1.09–5.06, $n = 79$ cases, $P_{\text{trend}} = 0.033$). Relative risks for CML at 100 mSv were not elevated (RR = 0.36, 95% CI: 0.00–2.36, $n = 36$ cases, $P_{\text{trend}} = 0.394$). In general, little epidemiological evidence supports increased childhood AML risks from preconception maternal X-rays. Additionally, several case-control studies have not reported elevated AML risks for children receiving postnatal diagnostic X-rays. A Chinese population/interview-based case-control study did not report a statistically significant increased ANLL (primarily AML) incidence in children receiving 1–5 postnatal X-rays (OR = 0.9, 95% CI: 0.5–1.5, $n = 25$ cases/68 controls, $P_{\text{trend}} = 0.81$).[170] A US case-control study of 116 AML cases aged ≤14 years also did not detect an association between self-reported child X-rays and AML risks (OR = 1.05, 95% CI: 0.90–1.22).[168]

Extremely Low Frequency Electromagnetic Fields

Analysis of data from the Los Angeles County Cancer Surveillance Program on 412 adult AML cases using interview information and age/race/gender-matched population controls did not support an association between AML risks and exposure to electric blankets, electrically heated waterbeds, or occupations associated with high potential exposures to electromagnetic fields.[171] The study reported no association for work near high-voltage equipment (OR = 1.0, 95% CI: 0.6–1.6, $n = 42$ cases/42 controls) or large electrical motors (OR = 1.1, 95% CI: 0.7–1.7, $n = 50$ cases/46 controls). The study also reported similar results for the highest categories of electric waterbed (6–23 years, $n = 79$ cases/83 controls) and electric blanket (10–45 years, $n = 14$ cases/21 controls) use when compared with nonusers. Even though electric blankets emit relatively large electromagnetic fields, a population-based case-control study did not detect an increased AML risk in adults aged 20–69 years regularly using electric blankets when compared with nonusers (OR = 0.9, 95% CI: 0.5–1.6, $n = 40$ cases/43 controls).[172]

Chemicals

Benzene

There is general scientific agreement that exposure to high benzene concentrations causes AML and related diseases; however, controversy remains regarding the association of low benzene exposures (<30–40 ppm-years) and leukemias, particularly with other hematological neoplasms (lymphomas, multiple myeloma). AML includes most leukemias previously classified as acute nonlymphocytic leukemia (ANLL). Both case-control[173] and retrospective cohort[174] studies of petroleum and rubber workers demonstrate a 5–10-fold increase in AML risks following exposure to high benzene concentrations (usually >100–400 ppm-years). Most studies of workers exposed to low benzene concentrations report null findings or slightly elevated rates of ANLL or all leukemias.[175,176,177,178] In a meta-analysis of 1 case-control and 8 cohort studies using fixed effects models, the summary-effect estimate for AML in benzene-exposed workers was significantly elevated at 1.38 (95% CI: 1.15–1.64, $I^2 = 51.4\%$, $P_{\text{heterogeneity}} = 0.036$) with moderate heterogeneity.[179] Dose-response analysis of cumulative benzene exposure indicates the summary-effect estimate for high dose exposure (≥100 ppm-years) was positive and statistically significant at 3.20 (95% CI: 1.09–9.45, $n = 12$ cases, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.624$). The estimate for low cumulative benzene exposure (>0–<40 ppm-years) was not statistically significant (summary-effect estimate = 1.94, 95% CI: 0.95–3.95, $n = 18$ cases, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.737$).

Several large studies of petrochemical workers exposed to low benzene concentrations did not detect an elevated leukemia risk;[173,180] however, the lack of quantitative exposure data raises methodological

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. questions regarding potential misclassification of the exposed cohort.

A large study of Chinese workers exposed to relatively low benzene concentrations (<10 ppm benzene) reported no statistically significant increase in AML with increasing exposure to benzene.[181]

Non-benzene Solvents

Few studies investigate the association between solvents other than benzene and AML risks; existing data are inconsistent. A Texas study enrolled 638 *de novo* adult AML cases (87% participation rate) and 636 controls from random digit dialing.[182] Occupational solvent exposure was estimated using a job-exposure matrix developed by the National Cancer Institute for each job held for at least 1 year using information from patient interviews (11% proxy interviews). The solvent category contained benzene (a known carcinogen) as well as gasoline and other organic solvents as measures of solvent exposure because of the low prevalence of workers with AML and individual chemical exposures. Compared with no solvent exposure, medium/high solvent exposure was associated with statistically significant positive odds ratios for women (OR = 4.18, 95% CI: 2.28–7.64, $n = 50$ cases, $P_{trend} = 0.013$) and men (OR = 4.26, 95% CI: 3.00–6.04, $n = 168$, $P_{trend} = <0.0001$). The inclusion of benzene confounds the estimated odds ratios. A nested case-control design using data from the Nordic Occupational Cancer Study identified 15,332 incident AML cases and 76,660 age/sex/country-matched controls.[183] Cases and controls could have a previous history of any cancer other than AML. Individual solvent exposures were estimated by a job-exposure matrix designed for the study; the solvents included aliphatic and alicyclic hydrocarbon solvents, aromatic hydrocarbon solvents, benzene, chlorinated hydrocarbon solvents, methylene chloride, perchloroethylene, toluene, 1,1,1-trichloroethane, trichloroethylene, and other organic solvents. All of the hazard ratios for individual solvents were statistically nonsignificant with P_{trend} ranging from 0.13–0.58 consistent with the lack of evidence associating trichloroethylene with myeloid leukemias.[184]

Pesticides and Other Agricultural Exposures

Adults

Few data associate pesticide use with adult AML. A Minnesota population-based study investigated chemical exposures and AML risks using data from the Minnesota Cancer Surveillance System with controls identified through driver licenses (participation rate = 64%).[185] The study reported no association between pesticide classes and AML. Comparing any versus no occupational pesticide exposure, the adjusted OR for AML was inverse, but statistically nonsignificant (aOR = 0.89, 95% CI: 0.64–1.24, $n = 63$ cases); for the comparison of >10 years of occupational pesticide exposure with no pesticide exposure, the adjusted OR was also inverse, but statistically nonsignificant (aOR = 0.87, 95% CI: 0.51–1.47, $n = 20$ cases, $P_{trend} = 0.78$). An Italian study with limited power reported a statistically significant AML risk in female farmers (OR = 3.4, 95% CI: 1.3–8.9) and women exposed to pesticides (OR = 4.4, 95% CI: 1.7–11.5); however, the study detected no elevated AML risks in male farmers.[186]

Children

Several meta-analyses suggest an association between maternal, but not paternal occupational pesticide exposure and childhood AML risks in offspring;[187,188] however, low-to-moderate quality epidemiological evidence, the lack of accurate exposure and dose-response data, heterogeneity in structure/mechanisms of action (e.g., fungicide, insecticide, herbicide), small case numbers, potential recall/selection biases, and misclassification limit definitive conclusions about causation. In a meta-analysis of five case-control studies from the Childhood Leukemia International Consortium on AML risks in offspring of mothers with occupational pesticide exposures during pregnancy, the summary OR for childhood AML was 2.69 (95% CI: 1.49–4.86, $I^2 = 0\%$, $n = 895$ cases/5,428 controls).[189] Only studies containing at least some cases with high likelihood of pesticide exposures (category 1) during pregnancy were included in the meta-analysis. Using unconditional logistic regression to estimate pooled odds ratios from data in 10 case-control studies, the adjusted pooled OR for childhood AML comparing category 1 with category 4 (no or minimal likelihood of pesticide exposure during pregnancy) as the control was 1.94 (95% CI: 1.19–3.18, $n = 1{,}329$ cases/12,141 controls). When exposure assessment was based only on coded job titles, the adjusted summary OR for childhood AML was positive, but no longer statistically significant (OR = 1.63, 95% CI: 0.90–2.98, $n = 760$ cases/10,212 controls). Paternal occupational pesticide exposure around the time of conception was not associated with childhood AML.

As reported in the previous meta-analysis, the results of a meta-analysis of 22 case-control studies after stratification were consistent with the lack of an association between paternal pesticide exposure and childhood AML.[26] The meta-rate ratio for childhood acute nonlymphocytic leukemia (ANLL, primarily AML) in fathers with occupational pesticide exposure was 0.73 (95% CI: 0.19–2.76, $n = 2$ studies, $I^2 = 0\%$).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The meta-rate ratio for ANLL in offspring of women with occupational pesticide exposure was statistically significant (mRR = 2.68, 95% CI: 1.06–6.78, $n = 2$, $I^2 = 0\%$). The limited statistical power of these two studies resulted in imprecise estimates. The job title of farming/agriculture for men or women was not associated with elevated leukemia risks.

The relationship between residential pesticide use during pregnancy and childhood AML is inconsistent, based almost exclusively on unvalidated self-reports in case-control study designs with very limited data on the timing, intensity, type, class, or specific pesticide involved. A systematic review and meta-analysis of case-control studies examining residential pesticide exposures during pregnancy and childhood leukemia identified three case-control studies that reported data on AML incidence with and without unspecified residential pesticide exposure.[27] The summary OR was positive, but statistically nonsignificant (OR = 1.44, 95% CI: 0.81–2.59, $I^2 = 80\%$) with substantial heterogeneity. Limiting pesticide exposures to insecticides only, the summary OR was statistically significant (OR = 1.85, 95% CI: 1.29–2.64, $n = 2$ studies, $I^2 = 0$).

Lifestyle

Smoking

Adults

Although tobacco smoking is the strongest lifestyle factor associated with adult AML consistent with tobacco smoke containing multiple genotoxic constituents including benzene,[105] the association with smoking is relatively modest and mixed. In a prospective cohort study of 330,000 Swedish construction workers, the incidence rate ratio of AML in current smokers was 1.5 (95% CI: 1.06–2.11) compared with nonsmokers.[112] The smoking status was established by self-administered questionnaire and face-to-face interviews with a nurse. In a California population-based study of 412 AML cases (57% participation rate) and 412 age/gender-matched matched controls, the odds ratio for AML comparing ever-smokers with never-smokers was not statistically significant (OR = 1.2, 95% CI: 0.9–1.6, $n = 250$ cases/232 controls).[190] For cases aged 60–75 years, the OR was marginally significant (OR = 1.6; 95% CI: 1.0–2.6, $n = 120$ cases). AML is a heterogeneous disease with distinct histological subtypes that have undergone several reclassifications since publication of this study; however, this study suggests some differences in the effect of smoking on AML subtypes based on older French-American-British AML classifications. A Canadian population-based study of 307 AML cases and 5,039 controls (63% participation rate) reported a statistically significant positive association comparing AML risks in never- and current-smokers (adjusted OR = 1.4, 95% CI: 1.1–1.8, $n = 83$ cases/1130 controls, $P_{trend} = 0.03$); the results suggest a dose-response relationship in heavy smokers with >20 pack/year smoking history (adjusted OR = 1.5, 95% CI: 1.1–2.0, $n = 88$ cases/1,178 controls, $P_{trend} = 0.003$).[114] Odds ratios were adjusted for occupational benzene/ionizing radiation exposures and 10-year age groups.

In the US NIH-AARP Diet and Health Study using multivariate Cox models and never-smokers as controls, the hazard ratios were significantly elevated for former smokers of >1 pack/day (HR = 1.79, 95% CI: 1.32–2.42, $n = 97$ cases), current smokers of ≤1 pack daily (HR = 2.42, 95% CI: 1.63–3.57, $n = 37$ cases), and current smokers using >1 pack daily (HR = 2.29, 95% CI: 1.38–3.79, $n = 19$ cases) based on questionnaires. The P_{trend} was 0.09. The OR for AML comparing never- and ever-smokers in a Chinese hospital-based case-control study was marginally elevated (OR = 1.28, 95% CI: 1.00–1.63, $n = 227$ cases/508 controls); the OR for men was statistically significant (OR = 1.36, 95% CI: 1.04–1.77).[191] Smoking duration in years was marginally positive ($P_{trend} = 0.05$), but not smoking intensity in pack-years ($P_{trend} = 0.08$). The results for passive smoking were statistically nonsignificant (OR = 1.08, 95% CI: 0.83–1.41, $n = 19$ cases/209 controls).

Children

Epidemiological evidence associating childhood AML with tobacco smoke is weaker for passive than active smoking. Overall, most studies report no association between childhood AML risks and maternal smoking during pregnancy, whereas the results for paternal smoking are mixed. In a meta-analysis of 14 case-control and 1 cohort study comparing any and no maternal smoking during pregnancy using fixed effects models, the summary AML OR was null (summary OR = 0.99, 95% CI: 0.90–1.09, $I^2 = 28.6\%$, $P_{heterogeneity} = 0.14$) with mild heterogeneity.[192] All studies were North American or European. The only cohort study enrolled 1,440,542 Swedish children and identified 48 incident AML cases.[193] Comparing any smoking with no smoking during pregnancy based on a standardized questionnaire collected by a nurse-midwife, the adjusted hazard ratio was positive, but statistically nonsignificant (aHR = 1.41, 95% CI: 0.74–2.67, $n = 15$ cases). The aHR was 0.91 (95% CI: 0.38–2.21) for women smoking 1–9 cigarettes daily during early pregnancy and 2.28 (95% CI: 1.05–4.94) for women smoking ≥10 cigarettes daily, with a statistically nonsignificant trend ($P_{trend} = 0.084$).

TABLE 59.5. Acute myeloid leukemia (AML) risks associated with intensity and the time of paternal and maternal smoking surrounding the child's birth using nonsmokers as referents and pooled data from the Childhood Leukemia International Consortium. Moderate smokers were defined by 1–15 cigarettes daily, whereas ≥16 cigarettes daily defined heavy smoking. The odds ratios were adjusted for age, sex, ethnicity, parental education, and study center. (Adapted from Metayer et al.).[194]

Abbreviation: CI = confidence interval.

Paternal smoking was not associated with an increased childhood AML risk in this meta-analysis; however, a pooled analysis of data from the Childhood Leukemia International Consortium supported a statistically significant and modest association between heavy (≥16 cigarettes daily), but not moderate (1–15 cigarettes daily) paternal smoking and childhood AML using nonsmoking fathers as referents.[194] The vulnerable exposure time period was difficult to determine; the adjusted OR was positive and statistically significant for heavy smoking fathers during the prenatal, preconception, pregnancy time periods, but not during the postnatal time period, as displayed in Table 59.5. Overall, pooled results indicated maternal smoking was not associated with increased childhood AML risks. The meta-analysis of nine case-control studies in this study using random and fixed effects models demonstrated no significant association with childhood AML comparing self-reported, ever-smoking, and nonsmoking mothers (meta-OR = 1.02, 95% CI: 0.88–1.18, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.468$).

The French nationwide, population-based (ESTELLE) study of 100 childhood AML cases and age/sex-matched controls reported no association between self-reported maternal smoking during pregnancy and childhood AML comparing ever-smokers with never-smokers with no evidence of a dose-response relationship (summary OR = 0.9, 95% CI: 0.5–1.5, $n = 51$ ever-smokers/48 never-smokers, $P_{\text{trend}} = 0.83$).[123] The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

association between self-reported paternal smoking during preconception and childhood AML comparing ever-smokers with nonsmokers was marginally significant (summary OR = 1.5, 95% CI: 1.0–2.3, $n = 585$ ever-smokers/806 never-smokers) with a positive dose-response ($P_{trend} = 0.03$).

Alcohol

Adults

Little epidemiological evidence supports an association between alcohol consumption and adult AML risks. The California case-control study on lifetime alcohol consumption in 164 pairs matched for smoking, sex, age, and ethnicity did not detect an elevated adult AML risk for lifetime consumption of >1 alcoholic drink/day (OR = 0.8, 95% CI: 0.4–1.6, $n = 6$ cases/4 controls, $P_{linear\ trend} = 0.20$).[195] A Chinese hospital-based study of 722 confirmed AML cases and 1,444 age/gender-matched patient controls suggests an association between any alcohol consumption and adult AML risks (OR = 1.53, 95% CI: 1.17–2.01) based on interviews, particularly for wine.[191] Multiple comparisons, potential for recall bias, and comparability of patients to the general population limit definitive conclusions regarding causation.

Children

Most case-control studies suggest a positive association between maternal alcohol consumption during pregnancy and childhood AML; in a meta-analysis of 39 case-control studies, the summary OR was elevated significantly for AML risks in offspring of women consuming moderate (OR = 1.64, 95% CI: 1.23–2.17) and high (OR = 2.36, 95% CI: 1.60–3.49) alcohol doses during pregnancy.[196] In a meta-analysis of eight case-control studies comparing women ever consuming alcohol during pregnancy with abstinent women, the childhood AML risk was elevated with moderately high heterogeneity (summary OR = 1.56, 95% CI: 1.13–2.15, $P_{random\ effects\ model} = 0.007$, $I^2 = 52.5\%$, $P_{heterogeneity} = 0.032$).[127] The AML risk was substantially higher in children aged 0–4 years (summary OR = 2.68, 95% CI: 1.85–3.89, $n = 5$ studies, $P_{random\ effects\ model} = 0.001$, $I^2 = 0.1\%$, $P_{heterogeneity} = 0.761$). Wine, but not spirits or beer, was associated with increased childhood AML risk (summary OR = 1.67, 95% CI: 1.21–2.32, $n = 4$ studies, $P_{heterogeneity} = 0.870$). Insufficient published data were available to calculate dose-response relationships.

The nationwide French ESTELLE study identified 100 childhood AML cases, 348 ever-maternal alcohol use during pregnancy, and 1,069 population-based controls.[123] Comparing ever-drinkers during pregnancy with never-drinkers, the summary odds ratio was positive, but statistically nonsignificant (OR = 1.3, 95% CI: 0.8–2.0). Dividing alcohol consumption during pregnancy into low (<1 drink/week), moderate (1–2 drinks/week), and high (>2 drinks/week) categories, the estimated childhood AML risk for the highest tertile was statistically elevated (OR = 2.8, 95% CI: 1.2–6.7, $n = 7$ cases, $P_{trend} = 0.02$) compared with controls; however, the estimate was imprecise from small case numbers, and alcohol consumption categories were lower than most studies. The study did not report statistically significant differences between childhood AML risks and beverage classes (wine, beer, beverages). Paternal alcohol consumption during preconception is not associated with elevated childhood AML risks in offspring.[196]

Caffeinated Beverages

Data are limited on any association between caffeinated beverages and AML risks. Some case-control studies report modestly positive, but mostly statistically nonsignificant childhood AML risks in offspring of mothers who consumed high amounts of coffee during pregnancy. An exception was high coffee use (>2 cups/day) based on self-reported questionnaires by mothers recruited in the French ESCALE population-based case-control study (adjusted OR = 1.5, 95% CI: 1.1–2.0, $P_{trend} = 0.0027$).[197] In another French population-based case-control study, self-reported maternal coffee consumption during pregnancy exceeding three cups daily was associated with a positive, but statistically nonsignificant adjusted odds ratio for childhood AML in offspring (aOR = 1.4, 95% CI: 0.5–4.4, $n = 5$ cases) compared with nondrinkers.[126] The French ESTELLE population-based case-control study reported a statistically nonsignificant AML risk *reduction* in offspring (aOR = 0.5, 95% CI: 0.2–1.1, $n = 8$ cases) of mothers drinking >2 cups of coffee during pregnancy using mothers classified as never/occasional coffee users.[123] In a meta-analysis of seven case-control studies comparing the highest-level with non/lowest maternal coffee drinkers during pregnancy, the estimated childhood AML risk in offspring was significantly elevated (summary OR = 1.58, 95% CI: 1.20–2.08, $n = 4$ studies, $I^2 = 0\%$).[198] Dose-response analysis estimated the OR for childhood AML risks in offspring of mothers drinking coffee during pregnancy ranged from 1.15 (95% CI: 0.98–1.34) for 1–2 cups daily to 1.65 (95% CI: 1.26–2.16) for 10 cups daily.

In a meta-analysis of six case-control studies comparing childhood AML risks in offspring, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

summary odds ratio was statistically significant for mothers ever drinking coffee during pregnancy using never-drinkers as referents (summary OR = 1.44, 95% CI: 1.01–2.04, $I^2 = 39.8\%$, $P_{\text{heterogeneity}} = 0.14$) with some heterogeneity.[131] Comparing high versus never/lowest coffee consumption categories, the summary OR was positive, but statistically nonsignificant (OR = 1.81, 95% CI: 0.93–3.53, $I^2 = 53.7\%$, $P_{\text{heterogeneity}} = 0.056$) with moderate heterogeneity. The association between maternal consumption of other caffeinated beverages during pregnancy and childhood AML is much weaker. Maternal tea consumption during pregnancy was not associated with increased childhood AML risks in the latter meta-analysis.

The Japan Public Health/Center-based Prospective Study identified 85 AML and 70 myelodysplastic syndrome cases among 95,807 Japanese participants followed for a mean of 18.3 years.[199] No statistically significant difference was detected by comparing the lowest and highest consumption categories using Cox proportional hazard models with adjustment for potential confounders. For the highest coffee consumption category (≥1 cup daily), the adjusted HR for AML was 0.95 (95% CI: 0.34–1.66, $n = 27$ cases, $P_{\text{trend}} = 0.796$) and 1.20 (95% CI: 0.62–2.32, $n = 28$, $P_{\text{trend}} = 0.449$) for the highest green tea consumption category (≥5 cups daily). The study reported a statistically significant inverse association between coffee and myelodysplastic syndrome (MDS) risks for men consuming ≥1 cup daily (aHR = 0.47, 95% CI: 0.22–0.99, $n = 13$, $P_{\text{trend}} = 0.049$), but not for women; green tea consumption did not alter MDS risks.

Diet

Limited data on maternal diet and childhood leukemia suggest diet is not an important risk factor for childhood AML; however, AML is a heterogeneous disease with multiple subtypes that may differ in risk factors. Approximately 75% of infants with leukemia have a rearrangement of the *MLL* gene at chromosome 11q23, particularly in children treated for secondary leukemias following therapy with the DNA topoisomerase II inhibitor, epipodophyllotoxin.[200] Dietary sources of DNA topoisomerase II inhibitors include beans, flavonoids (e.g., quercetin), some fruits and vegetables, soy (e.g., genistein), and catechins (coffee, green/black tea, cocoa, wine). In a case-control study of 240 incident acute leukemia cases in infants of ≤1-year-old and 255 random controls, mothers of these children completed a food frequency questionnaire. Comparison of the highest and lowest (reference) quartiles of the DNA topoisomerase II inhibitor index demonstrated no overall elevated risk of acute leukemia, or for AML-MLL$^+$ or AML-MLL− subtypes, whereas the adjusted AML-MLL+ subgroup risk was increased, but statistically nonsignificant and imprecise (aOR = 3.2, 95% CI: 0.9–11.9, $n = 9$ cases, $P_{\text{trend}} = 0.10$).[201]

Obesity

Some recent studies suggest adult obesity increases AML risk more than other common leukemia subtypes; however, the findings are mixed. In a meta-analysis of 16 primarily North American and European prospective studies, the maximumly adjusted RR for overall leukemia in obese participants was positive for AML (RR = 1.53, 95% CI: 1.26–1.85, $p = <0.001$, $I^2 = 50\%$) with moderate heterogeneity.[128] The RR was also statistically significant for obese men (RR = 1.30–2.07, $p = <0.001$, $I^2 = 55\%$), but marginally significant in obese women (RR = 1.48, 95% CI: 1.00–2.20, $p = 0.05$, $I^2 = 0\%$). There was little support for an association between overweight participants and increased AML risks. In a Minnesota study of 420 AML cases, 265 myelodysplastic syndromes (MDS), and 1,388 age-matched controls (64% participation rate) using self-reported height and weight, the increased AML risk for obese participants (BMI = 30–34.9 kg/m^2) compared with normal weight participants (BMI = 18.5–24.9 kg/m^2) 2 years before diagnosis was statistically significant for men (OR = 2.24, 95% CI: 1.40–3.59, $P = 0.001$, $n = 75$ cases/181 controls) and women (OR = 1.85, 95% CI: 1.08–3.15, $P = 0.02$, $n = 32$ cases/113 controls). Limited data support an association between MDS and obesity in women, but not in men, whereas the results for AML in overweight participants were null consistent with most epidemiological studies. Weight change during adulthood was not associated with AML or MDS risks.

The US NIH-AARP Diet and Health Study identified 338 *de novo* AML cases. Using multivariate Cox models to estimate hazard ratios, the HR comparing overall AML risks in obese (≥30 kg/m^2) and normal weight participants (BMI = 25 to <30 kg/m^2) was positive, but not statistically significant (HR = 1.24, 95% CI: 0.92–1.66, $P_{\text{trend}} = 0.52$, $n = 80$ cases) based on baseline questionnaires.[202] A Chinese hospital-based study of 722 confirmed AML cases and 1,444 gender/age-matched controls reported a statistically significant reduction in AML risks (OR = 0.67, 95% CI: 0.46–0.97, $P_{\text{trend}} = 0.03$, $n = 43$ cases/120 controls) comparing obese (BMI = >28 kg/m^2) with normal weight participants (18.5–23.9 kg/m^2).[191] Height was negatively associated with AML risks ($P_{\text{trend}} = 0.01$).

Medications

In general, maternal infections (viral, urinary tract, lower genital tract) and use of antibiotics are not associated with increased childhood AML risks, except for chloramphenicol- or phenylbutazone-induced aplastic anemia.[203,204,205] Chemotherapeutic agents associated with AML include alkylating agents (melphalan, chlorambucil, busulfan, cyclophosphamide, combined chemotherapy with alkylating agents, MOPP for treatment of Hodgkin disease, and epipodophyllotoxins).[206]

HISTOLOGY

AML is a genetically complex, clonal stem cell cancer that causes maturation arrest and proliferation of immature myeloid cells. Prior to the 1980s, early pathological studies considered leukemia a single diagnostic category. Subsequently, pathologists divided leukemias into four categories (AML, CML, ALL, CLL); however, by 2001, the World Health Organization began subdividing these categories into multiple subcategories based on cytogenetic, morphological, and molecular criteria with further revisions in 2008 and 2016. The latter classifications are displayed in Table 59.1. AML results in the clonal expansion of myeloid blast cells with accumulation of immature progenitor cells and impairment of normal hematopoiesis. Most AML tumors display clonal heterogeneity that involves the presence of at least one founding clone and one subclone.[149] The recent WHO classifies acute myeloid leukemia into subcategories, as displayed in Table 59.1.

HOST SUSCEPTIBILITY

Several observational studies including reports of familial AML clusters suggest an association between family history of hematological malignancies in first- and second-degree relatives and increased AML risks;[207] however, small sample sizes, few studies, and imprecise risk estimates limit definitive conclusions. In a French population-based study of 472 *de novo* acute leukemia cases and 567 age/gender/region-matched controls, a family history of hematological cancer in first- or second-degree relatives was associated with elevated AML risks (OR = 4.3, 95% CI: 1.4–13, $n = 5$ cases) compared with controls without a positive family history of AML.[208] AML risks were similarly imprecise in a French hospital-based study of 279 *de novo* childhood acute leukemia cases and 285 age/gender/region-matched controls.[209] A family history of hematological cancer in first- or second-degree relatives was associated with an elevated, albeit imprecise, estimated AML risk (OR = 13.3, 95% CI: 2.5–70.9, $n = 4$ cases).

In children, genetic disorders and constitutional genetic defects are associated with increased AML risks, particularly the AML subtype acute megakaryocytic leukemia. A case series suggests a 10–20-fold increase in acute leukemia incidence occurs in patients with Down syndrome, including elevated AML risks.[210] The most common genetic factor associated with AML is trisomy 21. Approximately 10% of Down's syndrome infants have transient abnormal myelopoiesis with mutations of the *GATA1* gene that progresses to myeloid leukemia in ~20% within the first 5 years of life. Additional mutations beside the *GATA1* gene are necessary to develop this AML subtype. Myeloid leukemia is a specific AML subtype characterized by megakaryoblastic cells. Other congenital disorders associated with aneuploidy demonstrate an increased AML incidence including ataxia telangiectasia, Bloom syndrome, familial monosomy 7, Klinefelter syndrome, Li–Fraumeni syndrome, Fanconi anemia, Shwachman–Diamond syndrome, and von Recklinghausen's neurofibromatosis.[203,211]

Only ~5% of childhood leukemias involve high-penetrance germline mutations, more commonly in AML than ALL. Common germline mutations of genes associated with familial myeloid neoplasms include ANKRD26, CEBPA, DDX41, ETV6, GATA2, RUNX1, SRP72, TERC, TERT, and TP53.[212,213] Somatic mutations of genes involved in epigenetic regulation (e.g., *ASXL1*, *DNMT3A*, *TET2*) increase with age, resulting in an increased AML risk with increasing age in adults.[214] Clinical testing is available for *CEBPA*-associated familial acute myeloid leukemia, inherited bone marrow failure syndromes (dysregulated telomere maintenance associated with dyskeratosis congenita), familial platelet disorder with AML susceptibility (*RUNX1*), and *GATA2*-associated familial myelodysplastic syndrome/acute myeloid leukemia.

CLINICAL FEATURES

The clinical features of AML reflect bone marrow failure and organ infiltration include fatigue, dyspnea, severe sepsis, bruising, and epistaxis. Extramedullary involvement may occur, including CNS involvement. Life-threatening coagulopathy (i.e., acute promyelocytic leukemia) or rapidly fatal tumor lysis syndrome may occur. In childhood, AML usually occurs in the first year of life with similar incidence rates in boys and girls.[115] Myelodysplastic syndrome (MDS) frequently precedes AML development in the elderly. The median age of diagnosis for adult AML patients is ~66–70 years with almost 70% being >55 years.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Secondary AML peaks ~5–10-years after chemotherapy, whereas the peak AML incidence in the Life Span Study of Japanese atomic bomb survivors was 5–7 years.[215] The data from Hiroshima and Nagasaki are limited by a lack of prospective data from the first 5 years after the atomic bomb explosions; subsequent data suggest that the latency period is <5 years.[31] European studies suggest the occurrence of space-time and/or spatial clustering of childhood leukemias related to time/place of birth and time/place of diagnosis, suggesting environmental factors (e.g., viruses).[216]

AML is a rapidly fatal disease if untreated; even with treatment, adult AML has the lowest survival rates of all leukemias. Specific chromosomal abnormalities affect AML prognosis. Favorable subtypes include acute promyelocytic leukemia (t(15;17) translocation, PML-RARA rearrangement)) and core-binding factor-associated AML leukemia subtypes (8:21 translocation, chromosome 16 inversion), whereas adverse AML risk groups include monosomal and complex karyotypes (e.g., aberrations of chromosomes 5 and 7).[217] Approximately 50–60% of adult AML patients have chromosomal abnormalities detectable on cytogenetic testing that are significantly associated with survival. The remaining AML patients with cytogenetically normal testing have variable clinical outcomes depending on acquired gene mutations, miRNA/gene-expression profiles, age, coexisting diseases, and other risk factors.[148] The 5-year survival rate ranges from ~5–15% in AML patients of >60 years of age compared with 35–40% for adult AML patients presenting at age ≤60 years.[212,218] The recent development of more targeted AML therapy may improve these survival rates. For childhood AML, survival rates increased over the last several decades with improvements in chemotherapy, stem cell transplants, and supportive care. The overall survival rate now is ~65–70% with event-free survival of 50–60%; however, the cumulative relapse rate remains high (35–40%), depending in part on the specific AML subtype.[219,220]

ACUTE LYMPHOBLASTIC LEUKEMIA (ALL)

ALL is the predominant childhood leukemia (<15 years of age), with ~60% of cases occurring before 20 years of age.[221] The annual childhood ALL incidence is five times higher for ALL than AML, with ALL incidence decreasing with age relative to AML. Childhood ALL accounts for the most cancer-related deaths in patients of <20 years of age. The incidence rates vary between countries; ~6,000 ALL cases occur annually in the United States, with 75–80% of the disease in children/adolescents.[5,222] The annual ALL incidence is ~4/100,000 population in the United Kingdom. The highest reported incidence exists in Europe, Oceania (Australia, New Zealand), and North America, whereas lower reported rates are reported in Africa, Asia, and South America. Time trends in developing countries demonstrate a modest increase in childhood ALL rates in the last three decades of the 20th century followed by a flattening of the curve in the early 2000s; however, the temporal trend may also represent improvements in diagnosis, reporting, and healthcare access.[223] Immigrants to developed countries acquire incidence rates similar to those of the host nation.[224] The presentation of childhood ALL peaks during ages 2–5 years, with ALL incidence higher in boys than girls after the first year of life (i.e., 1.2:1), particularly for T cell ALL. Peak adult ALL incidence occurs at ~50 years old after a trough between 30 and 40 years of age.[225]

The overall age-adjusted annual incidence of ALL in the United States is 1.7/100,00 men and women. Although age patterns are consistent across racial/ethnic groups, some variation occurs with race/ethnicity (e.g., white/black ratio = ~1.6) reflecting genetic variation as well as socioeconomic factors.[106,226] African Americans have the lowest ALL incidence rate compared with European Americans and Asians, while Hispanics and probably Native Americans have higher rates.[227] Several ALL subtypes occur differentially in racial/ethnic groups (e.g., *CCRLF2*-rearranged ALL, Hispanics; *TCF3-PBX1* ALL, blacks).[228]

CARCINOGENESIS

ALL is a lymphoid malignancy affecting B (75–80%) or T (20–25%) cell lineages. Both B cell and T cell ALL comprise multiple subtypes containing distinct somatic structural DNA rearrangements and sequence mutations that disrupt lymphoid development (*ETV6*, *RUNX1*), Janus kinase and RAS signaling pathways, cytokine receptors, tumor suppression, DNA methylation, and chromatin modification along with oncogene activation (e.g., *MYC* gene).[229] Typically, childhood ALL genomes contain 10–20 non-silent coding mutations at presentation with the number doubling at relapse.[230]

Epigenetic alterations contribute significantly to leukemogenesis including ALL development,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

particularly DNA methylation. Methylation of cytosine residues in CpG dinucleotides establishes cellular identity by influencing gene expression. Recurrent ALL subtypes have subtype-specific signatures consisting of methylated CpG sites. Common genes associated with epigenetic dysregulation include *ASXL1*, *ATRX*, *CREBBP*, *EP300*, *KMT2A* (MLL rearrangements), *KMT2D*, *NSD2*, *PRC2* (polycomb repressive complex 2), and *SETD2*.[231] The KMT2A fusion protein is an important driver gene in the ALL landscape affecting histone methyltransferase involved with epigenetic regulation of blood–cell development.[232] Over 2/3 of B cell ALL tumors contain mutations involved with transcriptional regulation of B cell development (e.g., *EBF1*, *IKZF1*, *PAX5* genes), whereas >80% of T cell ALL tumors contain alterations of INK4/ARF tumor suppressors.[221]

The molecular phenotypes of childhood and adulthood ALL differ. The most common structural cytogenetic abnormality in adult ALL is the Philadelphia chromosome involving translocation t(9;22)(q34;q11), resulting in the BCR-ABL fusion gene and activation of tyrosine kinase, whereas TEL-AML1 t(12;21) translocation is the most frequent (i.e., ~20%) in childhood ALL. The mutations of the *TEL-AML1* gene and hyperdiploid childhood ALL subtypes account for half of childhood leukemias, while adult leukemias are dominated by more complex chromosome aberrations, including the Philadelphia chromosome (*BCR-ABL1* gene). The former two subtypes rarely occur in adult leukemia.[233] For infant *MLL*-positive ALL, prenatal initiation of a malignant clone appears sufficient to develop ALL; however, most childhood ALL requires further genetic changes. The TEL-AML1 fusion protein alone is insufficient to transform hematopoietic cell lines into leukemic cells.

Delayed, dysregulated immune responses to common infectious agents may contribute substantially to the conversion of preleukemic clones to overt precursor B cell ALL.[115] In the United Kingdom Childhood Cancer Study of 425 ALL cases aged 2–5 years and 1,031 sex/age/region-matched population controls from UK primary-care registers, the number of clinically diagnosed infectious episodes in infancy was greater in leukemia cases (3.6 infections, 95% CI: 3.3–3.9) than controls (3.1 infections, 95% CI: 2.9–3.2), particularly in the neonatal period (24% of cases vs. 18% of controls).[234] The onset of leukemia was ~7 months earlier in leukemia cases with >1 neonatal infection than in cases with ≤1 neonatal infection. The relative expression of various miRNAs helps diagnose and classify B and T cell ALL subtypes including miRNA 126, 128, 146b, 148, 151, 191, 424, 425-5p, and 629.

EXPOSURE

In contrast to AML, few environmental risk factors are causally associated with increased childhood or adult ALL, as displayed in Table 59.6.[235] The risk of acquiring ALL increases with ionizing radiation exposure similar to AML.[164] Increased ALL risks associated with overhead power lines, electromagnetic fields, and air pollution remain unsubstantiated.[2]

Ionizing Radiation

High- and medium-ionizing radiation doses are an established cause of adult and childhood ALL based on studies of Japanese atomic bomb survivors and the slightly increased ALL incidence in offspring of mothers receiving X-ray pelvimetry during pregnancy. Epidemiology studies on diagnostic X-rays and high-dose CT scans are inconsistent with a relatively weak association at radiation doses of <100 mSv. A retrospective UK cohort study of 176,587 patients from the NHS Central Registry identified 26 ALL cases among patients receiving CT scans (64% head CT). The excess relative risk (ERR) for ALL using controls with <5 mGy exposure was 1.719 (95% CI: >0–17.73, $P_{\text{dose-response}} = 0.0053$) with some estimate instability. Follow-up for leukemia began 2 years after the scans.

Although most ecological studies on leukemia and radon exposure report statistically significant positive results, case-control studies demonstrate mixed, generally weak results with few reporting statistically significant associations with leukemia reflecting difficulties with estimating radon exposures.[236] The retrospective, census-based cohort study of over 2 million Swiss children of <16 years of age suggests estimated dose rates of ≥0.2 mSv/hour increased childhood ALL risks (HR = 2.12, 95% CI: 1.09–4.16, $n = 9$ cases) based on a few cases and referents with exposure to <0.1 mSv/hour.[237] Using 10,843 direct indoor radon measurements and a co-kriging model, the French Geocap study of 7,434 ALL cases found little evidence of increased ALL risks with increased estimated radon doses (SIR by 0.01 mSv γ-radiation/hour = 1.01, 95% CI: 1.00–1.02).[238]

Adults

Significant dose-related elevated ALL risks occurred in the Life Span Study cohort of Japanese atomic bomb survivors, with ALL excess relative risks significantly decreasing with increasing time since exposure and increasing age at exposure.[215] Pooled data from 9 historical cohort studies involving 262,573 participants

receiving mean cumulative active bone marrow doses of 19.6 ± 22.7 mSv prior to age 21 identified 40 ALL cases. The odds ratio for ALL was positive and statistically significant, but unstable (OR = 5.66, 95% CI: 1.35–19.71, $P_{trend} = 0.023$).[169] The estimated dose-response curve for ALL remained positive below 50 mSv.

Children

For current radiation doses, little evidence supports an association of childhood ALL with preconception maternal abdominal/pelvic X-rays with conflicting results for preconception paternal and postnatal diagnostic radiation exposures. In an Australian study of 389 incident ALL cases and 876 frequency-matched controls (no diagnostic X-rays), little evidence supported an increased ALL risk in offspring with any maternal abdominal X-rays during pregnancy (OR = 0.46, 95% CI: 0.15–1.40) or any paternal preconception abdominal X-rays (OR = 1.17, 95% CI: 0.88–1.55).[239] The ALL risk increased for >1 paternal preconception X-ray (OR = 1.47, 95% CI: 0.98–2.21) or an intravenous pyelogram (OR = 3.56, 95% CI: 1.59–7.98). Little evidence supported an increased ALL risk

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with any childhood X-rays 6 months before diagnosis (OR = 1.15, 95% CI: 0.88–1.51). In a US study of 652 ALL cases aged ≤14 years diagnosed from 1995–2008 and age/sex/race-matched controls, *in utero* diagnostic X-rays were associated with a positive, but statistically nonsignificant childhood ALL risk (OR = 1.20, 95% CI: 0.71–2.04, $n = 652$ cases) based on in-home maternal interviews.[168]

Extremely Low Frequency Electromagnetic Fields

Although a meta-analysis suggests relatively high electromagnetic field (ELF) radiation (i.e., magnetic flux densities of >0.3–0.4 μT) may slightly increase childhood ALL,[46] the findings are inconclusive and relatively weak given the lack of a confirmed biological mechanism, credible models, difficulty assessing/comparing ELF exposures accurately, and the potential presence of bias and confounding.[240,241] Results from case-control studies on childhood ALL risks from ELF fields are mixed with both positive[242,243] and negative[244,245] findings. More recent pooled analyses from case-control studies using more direct methods comparing estimated high (≥0.3–0.4 μT) and low (<0.1 μT) ELF exposures suggest weaker, nonsignificant associations (RR = 1.44, 95% CI: 0.88–2.36, $n = 6$ studies)[49] than older epidemiological studies (RR = 2.00, 95% CI: 1.27–3.13, $n = 9$ studies).[246]

Chemicals

Benzene

Although benzene is a recognized cause of ALL in adults, the association between benzene exposure and childhood ALL is less clear.[247] Parental benzene exposure is a plausible ALL risk factor for offspring; however, epidemiological evidence for an association of ALL with benzene and other chemicals is limited. The available studies use less accurate indirect measures of benzene exposure (self-reported benzene/related product use, job titles/matrices, surrogates) than direct measurements (e.g., personal, prospective). The epidemiological evidence for increased ALL risks is stronger for maternal benzene exposure during pregnancy than paternal preconception exposure. A Danish population-based, case-control study used data from the Danish Cancer Registry to identify children born between 1968 and 1974 prior to banning workplace benzene and the nationwide pension fund records to match unexposed controls and parental occupational benzene exposure using a job-exposure matrix.[248] The adjusted ALL relative risk in offspring was statistically significant for any maternal benzene exposure during pregnancy (aRR = 2.28, 95% CI: 1.17–4.41, $n = 11$ cases), but not for any paternal benzene exposure within 3 months of conception (aRR = 1.40, 95% CI: 0.88–2.22, $n = 22$ cases).

A meta-analysis of 14 case-control studies on ALL and any occupational or household benzene exposure reported a summary relative risk of 1.57 (95% CI: 1.21–2.08) with significant heterogeneity ($P_{\text{heterogeneity}} = 0.03$) using a fixed effects model adjusted for between-study heterogeneity; the referents were nonexposed controls.[249] The use of multiple exposure types (occupational, residential), times (preconception, periconception, gestational, postnatal, overall), and persons (maternal, paternal) limits extrapolation of the results to any particular benzene exposure. All of the included ALL occupational case-control results were statistically nonsignificant, with the exception of a highly imprecise Columbian study that combined any benzene exposure in either parent with nonexposed controls (OR = 11.65, 95% CI: 2.98–45.59). Consistent with other studies, the associated risk was higher for AML than for ALL. A census-based cohort study on over 2 million Swiss children of <16 years of age identified 19 ALL cases.[250] Based on parental occupations reported at census and job-exposure matrix to assess benzene exposure, maternal occupations with any benzene exposure were associated with increased ALL risks in offspring (HR = 1.88, 95% CI: 1.16–3.04). Paternal benzene exposure at work was not associated with an elevated hazard ratio for ALL in their offspring. No information was available for prenatal exposures, smoking, or alcohol consumption. In a case-control study of 33 paternal occupations and 12,288 lymphoid leukemia cases identified in the UK National Registry of Childhood Tumors, no paternal occupation was associated with a statistically significant increased risk in offspring.[251]

Pesticides and Other Agricultural Exposures

Some epidemiological evidence suggests an association between parental occupational pesticide exposure and ALL, whereas the association of ALL with postnatal pesticide exposure is much weaker. Most of this evidence involves case-control designs with inability to identify specific pesticides, heterogeneity across studies, and potential design issues (recall/selection bias, confounding). A US study of 41 incident childhood ALL cases and mothers compared maternal questionnaire data with measured urine concentrations in the children. The results demonstrated little statistical correlation between the questionnaire and measurement data on

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

high and low pesticide exposures.[252] A meta-analysis of 12 case-control studies in the Childhood Leukemia International Consortium suggests maternal pesticide exposure during pregnancy does not increase ALL risks in offspring (summary OR = 1.03, 95% CI: 0.77–1.38, n = 8,236 cases/14,850 controls, I^2 = 11.2%), whereas paternal pesticide exposure around preconception may slightly increase ALL risks (summary OR = 1.22, 95% CI: 0.94–1.58, n = 8,157 cases/14,201 controls, I^2 = 68.7%).[189] The latter result demonstrated moderate heterogeneity. A meta-analysis of ALL risks in offspring and unspecified residential pesticide exposure during pregnancy reported an elevated ALL risk (summary OR = 2.04, 95% CI: 1.54–2.68, n = 3 studies, I^2 = 19%).[27] All pesticide exposures were based on self-reports without validation.

Lifestyle

Smoking

Although case-control studies of paternal smoking during the immediate preconception period suggest a modest association with childhood ALL in offspring in most, but not all studies,[253] epidemiological studies on ALL risk from maternal smoking during pregnancy report null results.[193] In the French ESTELLE study of 636 childhood ALL cases and 1,421 age/gender-matched population controls using self-reported smoking and never-smokers as referents, maternal smoking during pregnancy was not associated with childhood ALL risks.[123] For cigarette consumption in the highest maternal exposure group (≥11 cigarettes daily), the OR was 1.0 (95% CI: 0.5–2.0, n = 13 exposed cases/15 exposed controls, P_{trend} = 0.95). The odds ratio for childhood ALL in offspring of fathers who smoked during pregnancy was marginally elevated (OR = 1.3, 95% CI: 1.0–1.7, n = 115 exposed cases/213 exposed controls, P_{trend} = 0.09). In an Australian population-based study of 388 childhood ALL cases of 15-year-old and 868 nonsmoking controls, maternal smoking was not associated with increased childhood ALL risks, including the highest cigarette use category of ≥15 cigarettes/day during pregnancy (OR = 0.98, 95% CI: 0.67–1.44, n = 49 exposed cases/107 exposed controls, P_{trend} = 0.98).[254] The same category for paternal smoking was associated with an OR of 1.28 (95% CI: 0.97–1.70) with a significant trend (P_{trend} = 0.03).

Alcohol

Although alcohol is a potential ALL leukemogen, little epidemiological evidence supports an association between maternal or paternal alcohol consumption and increased childhood ALL risks based primarily on interviews using self-administered questionnaires. A meta-analysis of 21 case-control and no cohort studies reported no association between any maternal alcohol consumption during pregnancy and ALL risks in offspring ≤4 years old using nondrinkers as referents.[127] The summary OR for ALL was statistically nonsignificant using random effects models (sOR = 1.17, 95% CI: 0.83–1.65, n = 3 studies, I^2 = 31.7%, $P_{heterogeneity}$ = 0.231) with slight to moderate heterogeneity. Dose-response analysis was inconclusive due to inadequate study numbers. In the French ESTELLE study of 636 ALL cases (503 B cell precursors, 95 T cell precursors) and 1,421 population-based controls, maternal alcohol consumption (ever vs. never) during pregnancy was not associated with increased childhood ALL risks.[123] The odds ratio was 1.0 (95% CI: 0.8–1.2, n = 136 cases) with no dose-response relationship (P_{trend} = 0.38). An Australian study of 388 ALL cases and 1,396 family controls reported no evidence supporting an increased childhood ALL risk from maternal alcohol consumption before or during pregnancy; the odds ratio comparing any and no wine during pregnancy suggests an inverse ALL relationship (OR = 0.66, 95% CI: 0.49–0.89, n = 356 cases).[125] Although any versus no paternal alcohol consumption was not associated with childhood ALL (OR = 0.72, 95% CI: 0.48–1.08, n = 281 cases), the OR for high beer consumption (≥28 beers/week) was positive but statistically non-significant (OR = 1.23, 95% CI: 0.73–2.05, n = 36 cases) with a quadratic term P value of 0.03.

In the French population-based study of 407 childhood ALL cases and 567 age/gender/region-matched, nondrinking controls, maternal alcohol consumption of >1 glass/day was associated with increased childhood ALL risks (OR = 2.8, 95% CI: 1.3–5.9, n = 23 cases).[126] An exploratory pooled study of 152 ALL cases and 23,096 controls using data from 16 case-control studies suggests ALL risks from alcohol consumption may be stronger for B cell than T cell ALL.[255] Although overall ALL risks comparing any history of alcohol consumption (≥1 drink/month) with nondrinking referents were null (OR = 1.01, 95% CI: 0.63–1.61, n = 64 cases), B cell ALL risks were increased (OR = 2.87, 95% CI: 1.18–6.95), whereas T cell ALL risks were not (OR = 0.46, 95% CI: 0.18–1.19, n = 15 cases).

Diet

Limited observational studies suggest maternal diet is not an important risk factor for childhood ALL in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

offspring. Some studies suggest food groups in the traditional Mediterranean diet (fruit, legumes, vegetables), as well as folate and vitamin supplementation during pregnancy, have a modest inverse association with childhood ALL risks.[256] In a Greek hospital-based study of 131 ALL cases aged <5 years and age/gender-matched controls hospitalized for minor conditions, the ALL risks in offspring were lower with increasing maternal quintiles of fruit, vegetable, and fish/seafood groups based on in-person interviews.[257] The increasing risks were associated with the maternal sugar/syrup group and marginally increased with quintiles of the meat/meat products group. A population-based study of 282 ALL cases (86% participation rate) from the Northern California Childhood Leukemia Study and age/sex/racially matched controls (56% participation rate) reported ALL risk reductions for maternal consumption of similar food groups using conditional logistic regression models.[258] Adjusted odds ratios for offspring ALL risks were reduced for maternal consumption (median times/day) of vegetables (aOR = 0.65, 95% CI: 0.50–0.84), legumes (aOR = 0.75, 95% CI: 0.59–0.95), protein sources (aOR = 0.55, 95% CI: 0.32–0.96), and marginally for fruit (aOR = 0.81, 95% CI: 0.65–1.00) food groups. The participation rate of controls was modest with higher incomes, more education, and older maternal ages than cases.

An analysis examined prenatal folic acid and vitamin supplementation from 12 case-control studies participating in the Childhood Leukemia International Consortium (6,963 ALL cases, 11,635 controls).[259] Any maternal supplementation before conception or during pregnancy was associated with reduced childhood ALL risk for vitamin (OR = 0.85, 95% CI: 0.78–0.92) and folic acid (OR = 0.80, 95% CI: 0.71–0.89) use. Neither ALL-MLL+ nor ALL-MLL− risks or linear trends were significantly associated with total maternal consumption of dietary DNA topoisomerase II inhibitors based on food frequency questionnaire and a calculated DNA topoisomerase II inhibitor food index.[201] The overall P_{trend} was 0.19 for ALL-MLL+ and 0.83 for ALL-MLL−.

Although caffeine is a topoisomerase II inhibitor, observational studies on caffeinated products and ALL risks are inconsistent with some evidence of a positive effect. In a meta-analysis of five case-control studies comparing the highest and never/lowest coffee drinkers during pregnancy, the odds ratio was statistically significant (OR = 1.65, 95% CI: 1.28–2.12, $I^2 = 47\%$) with moderate heterogeneity and a linear dose-response ($P_{\text{nonlinearity}} = 0.67$).[198] In a meta-analysis of eight case-control studies on maternal coffee consumption during pregnancy, the OR was not statistically significant (OR = 1.10, 95% CI: 0.99–1.22, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.434$) comparing ever- versus never-coffee drinkers; however, the odds ratio was statistically significant comparing the highest and never/lowest categories (OR = 1.43, 95% CI: 1.22–1.68, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.464$).[131] The French ESCALE study identified 648 ALL cases of <15 years of age; mothers were interviewed during their pregnancy using a standardized questionnaire. Comparing regular maternal coffee consumption of ≥1 cup/week during pregnancy with never/occasional use, the adjusted OR was marginally significant (aOR = 1.6, 95% CI: 1.0–2.6, $n = 71$ cases); however, the trend was significant ($P_{\text{trend}} = 0.002$) with an elevated childhood ALL risk for regular maternal coffee consumption of >2 cups daily (aOR = 2.4, 95% CI: 1.3–4.3 $n = 25$ cases).[197] Observational studies typically do not associate tea consumption with childhood ALL risks.

Obesity

Limited data from cohort studies suggest obesity defined by a BMI of ≥30 kg/m^2 and based on self-reported height and weight increases adult ALL risks relative to normal weight participants. In a meta-analysis of five cohort studies comparing obese and nonobese (BMI <25 kg/m^2) participants, the summary relative risk for adult ALL was 1.65 (95% CI: 1.16–2.35, $n = 588$ cases, $I^2 = 6.8\%$).[260] A meta-analysis of four cohort studies reported statistically significant summary rate ratios for adult ALL using normal weight referents (18.5–24.9 kg/m^2) in obese men (sRR = 1.69, 95% CI: 1.04–2.73, $P = 0.03$, $I^2 = 29\%$), but not for obese women (sRR = 1.09, 95% CI: 0.38–3.07, $P = 0.88$, $I^2 = 32\%$).[128] The data also indicated an increased ALL risks in overweight participants (sRR = 1.36, 95% CI: 1.06–1.76, $P = 0.02$, $I^2 = 0\%$). Meta-regression analyses did not demonstrate a linear relationship between BMI and ALL risks in men or women. The mechanism for an association between ALL and obesity remains unclear.

Medications

An international population-based study examined data from the Children's Oncology Group, which enrolled 1,843 ALL cases of ≤14 years of age and 1,986 individually matched controls with information based on telephone interviews. For maternal exposure during pregnancy, use of vitamins (OR = 0.7, 95% CI: 0.5–1.0), $n = 1{,}287$ exposed cases/1,465 exposed controls, $P_{\text{difference}} = 0.01$) and iron supplements (OR = 0.8, 95%

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

CI: 0.7–1.0, $n = 490$ exposed cases/616 exposed controls, $P_{\text{difference}} = 0.01$) were borderline statistically significant.[261] Although some associations for 18 drug classes were positive, none were statistically significant, including antibiotics, anti-inflammatory drugs, hormones, and mind-altering drugs. An exploratory case-control study enrolled 157 mothers of infants <18 months of age with ALL and 255 control mothers identified by random digital dialing.[203] Although some medications had positive odds ratios, none of the specific antibiotics examined were associated with elevated infant ALL risk with the exception of trimethoprim/sulfamethoxazole (5 exposed cases/0 exposed controls). Antibiotic use in the peri-pregnancy period was not associated with ALL risks in offspring (OR = 0.96, 95% CI: 0.62–1.50, $n = 48$ exposed cases/65 control cases) in the population-based, case-control Northern California Childhood Leukemia Study.[262]

Diseases

Infectious diseases are suspected causes of childhood ALL because of dysregulated immune responses to common infections (e.g., influenza viruses/bacteria) in susceptible individuals. Although some animal models support a single transforming virus, this event has not been identified in human leukemia cells and no specific infection is causally linked to ALL with the exception of adult T cell leukemia/lymphoma and human T cell lymphotropic virus type1.[263,264] Case-control studies on the association between ALL in offspring and maternal infections during and immediately before pregnancy based on self-reports are varied. The population-based, case-control Northern California Childhood Leukemia Study reported a statistically significant elevation of self-reported influenza/pneumonia in mothers of ALL cases during the time period between 3 months prior to conception and the end of pregnancy (OR = 2.02, 95% CI: 1.28–3.18, $n = 64$ exposed cases/44 control cases).[262] Antibiotic use was correlated to influenza/pneumonia ($r = 0.14$, $P < 0.001$) and urinary tract infection ($r = 0.12$, $P < 0.001$).

HISTOLOGY

ALL arises from hematopoietic cells representing B cell precursors (BCP-ALL) or T cell lineage (T-ALL), with both immunophenotypes comprising multiple subtypes based on the initial transforming chromosomal alterations, as displayed in Table 59.1. Childhood ALL usually results from B cell lineage (i.e., ~80% typically CD19+/CD10+) and less often from T cell lineage (~20%), whereas adult ALL tumors are ~75% B cell and 25% T cell. Approximately 25–30% of B cell childhood ALL cells display high hyperdiploidy (>50 chromosomes) from nonrandom chromosome gains, whereas hypodiploidy (<44 chromosomes) occurs in 2–3% of children with B cell ALL. Low hypoploidy (30–39 chromosomes) suggests Li–Fraumeni syndrome.[265]

The predominant childhood leukemia involves the pre-B lymphocytic phenotype, primarily the cALL (common acute lymphoblastic leukemia) subtype that exhibits normal pre-B cell surface markers; these cells manifest characteristics of clonal expansion of normal pre-B cells that fail to mature. Teenagers typically trend toward increasing myeloid-type adult leukemias with disappearance of cALL as age increases. Circulating blast cells in peripheral blood indicate the presence of acute leukemia; characteristics of these blast cells include open chromatin, prominent nucleoli, and scant, basophilic cytoplasm. Myeloid blasts usually have large cytoplasmic granules (Auer rods), whereas lymphoid blasts are agranular. Immunotyping helps distinguish AML from ALL.

HOST SUSCEPTIBILITY

Overall, inheritance of several low-risk variants (e.g., *ARID5B*, *CDKN2A*, *CEBPE*, *IKZF1* genes) can increase childhood ALL risks;[266] however, little evidence supports the existence of highly penetrant ALL mutations in children or adults. ALL potentially can arise in monozygotic twins after *in utero* mutation and clonal expansion of one cell in one fetus reflecting the prenatal initiation of ALL by a chromosome translocation; however, some childhood leukemias require secondary transformation from acquired genetic mutations. Family clustering of ALL is limited. Examination of data from the Swedish Family-Cancer Database suggests a family history of leukemia increases ALL risks; however, the effect is very small. Of the 1,925 childhood ALL cases, 19 had a first-degree relatively diagnosed with ALL. Twins had a markedly increased standardized incidence ratio (SIR) for childhood ALL based on six cases. Siblings with a positive family history excluding twins had a positive, but statistically nonsignificant and imprecise estimated ALL SIR of 2.22 (95% CI: 0.51–7.32, $n = 5$ cases).[267] The addition of Finnish data yielded 3,994 cases.[268] The SIR for ALL in twins remained dramatically elevated, whereas the SIR for childhood ALL in singleton siblings was statistically significant (SIR = 3.2, 95% CI: 1.5–5.9, $n = 10$). An exploratory pooled study of 152 ALL cases and 23,096 controls from 16 case-control studies used referents with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

no familial hematological malignancies.[255] For families with any hematological malignancy in first-degree relatives, the risks were higher for B cell (OR = 3.30, 95% CI: 1.10–9.91, $n = 4$ cases/236 controls) than T cell ALL (OR = 3.33, 95% CI: 0.73–15.11, $n = 2$ cases/200 controls); however, the estimates were highly imprecise from a few cases. Rare germline mutations associated with familial ALL include *ETV6* [269] and *PAX5* genes.[270] The presence of Down syndrome substantially increases ALL risks.

CLINICAL FEATURES

Clinical features of ALL result from bone marrow failure and leukemic infiltration of the spleen, lymph nodes, and mediastinal masses. Bone marrow failure may produce infections from neutropenia, fatigue, and pallor from anemia, and/or easy bruising/hemorrhage from thrombocytopenia, whereas T cell ALL tumors may obstruct venous flow resulting in the superior vena caval syndrome. Coagulopathy is uncommon in ALL. Other nonspecific symptoms include fever, night sweats, and weight loss. Central nervous system involvement at presentation occurs in <10% of ALL cases manifested by meningismus and cranial nerve abnormalities.

With current therapy, >95% of children (age <12 years) achieve complete remission and ~80% have long-term event-free survival with ~90% overall survival compared with 10% in the 1960s.[219] Cure rates for older adult (age >59 years) ALL increased to the 40–50% range; the prognosis for infants (<1 year of age) is also worse than that for older children.[271] The main basis for ALL diagnosis, risk stratification, and prognosis includes structural chromosomal rearrangements (e.g., fusion genes), white blood cell count at diagnosis, and minimal residual disease status.[229] The higher prevalence of high-risk leukemia subtypes (e.g., BCR-ABL1 fusion gene, MLL rearrangement) along with a lower incidence of favorable subtypes (ETV6-RUNX1 fusion gene, hyperdiploidy) and poor tolerance of treatment in adolescents and adults reduce the prognosis compared with preadolescents.[272]

CHRONIC MYELOGENOUS LEUKEMIA (CML)

CML is a relatively rare, heterogeneous disease (0.6–2.0/100,000) accounting for ~15% of new leukemia cases in the Western hemisphere, with a male/female ratio ranging from 1.3–1.8.[273,274] In the United States, the age-adjusted CML incidence is 1.6/100,000, with a male/female ratio of ~1.75.[275] Some epidemiological data suggest ethnic differences (e.g., lower in Asians than Caucasians) and differences in incidence between European countries; however, the differences are relatively modest.[276] Although CML prevalence has increased as a result of the effectiveness of tyrosine kinase inhibitor therapy, CML incidence has been relatively stable over time. Estimates suggest the CML prevalence will increase from 70,000 in 2010 to a plateau of 181,000 in 2050 due to dramatic improvements in treatment.[277]

CARCINOGENESIS

CML is a clonal myeloproliferative disorder that results from a reciprocal translocation between the long arms of chromosomes 9 and 22 (Philadelphia chromosome).[278] In 1960, Nowell and Hungerford described the first malignancy (CML) associated with a recurrent cytogenetic abnormality, the Philadelphia chromosome (t(9;22)(q34;q11));[279] the latter was identified in 1973 by Janet Rowley.[280,281] This translocation occurs between the Abelson murine proto-oncogene (*ABL1*, chromosome 9) and the breakpoint cluster region (*BCR* gene, chromosome 22). Both genes are active tyrosine kinases. The oncogenic BCR-ABL1 fusion gene encodes a chimeric oncoprotein that markedly enhances tyrosine kinase activity producing unregulated cell proliferation, reduced stromal adhesion, and resistance to apoptosis via downstream pathways (JUN kinase, MYC, RAC, RAS, STAT).[282] This oncogene is a biomarker of CML and a drug target. The most frequently downregulated miRNAs include miRNA 10a, 17/92, 150, 203, and 328.[283] Progression to CML blast crisis involves downregulation of miRNA 328.

EXPOSURE

The only established causative agent for CML is high-dose ionizing radiation (e.g., Japanese atomic bomb survivors,[284] ankylosing spondylitis/pulmonary tuberculosis radiotherapy).[285] In the US National Institutes of Health-AARP Diet and Health study of 493,188 participants, 178 incident CML cases appeared during a median of 10.5 years of follow-up.[286] Using Cox proportional hazards models and data from self-reported baseline questionnaires, vigorous physical activity 3 times/weekly was inversely associated with CML (HR = 0.70, 95% CI: 0.49–0.99) compared with <1 time/week. Exclusion of the 41 CML cases

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

identified in the first 2 years of follow-up resulted in a statistically nonsignificant hazard ratio (HR = 0.75, 95% CI: 0.50–1.12, $P_{trend} = 0.15$). Little data associate CML with dietary factors; this study reported no association between CML and a variety of dietary factors (e.g., red/white meat, processed meat, fish, fruit, vegetables, grains, total fat/fiber, alcohol consumption, coffee/tea intake) consistent with previous studies.[112,287]

Occupation

A Swedish exploratory study of 255 CML-Ph+ cases and age/sex/county-matched controls reported limited evidence of an association between CML and moderate/high organic solvent exposure (OR = 3.4, 95% CI: 1.1–11, $n = 12$ cases) based on a Finnish job-exposure matrix using data primarily from next of kin (proxy = 81%).[288] The study reported no association between CML and gasoline, diesel, or agricultural exposures. Poor exposure data and the absence of exposure-response data limit extrapolation of the results. In a study of data on North American workers in the styrene–butadiene rubber industry, Cox proportional hazard models examined exposure-response curves based on cumulative 1,3-butadiene exposure data as predictors of CML risks.[78] The slope of the model was not statistically greater than zero for CML, indicating no relationship. The IARC lists benzene, formaldehyde, ^{32}P as phosphorus, ^{232}Th and decay products, and X- and γ-ray radiation as carcinogenic agents with sufficient evidence in humans.

Benzene

Most observational studies of CML and benzene exposures do not report a strong association. Although several studies in the UK petroleum industry and French gas/electric utility workers report statistically nonsignificant increases in CML risks, other studies show no association including two with quantitative benzene exposure estimates and no dose-response relationships.[104] In a nested case-control study of Canadian, Australian, and UK petroleum refinery workers exposed to low benzene concentrations using the lowest benzene exposure tertile (≤0.348 ppm-years, 4 cases/44 controls) as referents, the CML odds ratio for cumulative exposure in the 2nd tertile (>0.34–2.93 ppm-years) was 5.04 (95% CI: 1.45–17.50, $n = 16$ cases/38 controls) and 2.20 (95% CI: 0.63–7.68, $n = 8$ cases/40 controls) in the highest tertile (>2.93 ppm, $P_{trend} = 0.02$).[54] Conditional logistic regression models did not demonstrate a monotonic dose-response relationship between cumulative benzene exposure and CML incidence ($P_{spline} = 0.12$). Using never-exposed workers as referents, a nested case-control study of French gas/electric utility workers reported an increased overall leukemia risk in workers with ≥16.8 ppm-years benzene exposure (OR = 4.6, 95% CI: 1.2–17.4, $n = 6$ cases, $P_{trend} = 0.05$); however, no dose-response relationship was detected in CML incidence with only one case and imprecise exposure estimates ($OR_{\geq 5.5\,ppm\text{-}years} = 1.2$, 95% CI: 0.1–11.4, $n = 1$ case/4 controls, $P_{trend} = 0.85$).[289] Confounding could not be excluded as a cause of the positive CML odds ratio.

A meta-analysis of six studies on CML reported no evidence of an association between benzene exposure and CML.[179] The summary-effect estimate for CML was 1.05 (95% CI: 0.83–1.34) with no studies on cumulative exposure and no evidence of publication bias ($P = 0.57$). In a meta-analysis using stratification of the data, the overall CML meta-relative risk using data from 17 cohort studies was positive, but statistically nonsignificant (mRR = 1.23, 95% CI: 0.93–1.63, $n = 76$ exposed cases); however, stratification provided some evidence of a significant association.[290] Although loss of statistical power limited conclusions about the true association, restricting the start of follow-up to 1970 or later resulted in the m-RR becoming statistically significant (mRR = 1.67, 95% CI: 1.02–2.74, $n = 32$ exposed/8 studies). Stratifying for exposure assessment quality increased the mRR, but the mRR remained statistically nonsignificant with a wider confidence limit. Another meta-analysis of 6 case-control studies with a total of 410 CML cases (range, 6–255) reported a combined OR of 1.003 (95% CI: 0.941–1.07, $P = 0.918$), indicating no significant difference in CML risks between exposed and nonexposed groups using fixed and random models.[291] Over 95% of the cases were CML-Ph+.

Magnetic Fields

A Swedish exploratory study of 255 CML-Ph+ cases and age/sex/county-matched controls reported limited evidence of an association between extremely low frequency magnetic fields and CML based on a Finnish job-exposure matrix using data primarily from next of kin (proxy = 81%).[288] The odds ratio was marginally significant statistically for low exposure to extremely low frequency electromagnetic fields (OR = 2.0, 95% CI: 1.0–4.1, $n = 25$ cases), but not for more intense exposures. The poor exposure data, imprecise estimates, and lack of exposure-response data limit definitive conclusions

regarding causation. A population-based, case-control study reported null results for CML in adults aged 20–69 years regularly using electric blankets when compared with nonusers (OR = 0.8, 95% CI: 0.4–1.6, $n = 38$ cases/42 controls) based on self-reported electric blanket use during interviews.[172] The participation rates were low with 61% of eligible cases responding; 26% of the participating cases were not asked about electric blanket use.

Lifestyle

Tobacco Smoking

The association between CML and smoking is relatively weak, with most,[287,292] but not all,[293] case-control studies reporting negative results. A Canadian population-based case-control study using never-smokers as referents reported no association between CML and current smokers (adjusted OR = 0.7, 95% CI: 0.4–1.1, $n = 28$ cases among smokers) or >20 pack-years of smoking (adjusted OR = 0.9, 95% CI: 0.4–1.6, $n = 35$ cases among smokers, $P_{trend} = 0.72$).[287] A US population-based study of 185 CML cases and 692 adult controls used unconditional logistic regression and cubic spline modeling to examine CML risks in smokers based on self-administered questionnaires.[294] Compared with controls, the age/BMI adjusted OR for current heavy smokers (≥1 pack/daily) was positive, but statistically nonsignificant (aOR = 1.58, 95% CI: 0.84–2.98, $n = 16$ cases among smokers). Similarly, the adjusted OR for CML in smokers with >30 pack-year histories of smoking was positive, but statistically nonsignificant (aOR = 1.59, 95% CI: 0.97–2.60, $n = 61$ cases among smokers).

Obesity

Obesity is a postulated risk factor for CML with a modest effect. The US National Institutes of Health-AARP Diet and Health Study suggests a positive association between CML and obesity;[286] however, the results were inconclusive and statistically nonsignificant. The multivariable-adjusted HR for CML in participants with BMI ≥ 30 kg/m^2 was 1.46 (95% CI: 0.95–2.23, $n = 46$ cases, $P_{trend} = 0.08$) when compared with referents (<25 kg/m^2). Exclusion of the 41 CML cases identified in the first 2 years of follow-up resulted in a statistically significant hazard ratio (HR = 2.06, 95% CI: 1.25–3.39, $P_{trend} = 0.005$). In a meta-analysis of five US and European prospective studies comparing obese (BMI ≥ 30 kg/m^2) participants with normal weight controls (BMI = 18.5–24.9 kg/m^2), the overall maximumly adjusted RR for CML in obese men and women was statistically significant, but small in size (aRR = 1.16, 95% CI: 1.04–1.30; $I^2 = 0\%$, $P = 0.007$).[128] Separate analysis of men and women yielded similar results that were marginally significant statistically. Some studies used measured markers of obesity, whereas others used self-reported height and weights. A meta-analysis of four cohort studies comparing obese and nonobese (BMI <25 kg/m^2) participants reported a summary CML relative risk of 1.26 (95% CI: 1.09–1.46, $I^2 = 0\%$, $P_{heterogeneity} = 0.51$).[260] A Norwegian study measured the height and weight of 2 million men and women aged 20–74 years during 1963–2001 with normal weight (18.5–24.9 kg/m^2) as referents. For obese men (≥30 kg/m^2), the RR for CML was 1.65 (95% CI: 1.18–2.31, $n = 40$ obese cases, $P_{trend} = 0.009$), whereas the RR for obese women (30–34.9 kg/m^2) was 1.06 (95% CI: 0.76–1.48, $n = 47$ obese cases, $P_{trend} = 0.02$). A Texas study conducted at the M.D. Anderson Cancer Center on 253 CML cases (86% participation rate) and 270 age/gender/ethnicity-matched controls (40% friends, 36% spouses, 24% other family members) used self-reported weight and height to examine obesity and CML risks with a BMI of <25 kg/m^2 as referents.[295] At the time of diagnosis, moderate/severe obesity (≥35 kg/m^2) was associated with an odds ratio of 3.09 (95% CI: 1.56–6.13, $n = 35$ obese cases, $P_{trend} = <0.001$). An overweight BMI is not usually associated with increased CML risks in these studies.

Diseases

An exploratory study examined the association between 16 self-reported medical conditions, 701 population-based controls, and 186 CML cases using logistic regression.[296] Cases reported more tobacco smoking, obesity, and benzene exposures. CML was associated with peptic ulcers (OR = 2.0, 95% CI: 1.1–3.8, $n = 16$ cases), but not with other diseases including autoimmune conditions, diabetes mellitus, mononucleosis, or chronic fatigue syndrome. A personal history of cancer increased CML risks (adjusted OR = 3.6, 95% CI: 1.9–7.0, $n = 32$ cases). Controlling for therapy, personal history of cancer remained an independent risk factor.

HISTOLOGY

CML is a clonal myeloproliferative disorder involving unregulated bone marrow myeloid hyperplasia and increased peripheral blood myeloid cells with variable progression to pancytopenia and bone marrow failure;

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 59.4. Annual chronic myeloid leukemia (CML) incidence by age and gender at diagnosis during 2002–2012 adjusted to the World Standard Population based on Swedish Cancer Registry (SCR) data. CML incidence is usually higher in men than women after 50–60 years of age. (Redrawn from Höglund et al.).[275]

the origin is probably a primitive progenitor cell or a stem cell. The bone marrow is typically hypercellular with grossly elevated myeloid/erythroid ratios along with elevated immature granulocytes (neutrophils, basophils, eosinophils) in peripheral blood. Nucleated erythrocytes may appear.

HOST SUSCEPTIBILITY

Few epidemiological data demonstrate familial aggregation of CML.[297] In a population-based study of 4,287 cases from the Swedish CML Registry diagnosed by the Philadelphia chromosome and 20,930 age/sex/residence-matched controls, no cases had first-degree relatives with CML, whereas 4 CML cases appeared in first-degree relatives of controls.[298]

CLINICAL FEATURES

Most patients with AML present with the Philadelphia chromosome and an indolent chronic phase (<10% blasts, no extramedullary involvement). The classic natural history of CML is a chronic phase (CML-CP, median: 4–5 years) followed by an accelerated phase (CML-AP) manifested by increasing peripheral immature leukocytes that progresses to a blast phase (AML, ALL) or blast crisis.[299] In 5 CML patients receiving a median radiotherapy dose of 2,080 (range: 1,750–2,450), the median latency period between radiation exposure and CML diagnosis was 15 years with a range of 2–34 years.[300] The CML incidence increases with age up to at least 75 years and a median age at diagnosis of 57–60 years, as displayed in Figure 59.4.

The most frequent clinical features at diagnosis include nonspecific symptoms (fatigue, night sweats, malaise, weight loss) and symptoms related to splenomegaly (abdominal fullness/pain, early satiety); one-half are asymptomatic at presentation with only leukocytosis and splenomegaly.[278] Headaches, dyspnea, visual disturbances, or priapism may occur associated with leukostasis, whereas bone pain, lymphadenopathy, and extramedullary masses suggest advanced-phase disease.[273] About 85% of CML patients in the chronic phase present with leukocytosis and splenomegaly.

The introduction of tyrosine kinase inhibitors (bosutinib, dasatinib, imatinib, nilotinib, ponatinib) dramatically improved CML prognosis from a fatal leukemia to a chronic disorder responsive to oral medications.[301] The 5-year relative survival rate for newly

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. diagnosed chronic myeloid leukemia increased from 22% in the mid-1970s to 69% in 2014 with most patients treated with tyrosine kinase inhibitors experiencing nearly normal life expectancy (92–95%).[5,302] The treatment and prognosis are distictly different for CML-AP than CML-CP. Most patients presenting in the chronic phase have a good prognosis, whereas patients in the more advanced phases still have a poor prognosis due to resistance. About 2–4% of patients in the chronic phase and a significant portion of advanced phase patients are refractory to tyrosine kinase inhibitor treatment initially or acquire resistance later as a result of mutations to the *BCR-ABL* kinase domain genes.[303,304]

Chapter 60

LYMPHOMAS

Lymphomas are a heterogenous group of clinically and biologically distinct tumors originating in lymph tissues; historically, Hodgkin and non-Hodgkin lymphomas were the two major classic types. Leukemias evolve from lymphoid and myeloid cells depending on tumor subtype, whereas lymphomas develop from malignant transformation of B, T, or natural killer (NK) cells that originate from the lymphoid lineage. Lymphomas are usually clonal expansions of B cells (i.e., 85%), less often T cells (i.e., 15%), and rarely natural killer cells. Chronic lymphocytic leukemia/small lymphocytic lymphoma derives from mature B cells; therefore, this neoplasm is considered part of the lymphoma group. Non-Hodgkin lymphomas (NHL) represent a very large subset of lymphoid neoplasms, as noted in Table 60.1.

The incidence of malignant lymphoma subtypes varies with demographics and geography. Marginal zone B cell lymphomas occur more commonly in Asia than in Western countries, whereas Hodgkin lymphoma and chronic lymphocytic leukemia/small lymphocytic lymphomas are much rarer in Asia than in Western countries. The decreasing incidence of NOS (not otherwise specified) subtypes supports enhanced diagnostic specificity; however, the changing classification of lymphomas complicates the interpretation of incidence trends among lymphoma subtypes. Worldwide, lymphomas account for ~3–4% of all cancers.[1] Lymphomas are the third most frequent childhood malignancy (i.e., ~12–15%) behind acute leukemia and central nervous system tumors.[2] For adolescents and young adults (15–24 years), Hodgkin lymphoma represents 16% of all cancers, whereas NHL accounts for 6%, primarily mature B cell NHL.[3] The latter includes primarily high-grade lymphomas (Burkitt lymphoma, diffuse large B cell lymphoma, ALK+ anaplastic large cell lymphoma, lymphoblastic lymphoma).[4] Most lymphoma subtypes have a strong male predominance and a sharply increasing incidence with age.[5]

LYMPHOGENESIS

Acquired immunity to foreign agents/antigens requires the formation and interaction of thymus-derived lymphocytes (T cells) and bone-marrow-derived lymphocytes (B cells). Although lymphocytes circulate in lymph and blood, these cells concentrate in lymphoid organs including the thymus, bone marrow, lymph nodes, spleen, and upper respiratory/intestinal structures (e.g., adenoids, tonsils, Peyer's patches, appendix). Cellular immunity (e.g., graft-rejection, viral protection) depends on T cells, whereas humoral immunity depends on B cells and their antibody secretion. T cells help B cells produce antibodies; however, T cells do not produce antibodies themselves. Additionally, T cells interact with a variety of tissue processes, including disruption of tissue flora, metabolism, repair mechanisms, and pregnancy.

Figure 60.1 displays the development of high-affinity B cells (memory and plasma cells) in the germinal centers of the spleen and lymph nodes. Maturation of B cells in the bone marrow is independent of antigen stimulation; the B cell receptor becomes a monomeric IgM molecule before leaving the bone marrow. Immune activation of these cells occurs outside the marrow following antigen stimulation with or without helper

TABLE 60.1. 2022 World Health Organization (WHO) classification of lymphoid neoplasms, 5th edition. This edition represents a revision of the 2016 classification rather than a significant alteration of the categories. Tumors are organized based on increasing levels of specification by category, entity/type, and subtype. The order of classification follows cell lineage beginning with precursor cell neoplasms and progressing to mature malignancies. Provisional entities are not included in this edition compared with the 4th edition. See reference[12]. For details on specific diagnostic criteria, see Alaggio R, et al.[13]

Tumor-like lesions with B-cell predominance
Reactive B-cell-rich lymphoid proliferations that can mimic lymphoma
IgG4-related disease
Unicentric Castleman disease
Idiopathic multicentric Castleman disease
KSHV/HHV8-associated multicentric Castleman disease
Precursor B-Cell neoplasms
B-cell lymphoblastic leukemias/lymphomas
B-lymphoblastic leukemia/lymphoma, NOS
B-lymphoblastic leukemia/lymphoma with high hyperdiploidy
B-lymphoblastic leukemia/lymphoma with hyperdiploidy
B-lymphoblastic leukemia/lymphoma with iAMP21
B-lymphoblastic leukemia/lymphoma with *BCR::ABL1* fusion
B-lymphoblastic leukemia/lymphoma with BCR::ABL1-like features
B-lymphoblastic leukemia/lymphoma with KMT2A rearrangement
B-lymphoblastic leukemia/lymphoma with *ETV6::RUNX1* fusion
B-lymphoblastic leukemia/lymphoma with ETV6::RUNX1-like features
B-lymphoblastic leukemia/lymphoma with *TCF3::PBX1* fusion
B-lymphoblastic leukemia/lymphoma with IGH::IL3 fusion
B-lymphoblastic leukemia/lymphoma with TCF3::HLF fusion
B-lymphoblastic leukemia/lymphoma with other defined genetic abnormalities
Mature B-cell neoplasms
Pre-neoplastic and neoplastic small lymphocytic proliferations
Monoclonal B-cell lymphocytosis
Chronic lymphocytic leukemia/small lymphocytic lymphoma
Splenic B-cell lymphomas and leukemias
Hairy cell leukemia
Splenic marginal zone lymphoma
Splenic diffuse red pulp small B-cell lymphoma
Splenic B-cell lymphoma/leukemia with prominent nucleoli
Lymphoplasmacytic lymphoma
Lymphoplasmacytic lymphoma
Marginal zone lymphoma
Extranodal marginal zone lymphoma of mucosa-associated lymphoid tissue
Primary cutaneous marginal zone lymphoma
Nodal marginal zone lymphoma
Pediatric marginal zone lymphoma

TABLE 60.1. (Continued)

Follicular lymphoma
In situ follicular B-cell neoplasm
Follicular lymphoma
Pediatric-type follicular lymphoma
Duodenal-type follicular lymphoma
Cutaneous follicle center lymphoma
Primary cutaneous follicle center lymphoma
Mantle cell lymphoma
In situ mantle cell neoplasm
Mantle cell lymphoma
Leukemic non-nodal mantle cell lymphoma
Transformations of indolent B-cell lymphomas
Transformations of indolent B-cell lymphomas
Large B-cell lymphomas
Diffuse large B-cell lymphoma, NOS
T-cell/histiocyte-rich large B-cell lymphoma
Diffuse large B-cell lymphoma/ high grade B-cell lymphoma with *MYC* and *BCL2* rearrangements
ALK-positive large B-cell lymphoma
Large B-cell lymphoma with *IRF4* rearrangement
Lymphomatoid granulomatosis
EBV-positive diffuse large B-cell lymphoma
Diffuse large B-cell lymphoma associated with chronic inflammation
Fibrin-associated large B-cell lymphoma
Fluid overload-associated large B-cell lymphoma
Plasmablastic lymphoma
Primary large B-cell lymphoma of immune-privileged sites
Primary cutaneous diffuse large B-cell lymphoma, leg type
Intravascular large B-cell lymphoma
Primary mediastinal large B-cell lymphoma
Mediastinal grey zone lymphoma
High-grade B-cell lymphoma, NOS
Burkitt lymphoma
Burkitt lymphoma
KSHV/HHV8-associated B-cell lymphoid proliferations and lymphomas
Primary effusion lymphoma
KSHV/HHV8-positive diffuse large B-cell lymphoma
KSHV/HHV8-positive germinotropic lymphoproliferative disorder
Lymphoid proliferations and lymphomas associated with immune deficiency and dysregulation
Hyperplasias arising in immune deficiency/dysregulation
Polymorphic lymphoproliferative disorders arising in immune deficiency/dysregulation
EBV-positive mucocutaneous ulcer
Lymphomas arising in immune deficiency / dysregulation
Inborn error of immunity-associated lymphoid proliferations and lymphomas

TABLE 60.1. (Continued)

Hodgkin lymphoma
Classic Hodgkin lymphoma
Nodular lymphocyte predominant Hodgkin lymphoma
Plasma cell neoplasms and other diseases with paraproteins
Monoclonal gammopathies
Cold agglutinin disease
IgM monoclonal gammopathy of undetermined significance
Non-IgM monoclonal gammopathy of undetermined significance
Monoclonal gammopathy of renal significance
Diseases with monoclonal immunoglobulin deposition
Immunoglobulin-related (AL) amyloidosis
Monoclonal immunoglobulin deposition disease
Heavy chain diseases
Mu heavy chain disease
Gamma heavy chain disease
Alpha heavy chain disease
Plasma cell neoplasms
Plasmacytoma
Plasma cell myeloma
Plasma cell neoplasms with associated paraneoplastic syndrome
POEMS syndrome
TEMPI syndrome
AESOP syndrome
Tumor-like lesions with T-cell predominance
Kikuchi-Fujimoto disease
Indolent T-lymphoblastic proliferation
Autoimmune lymphoproliferative syndrome
Precursor T-cell neoplasms
T-lymphoblastic leukemia/lymphoma
T-lymphoblastic leukemia/lymphoma, NOS
Early T-precursor lymphoblastic leukemia/lymphoma
Mature T-cell and NK-cell neoplasms
T-prolymphocytic leukemia
T-large granular lymphocytic leukemia
NK-large granular lymphocytic leukemia
Adult T-cell leukemia/lymphoma
Sezary syndrome
Aggressive NK-cell leukemia
Primary cutaneous T-cell lymphomas
Primary cutaneous CD4-positive small or medium T-cell lymphoproliferative disorder
Primary cutaneous acral CD8-positive lymphoproliferative disorder
Mycosis fungoides

TABLE 60.1. (Continued)

Primary cutaneous CD30-positive T-cell lymphoproliferative disorder:Lymphomatoid papulosis
Primary cutaneous CD30-positive T-cell lymphoproliferative disorder: Primary cutaneous anaplastic large cell lymphoma
Subcutaneous panniculitis-like T-cell lymphoma
Primary cutaneous gamma/delta T-cell lymphoma
Primary cutaneous CD8-positive aggressive epidermotropic cytotoxic T-cell lymphoma
Primary cutaneous peripheral T-cell lymphoma, NOS
Intestinal T-cell and NK-cell lymphoid proliferations and lymphomas
Indolent T-cell lymphoma of the gastrointestinal tract
Indolent NK-cell lymphoproliferative disorder of the gastrointestinal tract
Enteropathy-associated T-cell lymphoma
Monomorphic epitheliotropic intestinal T-cell lymphoma
Intestinal T-cell lymphoma, NOS
Hepatosplenic T-cell lymphoma
Hepatosplenic T-cell lymphoma
Anaplastic large cell lymphoma
ALK-positive anaplastic large cell lymphoma
ALK-negative anaplastic large cell lymphoma
Breast implant-associated anaplastic large cell lymphoma
Nodal T-follicular helper (TFH) cell lymphoma
Nodal TFH cell lymphoma, angioimmunoblastic-type
Nodal TFH cell lymphoma, follicular-type
Nodal TFH cell lymphoma, NOS
Other peripheral T-cell lymphomas
Peripheral T-cell lymphoma, NOS
EBV-positive NK/T-cell lymphomas
EBV-positive nodal T- and NK-cell lymphoma
Extranodal NK/T-cell lymphoma
EBV-positive T- and NK-cell lymphoid proliferations and lymphomas of childhood
Severe mosquito bite allergy
Hydroa vacciniforme lymphoproliferative disorder
Systemic chronic active EBV disease
Systemic EBV-positive T-cell lymphoma of childhood
Mesenchymal dendritic cell neoplasms
Follicular dendritic cell sarcoma
EBV-positive inflammatory follicular dendritic cell sarcoma
Fibroblastic reticular cell tumor
Myofibroblastic tumor
Intranodal palisaded myofibroblastoma
Splenic vascular-stromal tumors
Littoral cell angioma
Splenic hamartoma
Sclerosing angiomatoid nodular transformation of spleen

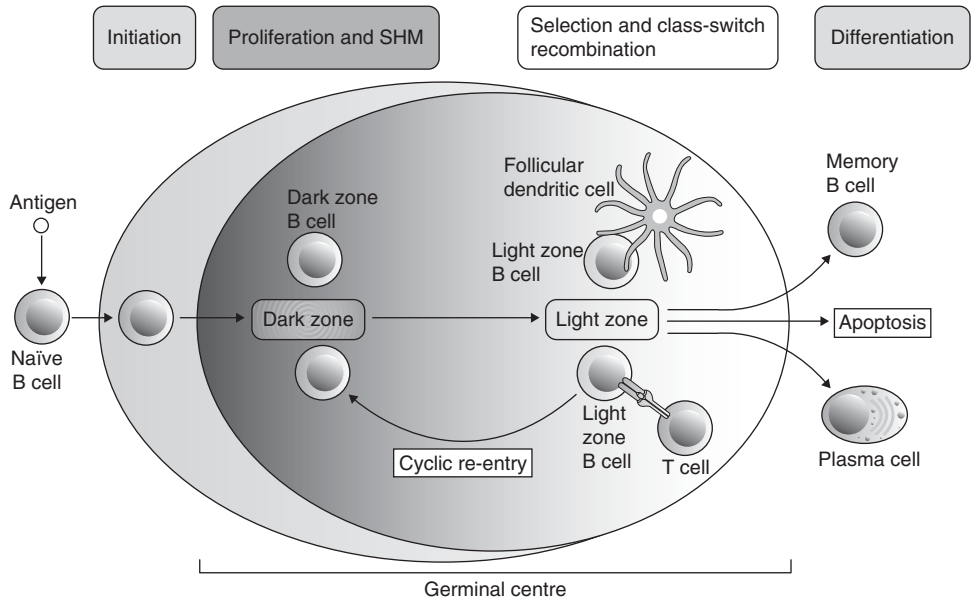

FIGURE 60.1. B cell development and germinal centers. Following V(D)J recombination in the bone marrow, naïve B cells with functional B cell receptors migrate to secondary lymphoid organs, where these cells interact with $CD4^+$ cells in T cell-rich areas; these cells aggregate into primary follicles to form germinal centers. Immunoglobulin gene remodeling processes (somatic hypermutation, SHM; class-switch recombination) generate various classes of high-affinity antibodies within the B cells that subsequently differentiate into plasma and memory B cells. The dark zone contains highly proliferating B cells, whereas B cell activation occurs in the light zone after interaction with follicular dendritic cells. Low-antigen B cells that fail to develop into high-antigen immune cells ultimately undergo apoptosis in the light zone. (Adapted from Basso and Dalla-Favera).[7]

T cells. Lymphocytes are the carriers of humoral immunity that arises from a common pluripotent stem cell in the bone marrow, where cleavage and rejoining of the variable (V), diversity (D), and joining (J) segments of the immunoglobulin heavy-chain gene (IgH locus) followed by rearrangement of the immunoglobulin light-chain gene segments (IgL) kappa and lambda occurs. The V(D)J recombination process assembles immunoglobulin heavy-chain and light-chain antibody foci in precursor B cells. Immunological B cells are divided into B1 and B2 cells. B2 cells are involved with classical antibody responses that generate specific antibodies against foreign antigens in secondary lymphoid organs. After an encounter with a foreign antigen, these mature, low-antigen affinity (naïve) B cells migrate to germinal centers in the spleen, mucosa-associated lymphoid tissue, and lymph nodes, where the B2 cell undergoes further maturation in a highly specialized microenvironment formed with help from antigen-presenting and CD4+ T cells.[6] Within the germinal centers, centroblasts rapidly proliferate and modify the variable region of Ig genes (*IgV*) in maturing B2 cells via a process called somatic hypermutation. These centroblasts express elevated levels of the transcriptional repressor, BCL6, that negatively regulates a variety of cellular processes including adaptive immune responses (CD40+ and B cell receptor (BCR) signaling, T cell-mediated B cell activation, cytokine/chemokine signaling), cellular processes (apoptosis, DNA damage sensing/repair), and plasma cell differentiation.[7] The centroblasts differentiate into centrocytes in the light zone of the germinal centers, where they select high-antigen affinity B2 cells for survival and terminally differentiate into memory B cells or plasma cells.[8] The former participates in secondary immune responses, whereas the latter secretes antibodies. B1 cells perform innate immune functions by expressing evolutionarily selected BCRs (BCR, RhoGEF, and GTPase activating protein) with limited somatic mutations; these immune cells occur primarily in the pleural and peritoneal cavities as an initial response to common bacterial pathogens. B2 cells have B1 cell differentiation potential in addition to their classical capacity to differentiate into memory and plasma cells.[9] Most B cell non-Hodgkin lymphomas with the exception of mantle cell lymphoma arise from germinal-center-experienced B cells during aberrant somatic hypermutation processes that alter *IgV* sequences via chromosomal translocation.[10] The tumor phenotype depends on the affected stage of differentiation. Arrested development in the early

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. lymphocyte progenitor stage results in ALL or lymphoblastic lymphoma, whereas intermediate-stage involvement produces mature lymphomas and terminal stages involving plasma cells and myelomas.

T cell development begins with the migration of committed lymphoid progenitor cells from the bone marrow to the thymus gland as T cell progenitor or double-negative 1-thymocytes without T cell receptors (TCR) or CD4/CD8 expression. These cells undergo rearrangement at the *TCRβ* locus to acquire pre-TCR expression along with further differentiation into double-positive cells (CD4+/CD8+) with a complete surface T cell receptor. After a selection process in the thymus to eliminate autoreactive clones, these cells exit into a pool of mature T cells. Most mature T cell non-Hodgkin lymphomas probably arise from post-thymic T cells in the lymphoid organs; however, some evidence suggests immature hematopoietic cells may also be involved in some of these tumors.[11] Natural killer (NK) cells are cytotoxic lymphocytes that lack T cell receptors and primarily eliminate malignant and infected cells.

CLASSIFICATION

Table 60.1 lists the major WHO 5th edition lymphoid neoplasms along with subgroups and new classifications based on updated genetic and molecular data.[2] The latest revision provides substantial data on the diagnosis and prognosis of the multiple subgroups of lymphoid neoplasms.[1]

CARCINOGENESIS

During differentiation, normal naïve lymphocytes undergo immense clonal expansion and mutations requiring DNA double-strand breaks and point mutations mediated by alterations of gene expression. The subsequent genetic instability predisposes lymphocytes to chromosomal translocations and oncogenic mutations conducive to malignant transformation when these processes become dysregulated. B cell development begins with proliferation of progenitor cells in the bone marrow, resulting in immunoglobulin production; surviving mature B cells migrate to germinal centers in secondary lymphoid tissues (lymph nodes, spleen), where interactions with antigen result in immunoglobulin gene modification and increased affinity for the antigen. These processes (somatic hypermutation, class switch recombination) produce small deletions, point mutations, insertions, and the potential to form chromosomal translocations and oncogenic mutations. Figure 60.2 displays the origins of B cell lymphomas in germinal centers from extra-marrow lymph tissues. Naïve B cells migrate to dark zones of secondary lymph tissues where these cells differentiate into centroblasts; point mutations in the variable region of Ig heavy- and light-chain sequences develop during somatic hypermutation in the dark zone generating variant B cell receptors. Centroblasts differentiate into centrocytes and migrate to the light zone. After moving to the light zone, variant B cells with advantageous mutations interact with follicular dendritic cells to receive T cell survival signals required to avoid apoptosis. These variant cells undergo multiple cycling back to the dark zone while proliferating, mutating, and forming translocations via class switch recombination until exiting the germinal center as memory B cells or plasma cells. This process changes the B cell isotype from IgM to IgA, IgE, or IgG. B cell lymphoma subtypes correspond to a normal cellular phenotype in the differentiation process, whereas determination of T cell NHL subtypes is often difficult.

EXPOSURE

In contrast to leukemias, the association of ionizing radiation with increased lymphoid cancer risks is relatively modest. The Life Span study did not report excess radiation-associated risks for T cell leukemia, Hodgkin lymphoma, or multiple myeloma. Epidemiology studies of diagnostic ionizing radiation exposure during early childhood do not report consistently elevated lymphoma risks; however, some of these studies have limited power to detect small increases in cancer risks.[15]

Occupation

The etiology of most lymphomas remains unknown. Recognized risk factors involve immune dysregulation and infectious processes; however, these risk factors account for a small portion of lymphoma cases. Epidemiology studies on occupational groups and lymphoma risks based on job-exposure matrices and self-reported occupations are exploratory with multiple comparisons lacking exposure data and confirmatory exposure-response data. These studies are subject to misclassification and recall bias, particularly for rare conditions (i.e., lymphomas). A meta-analysis of studies on TCE-exposed workers suggested a positive association with NHL (summary RR = 1.32, 95% CI: 1.14–1.54, n = 19 studies, I^2 = 25.20%, $P_{\text{heterogeneity}}$ = 0.12). The summary estimates did not indicate an association between occupational TCE exposure and Hodgkin

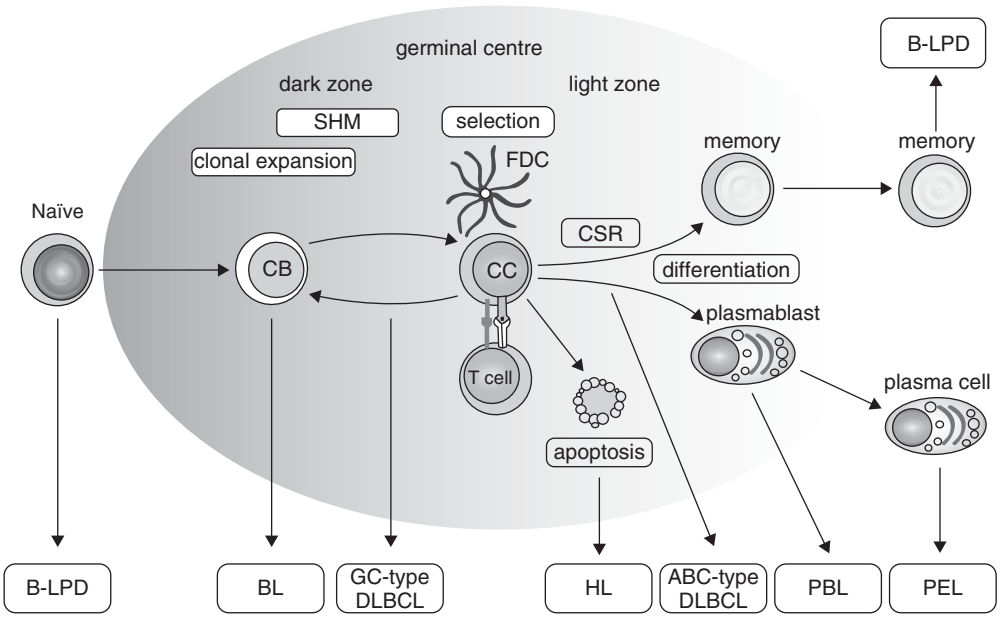

FIGURE 60.2. B cell lymphoma origins. Morphologically different B cell tumors develop from the processing of naïve B cells in the germinal centers depending on where in the differentiation process the initial clone develops, as noted in the text. (Adapted from Shannon-Lowe et al.).[14] *Abbreviations:* ABC-type DLBCL = activated B cell-like diffuse large B cell lymphoma; BL = Burkitt lymphoma; B-LPD = B-lymphoproliferative disease; CB = centroblast; CC = centrocyte; CSR = class switch recombination; FDC = follicular dendritic cells; HL = Hodgkin lymphoma; PBL = plasmablastic lymphoma; PEL = primary effusion lymphoma; SHM = somatic hypermutation.

lymphoma, multiple myeloma, or chronic lymphoblastic leukemia.[16] The summary RR for case-control studies was positive, but statistically nonsignificant (summary RR = 1.09, 95% CI: 0.94–1.25, $n = 12$ studies, $I^2 = 11.63\%$, $P_{\text{heterogeneity}} = 0.39$) with evidence of publication bias in five studies ($P_{\text{Egger}} = 0.003$).

Job Descriptions

Case-control studies suggest a variety of occupational exposures may increase risks for Hodgkin lymphomas (carpenters, chemical/solvent production workers, farmers, painters, paper industry workers, teachers, welders, woodworkers) and non-Hodgkin lymphomas (chemical workers, cobblers, cowmen, dairy workers, farmers, female physicians, furniture makers, leather manufacturing, workers machine fitters, metal workers, painters, porcelain industry workers, shoe printers, makers, woodworkers). These associations are relatively modest and inconsistent. A German case-control study of 710 adult lymphomas and sex/age/region-matched, population-based controls used unconditional logistic regression analysis to calculate odds ratios adjusted for smoking and alcohol consumption.[17] The adjusted OR for all lymphomas in this exploratory study was statistically significant for >1-year employment in food products, beverages, tobacco workers (OR = 1.7, 95% CI: 1.1–2.5, $n = 71$ cases/45 controls) and marginally significant in pulp paper, paper products, publishing, and print workers (OR = 1.7, 95% CI: 1.0–2.8, $n_{\text{NHL}} = 43$ cases/26 controls). The multicenter, prospective cohort study, European Prospective Investigation into Cancer and Nutrition (EPIC), identified 866 NHL and 48 HL cases during a mean of 9 ± 2 years of follow-up.[18] Compared with all other workers using Cox proportional hazards models and self-reported job status among a list of 52 occupations, the elevated adjusted hazard ratio for NHL, excluding multiple myeloma, was statistically significant in car repair workers (aHR = 1.51, 95% CI: 1.01–2.31, $n_{\text{NHL}} = 23$ cases) and marginally significant in butchers (aHR = 1.30, 95% CI: 1.00–2.66, $n_{\text{NHL}} = 11$ cases), but statistically nonsignificant in gasoline station workers. For HL, the adjusted OR was statistically significant for gasoline station workers (aHR = 4.59, 95% CI: 1.08–19.6, $n_{\text{HL}} = 2$ cases), but not for car repair workers or butchers. The cohort study did not confirm elevated lymphoma risks in other occupations noted in case-control studies. Analysis of data from 15 million Nordic residents enrolled in the nationwide registration of 2.8 million incident cancer cases reported the highest SIR for NHL among 54 occupational categories in male physicians (SIR = 1.22,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

95% CI: = 1.08–1.39, n_{NHL} = 234 cases) with no confirmation of increased NHL risks in hairdressers, food or tobacco workers, shoe and leather workers, or farmers.[19] For Hodgkin lymphoma, bricklayers had the highest risk (SIR = 1.33, 95% CI: 1.04–1.68) with marginally increased risks in female farmers (SIR = 1.21, 95% CI: 1.00–1.45, n_{HL} = 114 cases), but not male farmers (SIR = 1.03, 95% CI: 0.96–1.11, n_{HL} = 733 cases).

Dioxin

The association between lymphomas (i.e., HL, NHL, MM) and dioxin exposure remains controversial.[20] Dioxin (2,3,7,8-tetrachlorodibenzo-*p*-dioxin, TCDD) is an IARC human carcinogen (Group 1) based on limited evidence for all cancers in humans, sufficient evidence in animals, and a plausible genotoxic mechanism (altered gene expression, cell proliferation, and apoptosis from binding to the aryl hydrocarbon receptor).[21] TCDD is a weak initiator and a strong promoter. Seven polychlorinated dibenzo-*p*-dioxins can activate the aryl hydrocarbon receptor, with TCDD being the standard to compare with the six other dioxins. Exposure to dioxins occurs in military (Agent Orange defoliant), industrial trichlorophenol/pentachlorophenol production facilities, and environmental contamination (Seveso, waste-burning plants, widespread background dietary exposure). TCDD is a synthetic by-product of chlorophenol or chlorophenoxy herbicide manufacturing rather than a commercially produced chemical. Dioxins accumulate in food chains similar to other chlorinated compounds, with these chemicals being recognized as contaminants in the environment and diets.

Industrial cohort studies suggest a statistically positive association with NHL mortality; however, positive results are not consistent across nonindustrial cohorts or display a clear exposure-response relationship.[22] The US Institute of Medicine Committee to Review the Health Effects in Vietnam Veterans of Exposure to Herbicides study reviewed the scientific and medical evidence for Agent Orange and other herbicides used by the military in the Vietnam War. The Committee concluded the evidence was sufficient for a (statistically) positive relationship between herbicides and NHL with reasonable confidence that chance, bias, and confounding could be ruled out; however, the Committee noted the data did not establish the relationship as causal or specific to Agent Orange.[23]

The relative risks of NHL, Hodgkin lymphoma (HL), and multiple myeloma (MM) in most studies range from 0.3–3.0 based on <5 cases, with the exception of the IARC/NIOSH international cohort that reported more consistently positive risks with higher exposures.[24] In this historical cohort study of 21,863 male and female workers in 36 cohorts exposed to phenoxy and/or chlorophenol herbicides potentially contaminated with TCDD, the SMR for non-Hodgkin lymphoma was slightly elevated, but not statistically significant (SMR = 1.39, 95% CI: 0.89–2.06, n_{NHL} = 24 deaths);[25] however, NHL mortality did not increase with longer duration of exposure. Additionally, the NHL SMR was not substantially higher in production workers than sprayers, despite higher serum TCDD concentrations in the former group. Although many of the industrial and Seveso cohort studies demonstrate positive, statistically nonsignificant associations with NHL,[26,27] these studies did not exclude the lack of an association and other studies demonstrated no association resulting in inconsistent results.

A retrospective cohort study of 2,192 trichlorophenol and pentachlorophenol production workers reported no statistically significant increased mortality from NHL (SMR = 1.92, 95% CI: 0.83–3.79, n_{NHL} = 8 deaths) or Hodgkin lymphoma (SMR = 1.17, 95% CI: 0.14–4.22, n_{HL} = 2 deaths).[28] The dioxin concentrations were well above background with the highest estimated historical TCDD concentration of 8.848 ppb. Most studies of HL mortality were statistically null,[29,30] whereas limited studies of estimated Agent Orange/TCDD exposure and MM were positive in Seveso studies,[27] but not in Vietnam veterans[31] or industrial cohorts.[25] The industrial and Seveso cohorts do not demonstrate consistent trends between increased TCDD exposure and NHL mortality or HL incidence/mortality; however, MM incidence and mortality were increased in some cohorts with dioxin exposures.[27,32]

Lifestyle

Existing epidemiological evidence indicates lifestyle factors do not strongly influence lymphoma risks; however, limited data and the heterogeneity of lymphoma origins and etiologies complicate the determination of lifestyle factors for lymphoma subtypes.

Tobacco Smoking

Case-control and cohort studies suggest tobacco smoking modestly increases Hodgkin lymphoma risks, particularly nodular sclerosis and mixed cellularity subtypes.[33] The risks for lymphoma subtypes are mixed with weak evidence for a dose response reflecting small study sizes and inconsistent results/exposure classifications. The adjusted pooled estimated OR for HL using

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

data from 12 case-control studies in the InterLymph Consortium and random effects models was 1.10 (95% CI: 1.01–1.21) comparing ever- with never-smokers, whereas the association with mixed cellularity HL subtype was higher (adjusted OR = 1.60, 95% CI: 1.29–1.99).[34] In the prospective National Institutes of Health-former American Association of Retired Persons (NIH-AARP) Diet and Health Study using never-smokers as controls, Hodgkin lymphoma risks were elevated in current smokers (adjusted RR = 2.25, 95% CI: 1.04–4.88, n_{HL} = 11 cases) and recent former smokers quitting ≤4 years earlier (aRR = 4.20, 95% CI: 1.94–9.09).[35] Current cigarette smokers using >2 ppd did not have a statistically significant elevated RR for overall HL risk (RR = 1.00, 95% CI: 0.28–3.41, n_{HL} = 3 cases, P_{trend} = 0.52) or NHL (RR = 0.83, 95% CI: 0.65–1.06, n_{NHL} = 76 cases, P_{trend} = 0.16). The study reported a marginally significant reduced trend of follicular lymphoma risks in current smokers (RR = 0.66, 95% CI: 0.42–1.02, n_{FL} = 24 cases, P_{trend} = 0.005). Comparing current cigarette smokers with never-smokers in the UK Million Women Study, overall risks were significantly increased for Hodgkin lymphoma (RR = 1.57, 95% CI: 1.29–1.90, n_{HL} = 152 cases, P_{trend} < 0.001) and NHL (RR = 1.12, 95% CI: 1.05–1.18, n_{NHL} = 2,227 cases, P_{trend} = <0.001), but not for myeloma (RR = 0.92, 95% CI: 0.83–1.02, n_{MM} = 856 cases, P_{trend} = 0.1).[36] Additionally, the risks of mature T cell but not mature B cell lymphomas in current cigarette smokers were significantly increased.

The European Prospective Investigation into Cancer and Nutrition (EPIC) study reported similar results.[37] The overall HL risk comparing current with never-smokers was increased (HR = 2.14, 95% CI: 1.18–3.87), but not for NHL (HR = 1.06, 95% CI: 0.94–1.19), chronic lymphocytic lymphoma (HR = 0.77, 95% CI: 0.52–1.12, n_{CLL} = 40 cases), plasma cell neoplasms (HR = 0.88, 95% CI: 0.63–1.23), or mature B cell NHL lymphomas. In an Italian hospital-based case-control study, an analysis of NHL histological subtypes in heavy smokers revealed a statistically significant increased risk only for follicular NHL (OR = 2.43, 95% CI: 1.31–4.51).[38] Compared with never-smokers, the overall risks for current smokers were statistically nonsignificant for NHL (OR = 1.18, 95% CI: 0.91–1.54, n_{NHL} = 186 cases/326 controls) and HL (OR = 1.50, 95% CI: 0.93–2.44, n_{HL} = 80 cases/66 controls).

Alcohol

Epidemiological evidence from some cohort studies and pooled analyses of case-control studies suggests alcohol consumption decreases the risk of some lymphoma types, primarily non-Hodgkin lymphomas (NHL). Most studies on the association of multiple myeloma or chronic lymphocytic leukemia/small lymphocytic lymphoma with alcohol consumption report null results.[39] In general, the association between specific types of alcohol consumption and NHL subtypes is null to weakly inverse.[40] In a sex/smoking/age-matched, hospital-based Japanese study of 782 malignant lymphoma cases, frequent, heavy alcohol consumption (≥50 g daily) was inversely associated with all malignant lymphomas (OR = 0.40, 95% CI: 0.23–0.68, n = 20 cases/162 controls, P_{trend} = <0.001).[41]

The prospective National Institutes of Health-former American Association of Retired Persons Diet and Health Study identified 58 Hodgkin lymphoma and 1,381 non-Hodgkin lymphoma cases via linkage to cancer registries during a mean follow-up of 4.3 years.[35] Using baseline questionnaires on self-reported alcohol consumption with nondrinkers as controls, alcohol consumption decreased NHL risks including the most common NHL subtypes, but not Hodgkin lymphomas. For consuming 2–4 alcohol drinks daily, the overall NHL relative risk was 0.76 (95% CI: 0.59–0.97, n_{NHL} = 35 cases, $P_{trend\ among\ drinkers}$ = 0.008), whereas the HL risk was null ($P_{trend\ among\ drinkers}$ = 0.97). The inverse alcohol-lymphoma association persisted for common B cell subtypes (e.g., diffuse large B cell lymphoma, follicular lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma). The UK Million Women Study identified 7,047 lymphoid cancers in 1.3 million middle-aged, mostly moderate drinking women followed for a mean of 10.3 years with similar results.[42] Using self-reported alcohol consumption on baseline questionnaires and occasional drinkers (0.5–<3 drinks weekly) as referents, ≥7 drinks weekly was associated with a reduction in NHL risks (RR = 0.84, 95% CI: 0.77–0.92, n_{NHL} = 3,084 cases, P_{trend} = <0.001) and multiple myeloma (RR = 0.85, 95% CI: 0.74–0.98, n_{MM} = 1,262, P_{trend} = 0.02), but not HL (RR = 1.06, 95% CI: 0.76–1.49, n_{HL} = 173, P_{trend} = 0.6). The reduced risks of mature B cell NHL subtypes (diffuse large B cell lymphoma, follicular lymphoma, plasma cell neoplasms) were similar to overall NHL risks.

A meta-analysis of cohort studies reported that alcohol consumption reduced the risks of hematological malignancies, primarily NHL.[43] Moderate alcohol consumption (12.5–50 g daily) reduced NHL risks (pooled RR = 0.85, 95% CI: 0.80–0.90, n = 13 studies, I^2 = 1.6%, $P_{heterogeneity}$ = 0.430) consistent with heavy alcohol consumption (pooled RR = 0.88, 95% CI: 0.81–0.96, n = 5 studies, I^2 = 8%, $P_{heterogeneity}$ = 0.361). Similar pooled estimates supported reduced risks of diffuse

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

large B cell lymphoma and follicular lymphoma. Alcohol consumption did not affect pooled estimates of Hodgkin lymphoma risks.

Obesity

Epidemiological studies on the association of obesity with malignant lymphomas (NHL, HL, CLL, multiple myeloma) are mixed with the association stronger for early adulthood obesity than baseline BMI, particularly for diffuse large B cell lymphoma.[44] Pooled data from 18 case-control studies in the International Lymphoma Epidemiology Consortium did not support an increased lymphoma risk in obese participants.[45] Using logistic regression and random effects models, severe obesity ($BMI \geq 40\,kg/m^2$) was not associated with overall NHL risks (pooled OR = 1.00, 95% CI: 0.70–1.41) or most NHL subtypes with the exception of diffuse large B cell lymphoma (pooled OR = 1.80, 95% CI: 1.24–2.62). The large Multiethnic Cohort (African Americans, Caucasians, Japanese, Latinos, Native Hawaiians) of 87,079 men and 105,972 women identified 461 male and 378 female NHL cases.[46] Using Cox regression to model NHL risk and adjusting for age at baseline, alcohol intake, education, ethnicity, and age at first live birth, BMI at age 21 was a stronger predictor of NHL risk than anthropometric characteristics at baseline. The increased overall NHL risk was statistically significant, but not dose-related for obese men at age 21 (HR = 1.86, 95% CI: 1.02–3.40, n_{NHL} = 11 cases/338 controls, P_{trend} = 0.27); in obese women, the overall NHL hazard ratio was not statistically significant (HR = 1.07, 95% CI: 0.47–2.41, n_{NHL} = 6 cases/267 controls, P_{trend} = 0.03). Height was associated with overall NHL risks in men (P_{trend} = 0.02), but not in women (P_{trend} = 0.14), suggesting height is a potential confounder of BMI-associated NHL risks in men. The evidence for an association with NHL subtypes was modest.

Several meta-analyses support a relatively small, but statistically significant increased association between lymphoma risk and obesity. In a meta-analysis of 16 prospective studies on NHL and 5 studies on HL incidence, the overall summary relative risk for NHL/5 kg/m^2 BMI increments was 1.07 (95% CI: 1.04–1.10, I^2 = 9.6%, $P_{heterogeneity}$ = 0.33).[47] BMI was positively associated with diffuse large B cell lymphoma (summary RR/5 kg/m^2 = 1.13, 95% CI: 1.02–1.26, n = 8 studies, I^2 = 37%, $P_{heterogeneity}$ = 0.13), but not for follicular lymphoma or CLL. Obesity ($\geq 30\,kg/m^2$) was also associated with increased HL risks (summary RR = 1.41, 95% CI: 1.14–1.75, n = 4 studies, I^2 = 21.6%, $P_{heterogeneity}$ = 0.30). Most weights/heights were self-reported. In a meta-analysis of 44 cohort studies, the summary relative risks were modestly positive and statistically significant in men and women for NHL, HL, and MM.[48] The DLBCL risks were also statistically significant in women, but not in men, as displayed in Table 60.2. Waist circumferences and waist-to-hip ratios in women were not associated with any hematological malignancies.

A meta-analysis of 62 prospective cohort studies, 1 case–cohort study, and 2 pooled analyses was consistent with modestly elevated risks of hematological lymphomas in studies of adult obesity using mostly self-reported BMI.[49] The summary RR/5 kg/m^2 increments in BMI were statistically significant for NHL (RR = 1.05, 95% CI: 1.03–1.08, n = 20 studies, I^2 = 45%, $P_{heterogeneity}$ = 0.02), HL (RR = 1.12, 95% CI: 1.05–1.20, n = 5 studies, I^2 = 1.6%, $P_{heterogeneity}$ = 0.40), DLBCL (RR = 1.11, 95% CI: 1.05–1.16, n = 19 studies, I^2 = 16%, $P_{heterogeneity}$ = 0.29), MM (RR = 1.06, 95% CI: 1.03–1.10, n = 23 studies, I^2 = 13%, $P_{heterogeneity}$ = 0.31), and

TABLE 60.2. Summary of relative risks for hematological malignancies in obese participants based on 44 studies using mostly self-reported baseline body mass index (BMI). Substantial heterogeneity exists in the estimated summary risks for NHL, MM, and CLL/SLL. (Adapted from Psaltopoulou et al).[48]

Hematological Malignancy	Studies Men/Women	Men Summary Relative Risk (95% CI)	Heterogeneity Men (I^2 %)	Women Summary Relative Risk (95% CI)	Heterogeneity Women (I^2 %)
NHL	15/20	1.17 (1.06–1.28)[a]	52.4	1.14 (1.05–1.24)[a]	58.7
DLBCL	3/8	1.07 (0.64–1.78)	41.3	1.33 (1.18–1.50)[a]	0.0
FL	3/8	1.35 (0.83–2.20)	0.0	1.17 (0.97–1.42)	33.5
CLL/SLL	6/12	1.13 (0.91–1.40)	66.0	0.98 (0.82–1.17)	50.7
HL	7/5	1.36 (1.09–1.69)[a]	33.7	1.61 (1.34–1.93)[a]	0.0
MM	12/11	1.17 (1.01–1.34)[a]	45.6	1.27 (1.15–1.40)[a]	24.7

Abbreviations: 95% CI = 95% confidence limit, I^2 = I^2 statistic; CLL/SLL = chronic lymphocytic leukemia/small lymphocytic lymphoma; DLBCL = diffuse large B cell lymphoma; FL = follicular lymphoma; HL = classic Hodgkin lymphoma; MM = multiple myeloma; NHL = non-Hodgkin lymphoma.

[a] Statistically significant summary relative risks ($P < 0.05$).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. marginal for CLL (RR = 1.04, 95% CI: 1.00–1.09, $n = 7$ studies, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.65$). The data provided little support for an association between obesity and follicular lymphoma or between waist circumference/waist-to-hip ratio and hematological malignancies.

Diet

The results of studies on the effect of diet on lymphoma risks are conflicting, with mostly positive and statistically nonsignificant associations; most results were from case-control studies subject to selection and recall biases, particularly among NHL subtypes. The European Prospective Investigation into Cancer and Nutrition (EPIC) study examined the effects of consuming foods of animal origin by dietary questionnaires assessing dietary choices in the preceding 12 months using Cox proportional hazard regression.[50] Overall, the consumption of foods of animal origin (red/processed meats, poultry, milk/dairy products) was not associated with increased lymphoma risks; however, some increased risks were reported in NHL subgroups (↑B cell chronic lymphocytic leukemia and meat, ↓follicular lymphoma and meat, ↑B cell lymphomas and poultry). In contrast to other cohort studies,[51] high poultry consumption was associated with increased risks of B cell CLL, follicular lymphoma, and B cell lymphomas, whereas milk and dairy products were not associated with elevated risks of B cell, T cell, or Hodgkin lymphomas.

A meta-analysis of 23 case-control and 10 cohort studies using random effects models reported a statistically significant, positive association between red meat consumption and NHL (summary RR = 1.22, 95% CI: 1.03–1.44, $n = 14$ studies, $I^2 = 35\%$), whereas the consumption of fish and seafood was inversely associated with multiple myeloma (summary RR = 0.71, 95% CI: 0.51–1.00, $n = 11$ studies, $I^2 = 82\%$) with very substantial heterogeneity between studies and marginal statistical significance.[52] Dairy consumption was associated with NHL (summary RR = 1.26, 95% CI: 0.99–1.60, $n = 6$ studies, $I^2 = 49\%$), also with moderate heterogeneity and marginal statistical significance. The risks of NHL, CLL, and multiple myeloma from processed and white meat consumption were similar to the null. A Sardinian study of 322 incident lymphoma cases and 446 randomly selected population controls compared the highest and lowest quintiles of food consumption based on food frequency questionnaires covering 112 food items using unconditional and polytomous logistic regression analysis and adjusting for age, education, and gender.[53] The association was positive, but statistically nonsignificant between overall lymphoma risks and well-done red meat (OR = 1.3, 95% CI: 0.8–2.0, 74 cases/81 controls) and processed meat (OR = 1.1, 95% CI: 0.7–1.8, 84 cases/89 controls), whereas the results for consumption of fresh seafood (OR = 0.8, 95% CI: 0.4–1.3, 49 cases/84 controls) and overall Mediterranean diet score (OR = 0.9, 95% CI: 0.6–1.5, 57 cases/99 controls) were not different than the null. Subgroup analysis of lymphoma subtypes suggests a positive association with B cell lymphoma for well-done/roasted chicken ($P_{\text{trend}} = 0.01$) and pizza ($P_{\text{trend}} = 0.047$); the analysis included >130 comparisons with few statistically significant results consistent with chance.

Physical Activity

Epidemiological evidence does not support a significant effect of physical activity on lymphoma risks. In a meta-analysis of seven case-control and five cohort studies, the pooled OR was 0.90 (95% CI: 0.79–1.02, $P_{\text{effect}} = 0.10$, $I^2 = 59\%$).[54] Although case-control studies suggest an inverse effect with physical activity (pooled OR = 0.81, 95% CI: 0.68–0.96, $P_{\text{effect}} = 0.02$, $I^2 = 49\%$), cohort studies confirmed the lack of an association with lymphoma and physical activity (pooled OR = 1.02, 95% CI: 0.88–1.19, $I^2 = 52\%$, $P_{\text{effect}} = 0.76$). The study did not detect statistically significant differences between results for HL and NHL or between recreation and occupational physical activities. The meta-analysis reported moderate heterogeneity between case-control and cohort studies.

Medication

Immunosuppressive drugs (e.g., azathioprine, cyclosporine) used to treat cancers, autoimmune diseases, and organ transplants confound risk assessments of hematological neoplasms including lymphomas. In a cohort of 12,656 incident rheumatoid arthritis cases from the Swedish Cancer Register, treatment with methotrexate or tumor necrosis factor inhibitors was not associated with increased leukemia risks (HR = 0.9, 95% CI: 0.4–1.9).[55]

Diseases

Diseases associated with increased lymphoma risks include infections, immune-deficient states/organ transplantation, and autoimmune conditions.

Infections

Using electron microscopy in 1964, Anthony Epstein and Yvonne Barr discovered the first known human

oncovirus when they identified the Epstein–Barr virus (EBV) in Burkitt lymphoma cells from a Ugandan patient.[56] Almost all endemic (African) Burkitt lymphomas contain latent EBV with clear evidence that EBV infection precedes B cell clonal expansion.[57] Viruses associated with lymphoproliferative cancers include Kaposi sarcoma herpesvirus-8 (primary effusion lymphoma), HIV-1 (non-Hodgkin/Hodgkin lymphoma), Epstein–Barr virus (non-Hodgkin/Hodgkin lymphoma, Burkitt lymphoma), hepatitis C virus (non-Hodgkin lymphoma), and human T cell lymphotropic virus type 1 (adult CD4+ CD25+ T cell leukemia/lymphoma).[58] Human T-lymphotropic virus 1 (HTLV-1) is an RNA retrovirus that develops most commonly in adults of African, Caribbean, Japanese, and South American descent 20–60 years after infection.[59] The herpesvirus-8 (HHV-8) is a DNA virus infecting primarily immunocompromised patients, with Kaposi sarcoma being the most frequent cutaneous manifestation. Latent HHV-8 proteins activate various cytokine-mediated proliferation and oncogenic pathways, while lytic replication disseminates the reactivated virus in immunocompromised patients.[60]

EBV is a B cell lymphotropic, human gamma-1 DNA herpesvirus that infects >90% of the population, primarily during childhood and usually resulting in a latent asymptomatic infection. Under certain circumstances, EBV eventually produces latent membrane protein 1 (LMP1); this oncoprotein activates CD40 receptors using host cell replication machinery and transforms B lymphocytes into proliferating lymphoblastoid cells.[61] A wide range of B, T, and NK cell malignant lymphomas and lymphoproliferative lesions are causally linked to EBV, primarily involving the B cell malignancies, including Burkitt lymphoma, Hodgkin lymphoma, diffuse large B cell lymphoma, and other rare B cell tumors (e.g., primary effusion lymphoma, plasmablastic lymphoma).[14] EBV does not typically infect T or NK cell lineages; on rare occasions, T and/or NK cell infections cause chronic active EBV infection or highly aggressive monoclonal malignancies (e.g., aggressive NK leukemia, extranodal NK/T cell lymphoma). T cell-mediated immune surveillance probably controls EBV infections during primary inoculation and throughout life.[62]

Autoimmune Diseases

Dysregulation of the adaptive immune system (e.g., loss of T cell regulatory mechanisms) and chronic inflammation from autoimmune conditions (e.g., systemic lupus erythematosus, rheumatoid arthritis, psoriasis, Sjögren syndrome, Hashimoto thyroiditis) are associated with elevated lymphoma risks, including Hodgkin lymphomas and non-Hodgkin lymphomas, particularly diffuse large B cell lymphoma, based on observational studies. The risk estimates in these studies vary substantially with relatively wide confidence intervals.[63] Germline and somatic mutations of normal regulatory signaling pathways probably contribute to dysregulation of lymphoid cell proliferation in these patients. In a population-based case-control study of ~25,000 non-CLL NHL cases and 55,000 controls using linkages to central Swedish and Danish Cancer Registries, the overall NHL odds ratio for patients with systemic autoimmune diseases was 2.6 (95% CI: 1.7–4.1).[64] The NHL odds ratios for specific autoimmune diseases ranged from 1.6–5.4.

A family history of systemic autoimmune disease in first-degree relatives was not associated with statistically significant NHL risks (OR = 1.3, 95% CI: 0.85–2.0). The overall Hodgkin and non-Hodgkin lymphoma risks in systemic autoimmune disease patients are similar, whereas associations with CLL and multiple myeloma in these patients are weaker and mostly statistically nonsignificant.

Using Cox regression to analyze lymphoma risks in a cohort of 12,656 incident rheumatoid arthritis cases from the Swedish Cancer Register, the overall hazard ratio for lymphomas was 1.6 (95% CI: 1.2–2.1, n = 62 cases); each case had 10 population-matched controls.[55] The risk of Hodgkin lymphoma was elevated (HR = 4.1, 95% CI: 1.9–9.1, n_{HL} = 9 cases). Inflammatory activity did not correlate to future lymphoma risks. In a Taiwanese study of 23,644 rheumatoid arthritis patients, the highest reported risk among hematological malignancies was for NHL (SIR = 3.54, 95% CI: 3.45–3.63, n_{NHL} = 59 cases); however, this subgroup included many other lymphomas, including multiple myeloma, lymphosarcoma, and reticulosarcoma.[65] The reported SIR for Hodgkin lymphoma was also positive (SIR = 1.76, 95% CI: 1.45–1.56, n_{HL} = 1 case); however, the results were statistically nonsignificant and limited by inadequate sample size. In a pooled analysis of a multisite international systemic lupus erythematosus (SLE) cohort containing 16,409 patients, the standardized incidence ratio was elevated for non-Hodgkin lymphoma (SIR = 4.39, 95% CI: 3.46–5.49, n_{NHL} = 76 cases).[66] The SIR was positive, but statistically nonsignificant for Hodgkin lymphoma (SIR = 2.28, 95% CI: 0.92–4.70, n_{HL} = 7 cases) and multiple myeloma (SIR = 1.88, 95% CI: 0.90–3.46, n_{MM} = 10 cases).

HISTOLOGY

Lymphomas are malignancies of hematological cells that may occur throughout the body where lymph tissue exists. The two main histological types of lymphomas are Hodgkin (HL) and non-Hodgkin (NHL) lymphomas distinguished by the presence of Reed–Sternberg cells in Hodgkin tumors; NHL is 10-fold more common than Hodgkin lymphoma.[67] All Hodgkin and most non-Hodgkin tumors arise from B cells; NHL has >35 subtypes with some NHL subtypes originating from T cells or natural killer cells. Lymphoma subtypes vary in aggressiveness, geographic/demographic distribution, and nongenetic risk factors (e.g., diseases, pharmaceuticals, radiation, immune suppression).

HOST SUSCEPTIBILITY

Most lymphomas are sporadic, with no known familial history; however, a small fraction have germline genetic abnormalities that predispose to lymphomas and other cancers including rare family clusters of ≥2 lymphomas.[68] These inherited syndromes include ataxia-telangiectasia, Bloom syndrome, Li–Fraumeni syndrome, Lynch syndrome (constitutional mismatch repair deficiency syndrome), Nijmegen breakage syndrome, and Wiskott–Aldrich syndrome. Few genes associated with familial lymphoid cancer have been identified. Biological mechanisms involving increased lymphoma susceptibility include genomic instability, disruption of lymphoproliferative homeostasis, immune deficiencies (genetic, immunosuppressive drugs), and chronic antigen stimulation from autoimmune-related diseases, including celiac disease, rheumatoid arthritis, Sjögren syndrome, and systemic lupus erythematosus.[67] Dysregulation of the cell cycle (e.g., mutations in *ATM* gene in ataxia-telangiectasia) or interruption of DNA repair processes (mutations in *TP53*/*CHEK2* genes in Li–Fraumeni syndrome) produce a general predisposition to several cancers. Enhanced production of lymphoid cells from an imbalance between proliferation and apoptosis (e.g., mutations in *FAS* gene in autoimmune lymphoproliferative syndrome) increases lymphoid malignancy risk. Inappropriate lymphoid proliferation also occurs in immunodeficient patients with persistent oncogenic viral infections (e.g., EBV, Kaposi sarcoma-HHV-8), resulting in insufficient cancer surveillance and the formation of premalignant and/or malignant cells (e.g., PASL1 disease, AIDS-related cancers).

Although the relative risks are not well defined, a family history of hematopoietic malignancy increases NHL and HL risks, with lymphoma subtypes sharing some inherited genetic susceptibility while displaying substantial heterogeneity. Generally, a family history of a specific lymphoma subtype is most strongly associated with the risk of a specific lymphoma reflecting the unique genetic landscape for each lymphoma; for HL, the risk of HL is stronger for a personal history of HL in siblings than parents.[69] Approximate increased lymphoma risks among relatives of family members with lymphomas range from 20–50% for HL, 20–60% for CLL, 15% for multiple myeloma, and 9–16% for diffuse large B cell lymphoma (NHL subtype). Lymphoma susceptibility varies significantly between NHL subtypes with particularly high risks for first-degree relatives of family members with diffuse large B cell lymphoma, follicular lymphoma, and Hodgkin lymphoma.[70,71] In a population-based study of 1,506 lymphoma cases (85% participation rate) and 1,229 controls (75% participation rate) linked to the Swedish Multi-Generation and Cancer registries, the occurrence of a first-degree relative with a hematopoietic malignancy increased NHL, HL, and some B cell NHL subtype risks.[72] Using multiple logistic regression to estimate odds ratios, a first-degree relative (parent, sibling) with a hematopoietic malignancy increased NHL risk (OR = 1.8, 95% CI: 1.2–2.5); the NHL risk was stronger for a history of hematopoietic cancer in a sibling (OR = 3.2; 95% CI: 1.3–7.6) than a parent (OR = 1.6, 95% CI: 1.1–2.3). A family history of NHL increased NHL risks (OR = 2.2, 95% CI: 1.4–3.5, n_{NHL} = 62 cases/26 controls), whereas a family history of HL did not significantly increase HL risks (OR = 3.3; 95% CI: 0.5–21.5, n_{HL} = 2 cases) based on a few cases. For NHL subtypes, a history of paternal hematopoietic cancer was statistically significant only for diffuse large B cell lymphoma (OR = 2.2; 95% CI: 1.1–4.2, n_{DLBCL} = 321 cases), whereas a maternal hematopoietic cancer history was associated only with chronic lymphocytic leukemia (OR = 2.4, 95% CI: 1.2–5.0, n_{CLL} = 272 cases). Estimated risks for T cell lymphoma were unstable because of the few cases and inadequate statistical power. The study did not detect any difference in environmental risk factors between familial and nonfamilial NHL.

CLINICAL FEATURES

No presenting clinical features distinguish lymphomas from other diseases except for tumor expansion; the clinical presentations of Hodgkin and non-Hodgkin lymphomas are also similar. Lymphadenopathy in a well-appearing child frequently is a self-limited, transient process that resolves without medical interventions. Physical signs associated with lymphadenopathy

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and increased lymphoma risk include duration >6 weeks; size >2.5 cm with matted, painless, nonmobile appearance; and >1 noncontiguous lymph node area.[2] Complications from tumor growth include superior vena cava syndrome (chest discomfort, tachypnea, orthopnea), abdominal masses (abdominal discomfort, musculoskeletal pain), and CNS involvement (headache, seizures, focal paresthesias/weakness). Nonspecific symptoms from inflammatory cytokine release from advanced tumors may involve fatigue, anorexia, fever (bone marrow infiltration), night sweats, and weight loss.

Patients with lymphomas secondary to inherited cancer predisposition syndromes typically present earlier (i.e., 6–9 years) compared with sporadic cases;[70] Hodgkin lymphoma has a bimodal age distribution peaking in childhood and later adulthood. In an analysis of the Surveillance, Epidemiology, and End Results (SEER) database, the median age at diagnosis for CLL was 71 years compared with 66 years for NHL, 39 years for HL, and 69 years for multiple myeloma.[73] An analysis of data from the Swedish Family-Cancer database indicates the overall mean age at diagnosis was 57 ± 6.9 years for chronic lymphocytic leukemia, 57 ± 7.8 years for multiple myeloma, and 51 ± 13.8 years for NHL.[74] For NHL subtypes, the mean age at diagnosis for diffuse large B cell lymphoma was 51 ± 13.0 years compared with 49 ± 15.0 years for T cell lymphoma and 51 ± 13.0 years for follicular lymphoma, similar to overall NHL rates.

CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

The World Health Organization classifies chronic lymphoid leukemias (CLL) with small lymphocytic lymphoma (SLL) based on a common immunophenotype and a similar clinical course. These tumors are mature B cell neoplasms derived from clonal expansion and accumulation of these malignant cells in bone marrow, spleen, lymph nodes, and peripheral blood. The difference between these two tumors is greater tumor involvement in bone marrow (CLL) than solid lymphoid tissue (SLL).[75] CLL is the most common adult leukemia in Western countries, accounting for ~30% of all leukemia cases; the US age-adjusted CLL incidence is ~4–6/100,000 population, with an estimated ~21,000 new cases, ~4,000 deaths annually, and fairly stable rates.[76] CLL incidence varies with race; a lower incidence occurs in African Americans than Caucasians, with a particularly low incidence in Asian countries (China, Japan, Korea). The difference remains for Asian Americans migrating to the United States.[77] CLL incidence in African American men is 4.6/100,000 compared with 6.2/100,00 for Caucasian men; however, age-adjusted 5-year CLL/SLL survival is higher in Caucasian men (76%) than African American men (63%).[78] The latter is frequently present at later clinical stages with significantly shorter subsequent event-free survival periods.

CARCINOGENESIS

Chronic lymphocytic leukemia/small lymphocytic lymphoma (CLL/SLL) is a highly proliferative disorder of multipotent, self-renewing hematopoietic stem-like cells with a high apoptotic rate. Slow expansion of a B cell clone of antigen-experienced cells occurs in lymphoid tissues, peripheral blood, and bone marrow with the accumulation of incompetent B cell (CD19+/CD23+) and T cell (CD5+) surface antigen-positive lymphocytes despite the high apoptotic rate.[79,80] Additionally, this leukemia is associated with low concentrations of surface immunoglobulins/B cell receptors (IgM, IgD), CD20, CD22, and CD79b; the B cell receptor (BCR) functions as a component of the B lymphocyte antigen-actuated signal transduction pathway.[81] The current diagnostic criteria for CLL require an absolute peripheral B cell count of ≥5,000 cells/μL. Small lymphocytic lymphoma require an absolute peripheral B cell count of ≥5,000 cells/μL, clonal B cell-induced lymphadenopathy with CLL phenotype, and the absence of cytopenias from marrow infiltrates.

Chromosomal Aberrations

CLL/SLL is a very complex, heterogeneous disease with strong familial risks but no CLL-specific genomic aberrations; individual CLL tumors contain wide intra-clonal heterogeneity with different CLL subpopulations and diverse genomic aberrations that evolve in response to the microenvironment and chemotherapeutic pressures.[82] The most common chromosomal abnormality is the 13q14.3 deletion (downregulation of miRNA-15a.16-1 expression) present in ~50–60% of CLL cases.[83,84] This deletion also occurs in other hematopoietic malignancies (diffuse large B cell lymphoma, mantle cell lymphoma, mature T cell lymphoma, multiple myeloma) and some solid tumors.[85] Other common CLL aberrations involve other chromosomal

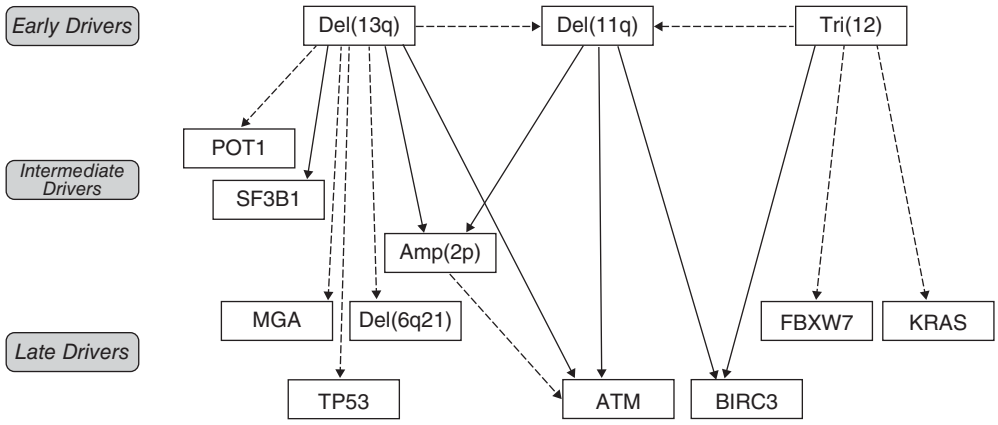

FIGURE 60.3. Chronic lymphocytic leukemia (CLL) deletions and drivers of tumor initiation and progression. Although cancers result from somatically acquired DNA changes in the tumor cells, all mutations do not contribute to cancer development. Malignant neoplasms contain driver and passenger mutations. Driver mutations are selected by the tumor microenvironment to confer a growth advantage and enhance oncogenesis. Passenger mutations are not selected by the microenvironment because they do not confer a growth advantage or contribute to cancer development. (Adapted from Hallek et al.).[87] *Abbreviations:* ATM = Ataxia-telangiectasia mutated serine/threonine kinase; BIRC3 = baculoviral IAP repeat containing 3 (apoptosis inhibitor); FBXW7 = F-box and WD repeat domain containing 7 (tumor suppressor); *KRAS* = *KRAS* proto-oncogene, GTPase; MGA = MAX dimerization protein MGA (3-methylglutaconic acid); POT1 = protection of telomeres 1; SF3B1 = splicing factor 3b subunit 1; *TP53* = tumor suppressor gene expressing p53 protein.

material loss/gain including deletions (11q, 17p, 6q) and gains (trisomy 12, chromosome 19), as well as mutations of tumor suppressors (*TP53*, *ATM*), immunoglobulin heavy-chain variable region (IGHV)-containing genes, and oncogenes (*MYCN, MYCN* proto-oncogene, basic helix-loop-helix transcription factor).[86] Comprehensive genomic analyses indicate the malignant CLL transformation begins with the loss or gain of chromosomal material (e.g., trisomy 12, deletion of chromosomes 13q), as displayed in Figure 60.3.[87] Later, frequent deletions in chromosome 13q (tumor suppressor inhibition) enhance proliferation by dysregulating cell-cycle control and apoptosis; chromosome 11p deletion (DNA damage response kinase, *ATM* gene) and 17 p deletion (*TP53* gene) help drive tumor progression, relapse, and treatment resistance.[88,89]

Mutations

CLL typically has a low mutation rate; these tumors contain large numbers of relatively infrequent mutations rather than a few common mutations. The most common somatic mutations beginning with the most frequent occur in the following genes: *NOTCH1*, *ATM*, *SF3B1*, *BIRC3*, *CHD2*, *TP53*, and *MYD88*; none of these mutations are specific to CLL.[90] These genetic aberrations affect genes in multiple critical cellular pathways including DNA damage/cell-cycle control (*ATM*, *BIRC3*, *TP53*), messenger RNA processing (*SF3B1*), and inflammatory pathways (*MYD88*), NOTCH signaling (*NOTCH1*), as well as BCR signaling, NF-κB signaling, and chromatin remodeling.[91] The latter pathway encodes a class 1 transmembrane protein that acts as ligand-activated transcription factor important for cell proliferation, differentiation, and apoptosis. The *SF3B1* gene encodes a component of the spliceosome that impairs protein binding. The *BIRC3* gene inhibits apoptosis and regulates NF-κB nuclear factor/proinflammatory signaling pathway for cytokines, chemokines, and adhesion molecules (e.g., interleukin 1, tumor necrosis factor α) necessary for inflammatory responses to infection and tissue injury. The mutations in the *TP53* (DNA repair) genes are low at diagnosis but increase with disease progression.

Monoclonal B Cell Lymphocytosis

Monoclonal B cell lymphocytosis (MBL) is defined by the presence of <5,000 B cells/μL in the absence of other lymphoid symptoms and features (i.e., B symptoms, cytopenia, hepatomegaly, lymphadenopathy, splenomegaly). This disorder shares the morphology and immunophenotype of CLL without the leukemic characteristics. This entity is subdivided into low-count (LC-MBL) and high-count (HC-MBL) monoclonal B cell lymphocytosis. The former has <500 CLL-like immunophenotype B cells/μL, whereas the latter has ≥500–<5,000 B cells/μL. LC-MBL is usually an

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

incidental finding identified by highly sensitive flow cytometry techniques.[92] MBL often precedes CLL with a conversion rate to CLL of ~1–2%/year;[93,94] up to 5–12% of healthy individuals have monoclonal B cell lymphocytosis without obvious evidence of CLL, depending on the population studied, age, and cytometry sensitivity.[95]

EXPOSURE

Currently, no acquired risk factors are causally associated with increased CLL/SLL risks reflecting, in part, the difficulty establishing causation for risk factors in rare diseases.[91] A pooled analysis of 2,440 CLL/SLL cases and 15,186 age/sex/race/ethnicity/social/economic status-matched controls from 13 North American, European, and Australian case-control studies used multivariate logistic regression analysis to estimate odds ratios based on telephone or in-person interviews.[96] Positive results suggested potential associations with infection (hepatitis C virus seropositivity), family history, and self-reported height; the results also suggested inverse association with immune function (any atopic condition, recreational sun exposure) and smoking. CLL/SLL risk was not associated with body mass index, weight, specific autoimmune disease, or reproductive history/hormone replacement therapy. The Spanish population-based MCC-Spain study of 560 CLL/SLL cases (87% participation rate) and 1,845 controls (53% participation rate) reported statistically significant increased CLL/SLL risks for central obesity as measured by waist-to-hip ratios ($P_{\text{interaction}} = 0.03$) based on face-to-face interviews.[97] The interaction was statistically significant in women (OR = 1.67, 95% CI: 1.14–2.01, $n_{\text{CLL}} = 175$ cases), but not in men (OR = 1.22, 95% CI: 0.81–1.83, $n_{\text{CLL}} = 299$ cases) or with current BMI. Alcohol consumption was inversely associated with CLL/SLL risks comparing the third and first tertiles of alcohol consumption (OR = 0.65, 95% CI: 0.46–0.92, $P_{\text{trend}} = 0.02$).

Occupation

Although animal data and limited epidemiological data suggest the possibility of an association between leukemia and some chemicals (atrazine, dichlorvos, dioxins, formaldehyde, butadiene, ethylene oxide),[98] there is little definitive evidence linking CLL to specific chemical toxins.[99,100] Observational studies report excess CLL/SLL risks in some industries (agriculture, mining, petroleum, rubber–styrene, wood processing, hairdressers/hair dye) and high occupational exposures (butadiene, ethylene oxide, solvents, styrene);[101] however, study results are generally relatively modest and inconsistent, with some studies reporting no elevated CLL/SLL risks.[98,102] Analysis of human data on CLL is limited by inconsistent classification schemes of lymphohematopoietic malignancies, imprecise exposure data, multiple chemical exposures, long latency/morbidity periods, and small sample size.[103,104]

Benzene

Although occupational benzene exposure is associated with myeloid leukemia, the association with CLL and other non-Hodgkin lymphomas is not conclusive.[105] In a review of benzene exposure and leukemia subtypes, nested case-control studies demonstrated some increased CLL risks with suggestive dose-response relationships, but cohort studies and most population-based case-control studies demonstrated no elevated CLL risks.[106] There is no clear relationship between CLL and chemical exposures including work in the petrochemical industry; most mortality studies of petrochemical workers do not demonstrate a statistically significant increased risk of CLL-induced mortality.[107,108] Although a cohort study of male workers at a Louisiana refinery and chemical plant detected a statistically significant increase in CLL-related deaths (SMR ≈ 3.5, 95% CI: 1.68–6.45), there was no association between CLL and any job or work area.[109] A cross-sectional cohort study of 81,746 former and current male petrochemical workers found a non-statistically significant increase in CLL-related mortality (SMR = 1.60, 95% CI: 0.85–2.73), primarily among white, office-based workers.[110] There were 13 cases of CLL-related deaths with no increased risk by job type. Eleven of the decedents began work from 1934–1955; the latency period was >35 years. A meta-analysis of leukemia subtypes among ~208,000 US and UK petroleum worker cohorts reported a meta-SMR for CLL mortality of 0.84 (95% CI: 0.67–1.04, n = 98.89 deaths expected/83 deaths observed).[111] Thirteen of the 17 US cohorts reported lower than expected CLL mortality rates. CLL incidence was not increased in a cohort of 8,942 Louisiana petrochemical workers with 4 cases of CLL identified among 7,773 workers employed before 1950 compared with 3.27 cases expected.[112] A nested case-control study of petroleum distribution workers in the UK detected 31 incident CLL cases.[113] Analysis of these 31 cases and matched controls from the same company associated CLL with duration of employment; however, the highest risk occurred in white-collar workers with long service and low chemical exposure. There was no definite evidence of an association between benzene exposure and CLL. The mean cumulative benzene exposure for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cases and controls was 2.6 ppm-years and 3.6 ppm-years, respectively. Examination of shoe workers exposed to very high benzene concentrations did not detect any CLL cases in a case series of 26 Turkish workers.[114,115]

Pesticides

Some case-control studies suggest a slightly elevated CLL risk for ever-working as a farmer (e.g., range, 1.4–1.7) based on mortality studies, death certificates, and interviews;[97] however, the results are inconsistent and generally lack an exposure-response relationship between any particular pesticide and CLL risks. In a population-based study of 578 Minnesotan and Iowan Caucasian farmers (40% deceased) and 1,245 controls (34% deceased), the CLL risk in ever-farmers was elevated (OR = 1.4, 95% CI: 1.1–1.9, n_{CLL} = 156 cases) using never-farmers as referents.[116] No common leukemia subtype was positively associated with farming duration; the odds ratio for CLL risk for >45 years of farming was 1.1 (95% CI: 0.7–1.8, n_{CLL} = 28 cases). The CLL risk was statistically marginal for using insecticides (OR = 1.3, 95% CI: 1.0–1.8, n_{CLL} = 122 cases) and herbicides (OR = 1.4, 95% CI: 1.0–2.0, n_{CLL} = 74 cases). No specific pesticide was associated with increased CLL risks. In a pooled analysis of 13 mostly Caucasian North American, European, and Australian studies, ever-living or ever-working on a farm was associated with modestly increased CLL/SLL risks (OR = 1.21, 95% CI: 1.07–1.36, n_{CLL} = 835 cases, $P > 0.002$) using nonfarm residents as referents. Individually, CLL/SLL risks for ever-working on a farm were marginally significant (OR = 1.16, 95% CI: 1.00–1.35, n_{CLL} = 290, $P = 0.051$); however, the CLL/SLL risk for ever-living on a farm was statistically nonsignificant (OR = 1.12, 95% CI: 0.97–1.30, n_{CLL} = 487 cases, $P = 0.130$) compared with never-living on a farm.

Ionizing Radiation

In contrast to other major leukemia subtypes, CLL is not typically associated with elevated risks following ionizing radiation exposure. CLL does not share the same risk factors as CML or AML, including no statistically significant increased CLL incidence or a definite dose-response relationship in cohorts exposed to high ionizing radiation doses. However, the potential for a positive, albeit lower, risk than other leukemia subtypes remains because of study limitations including long latency, low morbidity, and small sample size.[117,118] Analysis of cohorts (e.g., X-ray therapy for ankylosing spondylitis, Japanese atomic-bomb survivors) receiving high ionizing radiation doses has not detected statistically significant increased CLL risks.[119,120] Newly identified CLL cases in the Japanese Life Span Study suggest CLL risk might increase at higher ionizing radiation doses (P = <0.05) with longer follow-up based on linear age/gender-adjusted baseline model; however, the statistical significance was marginal.[121] In predominately European populations, CLL risks were marginally elevated following ionizing radiation exposure in Czech uranium miners and Chernobyl cleanup workers,[122] but not significantly elevated in Russian radioactive waste Techa River workers, Canadian uranium miners, or medical radiation treatment including radiation-treated primary cancers.[123]

Lifestyle

Lifestyle is not a strong CLL risk factor. In a pooled analysis of 13 mostly Caucasian North American, European, and Australian studies, total (OR = 0.75, 95% CI: 0.59–0.96, n_{CLL} = 173 cases, $P = 0.005$) and recreational (OR = 0.80, 95% 0.69–0.94, n_{CLL} = 428 cases, $P = 0.029$) sun exposures were inversely associated with CLL/SLL risks comparing the highest and lowest exposure quartiles. The study results did not support an association between CLL/SLL risks and alcohol consumption or physical activity. Overall, CLL risks are not associated with alcohol consumption. In a meta-analysis of four case-control and one cohort study using random effects models to estimate relative risks and nondrinkers as referents, the overall pooled RR for any alcohol drinkers was 0.94 (95% CI: 0.77–1.15, n = 5 studies, $I^2 = 0.0\%$, $P_{heterogeneity} = 0.639$).[124] The results demonstrated no dose-response relationship between CLL risks and light (RR = 0.89, 95% CI: 0.62–1.29, n = 5 studies, $I^2 = 32.4\%$, $P_{heterogeneity} = 0.218$) or moderate-heavy (RR = 0.99, 95% CI: 0.78–1.24, n = 5 studies, $I^2 = 0.0\%$, $P_{heterogeneity} = 0.240$) alcohol consumption.

Tobacco Smoking

Some epidemiological data support an inverse association between CLL risks and cigarette smoking. In a pooled analysis of 13 mostly Caucasian North American, European, and Australian studies, a history of cigarette smoking was inversely related modestly to CLL/SLL risks (OR = 0.90, 95% CI: 0.81–0.99, n_{CLL} = 1,246 cases, $P = 0.38$) compared with never-smokers.[96] The frequency ($P = 0.68$) and duration of smoking ($P = 0.165$) were positive, but not statistically different than CLL/SLL in nonsmokers. The Spanish population-based MCC-Spain study of 560 CLL/SLL cases (87% participation rate) and 1,845 controls (53% participation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

rate) reported no increased CLL/SLL risks for cigarette smokers based on data from face-to-face interviews.[97] The age/sex/region-adjusted odds ratio for CLL/SLL in ever-smokers was 0.95 (95% CI: 0.61–1.46, n_{CLL} = 64 cases) using never-cigarette smokers as referents.

Obesity

The association between obesity as measured by BMI and CLL/SLL risks is weak. In a meta-analysis of six prospective studies using random effects modeling, the relative risk/5-kg/m^2 increased BMI was marginally significant and small (RR = 1.04, 95% CI: 1.00–1.09, I^2 = 0.0%, $P_{heterogeneity}$ = 0.648).[125] Another meta-analysis using random effects modeling and normal weight participants as referents reported no significant relationship between BMI and CLL/SLL risks.[48] The pooled RR for overweight participants was 1.10 (95% CI: 0.98–1.22, n = 10 studies, I^2 = 54.8%, $P_{heterogeneity}$ = 0.217) and 0.98 (95% CI: 0.82–1.17, n = 12 studies, I^2 = 50.7%, $P_{heterogeneity}$ = 0.022) for obese participants. CLL/SLL risks were not associated with abdominal fatness (waist circumference, waist-to-hip ratio) comparing the highest and lowest categories (RR = 0.82, 95% CI: 0.56–1.19, n = 6 studies, I^2 = 60.0%, $P_{heterogeneity}$ = 0.028).

Diet

The Iowa Women's Health Study on 35,221 women aged 55–69 years followed for 14 years reported little evidence of an association between dietary factors and leukemogenesis based on baseline food frequency data.[126] Examining 17 food groups in 58 CLL cases, none of the food groups were associated with statistically significant elevated CLL risks; the P_{trend} ranged from 0.08–0.99. The European Prospective Investigation into Cancer and Nutrition (EPIC) study involving 476,160 participants from 10 European countries examined the effect of the Mediterranean diet on lymphoma risks using an adapted relative Mediterranean diet score.[127] After adjusting for potential confounders using multivariate Cox proportional hazards regression models stratified for age, sex, education, BMI, height, physical activity, smoking, and alcohol consumption, analysis of lymphoma subtypes did not display any statistically significant associations. Comparing the highest and lowest diet scores, the hazard ratio for CLL/SLL was not positive or statistically significant (HR = 0.92, 95% CI: 0.68–1.25, P_{trend} = 0.45).

Diseases

The Spanish population-based MCC-Spain study of 560 CLL/SLL cases (87% participation rate) and 1,845 controls (53% participation rate) reported an inverse association between diabetes type II and CLL/SLL risks (OR = 0.72, 95% CI: 0.54–0.97, n_{CLL} = 69 cases).[97] In a pooled analysis of 13 North American, European, and Australian studies, hepatitis C virus seropositivity was strongly associated with increased CLL/SLL risks (OR = 2.08, 95% CI: 1.23–3.49, n_{CLL} = 95 cases) compared with seronegative referents.[96] A family history of any atopic disorder was inversely associated with CLL/SLL risks (OR = 0.86, 95% CI: 0.78–0.95, n_{CLL} = 705 cases) and allergies (OR = 0.87, 95% CI: 0.77–0.98, n_{CLL} = 462), but not specifically with food allergies, asthma, hay fever, or eczema.

HISTOLOGY

Chronic lymphocytic leukemia and small lymphocytic lymphoma are lymphoid neoplasms classified together by the World Health Organization as a non-Hodgkin lymphoma subtype; these tumors originate from the expansion of a clone of mature CD5+ B cells. Peripheral blood smears demonstrate many small lymphocytes with scanty cytoplasm, dense nucleus without nucleoli, and clumped chromatin. A histological hallmark of CLL/SLL is the presence of smudge cells (Gumprecht nuclear shadows); these leukemic cells rupture during peripheral blood smear preparation due to increased cell membrane fragility.[128] Lymphoid infiltration of the bone marrow typically represents >30% of the cellularity in CLL. Peripheral blood immunophenotyping usually demonstrates high expression of CD5, CD19, CD23, and CD200, whereas CD20 and surface immunoglobulins (IgM/IgD) expression is typically low (dim) with light-chain restriction to either kappa or lambda.[91] B cell clones in CLL develop predominately in the bone marrow and blood, whereas small lymphocytic lymphoma localizes primarily in the lymph nodes. Small B cell clones with CLL phenotype characterize monoclonal B cell lymphocytosis (MBL) in the *absence* of clinical features of a lymphoproliferative disorder (e.g., cytopenia, B symptoms, lymphadenopathy, organomegaly).

HOST SUSCEPTIBILITY

The inherited susceptibility to chronic lymphocytic leukemia is one of the strongest of all hematological malignancies. A family history of CLL or non-Hodgkin lymphoma is a strong risk factor for CLL, with ~10% of incident CLL cases having at least two close family members with CLL.[69,129] In a case-control study of 14,336 first-degree relatives of 5,918 CLL cases from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the Swedish Family-Cancer Database using 28,876 first-degree relatives of 11,778 controls in the database, the CLL relative risk in first-degree relatives of CLL patients was 7.52 (95% CI: 3.63–15.56).[130] The large confidence interval suggests imprecise risk estimates. Excess non-Hodgkin subtypes include lymphoplasmacytic lymphoma/Waldenström macroglobulinemia and hairy cell leukemia.[131] In a pooled analysis of 13 North American, European, and Australian studies, a family history of any hematological malignancy was strongly associated with increased CLL/SLL risks (OR = 2.17, 95% CI: 1.77–2.65, n_{CLL} = 153 cases, P = <0.001) including non-Hodgkin lymphoma (OR = 1.92, 95% CI: 1.41–2.61, n_{NHL} = 62 cases, P = <0.001).[96]

CLL/SLL tumors have >30 identified susceptibility loci. Meta-analyses of genome-wide association studies indicate established loci explain ~20–30% of familial CLL risks; these hereditary analyses confirm the importance of apoptosis and/or immune function in CLL susceptibility.[132,133] The histological features of familial and sporadic CLL are similar, with the exception of a higher frequency of somatic immunoglobulin heavy-chain variable region (IGHV) gene hypermutation.[134]

The major histocompatibility complex (HLA) plays an important part in immune surveillance by identifying malignant cells for T cell-mediated destruction. HLA class I proteins present peptides from endogenous proteins to cytotoxic CD8+ T cells, whereas HLA class II proteins detect exogenous proteins and present their peptides to CD4+ helper T cells. Downregulation of HLA class I/II and dysregulated immune surveillance occur in CLL/SLL cells. A German Caucasian case-control study suggests an increased CLL/SLL risk associated with HLA class II ($RR_{HLA\text{-}DRB4*0103}$ = 2.74, P < 0.0025).[135] In a HLA genotyping study of 3,491 US whites, 397 African Americans, and 90 Hispanic CLL patients requiring stem cell transplants for survival with 50,000 population-based controls, predisposing HLA alleles differed between races.[136] Two HLA class II predisposing HLA genotypes (HLA-A*02:01, HLA-DRB4*01:01) were overrepresented in whites, whereas several other predisposing haplotypes (DRB4*01:01~DRB1*07:01~DQB1*03:03) occurred across all three racial populations.

CLINICAL FEATURES

CLL is typically a slowly progressive disease associated with an increased incidence with age. Chronic lymphocytic leukemia is a disease primarily of the elderly with >70% presenting over the age of 65 years and a median age at diagnosis of 72–73 years. CLL occurs more often in men than women (male/female range, 0.5–2.1). Although frequently asymptomatic and discovered as an incidental finding of sustained lymphocytosis or lymphadenopathy, some CLL patients develop a more fulminant course depending on tumor genetics (e.g., miRNA-15a/16.1, miRNA-29b).

Patients may complain of nonspecific symptoms (fatigue, fever, night sweats, weight loss) from marrow infiltration (anemia, thrombocytopenia, neutropenia), splenomegaly (abdominal pain, bloating), lymphadenopathy, or immune dysfunction (recurrent infections). B symptoms include fever of unknown origin (>100.5°F for ≥2 weeks), ≥10% weight loss within 6 months, and night sweats >1 month without infection; occurrence of these symptoms with CLL is uncommon. Autoimmune hemolytic anemia and less commonly immune thrombocytopenia are the most frequent autoimmune manifestations. Opportunistic infections and secondary malignancies may complicate the clinical course of monoclonal B cell lymphocytosis and CLL/SLL. Reduced humoral and cell-mediated immunity predisposes the CLL patient to infections (e.g., upper/lower respiratory and urinary tracts, reactivated herpes zoster).

CLL is an incurable disease; however, treatment with kinase inhibitors (ibrutinib, idelalisib), BCL-2 antagonists (venetoclax), and anti-CD20 monoclonal antibodies (rituximab) significantly improves the lifespan of these patients. Survival after CLL diagnosis is highly variable, ranging from a normal lifespan for age/sex-matched healthy individuals to death shortly after diagnosis.[137] Unmutated immunoglobulin heavy-chain variable (*IGHV*) genes, CD38 overexpression, 11q deletion, SF3B1 mutation, and the presence of *TP53* deletion and/or mutation worsen CLL prognosis, whereas the presence of *IGHV* gene hypermutation and deletion of the long arm of chromosome 13 improves survival.[138] The overall 5-year survival rate is 66% in the United States with a median survival of ~10 years depending on the initial clinical stage.[139]

HODGKIN LYMPHOMA

Hodgkin lymphoma (HL) is a unique tumor characterized by malignant Hodgkin–Reed–Sternberg cells surrounded by a large inflammatory microenvironment. In the United States, the annual incidence of HL is ~8,000 cases with an estimated 1,000 HL-related deaths. Hodgkin lymphoma accounts for ~10–12% of lymphomas, whereas non-Hodgkin lymphoma incidence

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

is ~9-fold higher.[76] The estimated worldwide annual incidence of Hodgkin lymphoma is ~80,000 (i.e., 27th most common cancer) with ~26,000 annual attributable deaths.[1] These rates have been relatively stable in the recent past, while mortality rates have steadily declined by ~75% over the last 40 years in economically developed countries. Little racial differences in HL incidence exist between whites and blacks; Asian/Pacific Islanders and American Indians/Alaskan Natives have ~½ the HL incidence of blacks/whites. Hodgkin lymphoma incidence has a bimodal peak (young adults 15–24 years, elderly) in economically developed countries, with a median age of ~39 years depending somewhat on the distribution of subtypes.[140,141] For adolescents aged 15–19 years, lymphomas are the most common cancer accounting for 21% of newly diagnosed (incident) cases with ~2/3 being Hodgkin lymphoma.

CARCINOGENESIS

Hodgkin lymphoma arises from germinal center B cells that proliferate and overcome apoptotic signals from activation of NF-κB and JAK/STAT pathways as well as expression of latent membrane protein (LMP1) in tumors with Epstein–Barr virus (EBV)-infected cells. EBV+ Hodgkin–Reed–Sternberg cells express three viral proteins (LMP1, LMP2, EBNA1). LMP1 activates JAK/STAT, NF-κB, and PI3K cell signaling pathways along with inducing transcriptional changes in germinal center B cells.[142] NF-κB complexes regulate a variety of proinflammatory cytokines and antiapoptotic factors, whereas the JAK/STAT pathway mediates cytokine stimulation to enhance the inflammatory microenvironment. In addition to inhibiting apoptosis, LMP1 also suppresses the virus lytic cycle. EBV nuclear antigen 1 (EBNA1) contributes to malignant transformation by downregulating protein-tyrosine phosphatase-κ (tumor suppressor); this viral protein also helps maintain the HL microenvironment by attracting regulatory T cells through upregulation of chemokine CCL20 (macrophage inflammatory protein 3 alpha). PD-1 (program death receptor-1) and CTLA-4 (cytotoxic T cell-associated protein 4) are immune checkpoint receptors in activated T cells that recognize host tissue and prevent autoimmune disease.[143] PD-1 mutations exhaust activated T cells, reduce tumor surveillance, and provide a favorable environment for tumor growth.

EXPOSURE

There are few established risk factors for Hodgkin lymphoma. Classic Hodgkin and non-Hodgkin lymphomas share some risk factors including EBV, certain autoimmune disorders, family hematopoietic malignancies, and severe congenital/acquired immune deficiencies.

Occupation

Several studies investigated the association of Hodgkin lymphoma with multiple occupational categories including pesticide exposures (insecticides, fungicides, herbicides, fumigants), farming, woodworking, and ionizing radiation; however, inconsistent results, multiple comparisons, overly broad, heterogeneous exposure categories, and small sample size limit definitive conclusions regarding causation and specific exposures. Although these studies suggest several potential occupational HL carcinogens, particularly multiple carcinogens, no single occupation, chemical exposure, or pesticide has been causally linked to HL.[144] A review of the Silver Platter Occupational and Environmental Medicine CD-ROM database on articles published on Hodgkin lymphoma through 5/1997 noted no particular occupation or chemical exposure was a confirmed increased HL risk with the possible exception of woodworkers.[145] In that database, 5 of 12 observational studies reported statistically significant increases in HL risks ranging from 1.8–7.2; however, no specific chemical carcinogen was identified and subsequent studies have not confirmed an elevated HL risk in these workers. In a meta-analysis of glyphosate and Hodgkin lymphoma, the meta-relative risk was statistically null (metaRR = 1.1, 95% CI: 0.7–1.6, $n = 2$ studies).[146]

Solvents are a very broad chemical class. An Italian study identified 304 HL cases and 1,530 population controls (no solvent exposure); they investigated age/sex/education/region-adjusted HL risks for six solvent classes (aromatic, chlorinated, technical, aliphatic, and derivative oxygenate hydrocarbons) using in-person interviews and expert ratings of exposure intensity/duration.[147] For medium/high exposure to any solvent, the HL risk was not statistically significant (adjusted OR = 1.4, 95% CI: 0.9–2.1, $n_{HL} = 49$ cases/208 controls, $P_{trend} = 0.09$). None of the six solvent classes demonstrated statistically significant trends in HL risks for exposure intensity (P_{trend} range, 0.28–0.78) or duration (P_{trend} range, 0.13–0.90). The trend comparing exposure duration ≤15-year and >15-year exposures to any solvent was statistically significant ($P_{trend} = 0.01$), along with the HL risks for >15-year exposure to technical and aliphatic hydrocarbons. A systematic review and meta-analysis of 41 cohort studies of polycyclic aromatic hydrocarbon (PAH) exposure workers did not detect any statistically significant excess HL risks

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in jobs or industries with high PAH exposure.[148] The highest reported positive HL risk occurring in iron and steel foundry workers was statistically nonsignificant (metaRR = 1.38, 95% CI: 0.95–2.01, n = 6 studies/27 cases, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.53$).

Job Title

A Canadian study on 316 HL cases and ~5 age-matched male adult controls (no exposure) for each case investigated HL risks for 7 broad classes and 49 individual occupational exposure categories based on self-reported mail questionnaires.[149] Ionizing radiation was the only broad class associated with a statistically significant increase in HL risks based primarily on uranium exposure (adjusted OR = 2.42, 95% CI: 1.12–5.24). None of the 49 individual exposure categories were associated with a statistically significant increased HL risk, whereas 1 class (nonionizing radiation, primarily sunlight) and 3 categories (grain dust, sour gas, ultraviolet light) had an inverse association between HL risks and occupational exposures. The study reported no association between HL risks and long-held jobs (>1 year) or specific classical HL subtypes.

Pesticides

Although some studies associate chlorophenol and pesticide exposure with elevated Hodgkin lymphoma risks, large case-control studies report no consistently elevated Hodgkin lymphoma risks in these workers.[150] A meta-analysis of 30 observational studies on farmers and Hodgkin lymphoma suggests male, but not female, farmers have a slightly elevated Hodgkin lymphoma risk; however, the specific cause (e.g., pesticides or infections) was not identified.[151] The combined RR for HL risk was statistically significant (metaRR = 1.25, 95% CI: 1.11–1.42) with significant heterogeneity, whereas the metaRR for women was not statistically significant (metaRR = 1.08, 95% CI: 0.91–1.29). Only one cohort study reported a statistically significant increased RR with the combined estimate HL risk for cohort studies of 1.08 (95% CI: 0.97–1.20). HL risks decreased in more recent studies. Limited observational data do not support an exposure-response relationship between farming and HL risks.[152]

A French study identified 87 HL cases and 265 hospital controls (no exposure).[153] Based on self-reported use in face-to-face interviews, HL risks were statistically significant for domestic insecticide use (OR = 2.9, 95% CI: 1.6–5.4, n_{HL} = 38 cases/74 controls), but not herbicide use (OR = 1.5, 95% CI: 0.6–4.1, n_{HL} = 7 cases/22 controls) or occupational pesticide use (OR = 2.1, 95% CI: 0.8–5.2, n_{HL} = 9 cases/24 controls). Dramatically elevated HL risks were reported for triazole fungicides (OR = 8.4, 95% CI: 2.2–32.4, n_{HL} = 6 cases/6 controls) and urea herbicides (OR = 10.8, 95% CI: 2.4–48.1, n_{HL} = 5 cases/4 controls). The large confidence intervals reflect small sample size and imprecise estimates. In a Canadian case-control study of 316 HL cases and 1,506 population-based controls (no herbicide exposure), the HL risk for any phenoxy herbicide exposure was null (OR = 0.99, 95% CI: 0.70–1.38, n_{HL} = 65 cases).[154]

Lifestyle

Few risk factors are associated with Hodgkin lymphoma (HL) including childhood HL. In a US study of 17,672 childhood cancer cases (390 Hodgkin lymphomas) and 57,966 controls using pooled population data, maternal age was not associated with childhood HL (OR = 0.97, 95% CI: 0.83–1.12) after adjustment for paternal age and multiple potential risk factors (sex, birthweight, birth order, birthyear, region, gestational age, and maternal race).[155] The association between tobacco smoking and HL is suggestive, but not conclusive.

Tobacco Smoking

Although tobacco smoking is the best-studied potential HL risk factor, results are inconsistent with statistically inverse (OR = 0.7, 95% CI: 0.5–0.9, n_{HL} = 134 cases/289 controls, P = 0.02),[156] null (OR = 0.8, 95% CI: 0.6–1.3, n_{HL} = 88 cases/261 controls),[157] and positive (OR_{men} = 2.83, 95% CI: 1.37–5.84, n_{HL} = 47 cases/259 controls)[158] associations comparing ever- and never-tobacco smokers. In a population-based case-control study, current male smokers aged 32–60 years had a significantly increased Hodgkin lymphoma risk (OR = 1.8, 95% CI: 1.4–2.5, n_{HL} = 155 cases) using never-smokers as referents.[159] The trend for tertiles of smoking duration in years (P_{trend} = <0.001) and cumulative smoking in pack-years (P_{trend} = <0.001) was statistically significant. The OR for the tertile of smokers with ≥40 pack-years was 2.7 (95% CI: 1.8–4.3, n_{HL} = 51 cases). The odds ratio for the most common HL subtypes (nodular sclerosis, mixed cellularity) was also significantly increased. Specific smoking information was available for only a portion of the 308 HL cases (155 cases for current smokers, 51 cases for ≥40 pack-year smokers).

A pooled analysis of data from the European International Lymphoma Epidemiology Consortium

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(InterLymph) containing 12 case-control studies reported marginally increased adjusted HL risks comparing ever- and never-smokers (OR = 1.10, 95% CI: 1.01–1.21).[34] Stratified analyses demonstrated increased risks for mixed cellularity and EBV+ classical HL subtypes, whereas the risks for nodular sclerosis and EBV− classical HL subtypes were not statistically significant. The study did not find supportive evidence for monotonic dose-response associations between classical HL risks and smoking. In a Danish-Swedish Scandinavian Lymphoma etiology (SCALE) study of 586 classical HL cases and 3,187 population controls using never-smokers as referents, the odds ratios were statistically significant for ever-smokers with EBV+ classic HL and HL overall in current smokers, but not in ever-smokers with overall HL risks or EBV− classic HL, as displayed in Table 60.3.[160] The smoking information was based on standardized telephone interviews. The authors opined that the limited evidence of a dose-response pattern suggests the association between tobacco smoking and classical Hodgkin lymphoma is causally weak.

A meta-analysis of 14 case-control and 3 cohort studies reported a modestly elevated adjusted meta-OR for Hodgkin lymphoma in ever-smokers of 1.13 (95% CI: 1.01–1.27, I^2 = 49.7%, P = 0.01) and 1.35 (95% CI: 1.17–1.56, I^2 = 48.9%, P = <0.001) in current smokers using never-smokers as referents.[161] The results for former smokers were null (meta-OR = 0.95, 95% CI: 0.81–1.10, I^2 = 43.1%, P = 0.48), with slight to moderate heterogeneity similar to current and ever smokers. The HL risk for current smokers of ≥10 cigarettes daily was not statistically different than the null.

Alcohol

A French study of 824 lymphoma cases and age/sex/center-matched controls reported an inverse association between ever- and never-alcohol consumption (OR = 0.5, 95% CI: 0.3–0.8, n_{HL} = 104 cases/337 controls, P = <0.01), including a statistically significant trend comparing the highest quartile (>21 drinks/week) and <3.8 drinks/week as referents (OR 0.3, 95% CI: 0.1–0.6, n_{HL} = 12 cases/80 controls, P_{trend} = <0.05).[157] A German case-control study also supported an inverse association between alcohol consumption and HL risks, with no specific association with beverage type. The HL risk was statistically marginal for men (OR = 0.51, 95% CI: 0.26–1.01, n_{HL} = 38 cases/329 controls) and significant for women (OR = 0.42, 95% CI: 0.20–0.89, n_{HL} = 30 cases/255 controls).[158]

Diseases

Epstein–Barr Virus

A substantial portion of Hodgkin lymphoma (HL) tumors contain evidence of Epstein–Barr virus (EBV) infection, with serologically confirmed infectious mononucleosis associated with persistently increased Hodgkin lymphoma risks. In a Danish cohort study of Hodgkin lymphoma incidence rates in 17,045 participants with serological evidence of a prior acute EBV infection and 24,614 controls without evidence of an EBV infection, the EBV+ Hodgkin lymphoma risk was significantly increased (RR = 4.0, 95% CI: 3.4–4.5) with an estimated median incubation time from mononucleosis to EBV-positive Hodgkin lymphoma of 4.1 years (95% CI: 1.8–8.3).[162] Although early EBV exposure has protective effects against Hodgkin lymphoma in children, EBV is associated with childhood classical HL (cHL) depending on subtype; for the most common histological cHL subtype in early childhood, EBV positivity occurs in 70–80% of mixed-cellularity cHL. The hallmark malignant cell of Hodgkin lymphoma (Hodgkin–Reed–Sternberg cell) contains genetic fragments produced by this virus.[163] EBV infection is not associated with the other major cHL type (nodular lymphocyte-predominant).[162]

TABLE 60.3. Multivariate odds ratios for association between classic Hodgkin lymphoma risk and categories of cigarette smoking, including Epstein–Barr virus (EBV) status, based on a Danish-Swedish case-control study. (Adapted from Hjalgrim et al.).[160]

Smoking Category	HL Overall Cases/Controls	HL Overall OR (95% CI)	EBV+ Classic HL OR (95% CI)	EBV− Classic HL OR (95% CI)
Never	299/1,460	Referent	Referent	Referent
Ever	275/1,665	1.18 (0.94–1.48)	1.62 (1.08–2.43)	1.13 (0.86–1.49)
Current	182/712	1.57 (1.22–2.03)	2.36 (1.51–3.71)	1.43 (1.05–1.97)

Abbreviations: CI = confidence interval; EBV+ = Epstein–Barr seropositive; EBV− = Epstein–Barr seronegative; HL = Hodgkin lymphoma; OR = odds ratio.

Immunodeficiency

Immunosuppression from a variety of medical conditions increases HL risks, including human immunodeficiency virus (HIV), organ transplants with immunosuppressive therapy, and primary immunodeficiency disorders (ataxia-telangiectasia, autoimmune lymphoproliferative syndrome). In the Surveillance, Epidemiology, and End Results (SEER) program of 13 US population-based, central cancer registries using data from 54,780 HIV-infected persons in the Adult and Adolescent Spectrum of HIV Disease Project (47,832 patients) and 6,948 patients in the HIV Outpatient Study, the standardized rate ratio for Hodgkin lymphoma in HIV+ participants was 14.7 (95% CI: 11.6–18.2, n_{HL} = 150 cases).[164] HL is a late complication of solid organ transplantation. A retrospective cohort study of US solid organ transplant recipients (1997–2007) reported an elevated HL risk (SIR = 2.2, 95% CI: 1.7–2.7, n_{HL} = 73 cases) that increased linearly over time.[165] Most HL cases with HIV were EBV+.

Autoimmune Disease

Analyses of cancer registry linkage and pooled cohort data suggest a positive association between a history of autoimmune disease and HL risks.[166] A Nordic case-control study using population-based linked registry data from Sweden and Denmark on 7,476 Hodgkin lymphoma cases and 18,573 matched controls (no autoimmune disease) reported elevated HL risks for rheumatoid arthritis (OR = 2.7, 95% CI: 1.9–4.0, n_{HL} = 61 cases/50 controls), systemic lupus erythematosus (OR = 5.8, 95% CI: 2.2–15.1, n_{HL} = 15 cases/6 controls), and sarcoidosis (OR = 14.1, 95% CI: 5.4–36.8, n_{HL} = 27 cases/5 controls).[167] In a nested case-control study from the Scandinavian Lymphoma Etiology (SCALE) study involving 585 HL cases and 3,187 population-based controls (no arthritis), self-reported history of rheumatoid arthritis was associated with increased overall cHL risks (OR = 2.63, 95% CI: 1.47–4.70).[168] Subgroup analyses indicated HL risks were higher in mixed-cellularity (OR = 4.25, 95% CI: 1.66–10.9, n_{HL} = 102 cases) and EBV+ (OR = 3.18, 95% CI: 1.23–8.17, n_{HL} = 142 cases) cHL subtypes than the statistically nonsignificant elevations of HL risks in nodular sclerosis (OR = 2.10, 95% CI: 0.96–4.58, n_{HL} = 409 cases) and EBV− (OR = 1.60, 95% CI: 0.64–4.01, n_{HL} = 356) cHL subtypes. The large confidence limits reflect imprecise OR estimates.

Atopy

In the Scandinavian SCALE study, self-reported atopic diseases (asthma, hay fever, atopic dermatitis) were not associated with elevated overall classical HL risks (OR = 0.81, 95% CI: 0.64–1.03, P = 0.09) compared with controls (no atopic disease) consistent with most previous epidemiological studies.[168] In the European, multicenter Epilymph study of 275 classical HL cases and 273 unexposed, age/sex-matched population controls, occupational exposure to eight common protein-derived, high-molecular-weight sensitizing agents was inversely associated with classical Hodgkin lymphoma (OR = 0.62, 95% CI: 0.40–0.98).[169] These agents included animal dander, flour, plant mites, enzymes, and latex antigens.

HISTOLOGY

Hodgkin lymphoma B cell tumors originate in germinal centers or postgerminal center B cells surrounded by a large reactive inflammatory microenvironment comprising lymphocytes, neutrophils, eosinophils, histiocytes, mast cells, macrophages, and plasma cells.[170] The presence of Reed–Sternberg cells in the tumor characterizes Hodgkin lymphoma. The major subtypes of Hodgkin lymphoma (HL) are nodular lymphocyte-predominant Hodgkin lymphoma (NLPHL) and classical Hodgkin lymphoma; the latter has four distinct subtypes (nodular sclerosis, 70–75%; mixed cellularity, 20–25%; lymphocyte rich, 5%; lymphocyte depleted, <1%), primarily reflecting differences in the surrounding nonneoplastic infiltrate and the abundance of Hodgkin–Reed–Sternberg cells. The first two subtypes account for 90% of all classical Hodgkin lymphoma cases.[171] NLPHL typically displays large cells (L&H cells) with a nodular architecture separated by green birefringent, dense collagenous fibrous bands, and single nucleus with multiple, small nucleoli producing a "popcorn-like" appearance. The nonneoplastic microenvironment contains small lymphocytes with histocytes that may form non-necrotizing granulomas. Neutrophils, eosinophils, and plasma cells are rarely present in the background. The mixed-cellularity classical HL subtype displays a diffuse, mixed, inflammatory background without bands of sclerosing fibrosis. A majority of this type of tumor expresses Epstein–Barr-encoded latent membrane protein 1 and EBV small nuclear RNA transcripts including patients without known immunodeficiencies.[140,172] The lymphocyte-depleted subtype frequently occurs in association with HIV; the tumor is diffusely infiltrated with Hodgkin–Reed–Stenberg cells without a significant reactive inflammatory infiltrate. Necrosis may occur in this tumor subtype.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Hodgkin–Reed–Sternberg cells are usually CD30+/CD15+, whereas the NLPHL lymphocyte predominate cells are CD30−/CD15− and CD45+/CD20+. The Hodgkin and Reed–Sternberg cells are common features of all classic Hodgkin lymphoma subtypes. The Reed–Sternberg cell is a large cell with ≥2 nuclear lobes, separate nucleoli, and an "owl's eyes" appearance, whereas the Hodgkin cell is the mononuclear form of the Reed–Sternberg cell. These most common classical HL cells comprise only 1–2% of the tumor mass with the remaining consisting of nonneoplastic cellular infiltrate (T cells, B cells, eosinophils, macrophages, neutrophils, plasma cells, fibroblasts).[173] These tumors primarily affect the lymph nodes, liver, and spleen.

HOST SUSCEPTIBILITY

Familial aggregation and ethnic variation in HL incidence suggest inherited susceptibility increases Hodgkin lymphoma risks, particularly in monozygotic twins and same-sex sibling pairs with familial HL accounting for ~4–6% of HL cases.[2,174] The role of inherited disease is substantially less in HL than in CLL or NHL.[175] The presence of inherited or acquired immune system abnormalities (e.g., autoimmune diseases, HIV, ataxia-telangiectasia, sarcoidosis) increases HL risks with long latency from the onset of the autoimmune disease to lymphoma diagnosis, suggesting the importance of chronic immune dysregulation. Epstein–Barr virus (EBV)–HL is strongly associated with specific human leukocyte antigen (HLA) complex polymorphisms, including HLA class I alleles with EBV-positive HL and HLA class II polymorphisms with EBV-negative HL.[176]

CLINICAL PRESENTATION

About half the annual incidence of Hodgkin lymphoma occurs in the age group 15–44 years, with a later peak in older adults (>50 years).[177] This tumor typically presents as a painless superficial lymphadenopathy involving cervical, supraclavicular, and mediastinal lymph nodes. Classical HL spreads by contiguity within the lymph network; extension to adjacent and distant viscera occurs late in the clinical course. Extranodal disease is much less common with splenic or bone marrow involvement developing in a minority of patients. B symptoms (recurrent fever, night sweats, weight loss) develop in ~1/3 of HL patients, usually associated with more advanced disease; alcohol-induced pain at disease sites is a unique but rare manifestation of Hodgkin lymphoma. A few HL patients develop severe, unremitting pruritus without obvious skin lesions as a presentation of occult HL.[178] Classical Hodgkin lymphoma is typically an aggressive neoplasm, whereas nodular lymphocyte-predominant HL has a more indolent clinical course and a better prognosis if left untreated.

Hodgkin lymphoma is one of the most curable cancers with current chemotherapy or combined with radiotherapy; however, overall survival in the elderly remains poor and adverse effects (e.g., secondary cancers, treatment-associated cardiovascular disease) are potentially life-limiting.[179] For early-stage disease, the overall survival rate with standard ABVD treatment (adriamycin, bleomycin, vinblastine, dacarbazine) combined with irradiation of involved nodes is >95%. Prognosis varies with HL subtype. Nodular lymphocyte-predominant Hodgkin lymphoma has a good prognosis, whereas lymphocyte-depleted classical Hodgkin lymphoma has a historically poor outcome. The prognosis of adolescents and young adults with HL has dramatically improved over the last several decades, with a 15-year survival rate of ~90–95% as a result of more effective chemotherapy (e.g., PD-1 axis inhibitors, cytotoxic T cell-associated protein 4 inhibitors), better risk stratification, and improved supportive care.[140,171] A relatively small portion of Hodgkin lymphoma patients are refractory or relapse after first-line therapy.

NON-HODGKIN LYMPHOMA (NHL)

Non-Hodgkin lymphoma (NHL) is the 13th most common worldwide cancer with an estimated annual incidence of ~510,000, with ~250,000 annual deaths compared with an estimated ~74,000 new cases and ~20,000 NHL-related deaths in the United States.[1,76] The NHL incidence is increasing throughout the world, regardless of economic development or geography, partly reflecting an aging population and improved reporting. The worldwide incidence rates vary ~5-fold geographically, with a majority occurring in developed countries and lower reported rates in Africa and East/Southeast Asia (2.7/100,000); the highest NHL incidence rates worldwide occur in the United States (13.7/100,000).[1,180] Some NHL subtypes (T cell leukemia/lymphoma, Burkitt lymphoma) are more common in the latter, less developed countries, particularly the African lymphoma belt (Congo, Malawi, Nigeria, Uganda).[181] Follicular lymphomas are uncommon in Europe and rare in Asia, whereas endemic Burkitt lymphoma has an almost exclusive distribution

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. with *Plasmodium falciparum* malaria in equatorial Africa. The incidences of T cell, natural killer (NK) cell, and high-grade B cell lymphomas are higher in low- and middle-income countries than in high-income countries.[182]

In most US cancer registries, overall NHL incidence rates increased in the last half of the 20th century beginning in the 1970s, probably reflecting, at least in part, from improved reporting, diagnosis, and case ascertainment; subsequently, the overall rates stabilized in the early 2000s with some subtype, age, sex, and ethnicity differences. The incidences of diffuse large B cell lymphoma, Burkitt lymphoma, marginal zone lymphoma, angioimmunoblastic T cell lymphoma, and mantle cell lymphoma continue to increase, while CLL and lymphoplasmacytic lymphoma/Waldenström macroglobulinemia decrease.[183,184] Non-Hodgkin lymphomas are primarily adult tumors, with <1% of NHL tumors occurring in children under 15 years of age, primarily in children with congenital immune deficiencies (severe combined system immunodeficiency, congenital X-linked immunodeficiency, ataxia-telangiectasia, Wiskott–Aldrich syndrome).[185] NHL accounts for ~7% of pediatric malignancies. The incidence of NHL increases with white ethnicity and male sex; the gender ratio increases with age,[2] whereas the median age varies with subtype. The median age at diagnosis is 65 years for follicular lymphomas compared with 52 years for Burkitt lymphomas and 36 years for mediastinal lymphomas. Overall, the age at diagnosis is younger for T cell than B cell NHL tumors with considerable subtype heterogeneity. The overall male/female NHL ratio indicates a male predominance (1.5/1), with higher ratios (i.e., ~3-fold) in hairy cell leukemia, Burkitt lymphoma, mantle cell lymphoma, and Waldenström macroglobulinemia).[186] The incidences of marginal zone and follicular lymphomas are similar in both sexes, whereas the DLCBL subtype, primary mediastinal B cell lymphoma, occurs more commonly in women.

CARCINOGENESIS

Non-Hodgkin lymphoma (NHL) is one of several major lymphoid neoplasms (e.g., Hodgkin lymphoma, lymphocytic leukemias, multiple myeloma) that includes >45 malignant lymphoproliferative subtypes originating from B cells and >20 from T cells, as displayed in the 2022 World Health Organization revision (Table 60.1). These tumors arise from immature (lymphoblastic) or mature B, T, or natural killer (NK) cells. B cells undergo rearrangement of their immunoglobulin gene segments in the bone marrow before antigen contact. These naïve B cells migrate to lymph nodes and spleen. After encountering antigens, they undergo rapid proliferation to form germinal centers in primary lymphoid follicles with the help of T cells. This process requires double-stranded DNA breaks via somatic hypermutation and class-switch recombination to select high-affinity, nonhost antibodies. This error-prone process promotes lymphomagenesis in the germinal centers, where the lymphoma type depends on the stage of differentiation disrupted. B cell NHLs result from translocations that deregulate gene expression of key transcription factor-producing genes (*BCL6*, *MYC*, *PRDM1*) associated with balancing active pathway-specific enhancers and promoters of B cell maturity. These translocations often involve the immunoglobulin heavy-chain (IGH) locus on chromosome 14q32 and the B cell surface receptors (BCL). Table 60.4 outlines the common aberrant mechanisms associated with lymphomagenesis.

TABLE 60.4. Common mechanistic alterations of lymphogenesis. (Adapted from Armitage et al.).[182]

Mechanism	Genes and Alterations
Enhanced proliferation/survival	Mutation in *CDKN2A* gene, JAK/STAT signaling pathway gene mutations
Upregulation signaling pathways	*CARD11* (immune function) gene, CD79B (B cell antigen receptor), *MYD88* gene (Toll-like receptors and interleukin-1 (IL-1) receptors in early immune responses) mutations
Apoptosis inhibition	BCL upregulation by translocation/gain
Terminal differentiation block	BCL translocation/PRDM1 deletion
Immune escape	PDL1 translocation, CD58, mutations in *B2M* gene
Epigenetic (chromatin remodeling, histone modification)	Mutations in *CREBBP*, *EP300*, *EZH2*, *KMT2D* genes

B Cell NHL

Burkitt Lymphoma

Burkitt lymphoma is an aggressive B cell NHL tumor that exists in three similar morphological, genetic, and immunophenotypic subtypes (endemic, sporadic, immunodeficiency associated); this neoplasm is the fastest-growing human tumor with a 24–48-hour doubling time.[187] In Africa and Papua New Guinea, Burkitt lymphoma is the most common childhood cancer often associated with malaria and Epstein–Barr virus, whereas

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sporadic Burkitt lymphoma accounts for ~30% of childhood (4–5 cases/100,000) and 1–5% of adult lymphomas in developed countries.[188] Malignant Burkitt lymphoma cells typically express B cell lineage (CD20+/CD79a+), with CD10/BCL-6 commonly co-expressed along with an absence of the antiapoptotic protein, BCL-2. The t(8;14)(q24;q32) translocation in this highly aggressive tumor overexpresses the *MYC* proto-oncogene encoding a nuclear phosphoprotein important in cell-cycle progression, apoptosis, and malignant transformation in 70–80% of patients. Variant translocations t(2;8)(p12;q24) and t(8;22)(q24;q11) occur in 10–15% of patients.[189] Other B cell lymphomas may contain these *MYC* translocations.

Little available epidemiological data exist on risk factors associated with Burkitt lymphoma other than infectious agents. Examination of age and gender in a Dutch study of 80 verified childhood and 27 adult cases of Burkitt lymphoma indicated this predominantly male tumor has a bimodal distribution in males (89% children, 78% adults), with peak incidence at 6–10 years in boys and a steadily increasing incidence >65 years in men.[190] Girls and women had similar Burkitt lymphoma risks, with the incidence increasing above the age of 60 years. Children more often displayed extranodal disease (81 vs. 59% adults), with abdominal disease presenting in 60–80% of sporadic cases.[191] The InterLymph Consortium identified 295 Burkitt lymphoma cases and 21,818 controls in 18 case-control studies separating the cases into younger (<50 years) and older (≥50 years) cases.[192] Regardless of age, alcohol consumption was inversely associated with these tumors in the multivariate models comparing any alcohol drinking (≥1 drink monthly) with nondrinkers (aOR= 0.63, 95% CI: 0.40–0.98, $P = 0.001$). Using the basic adjusted model (fixed effects logistic regression adjusted for age, sex, and race/ethnicity) in younger patients, the association with Burkitt lymphoma was inverse for history of allergy (OR = 0.52, 95% CI: 0.30–0.90, $n_{\text{Burkitt lymphoma}} = 21$ cases/1,093 controls, $P = 0.016$) and asthma (OR = 0.35, 95% CI: 0.13–0.95, $n_{\text{Burkitt lymphoma}} = 4$ cases/461 controls, $P = 0.015$). A history of asthma, allergy, atopy, hay fever, or eczema was not associated with Burkitt lymphoma in older patients. In the latter patients, hepatitis C virus seropositivity was associated with increased Burkitt lymphoma risks (OR = 4.1, 95% CI: 1.01–15.4, $n_{\text{Burkitt lymphoma}} = 3$ cases/109 controls, $P = 0.066$) with an imprecise estimate.

Diffuse Large B Cell Lymphoma (DLBCL)

DLBCL is the most common NHL subtype in Western countries, with an age-adjusted incidence of 3.1–5.7/100,000 US/European population; the median age at diagnosis occurs in the sixth decade of life.[193] This anatomically, histologically, and immunophenotypically diverse disease has the following mutations in genes for the three major genetic/phenotypic subtypes: 1) activated B cell (e.g., MYC/BCL6 mutations); 2) germinal center B cell (e.g., MYC/BCL2 mutations); and 3) unclassified origin based on gene-expression profiling. These subtypes differ in genetic aberrations, oncogenic pathway abnormalities, disease presentation, prognosis, therapeutic response, and origin. Major molecular pathways dysregulated in DLBCL include B cell receptor and NF-κB signaling along with chronic inflammation (IL-10 cytokines).[194] Examination of 574 DLBCL biopsy samples using exome and transcriptome sequencing detected four prominent genetic aberration subtypes, including *BN2* (BCL6 fusions/NOTCH2 gene mutations), EZB (EZH2 mutation/BCL2 translocations), *MCD* gene (CD79B/MYD88L265P mutations), and *N1* gene (NOTCH1 mutations).[195]

Multivariate analysis of pooled data in the InterLymph study of 19 European, US, and Australian case-control studies with 4,667 DLBCL cases and 22,639 controls supported a complex, multifactorial etiology of DLBCL.[196] The highest positive odds ratios occurred for B cell activating autoimmune diseases, HCV seropositivity, NHL family history, and higher young adult BMI, whereas reduced DLBCL risks were associated with atopic disease, higher socioeconomic status, and greater recreational sun exposure. Additional risk factors for women, but not men, include field crop/vegetable farm work (aOR = 1.78, 95% CI: 1.22–2.60, $P = 0.004$), hairdressing (aOR =1.65, 95% CI: 1.12–2.41, $P = 0.013$), and seamstress/embroider (aOR = 1.49, 95% CI: 1.13–1.97, $P = 0.005$). The DLBCL risk for the occupation of material handling equipment operator was elevated for men (OR 1.58, 95% CI: 1.02–2.44, $P = 0.047$). Table 60.5 displays the statistically significant positive and inverse associations for DLBCL risk factors based on the InterLymph non-Hodgkin Subtypes Study.

Follicular Lymphoma

Follicular lymphoma (FL) is an indolent lymphoproliferative disorder of germinal center B cells that is the second most common lymphoma in the United States and Western Europe after DLBCL.[13] In the United States, the incidence is ~3.4/100,000, with significant racial differences (~2–3-fold) and a marked increase in incidence at >65 years of age.[186,197] The median age at diagnosis is ~65 years.[198] Age-adjusted FL risks are slightly higher in men than women. Approximately 2–4% of follicular lymphoma cases transform into a

Abbreviations: BMI = body mass index; DLBCL = diffuse large B cell lymphoma; HCV = hepatitis C virus; NHL = non-Hodgkin lymphoma; NA = not available.
[a] Men only. [b] Women only.

more aggressive B cell neoplasm annually, typically diffuse large B cell lymphomas. In a Czechoslovakian study of 1,233 patients with follicular lymphoma grades 1–3A, histologically proven transformation to a more aggressive B cell tumor occurred in 58 cases at a median of 3.0 years from the initial FL diagnosis with a 4% transformation rate at 5 years.[199] Patients typically present with asymptomatic diffuse lymphadenopathy, bone marrow involvement (~70%), splenomegaly, and less commonly (<20%) with B symptoms (fever, weight loss, night sweats) and extranodal involvement.[200] The prognosis for pediatric follicular lymphoma is excellent, whereas the 10-year survival is age-dependent, ranging from 92% for ages 18–49 to 6% for ≥70 years.[198]

Follicular lymphoma has few recognized, mostly modest risk factors. Several observational studies associate follicular lymphoma with cigarette smoking, particularly in women. The California Teachers Study evaluated self-reported baseline cumulative active and passive smoking using Cox proportional hazards models to estimate multivariable-adjusted relative risks of women smokers.[201] For ever-smokers (>100 cigarettes lifetime), the NHL RR was elevated, but statistically nonsignificant (aRR = 1.22, 95% CI: 0.95–1.57, n_{NHL} = 252 cases) after exclusion of passive smoking-exposed, never-smokers (referents). Comparisons of the highest and lowest quintiles of cumulative passive smoking (years) demonstrated a statistically significant aRR for follicular lymphoma (aRR = 2.89, 95% CI: 1.23–6.80, n_{FL} = 26 cases, P_{trend} = 0.01), but no similar exposure-response relationship for DLBCL (P_{trend} = 0.24) or chronic lymphocytic leukemia/small lymphocytic lymphoma (P_{trend} = 0.32). The InterLymph Non-Hodgkin Lymphoma Subtypes Project pooled data from 19 case-control studies involving 3,530 FL cases and 22,639 controls using logistic regression and self-reported baseline questionnaires to estimate age/race/ethnic, sex, study-adjusted odds ratios.[202] Table 60.6 lists statistically significant associations between follicular lymphoma and examined risk factors from this study.

Comparing ever- and never-smokers, the odds ratios for follicular lymphoma were statistically nonsignificant in men (aOR = 0.98, 95% CI: 0.87–1.10, n_{FL} = 987/8,047 controls, $P_{difference}$ = <0.695). The study reported no statistically significant association between FL and autoimmune disease, eczema, HCV seropositivity, hair dye, hormonal drugs, or farming.

Early alterations in follicular lymphomagenesis frequently involve mutations of multiple genes including

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 60.6. Statistically significant, self-reported risk factors for follicular lymphoma (FL) reported in the InterLymph Non-Hodgkin Subtypes Study from pooled analysis of 19 case-control studies containing 3,530 FL cases and 22,639 controls. Statistically nonsignificant, but positive or inverse odds ratios for overall FL risks are not included in the table. Although the Body Mass Index (BMI) of young women was associated with a statistically significant positive odds ratio, almost all cohort studies have not supported this finding. The epidemiological support for an inverse association between FL and blood transfusions is mixed. The other risk factors are consistent with most epidemiological evidence. Statistically nonsignificant, but positive or inverse odds ratios for overall follicular risks are not included in the table (Data adapted from Linet et al.).[202]

CREBBP (CREB protein), *EZH2*, and *KMT2D* (*MLL2*).[203] CREB-binding protein is a transcriptional coactivator that affects many genes involved with cell proliferation and differentiation, whereas *EZH2* encodes a histone methyltransferase that suppresses genes involved in cell maturation. The *KMT2D* gene (lysine methyltransferase 2D) produces a histone methyltransferase important for cell development. The t(14;18)(q32;q21) translocation enhances expression of the antiapoptotic protein BCL2, resulting in the blockage of germinal center-associated cell death and tumor proliferation. About 70–90% of FL tumors are t(14;18)-positive; however, this translocation is not unique to follicular lymphoma. Approximately 20–30% of DLBCL and 5–10% of other NHL subtypes also contain this translocation.[13,204] Additionally, the t(14;18) translocation occurs in healthy individuals, indicating this chromosomal abnormality contributes to early lymphogenesis, but is not sufficient alone to cause the disease; hence, multiple genetic and epigenetic events are necessary to produce follicular lymphoma (e.g., altered T cell motility, chromatin modification).[205,206]

Hairy Cell Leukemia

Hairy cell leukemia (HCL) is a rare, indolent mature B cell lymphoproliferative disorder with clear male predominance. In the UK Hematological Malignancy Research Network containing ~3.6 million adult and pediatric incident hematological malignancy cases, the registry identified 55 hairy cell leukemia cases with a median age of 65.7 years.[207] The median age at diagnosis varies in different countries, ranging from 50–65 years in international studies.[208] The estimated annual incidence of hairy cell leukemia was 0.3/100,000 (95% CI: 0.2–0.4) with a male/female ratio of 3.44 (95%

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. CI: 1.81–6.98). The HCL incidence has been relatively stable in recent times.[209] Substantial ethnic differences exist in HCL incidence with the rates several-fold higher in Caucasians and Latinos than African Americans or Asians.[210] The typical clinical presentation includes peripheral lymphocytes with characteristic "hairy" cytoplasmic projections, pancytopenia, splenomegaly, and a distinctive phenotype. The life expectancy of HCL patients is close to that of healthy, age-matched adults because of durable remissions in response to purine analogs (e.g., cladribine, pentostatin).[211]

Early case-control studies suggest an association between hairy cell leukemia and several risk factors (e.g., farming operations, tobacco smoking); however, small sample sizes, inadequate study power, and imprecise estimates limit definitive conclusions about causation. A French study of 226 male HCL cases (60% participation rate) and 116 hospital-based referents (57% participation rate) used self-administered questionnaires, expert reviews, and conditional logistic regression to estimate odds ratios for hairy cell leukemia risks.[212] The HCL odds ratio was statistically marginally significant for HCL in all farmers (OR = 1.5, 95% CI: 1.0–2.2, n_{HCL} = 77 cases/116 controls) and significant for farming duration ($OR_{\geq 20\ years}$ = 1.8, 95% CI: 1.1–3.0, n_{HCL} = 59 cases/50 controls) using nonfarmers as referents. For definitive exposures to pesticides, the HCL OR was statistically marginally significant (OR = 1.7, 95% CI: 1.0–2.6, n_{HCL} = 47 cases/65 referents). A French study of 824 lymphoid neoplasms and 752 hospital-based controls identified 36 NHL cases with self-reported lifelong smoking histories based on face-to-face interviews.[157] Ever-smokers were classified as smoking ≥1 cigarette daily for 6 months. Compared with never-smokers, ever-smoking was inversely associated with hairy cell leukemia (OR = 0.2, 95% CI: 0.1–0.5, n_{HCL} = 15 cases/21 controls) with an inverse, but imprecise dose-response relationship comparing the highest and lowest quartiles of duration ($OR_{>31\ years}$ = 0.1, 95% CI: 0.0–0.7, n_{HCL} = 2 cases highest/2 cases lowest) and cumulative consumption ($OR_{>32\ pack\text{-}years}$ = 0.1, 95% CI: 0.0–0.4, n_{HCL} = 1 highest/1 lowest). In a pooled analysis of 154 HCL cases and 8,834 controls in 5 case-control studies from the InterLymph Non-Hodgkin Lymphoma Subtypes Project, cigarette smoking was inversely related to HCL risks.[213] The age/sex/study/race/ethnicity-adjusted odds ratio comparing current smoking status 1 year before diagnosis and nonsmoking referents was inverse and statistically significant (aOR = 0.34, 95% CI: 0.21–0.55, n_{HCL} = 21 cases/2,112 controls). The dose-response for quartiles of cumulative smoking was also significantly inverse, including lifetime pack-years (P = <0.01) and duration (P = <0.01). The association between HCL and ever-working on a farm was not statistically significant (aOR = 1.61, 95% CI: 0.95–2.53, n_{HCL} = 24 cases/1,099 controls, P = 0.067), but duration as a farmer of >10 years was statistically significant (aOR = 1.79, 95% CI: 1.50–5.93, n_{HCL} = 14 cases/609 controls). Alcohol consumption and atopic/autoimmune conditions were not associated with HCL.

Virtually all hairy cell leukemias contain the mutation in *BRAF V600E* (*B-RAF* proto-oncogene, serine/threonine kinase); this abnormality alters the RAS/MAPK (mitogen-activated protein kinase) signaling pathway involved with extranuclear-to-intranuclear communication essential for cell development (proliferation, differentiation, migration, apoptosis).[214]

Lymphoplasmacytic Lymphoma/Waldenström Macroglobulinemia

Proliferation of small B cell lymphocytes, plasmacytoid lymphocytes, and plasma cells characterize lymphoplasmacytic lymphoma (LPL), usually with IgM paraproteins and less often with IgG or other paraproteins. Waldenström macroglobulinemia (WM) is a subset of LPL tumors associated with monoclonal IgM gammopathy and bone marrow involvement. Established risk factors include male gender, older age, white race/ethnicity, and family history of monoclonal IgM gammopathy. Other potential risk factors are chronic immune stimulation, germline susceptibility genes, autoimmune diseases, allergies, and specific infectious diseases. The InterLymph Non-Hodgkin Lymphoma Subtypes used logistic regression models to estimate self-reported risk factors based on pooled data on 374 lymphoplasmacytic lymphoma/Waldenström macroglobulinemia (LPL/WM) cases in 11 case-control studies.[215] Table 60.7 lists the statistically significant associations between LPL/WM and specific risk factors based on self-reported exposures. The study results were consistent with autoimmune conditions associated with activated B cells, but not activated T cells. Alcohol consumption and farming were not associated with LPL/WM.

Mantle Cell Lymphoma

Mantle cell lymphoma (MCL) is a recently classified NHL subtype with no confirmed risk factors.[216] Epidemiology data are limited by the delay in the acknowledgment of MCL as an NHL subtype until 1992 and the rare occurrence of this aggressive B cell tumor. MCL tumors originate in the mantle zone of lymphoid follicles accounting for ~2–10% of NHL subtypes, with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 60.7. Statistically significant, self-reported risk factors for lymphoplasmacytic lymphoma/Waldenström macroglobulinemia (LPL/WM) based on multivariate analysis of pooled data from 374 LPL/WM cases and 2008 WHO lymphoma classifications in 11 predominately population-based case-control studies within the InterLymph Consortium adjusting for age, sex, race/ethnicity, Sjögren syndrome, systemic lupus erythematosus, hay fever, usual adult eight, smoking duration, hepatitis C serology, family history of hematological malignancy, and medical occupation. Statistically nonsignificant, but positive or inverse odds ratios for overall LPL/MM risks are not included in the table. The limited number of exposures and many comparisons limit the power and precision of these estimates. Novel findings included decreased risks for hay fever history and high usual adult weight along with increased risks for cigarette smoking of ≥40 years and working as a physician. (Data adapted from Vajdic et al.).[215]

Risk Factor	LPL/WM in Cases and Controls	Adjusted Odds Ratio	95% Confidence Interval	*P* Value
	Positive			
Sjögren syndrome	3/9	14.0	3.60–54.6	0.002
Systemic lupus erythematosus	4/24	8.23	2.69–25.2	0.003
Medical doctor	6/43	5.54	2.19–14.0	0.002
Hepatitis C virus seropositive	6/95	2.51	1.03–6.17	0.075[a]
Family leukemia history	13/215	2.19	1.21–3.96	0.018[b]
Hematological malignancy family history	21/452	1.64	1.02–2.64	0.060
Cigarette smoking duration (highest quartile, ≥40 years)	57/1,194	1.46	1.04–2.05	0.148
	Inverse			
Usual weight (highest vs. lowest quartile)	79/3,299	0.61	0.44–0.85	0.024[c]
Hay fever	64/2,511	0.73	0.54–0.99	0.017

[a] *P* value using likelihood ratio test. [b] Basic adjusted association using age, sex, race/ethnicity, and study. [c] *P* value using Wald test = 0.021.

an age-adjusted incidence rate of 0.5–1/100,000 inhabitants and a clear male predominance. The median age at diagnosis is 65–70 years with the majority (i.e., ~80%) presenting with advanced Stages III–IV disease. In the French population-based case-control study of 135 MCL patients, the median age at diagnosis was 72 years (range, 30–92 years), with a median net survival time of 41 months (95% CI: 38–62 months).[217] The male/female ratio was 3.9. Characteristic clinical features of MCL at presentation include diffuse lymphadenopathy, anorexia, fatigue, and B symptoms (fever, night sweats, weight loss). The 5-year MCL survival rate ranges from ~70% for lower stages to ~50% for advanced stages.[218]

Although the causes of MCL remain unknown, immunosuppression is not a strong MCL risk factor. Exploratory studies suggest the possible association of MCL with inflammation/infection, antigen presentation, and family malignancy history. The InterLymph Non-Hodgkin Lymphoma Subtypes Project examined MCL risks for self-reported risk factors associated with 557 MCL cases and 13,766 controls using multivariate logistic regression models.[219] Table 60.8 displays the statistically significant MCL risk factors. Alcohol consumption, BMI, and cigarette smoking were not associated with MCL risks.

Mantle cell lymphoma has a distinct genetic profile from other B cell NHL subtypes. These tumors display multiple secondary chromosomal and molecular alterations of genes that target cell cycle and senescence (*ARF*, *BMI1*, *CDK4*, *INK4a*, *RB1*) and interfere with DNA repair (*ATM*, *CHK2*, *TP53*). Exome sequencing of 56 mantle cell lymphoma tumors identified several novel, recurrently mutated genes (POT1, RB1, SMARCA4, WHSC1) along with epigenetic modification of histones.[220] The t(11;14)(q13;q32) translocation of *CCND1* (cyclin D1) gene is a defining feature of mantle cell lymphoma that deregulates cyclin D1, resulting in cell proliferation from overexpression of this key regulator of the cell cycle and G1 phase progression. Pathological MCL characteristics include CD5+, CD20+, and overexpression of the CDK kinase regulator, cyclin D1 (*CCND1* gene).

Marginal Zone Lymphoma

Marginal zone lymphoma is an indolent (low-grade B cell) neoplasm accounting for ~5–10% of NHL subtypes (1.8/100,000) with a median age at presentation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Any atopic disorder	174/5,336	0.74	0.61–0.89	0.001

Abbreviation: CI = Confidence Interval.

of 67 years.[221] Three distinct, heterogeneous types of marginal zone lymphoma (MZL) exist with incidence, distribution, susceptibilities, and risk factors varying between these types, potentially reflecting different marginal-zone B cell origins.[222] Approximately 70% of MZL (EMZL) tumors are extranodal affecting the stomach and less often other gastrointestinal tract sites, eye/adnexa, lung, skin, salivary glands, and thyroid, that typically do not contain organized lymphoid tissues. Extranodal marginal zone lymphomas (also known as mucosa-associated lymphoid tissue, MALT) tumors are small B cell lymphomas strongly associated with inflammatory diseases (i.e., infections, autoimmune diseases) at specific anatomic sites including *Helicobacter pylori* in the stomach, *Campylobacter jejuni* in the small intestine,[223] *Borrelia burgdorferi* (Lyme disease spirochete) in the skin, *Chlamydia psittaci* in the ocular adnexa, Hashimoto thyroiditis in the thyroid, and Sjögren's syndrome in the salivary gland.[172,224] Less common MZL types include splenic MZL (SMZL) and nodal MZL (NMZL); the former is associated with hepatitis C viral (HCV) infections and endemic malaria accounting for ~20% of MZL tumors. NMZL is the least common marginal zone lymphoma type (~10%); this indolent, small B cell, primarily adult lymphoma is also associated with HCV.[225,226] HCV infections occur in ~1/2 of gastric MALT MZL and ~1/3–1/2 of other MALT MZL cases with viremia present in >90% of cases.[227]

For MALT-type EMZL neoplasms, characteristic immunotypes include common B cell-associated antigens CD19+, CD20+, CD22+, CD43±, CD79a+, Bcl-2+, IgM+/CD3−, CD5−, CD10−, CD23−, cyclin DA−, and IgD−, with κ or λ immunoglobulin light-chain restriction. The most common chromosomal translocation is t(11;18)(q21;q21)/*API2-MALT1*; this translocation results in the activation of the NF-κB signaling pathway (regulation of immune response to infection) and inhibition of apoptosis.[228]

The InterLymph Non-Hodgkin Lymphoma Subtypes pooled data from 12 case-control studies identifying 633 extranodal marginal zone lymphomas, 157 nodal marginal zone lymphomas, and 140 splenic marginal zone lymphomas.[229] Based on self-reported questionnaires and/or interviews and adjusted unconditional logistic regression models to estimate overall MZL risks, the study demonstrated statistically significant positive associations with B cell activating autoimmune diseases (e.g., Sjögren syndrome, systemic lupus erythematosus), hepatitis C virus seropositivity, and family history of any hematological or non-Hodgkin lymphoma. Inverse, statistically significant overall MZL risks were associated with the occupation of teaching, recreational sun exposure, and alcohol consumption, as displayed in Table 60.9.

Examination of MZL subtypes demonstrated significant heterogeneity between subtype risks and specific risk factors. The estimated EMZL odds ratio was positive and statistically significant ($P_{trend} \leq 0.05$) for alcohol consumption and family history of any hematological malignancy (but not NHL) or leukemia; NMZL and wine consumption or metalworking; and SMZL and ever-using hair dye, teaching, or general/unspecified

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 60.9. Statistically significant, self-reported risk factors for marginal zone lymphoma (MZL) based on pooled data from 12 case-control studies in the InterLymph Consortium. Statistically nonsignificant, but positive or inverse odds ratios for overall MZL risks are not included in the table. The study also included estimated risks for the three MZL subtypes; however, the limited number of exposures and many comparisons limit the power and precision of these estimates. (Data adapted from Bracci et al.).[229]

Risk Factor	MZL in Cases/Controls	Adjusted Odds Ratio	95% Confidence Interval	*P* Value
	Positive			
Autoimmune disease (B cell activation)	45/125	5.75	3.97–8.33	<0.001
HCV seropositive	14/95	3.4	1.65–5.60	0.001
Hematological malignancy family history (≥1 1° relative)	78/492	1.73	1.33–2.25	<0.001
NHL family history (≥1 1° relative)	31/205	1.65	1.10–2.46	0.020
	Inverse			
Teacher	36/800	0.50	0.35–0.70	<0.001
Recreation sun exposure (highest quartile)	155/2,983	0.68	0.54–0.85	0.001
Alcohol consumption (highest quartile)	48/888	0.61	0.42–0.88	0.017

laborer.[229] Multiple comparisons and small sample sizes limit the power and precision of these estimates. Some of the statistically significant associations (e.g., hair dye/SMZL, wine consumption/NMZL) are novel findings.

The clinical presentation of MZL tumors depends on the location of the affected tissues. For gastric EMZL, the most common clinical features are epigastric pain, dyspepsia, anemia, melena, hematemesis, and weight loss, whereas B symptoms are rare. The most common extraintestinal site is the lung, with the presentation including cough, dyspnea, and/or chest pain. Ocular adnexal MALT-type MZL occurs more often in women than men, particularly in rural areas with prolonged contact with animals and *Chlamydia psittaci*-associated chronic conjunctivitis.[230] Cutaneous MALT-type MZL is an indolent disease typically confined to the skin with frequent relapses, rarely associated with a life-threatening condition (10-year survival rate ~90%); occasionally spontaneous resolution occurs.[228] The prognosis for indolent MZL tumors is generally good, with overall 5-year survival >90% and 10-year survivals 75–80%.[226,231]

T Cell NHL

Peripheral T Cell Lymphoma

Peripheral T cell lymphomas are markedly heterogeneous category of >20 types of mature T and natural killer (NK) cells based on clinical, molecular, and pathological criteria, resulting in the complex classifications displayed in Table 60.1.[232] These classifications separate T cell NHL tumors arising from NK cells and γ, δ T cell lymphocytes in the nonantigenic *innate* immune system critical for the rapid response to new antigens from the antigen-specific *adaptive* immune system (CD4+/CD8+ α,β T cells, regulatory T cell lymphocytes). The latter system responds slowly, but *specifically*, to new antigens. Recurrent translocations are less common in peripheral lymphomas than in other T cell lymphomas. Although mutations of *TP53* genes are relatively uncommon in peripheral T cell lymphomas, whole-genome sequencing indicates recurrent rearrangements/fusion genes of *TP53*-related genes inhibit p53 protein function.[233]

Mycosis Fungoides and Sézary Syndrome

Mycosis fungoides and Sézary syndrome are rare cutaneous T cell lymphomas, characterized by malignant monoclonal T cell proliferations and an age-adjusted incidence of 0.55/100,00 and 0.01/100,000, respectively.[234] The incidence increases with age. The highest rates occur in blacks and non-Hispanic whites, whereas mycosis fungoides rates are ~50% lower in Hispanics and Asian/Pacific Islanders. The mycosis fungoides/Sézary syndrome (MF/SS) incidence is ~1½-fold higher in men than in women.[235] The few epidemiological studies on these cutaneous T cell neoplasms have identified elderly age, male gender, and African American descent as established risk factors. The InterLymph Non-Hodgkin Lymphoma Subtypes used logistic regression models to examine self-reported risk factors in pooled multivariate analysis of 324 mycosis fungoides/Sézary syndrome cases in 14 case-control studies.[236] Table 60.10 displays the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 60.10. Statistically significant, self-reported risk factors for mycosis fungoides/Sézary syndrome (MF/SS) based on pooled data from 14 case-control studies in the InterLymph Consortium using multivariate models adjusted for age, sex, race, and all the variables in this table.[236] Statistically nonsignificant, but positive or inverse odds ratios for overall MF/SS risks are not included in the table. The limited number of exposures and many comparisons limit the power and precision of these estimates. (Adapted from Leiter et al.).[238]

Risk Factor	MF/SS in Cases and Controls	Adjusted Odds Ratio	95% Confidence Interval
Multiple myeloma family history (yes vs. no)	6/36	8.49	3.31–21.80
General carpenter	5/71	4.07	1.54–10.75
Painter	11/194	3.71	1.94–7.07
Eczema history	55/1,460	2.38	1.73–3.29
Crop/vegetable farmworker	9/226	2.37	1.14–4.92
Woodworker	12/324	2.20	1.18–4.08
Body Mass Index ($30–50\ kg/m^2$ vs. $18.5–22.5\ kg/m^2$)	55/2,175	1.57	1.03–2.40
Cigarette smoking (≥40 years vs. nonsmokers)	40/1,742	1.55	1.04–2.31

statistically significant positive associations in this study. The imprecise estimates reflect small sample sizes of these rare cutaneous tumors. This study did not detect significant associations between MF/SS and alcohol consumption, cigarette smoking other than the highest quartile of smoking duration (≥40 years), atopic diseases other than eczema, sun exposure, or specific infectious agents associated with other lymphomas. Patches/plaques of small–medium-sized T cells with cerebriform nuclei infiltrating the epidermis and dermis characterize mycosis fungoides. The prognosis is usually good when diagnosed early with a median survival exceeding 25 years.[237] Sézary syndrome is a more aggressive tumor characterized by lymphadenopathy, erythroderma, and peripheral neoplastic T cell lymphocytes with a median survival of ~5 years.

EXPOSURE

Most non-Hodgkin lymphoma (NHL) cases are sporadic with no identifiable risk factor. NHL is a heterogeneous, multifactorial disease that contains >60 subtypes with further complexity related to age, anatomic site, and gene expression. This diversity, imprecise estimates, and limited statistical power from small sample sizes limit definitive conclusions regarding true associations and exposure-response relationships to a few established risk factors, particularly with NHL subtypes. Established risk factors for NHL include male sex, older age, family history of hematopoietic tumors, certain autoimmune diseases, infections, medications, and immune deficiencies (e.g., HIV/AIDS, organ transplantation, ataxia-telangiectasia); other lifestyle and environmental factors remain controversial. Birth order is not clearly associated with overall NHL risks.[239] Potential lifestyle factors positively associated with NHL include smoking and obesity, whereas an inverse relationship is potentially associated with sun exposure and alcohol consumption. Non-Hodgkin lymphoma subtypes probably have different risk factors, including variations between B and T cell NHL subtype risk factors; however, small sample sizes limit the power to detect associated risk factors. The InterLymph Non-Hodgkin Lymphoma Subtypes Projects used pooled data from 17,471 NHL cases and 23,096 controls in 14 population-based and 6 hospital-based case-control studies to examine the associations between 11 NHL subtypes and self-reported lifestyle, occupation, personal disease history, and family history of hematological cancers.[240] The study population was predominately male (58%) and non-Hispanic whites (93%). Overall, a family history of any hematological cancer in a first-degree relative was the strongest risk factor. B cell-activating autoimmune diseases (i.e., Sjögren syndrome, systemic lupus erythematosus) were strongly associated with certain B cell lymphomas (e.g., marginal zone lymphoma, lymphoplasmacytic lymphoma/Waldenström macroglobulinemia, diffuse large B cell lymphoma), whereas T cell-activating autoimmune diseases (e.g., celiac disease, systemic sclerosis/scleroderma) were closely associated with T cell lymphomas (e.g., peripheral T cell lymphoma, mycosis fungoides/Sézary syndrome). Some lifestyle factors (e.g., smoking) and a few occupations (e.g., painting) were modestly associated with some NHL subtypes; however, no consistent patterns emerged.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Occupation

Self-reported occupation is probably not a strong risk factor for NHL in most populations. Although some observational studies suggest possible lymphomagenic exposures for a few occupations, none of these observational studies clearly establish a causal relationship between any occupational exposure and NHL risks.[241,242] Occupations potentially associated with NHL in exploratory observational studies include farming/agricultural work, meat handling/processing, shoe/leather manufacturing, wood processing, painters, printing/paper industry, painters, medical professionals, hairdressers, and teachers with suspected carcinogens including pesticides, herbicides, benzene and other solvents, paints, varnishes, organic/inorganic dust, aromatic amines, and hair dyes. However, the study results are too inconsistent and heterogeneous to determine definite causal associations because of the lack of accurate exposure data, potential bias, and difficulty controlling confounding. Some occupations identified in these studies are not associated with recognized carcinogenic agents.

Job Classifications

The European Prospective Investigation into Cancer and Nutrition (EPIC) study examined lymphoma risks in 52 occupations associated with suspected carcinogens using self-administered standardized questionnaires to estimate NHL risks.[18] The EPIC study identified 866 incident NHL cases in 348,555 participants followed by a mean of 9 ± 2 years. Using Cox proportional hazard models and multivariate analysis, the adjusted hazard ratios comparing NHL risks in participants ever-working in an occupation with controls (never-working in the occupation) were statistically significant for butchers (aHR = 1.53, 95% CI: 1.05–2.48, n_{NHL} = 28 cases/587 controls) and car repair workers (aHR = 1.50, 95% CI: 1.01–2.00, n_{NHL} = 17 cases/646 controls). The study detected no statistically significant association in the other 50 occupations, including farming, painting, chemical/rubber industry, printing, and the leather industry.

A large US population-based case-control study identified 1,189 histologically confirmed malignant NHL cases (participation rate: 76%) in the National Cancer Institute SEER Program and 982 randomly selected controls (52% participation rate). Using unconditional logistic regression analyses and adjusting for age, sex, ethnicity, and study center, the study examined NHL risks comparing ever- and never-workers in 86 occupations and 97 industries based on computer-assisted personal interviews. Table 60.11 lists the statistically significant positive and inverse NHL risks from this study. Several occupations had at least six NHL cases and none in controls, including supervisors in food/beverage preparation/service, carpet/soft tile installers, drilling/boring machine operators/tenders, religious workers, clergy, and physical therapists. The latter three occupations, purchasing agents/buyers and information clerks, are white-collar occupations, typically without recognized exposure to carcinogens. The study reported no statistically significant increases in follicular or diffuse large B cell lymphomas in any occupation. The occupations involving editors, reporters, public relations specialists, and announcers were associated with 6 NHL cases compared with 18 cases in controls.

A New Zealand study on NHL risks in *a priori* high-risk occupations enrolled 291 incident NHL cases (69% participation rate) and 471 population-based controls (48% participation rate),[243] using unconditional regression analysis to estimate odds ratios for ever- versus never-employment in 235 occupational and 228 industries based on self-reported occupations coded according to the New Zealand Standard Classification of Occupations and the Australian/New Zealand Standard Industrial Classification. The high-risk occupations included bakers/grain millers, drivers, farmers, firefighters, funeral directors, hairdressers, health professionals, leather/shoe workers, machinery mechanics/operators, meat workers, metal workers/welders, painters, printers, teaching professionals, textile workers, and woodworkers. The most robust findings based on semi-Bayes adjustment for multiple comparisons were elevated NHL risk for horticulture/fruit growing (OR = 2.28, 95% CI: 1.37–3.79, n_{NHL} = 43 cases/32 controls), metal product manufacturing (OR = 1.92, 95% CI: 1.12–3.28, n_{NHL} = 33 cases/30 controls), and cleaners (OR = 1.80, 95% CI: 1.11–2.94, n_{NHL} = 34 cases/32 controls). The study did not detect increased NHL risks ($P < 0.05$) for hairdressers, health professionals, leather/shoe workers, painters, printers, teaching professionals, textile workers, or woodworkers.

A pooled analysis of 10,046 NHL cases and 12,025 controls from 10 case-control studies participating in the InterLymph Consortium examined NHL risks in 25 *a priori* occupational groups previously associated with NHL, similar to the groups covered in the New Zealand case-control study listed above.[244] Data on occupations were classified according to the International Standard Classification of Occupations based on self-reported occupations. Using unconditional logistic regression to estimate odds ratios, none of the 24 broad *a priori* occupational groups had a statistically

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. [a] Women only.

significant positive association ($P < 0.05$) with NHL for ever-employment; however, some specific titles in 10 groups have statistically significant associations, as displayed in Table 60.12.

Subgroup analysis of InterLymph Consortium pooled data suggests different risk factors for the three most common NHL subtypes and some specific occupations and/or job titles; however, some of these associations were not supported by exposure-response relationships. Statistically significant increased risks for diffuse large B cell lymphoma (DLBCL) were associated with ever-employment as field crop farmworkers (OR = 1.48, 95% CI: 1.01–2.17, $P_{\text{heterogeneity}} = 0.61$) and women's hairdressers (OR = 1.60, 95% CI: 1.13–2.27, $P_{\text{heterogeneity}} = 0.03$); however, DLBCL was not associated with long-term employment (>10 years) in either job title. Follicular lymphoma was associated with long-term employment as a medical doctor (OR = 2.23, 95% CI: 1.17–4.26), but not ever-employment (OR = 1.29, 95% CI: 0.77–2.18); the follicular lymphoma risk was also elevated for ever-employment as a spray painter (OR = 2.67, 95% CI: 1.36–5.25). Peripheral T cell lymphoma (PTCL) was associated with ever-employment as an electrical fitter (OR = 2.02, 95% CI: 1.03–3.97), painter (OR = 1.74, 95% CI: 1.07–2.83), textile worker (OR = 1.60, 95% CI: 1.18–2.17, $P_{\text{heterogeneity}} = 0.02$), and woodworkers (OR = 1.54, 95% CI: 1.04–3.50, $P_{\text{heterogeneity}} = 0.15$). PTCL risks were also statistically significant for long-term employment in the latter two job titles with substantial heterogeneity.

Specific Industrial/Occupational Categories

Farming

The most consistent, but not causal or independent, associations with NHL are farm-related exposures and low-level education.[245] Some studies suggest farmers have a slightly increased NHL risk mostly from case-control studies often reporting statistically nonsignificant increases; the etiology of these increased risks is unclear. Multiple other potential exposures may account for these results besides pesticides, herbicides, and fungicides including study design, infectious agents, fuels, oils, dust, solvents, and lifestyle factors. In a meta-analysis of 18 case-control, 10 mortality/morbidity, and 8 cohort studies (1982–1997) examining the association of farming with NHL risks, 4 studies reported

TABLE 60.12. Statistically significant ($P < 0.05$) job titles associated with non-Hodgkin lymphoma (NHL) based on pooled analysis of data from the InterLymph Consortium with adjusted odds ratios and 95% confidence limits including comparisons of ever-employed and >10-year employment with never-employed controls.[244] None of the 24 broad, *a priori* occupations including any farming were associated with increased NHL risks, with the exception of female textile workers employed >10 years (OR = 1.23, 95% CI: 1.02–1.50). Some elevated NHL risks in specific job titles are not supported by exposure-response measures (duration of employment), including electrical wiremen, field crop and general farmworkers, women's hairdressers, and general carpenters. Odds ratios and confidence intervals are statistically significant at the $P < 0.05$ level. (Data adapted from t'Mannetje et al.).[29]

Job Title	NHL Cases	NHL Controls	Ever-Employed OR (95% CI)	>10 Years Employment OR (95% CI)
Electrical fitters/related workers	525	589	1.10 (0.98–1.25)	1.24 (1.02–1.50)
Electrical/electronic equipment assemblers	121	145	1.07 (0.84–1.37)	1.86 (1.10–3.12)
Electrical wiremen	177	178	1.24 (1.00–1.54)[c]	1.15 (0.83–1.59)
Farmers – crops	582	573	1.10 (0.97–1.24)	1.18 (1.00–1.41)[c]
Farmers – field crop workers	149	118	1.38 (1.07–1.77)	1.29 (0.91–1.82)
Farmers – general workers	437	404	1.19 (1.03–1.37)	1.19 (0.95–1.50)
Hairdressers, women's[a]	115	113	1.43 (1.08–1.89)	1.39 (0.88–2.19)
Medical doctors[b]	77	82	1.16 (0.84–1.60)	1.87 (1.23–2.85)
Painters – spray	49	29	2.07 (1.30–3.29)[b]	—
Textile workers[a]	728 (total)	773 (total)	1.08 (0.95–1.24)	1.23 (1.02–1.50)
Textile workers – milliners/hatmakers	27	14	2.46 (1.28–4.74)	—
Woodworkers – general carpenters[b]	98	74	1.40 (1.03–1.92)	1.18 (0.71–1.99)

Abbreviation: CI = Confidence Interval.
[a] Women only. [b] Men only. [c] Marginally statistically significant at $P < 0.05$ level.

no association, 11 studies reported an inverse association, and 21 reported a positive association, with 8 being statistically significant.[246] Overall, the positive association was relatively modest with a meta-relative risk for all studies of 1.10 (95% CI: 1.03–1.19) based mainly on case-control studies (metaRR = 1.19, 95% CI: 1.06–1.33). The metaRR for cohort studies was consistent with the null (metaRR = 0.95, 95% CI: 0.85–1.07, n_{NHL} = 8 studies). The metaRR for female farmers demonstrated no association with farming (metaRR = 0.93, 95% CI: 0.82–1.06, n_{NHL} = 11 studies/552 cases). Boffetta and de Vocht added 11 studies, with 4 studies reporting an association and 7 studies reporting no association, to the meta-analysis by Khuder et al.; the metaRR was 1.11 (95% CI: 1.05–1.17) with strong heterogeneity.[242] Subgroup analysis indicated the increased NHL risk involved animal breeding (metaRR = 1.31, 95% CI: 1.08–1.60) rather than crop farming (metaRR = 0.96, 95% CI: 0.83–1.09).

In a New Zealand case-control study, a statistically significant increase ($P < 0.05$) in NHL risks was associated with ever-employment in the agricultural industry for women (OR = 1.72, 95% CI: 1.01–2.92, n_{NHL} = 38 cases/43 controls), but not men (OR = 0.88, 95% CI: 0.53–1.46, n_{NHL} = 37 cases/58 controls).[243] Job titles associated with a statistically significant elevated NHL risk included field crop/vegetable growers (OR = 2.74, 95% CI: 1.04–7.25, n_{NHL} = 12 cases/7 controls) and nursery growers (OR = 3.16, 95% CI: 1.03–9.69, n_{NHL} = 10 cases/5 controls); however, the study reported no clear duration-response relationships between long-term farming occupations and NHL risks. The large confidence limits reflect imprecise estimates and small sample sizes. The multicenter prospective (EPIC) cohort study reported no association between farming or farmworkers and NHL risks.[18] Analysis of pooled data from the InterLymph Consortium suggests field crop farm work was more strongly associated with diffuse large B cell lymphoma than other NHL subtypes.[244]

Meat Workers

The association of meat workers with NHL is inconsistent with no specific causal agent in meat processing identified. The multicenter prospective (EPIC) cohort study reported a statistically significant elevated NHL

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk in butchers (OR = 1.53, 95% CI: 1.05–2.48, n_{NHL} = 17 cases/646 controls).[18] In contrast, a meta-analysis of nine observational studies of meat processing, butchers, meatpacking, and abattoir workers detected no association between the meat industry and NHL risks (metaRR = 0.99, 95% CI: 0.77–1.29) with substantial heterogeneity.[242] A New Zealand case-control study reported statistically nonsignificant elevated NHL risk in meat processors at the P = <0.05 level (OR = 1.97, 95% CI: 0.97–3.97, n_{NHL} = 22 cases/16 controls).[243] A US study of 268 follicular lymphomas and 1,659 controls reported a positive association between meat packaging/processing and follicular lymphoma (OR = 1.60, 95% CI: 0.99–2.06);[247] however, analysis of pooled data from the InterLymph Consortium detected no statistically significant elevated risks of four common NHL subtypes, including follicular lymphoma with ever- or long-term employment as a meat processor/worker.[244]

Printing Industry

Although most studies of printers and NHL risks are positive, the results are often statistically nonsignificant without demonstrating an exposure-response relationship. Employment as a printer was not associated with a statistically significant elevation of NHL risks in the US National Cancer Institute-SEER case-control (OR = 2.02, 95% CI: 0.79–5.17, n_{NHL} = 17 cases/6 controls),[241] a pooled analysis of InterLymph Consortium data (OR = 0.95, 95% CI: 0.78–1.17, n_{NHL} = 175 cases/230 controls),[244] the New Zealand case-control study (OR = 1.22, 95% CI: 0.43–3.45, n_{NHL} = 8 cases/8 controls), or the multicenter prospective (EPIC)[18] studies. In a meta-analysis of six studies on the printing industry and NHL risks, the metaRR for NHL was statistically significant based on a few cases (metaRR = 1.86, 95% CI: 1.37–2.52) with little heterogeneity or publication bias.[242] Analysis of pooled data from the InterLymph Consortium detected no statistically significant elevated risks in four common NHL subtypes associated with ever- or long-term employment as a printer.[244]

Woodworkers

The association between woodworkers and overall NHL risks is relatively modest and often statistically nonsignificant. This occupation includes a diverse range of workers ranging from sawmill operators and paper pulp workers to forestry workers and carpenters. In a meta-analysis of 11 observational studies on woodworkers, the relative risk for NHL was marginally significant (metaRR = 1.15, 95% CI: 1.00–1.31) with potential publication bias, but no significant heterogeneity.[242] In a pooled analysis of data from the InterLymph Consortium, male general carpenters had a statistically significant elevation of NHL risks (OR = 1.42, 95% CI: 1.04–1.93, n_{NHL} = 98 cases/74 controls), but not woodworkers overall (OR = 1.04, 95% CI: 0.89–1.22, n_{NHL} = 326 cases/352 controls).[244] Peripheral T cell lymphoma risks were significantly elevated in woodworkers who were ever-employed (OR = 1.54, 95% CI: 1.04–2.27) or employed for >10 years (OR = 2.04, 95% CI: 1.19–3.50), but there were no elevations of diffuse large B cell or follicular lymphoma risks. Employment as a woodworker was not associated with elevated NHL risks in the multicenter prospective (EPIC) study.[18]

Teachers

Although some studies of NHL risks in teachers are positive and statistically significant, little data suggest an exposure-response relationship or identify a specific carcinogen (e.g., viral infections). In a meta-analysis of 19 observational studies using random effects models, the metaRR for NHL in the teaching profession was 1.47 (95% CI: 1.34–1.61) with substantial heterogeneity and potential publication bias.[242] Subanalysis indicated no statistically significant difference between primary or secondary teachers, headmasters/principals, or teachers involved with arts/crafts. A New Zealand case-control study detected no statistically significant elevated NHL risks in female preschool/primary (OR = 1.69, 95% CI: 0.82–3.47, n_{NHL} = 16 cases/28 controls) or secondary school (OR = 0.48, 95% CI: 0.13–1.75, n_{NHL} = 3 cases/28 controls) education teachers.[243] The odds ratio for NHL in teachers ever-employed except in postsecondary institutions was not elevated (OR = 1.05, 95% CI: 0.70–1.58, n_{NHL} = 57 cases/45 controls) in the US National Cancer Institute-SEER case-control study.[241] Analysis of pooled data from the InterLymph Consortium detected no statistically significant elevated risks in four common NHL subtypes associated with ever- or long-term employment as preschool or higher education teachers.[244]

Ionizing Radiation

Little data support a strong, statistically significant association between occupational ionizing radiation exposures and NHL. An Australian study of 694 incident NHL cases (85% participation rate) and age/sex/region-matched controls (61% participation rate) examined occupation ionizing/nonionizing radiation exposures and overall NHL risks based on a Finnish job-exposure matrix and self-reported questionnaires/computer-assisted telephone interviews

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

on jobs held ≥1 year. The Finish job-exposure matrix assigns annual mean radiation doses to 19 ionizing radiation-exposed jobs, 102 UV radiation-exposed jobs, 4 radiofrequency (RF)-exposed jobs, and 74 extremely low-frequency (ELF) radiation-exposed jobs.[248] Overall, the study did not provide support for a positive association between NHL and cumulative occupational ionizing or nonionizing ELF radiation exposures.[249] Using unexposed controls, the adjusted odds ratio for the highest tertile of ionizing radiation exposure (0.2–19.6 mSv-years) was 0.94 (95% CI: 0.57–1.53, n_{NHL} = 33 cases/35 controls, P_{trend} = 0.81) consistent with US cohort mortality studies.[250,251] The highest tertile of UV radiation exposure was statistically significant only when lagged for 5 or 10 years (OR = 1.48, 95% CI: 1.01–2.18, n_{NHL} = 122 cases/93 controls, P_{trend} = 0.04) consistent with a modest positive effect.

The multicenter European Epilymph study investigated NHL subtype risks for occupational UV radiation exposures based on standardized questionnaires on ever- and never-exposed occupationally to artificial/natural UV radiation and expert evaluation of the intensity (weighted duration) of UV exposure.[252] None of the overall measures of UV exposure reached statistically significant associations with overall NHL risks. Comparing ever- versus never-UV radiation exposures, the adjusted OR was near the null (aOR = 1.02, 95% CI: 0.81–1.29, n_{NHL} = 756 cases/1,320 controls, $P_{heterogeneity}$ = 0.13). Although significant heterogeneity existed ($P_{heterogeneity}$ = 0.02), examination of estimated exposure tertiles on weighted duration in years yielded no evidence of a dose-response relationship (P_{trend} = 0.65). Subgroup analysis suggested an inverse relationship between occupational UV exposure and diffuse large B cell lymphoma (DLBCL) risks. The DLBCL risk was statistically significant for ever- versus never-exposed (aOR = 0.72, 95% CI: 0.54–0.97, $P_{heterogeneity}$ = 0.31) and the third tertile of weighted duration of UV exposure (aOR = 0.62, 95% CI: 0.42–0.92, P_{trend} = 0.21, $P_{heterogeneity}$ = 0.06).

Nonionizing Radiation

In the Finnish population-based case-control study, the adjusted OR was 1.25 (95% CI: 0.91–1.72, n_{NHL} = 147 cases/119 controls, P_{trend} = 0.52) for the highest extremely low frequency (ELF) tertile (3.1–160.4 μT-years) consistent with mortality studies of telecommunications employees[253] and Korean War navy technician veterans.[254] The adjusted odds ratio for the highest RF radiation tertile was imprecise in a few cases (OR = 3.15, 95% CI: 0.63–15.87, n_{NHL} = 6 cases/2 controls, P_{trend} = 0.09).

An Australian study of 694 incident NHL cases and 694 age/sex/region-matched population-based controls examined occupational magnetic field exposure using self-administered postal questionnaires and a US population-based job-exposure matrix.[255] After dividing cumulative magnetic field exposures into quartiles, multivariate logistic regression models estimated the odds ratios comparing NHL risks in the highest (>9.85 μT-years) and lowest (<3.92 μT-years) exposure quartiles. The adjusted odds ratio for NHL for total magnetic field exposure (μT-years) was slight and marginally statistically significant (aOR = 1.18, 95% CI: 1.00–1.48, n_{NHL} = 189 cases/158 controls, P_{trend} = 0.006). The adjusted odds ratio was statistically significant for a 5-year log exposure (aOR = 1.24, 95% CI: 1.05–1.46, n_{NHL} = 184 cases/163 controls, P_{trend} = 0.003).

Chemicals

Agricultural/Horticultural

Pesticides represent a structurally and mechanistically diverse group of chemicals that destroy weeds (herbicides), insects (insecticides), soil/airborne pests (fumigants), and fungi (fungicides). Some epidemiological evidence suggests herbicide and/or pesticide use increases NHL risks.[256] Meta-analyses of farmers and NHL suggest male, but not female, farmers have a slightly elevated risk of developing NHL, but the specific cause (e.g., pesticides, infections) of this increased risk could not be identified.[246,257] Epidemiological data associating increased NHL risks with pesticide exposures are primarily case-control studies with less convincing evidence from cohort studies.[258] Using random effects models, a meta-analysis of 13 case-control studies during 1993–2005 reported a statistically significant meta-OR for occupational pesticide exposure and NHL risks (meta-OR = 1.35; 95% CI: = 1.2–1.5); however, heterogeneity and publication bias were substantial.[259] The modest magnitude of positive study results, inconsistent results across studies, and lack of definite exposure-response relationships limit definite conclusions regarding causality.

Existing data do not associate insect repellants with elevated NHL risks. In a Canadian population-based case-control study using postal questionnaires and structured pesticide exposure telephone interviews, DEET exposure of ≥10 hours annually was not associated with NHL risks (OR = 0.89, 95% CI: 0.71–1.10, n_{NHL} = 239 male cases/801 male controls).[260] Controls were randomly selected male residents from the same Canadian province with no cancer history. The US Agricultural Health Study cohort contained 52,394 private

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pesticide applicators (mostly farmers) enrolled while attending mandatory certification sessions for applying restricted-use pesticides as well as 32,345 spouses.[261] The adjusted hazard ratio for growing up on a farm was associated with a statistically significant elevation of overall NHL risks (HR = 1.51, 95% CI: 1.15–1.98, n_{NHL} = 364 cases) compared with not growing up on a farm (n = 69 cases). Subgroup analysis using polytomous logistic regression models did not detect statistically significant differences in the adjusted overall NHL risk between NHL subtypes ($P_{heterogeneity}$ = 0.98). A history of atopy in applicators was inversely related to overall NHL risks (HR = 0.61, 95% CI: 0.42–0.87, n_{NHL} = 42 atopic cases/6,360 nonatopic cases, P_{trend} = <0.001) based on self-reported physician-diagnosed eczema/hay fever.

Fumigants

Fumigants include methyl bromide and carbon tetrachloride; the latter is rarely used now. In the US Agricultural Health Study cohort on 52,394 private pesticide applicators (mostly farmers), the adjusted relative risk comparing ever-using versus never-using methyl bromide as a fumigant was statistically significant for diffuse large B cell lymphoma (aRR = 1.9, 95% CI: 1.1–3.3, n_{NHL} = 28 cases ever-use cases/86 cases never-use cases), but statistically nonsignificant for overall NHL risks (adjusted OR = 1.1, 95% CI: 0.9–1.5, n_{NHL} = 85 ever-use cases/425 never-use cases).[262] However, the trend for cumulative methyl bromide exposure (lifetime days) was statistically significant for overall NHL risk (P_{trend} = 0.04), but not for diffuse large B cell lymphoma (P_{trend} = 0.67).

The multicenter Cross-Canada Study of Pesticides and Health of 517 male incident NHL cases (67% participation rate) and 1,506 population-based male controls (48% participation rate) examined NHL risks associated with >10 hours of annual exposure to the major chemical classes of pesticides using postal questionnaires and telephone interviews.[263] Compared with unexposed controls, the adjusted NHL odds ratio in carbon tetrachloride-exposed men was statistically significant (adjusted OR = 2.42, 95% CI: 1.19–5.14, n_{NHL} = 13 exposed cases/18 unexposed cases). The adjusted OR for indoor malathion exposure was not statistically significant (aOR = 1.54, 95% CI: 0.74–3.22, n_{NHL} = 12 exposed cases/23 unexposed cases).

Fungicides

Major fungicide classes include phthalimides (captan, captafol), dithiocarbamates (mancozeb, thiram), mercury-containing compounds, and sulfur compounds. Most, but not all, studies report no association between fungicide exposure and statistically significant elevations in NHL risks.[258] The AGRICOH consortium pooled data from 312,270 farmers and agricultural workers from the United States, France, and Norway followed over 3.5 million person-years using the French Agriculture and Cancer, Cancer in the Norwegian Agricultural Population, and the US Agricultural Health study cohorts.[264] Dithiocarbamate (adjusted HR = 0.96, 95% CI: 0.83–1.11, n_{NHL} = 961 cases, I^2 = 0%, $P_{heterogeneity}$ = 0.96) and phthalimide (adjusted HR = 1.10, 95% CI: 0.80–1.52, n_{NHL} = 921 cases, I^2 = 57%, $P_{heterogeneity}$ = 0.10) fungicide exposures were not associated with NHL risks. Subgroup analysis did not demonstrate any statistically significant difference between NHL risk and NHL subtypes (diffuse large B cell lymphoma, follicular lymphoma, chronic lymphocytic leukemia/small lymphocytic lymphoma, multiple myeloma/plasma cell leukemia). A Swedish study of 910 NHL cases and 1,016 age/sex-matched, national population registry controls examined NHL risks using unconditional logistic regression and self-reported exposure data (postal questionnaires, telephone interviews).[265] Fungicide exposure was not associated with significantly increased NHL risks (OR = 1.11, 95% CI: 0.56, 95% CI: 0.56–2.23, n_{NHL} = 16 cases/18 controls), with no exposure-response relationship or evidence of differences between NHL subtypes. Analysis of data from the US Agricultural Health Study did not demonstrate an association between fungicide exposure (benomyl, captan, chlorothalonil, maneb, mancozeb, metalaxyl) and total NHL cases or specific NHL subtypes.[262] Comparisons included ever- versus never-use and high/low exposure with unexposed controls.

Herbicides

Phenoxyacetic Acid Phenoxyacetic acid herbicides include 2,4-dichlorophenoxyacetic (2,4-D), 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), methyl-chlorophenoxyacetic acid (MCPA), and methylchlorophenoxypropionic acid (MCPP). 2,4,5-T and chlorophenol herbicides, but not 2,4-D, MCPA, or MCPP, may be contaminated by dioxins and dibenzofurans during production processes. Early Swedish (RR = 4.8, 95% CI: 2.9–8.1, n_{NHL} = 41 cases/108 controls)[266] and US (OR = 2.2, 95% CI: 1.2–4.1, n_{NHL} = 24 cases/78 controls)[267] case-control studies suggest an association between phenoxy herbicides and NHL risks with statistically significant but imprecise estimates of frequency and duration of use based on self-reported telephone interviews. Later case-control studies were more inconsistent without a strong dose-response relationship; cohort studies of farmers and pesticide applicators

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 60.13. Adjusted odds ratios of non-Hodgkin lymphoma (NHL) associated with exposure to phenoxyacetic acid herbicides. Pooled data from the A Consortium of Agricultural Cohorts (AGRICOH) did not detect statistically significant inverse relationships with individual phenoxyacid herbicide exposure and null results for individual herbicides within the group. The results for overall phenoxyacid exposure ever- versus never- was inversely statistically significant. The Cross-Canadian Study of Pesticides and Health reported statistically significant odds ratios for phenoxyacid herbicides and individual phenoxyacid herbicides except MCPA. The Swedish University Hospital case-control study also reported statistically significant odds ratios for ever- versus never-phenoxyacid herbicide exposure; however, none of these results demonstrated an exposure-response relationship.

Agent	Exposure Category	Odds Ratio	95% CI	NHL Cases/Controls
	AGRICOH Consortium Cohorts[264]			
Phenoxyacids, overall	Ever vs. never	0.81[a]	0.67–0.98	1,204 cases
2,4-D	Ever vs. never	0.88	0.75–1.04	1,167 cases
MCPA	Ever vs. never	0.81	0.53–1.23	775 cases
MCPP	Ever vs. never	0.94	0.61–1.46	776 cases
	Cross-Canadian Study of Pesticides and Health[263]			
Phenoxyacids, overall	>10-hour vs. <10-hour exposure/year	1.38[b]	1.06–1.81	131/319
2,4-D	>10-hour vs. <10-hour exposure/year	1.32	1.01–1.73	111/293
MCPA	>10 hour vs. <10 hour-exposure/year	1.10	0.60–2.00	17/46
Mecoprop	>10-hour vs. <10- hour exposure/year	2.33	1.58–3.44	53/81
	Swedish University Hospital Case-Control Study[265]			
Phenoxyacids, overall	Ever vs. never	2.0[b]	1.24–3.36	47/26
	≤45 days/year vs. unexposed	2.83[b]	1.47–5.47	32/13
	≥45 days/year vs. unexposed	1.27	0.59–2.70	15/13
2,4-D and/or 2,4,5-T	Ever vs. never	1.61	0.87–2.97	33/21
	≤29 days/year vs. unexposed	2.08	0.99–4.38	21/11
	≥29 days/year vs. unexposed	1.33	0.57–3.13	12/10
MCPA	Ever vs. never	2.81	1.27–6.22	21/9
	≤32 days/year vs. unexposed	3.76	1.35–10.5	15/5
	≥32 days/year vs. unexposed	1.66	0.46–5.96	6/4

Abbreviations: CI = Confidence Interval; 2,4-D = 2,4-dichlorophenoxyacetic acid; 2,4,5-T = 2,4,5-trichlorophenoxyacetic acid; MCPA = 4-chloro-2-methyl-phenoxyacetic acid; MCPP = methylchlorophenoxypropionic acid; mecoprop = phenoxy-2-propionic acid.
[a] Statistically significant inverse relationship. [b] Statistically significant positive relationship.

in the late 1990s and early 2000s reported equivocal results.[258] A 2015 review of cohort and case-control studies did not detect a clear relationship between phenoxyl herbicides and NHL incidence; however, the authors opined that a slight increased NHL risk could not be excluded, but the absolute risk would be small.[268] Table 60.13 displays adjusted odds ratios for overall phenoxyacid herbicides and non-Hodgkin lymphoma risks for pooled results from cohorts in the AGRICOH Consortium along with two case-control studies. In general, the results are less convincing for cohort studies than case-control studies with little evidence of exposure-response relationships.

The IARC classifies 2,4-D as a possible human carcinogen (Group 2B) based on limited evidence of carcinogenicity in experimental animals and inadequate evidence of carcinogenicity in humans.[269] As noted in Table 60.13, the results of observational studies on 2,4-D exposure and NHL are conflicting and mostly statistically nonsignificant. A meta-analysis of 11 case-control studies, 2 nested case-control studies, and 1 cohort study used random and fixed effects models. The summary risk ratio for NHL in ever- versus never-2,4-D users was statistically significant (summary RR = 1.38, 95% CI: 1.07–1.77, $I^2 = 50\%$, $n = 12$ studies, $P_{\text{heterogeneity}} = 0.024$) with moderate heterogeneity.[270] Analysis of only the highest 2,4-D exposure category from 12 studies yielded a statistically significant and higher summary RR (sRR = 1.73, 95% CI: 1.10–2.72, $I^2 = 56\%$, $P_{\text{heterogeneity}} = 0.009$) with moderate heterogeneity. The magnitude of the summary RR ranged from 0.6–13 with 3 of 12 results being statistically significant.

The meta-analysis did not include data from the large prospective Agricultural Health Study (AHS) cohort. In this cohort, ever- versus never-2,4-D exposure was not associated with NHL (RR = 1.02, 95% CI: 0.54–1.90) after adjustment for age, drinking, family cancer history, education, smoking, and 10 other pesticide exposures with no evidence of an exposure response in cumulative exposure categories ($P_{trend} = 0.77$).[271] An updated meta-analysis of 10 studies including the AHS cohort, reported no association with ever- versus never-use of 2,4-D (sRR = 0.97, 95% CI: 0.79–1.18, $I^2 = 20.4\%$, $P_{heterogeneity} = 0.255$) using random effects models.

Chlorophenols Major chlorophenol herbicides include pentachlorophenol and trichlorophenol; dioxin and dibenzofuran with different toxicities contaminate these herbicides during the production processes. 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD) may contaminate dichlorophenol or trichlorophenol herbicides, whereas primary contaminants of pentachlorophenol (PCP) include tetrachlorophenol, hexachlorodibenzodioxins, dibenzofurans, and other lower chlorophenols.[272] The IARC considers pentachlorophenol a human carcinogen (Group 1) with sufficient epidemiological and mechanistic evidence of carcinogenicity along with most cohort studies of highly exposed categories demonstrating NHL risks exceeding 2.[273] The IARC classifies 2,4,6-trichlorophenol as a possible human carcinogen (Group 2B) based on inadequate evidence in humans and sufficient evidence in experimental animals.[269] Commercial and technical grades of pentachlorophenol typically contain higher chlorinated dioxins of substantially lower potency than TCDD; the TCDD concentrations in pentachlorophenol are usually not significant.

The Dow Chemical plant in Midland, Michigan, produced trichlorophenols during 1937–1980 and pentachlorophenol during 1942–1980. In fall 2004, serum samples were drawn from 12 TCP-only production workers, 26 PCP-only production workers, and 36 unexposed workers from non-chlorophenol-producing departments (referents).[274] The mean lipid-adjusted serum TCDD concentration in TCP-only production workers was 36.8 ppt (IQR = 7.6–42.6 ppt) compared with 7.8 ppt (IQR = 3.2–8.7 ppt) in PCP-only workers and 6.0 ppt (IQR = 2.4–7.8) in controls.[275]

An early Swedish nested case-control study suggests an association between chlorophenol herbicide exposures and NHL risks, with imprecise exposure-response estimates using unexposed, age/sex/residence-matched controls. The NHL odds ratio was statistically significant for any chlorophenol exposure (OR = 4.8, 95% CI: 2.7–8.8, $n_{NHL} = 35$ cases/35 controls) and any pentachlorophenol exposure ≥1 week continuously or ≥1 month total (OR = 8.8, 95% CI: 3.4–24, $n_{NHL} = 19$ cases/25 controls) based on self-reported questionnaires or telephone review.[266,276] Most subsequent observational studies on herbicide applicators and chlorophenol production workers have not confirmed the Swedish results for chlorophenol compounds containing <4 chlorine molecules.[25,258,277]

A Washington state study of 576 NHL cases and 694 randomly selected controls without cancer did not detect an elevated NHL risk comparing any past occupational chlorophenol herbicide exposure with unexposed controls (OR = 0.99, 95% CI: 0.8–1.2).[278] In a nested case-control study within a multinational cohort of 21,863 workers exposed to phenoxy herbicides, chlorophenols, and/or dioxins, the SMR for non-Hodgkin lymphoma was modestly elevated, but statistically nonsignificant (SMR = 1.39, 95% CI: 0.89–2.06, $n_{NHL} = 24$ deaths) based on self-reported exposure and review by an industrial hygienist.[25] In the same cohort comparing 32 NHL cases ever-exposed to a chlorophenol herbicide and 158 never-exposure controls, the magnitude of the NHL OR was modestly elevated, but statistically nonsignificant (OR = 1.26, 95% CI: 0.52–3.08, $n_{NHL} = 9$ cases/38 controls).[279] The odds ratio for NHL comparing any pentachlorophenol exposure with unexposed controls was elevated, but imprecise and statistically nonsignificant (OR = 2.5, 95% CI: 0.45–17.00, $n_{NHL} = 3$ cases/9 controls). Overall, the IARC considered the associations observed in several studies in different countries consistent with observations of pentachlorophenol exposure-response trends and the elevated risks in the highest pentachlorophenol exposure category from two occupational cohort studies with high-quality exposure assessments. Together, the IARC concluded the evidence was sufficient for a causal association between NHL and pentachlorophenol exposure. Table 60.14 lists the results of the nested case-control and cohort studies used by the IARC to support their conclusion that pentachlorophenol is a human carcinogen.

Triazine Triazine herbicides include atrazine, cyanazine, metribuzin, and simazine. Findings of observational studies on triazine herbicide exposure and NHL risks are inconsistent. In a US study of 200 randomly selected NHL cases and 3 age-matched male controls/case, the NHL odds ratio comparing ever- versus never-triazine herbicide exposure was statistically significant (OR = 2.5, 95% CI: 1.2–5.4, $n_{NHL} = 14$ cases/43 controls).[267] A Midwestern US study of 622 NHL cases in Caucasian men and 1,245 age-matched controls detected no significant association between

[a] Statistically significant, positive relationship.

self-reported ever-handling atrazine and NHL using unexposed controls as referents (aOR = 1.1, 95% CI: 0.8–1.6, n_{NHL} = 59 cases/108 controls).[282] Logistic models adjusted for vital status, age, state, cigarette smoking status, family history of lymphopoietic cancer, high-risk occupations, and high-risk exposures. Analysis of data from the Agricultural Health prospective cohort study reported no statistically significant exposure-response relationship between NHL risks and quartiles of atrazine use for cumulative lifetime days (P_{trend} = 0.35) or intensity-weighted lifetime days (P_{trend} = 0.14).[283] Pooled analysis of three cohorts in the AGRICOH Consortium demonstrated no association between overall NHL risks and ever-exposure to triazine herbicides (HR = 0.87, 95% CI: 0.74–1.02, n_{NHL} = 1,165 cases), atrazine (HR = 0.97, 95% CI: 0.79–1.18, n_{NHL} = 546 cases), or simazine (HR = 0.92, 95% CI: 0.77–1.09, n_{NHL} = 303 cases).[264] In an Italian multicenter study of 1,145 NHL cases (80% participation rate) and 1,232 age/sex-matched, randomly selected, population-based controls (74% participation rate), the odds ratio for ever- versus never-using atrazine was 0.8 (95% CI: 0.3–2.0, n_{NHL} = 11 male cases) based on self-reported job-specific questionnaires and person interviews.[284]

Glyphosate Glyphosate (*N*-(phosphonomethyl)glycine; Roundup®, Monsanto, St. Louis, Mo.) is a broad-spectrum herbicide that began commercial sales in the United States in 1974; currently, this herbicide is among the most applied herbicides in the world. Although some epidemiological studies suggest an association between glyphosate exposure and non-Hodgkin lymphoma risks, the overall findings are inconsistent with modest exposure-response relationships. Hence, the existence of a causal relationship between NHL and glyphosate exposures remains controversial.[285,286] In 2014, the German Federal Institute for Risk Assessment examined glyphosate toxicity for the European Union; they concluded glyphosate lacked carcinogenic/mutagenic properties as well as evidence of validated or significant increased glyphosate-related carcinogenic risks; however, later in 2019, Germany decided to phase out glyphosate use by 2023 to protect biodiversity as well as the suspected carcinogenicity.[287] The International Agency for Research on Cancer (IARC) reclassified glyphosate as a probable human carcinogen (Group 2A) based on sufficient evidence in experimental animals (rodent hemangiosarcomas and pancreatic islet-cell adenomas, mechanistic evidence of genotoxicity/oxidative stress) and limited epidemiological evidence. In 2016, the Food and Agriculture Organization Panel of Experts on Pesticide Residues in Food/Environment and World Health Organization Core Assessment Group on Pesticide Residues concluded glyphosate was unlikely to pose a carcinogenic risk to humans from dietary exposures, affirming the current Acceptable Daily Intake (ADI) levels.[288] Similarly, other international organizations have classified glyphosate as unlikely to pose a carcinogenic risk to humans, including the Australian Pesticides and Veterinary Medicines Authority, the European Chemical Agency, the European Food Safety Authority, Health Canada, and the New Zealand Environmental Protection Agency. During the review process for glyphosate's classification as a Group E carcinogen (evidence of non-carcinogenicity for humans) in 2019, the US EPA issued an interim decision that the "EPA continues to find that there are no risks to public health when glyphosate is used in accordance with its current label and that glyphosate is not a carcinogen."[289]

A US prospective cohort study of 57,311 licensed pesticide applicators in Iowa and North Carolina (Agricultural Health Study) followed a median of

TABLE 60.15. Summary of five case-control and one cohort study comparing glyphosate exposure and overall non-Hodgkin lymphoma (NHL) risks. A meta-analytic summary estimate of the data from these studies reported a statistically significant meta-risk ratio with modest heterogeneity (metaOR = 1.5, 95% CI: 1.1–2.0, I^2 = 32.7%). Little data support a strong exposure-response relationship between overall non-Hodgkin lymphoma risks and glyphosate exposure, particularly when excluding other pesticide exposure in multivariate analysis. Limited results from case-control studies on associations between non-Hodgkin lymphoma subtypes and glyphosate exposures are also inconsistent. (Adapted from Schinasi and Leon).[291]

Study	Exposure Category	Odds Ratio	95% Confidence Interval	NHL Cases/Controls
Pooled Cross-Canada population-based (McDuffie H, 2001)[263]	≥10 hours/year	1.26	0.87–1.80	51/133
Pooled Swedish population-based case-control (Hardell L, 2002)[292]	≥8 hours/year	3.04 1.85[a]	1.08–8.52 0.55–6.20[a]	8/8
Pooled, US Midwest population-based case-control (De Roos A, 2003)[293]	Ever-used	2.1	1.1–4.0[b]	36/61
US Midwest Agricultural Health Study cohort (De Roos A, 2005)[290]	Ever-used	1.1	0.7–1.9	71 cases
Swedish population-based case-control (Eriksson M, 2008)[265]	Ever-used	2.02	1.10–3.71[c]	29/18
French hospital-based population-based (Orsi L, 2009)[153]	Ever-used	1.0	0.5–2.2	12/24

[a] Multivariate instead of univariate analysis. [b] Multivariate analysis with hierarchical regression yielded a statistically nonsignificant odds ratio (OR = 1.6, 95% CI: 0.9–2.8). [c] The estimated odds ratio became statistically nonsignificant after multivariate analysis for multiple pesticide exposures (OR = 1.51, 95% CI: 0.77–2.94).

6.7 years.[290] The study reported no association with overall NHL risk (aRR = 1.1, 95% CI: 0.7–1.9, n_{NHL} = 92 cases) for ever-glyphosate-exposed pesticide applicators (mostly farmers) followed through 2001 using non-glyphosate-exposed applicators as referents. Comparison of adjusted NHL risks also demonstrated no significant association with the highest and lowest tertiles of glyphosate exposure measures for cumulative exposure days (aRR = 0.9, 95% CI: 0.5–1.6, n_{NHL} = 17 cases, P_{trend} = 0.73) or intensity-weighted exposure days (aRR = 0.8, 95% CI: 0.5–1.4, n_{NHL} = 22 cases, P_{trend} = 0.99). Adjustments included age, demographics, lifestyle factors, and other pesticides. Subgroup analysis of NHL subtypes revealed no differences in glyphosate-related NHL subtype risk with the possible exception of multiple myeloma. In an updated report on this study, ~82.8% of the 54,251 pesticide applicators reported ever-using glyphosate accounting for 79.3% (5,779) of the incident cases. Unlagged analysis of the data yielded no statistically significant association with any cancer site including overall NHL or NHL subtypes as well as the absence of an exposure-response relationship for cumulative glyphosate use. Comparing the highest quartile of lifetime intensity-weighted lifetime days of glyphosate use with unexposed referents, the unlagged rate ratio was 0.87 (95% CI: 0.64–1.20, n_{NHL} = 111 cases, P_{trend} = 0.95). 5-Year and 20-year lagged exposure and unlagged results were similar.

Table 60.15 summarizes the results of 5 case-control and 1 cohort studies on the association between glyphosate exposure and NHL risks. Most of these studies use ever- versus never-use of glyphosate as the exposure category with little data on exposure-response relationships. Evidence for an association between NHL and glyphosate exposure is weaker for cohort studies than case-control studies. A pooled analysis of three large agricultural worker cohorts from the United States, France, and Norway identified 2,430 NHL cases in 316,270 farmers during 3,574,815 person-years of observation.[264] Comparing ever- versus never-use of glyphosate with Cox regression models and random effects meta-analysis, the results for glyphosate were null with moderate heterogeneity (adjusted metaHR = 0.95, 95% CI: 0.77–1.18, n_{NHL} = 1,131 cases, I^2 = 57%, $P_{heterogeneity}$ = 0.10). The estimated HR for diffuse large B cell lymphoma (DLBCL) was marginally elevated (metaHR = 1.36, 95% CI: 1.00–1.85, 221 cases, I^2 = 0%, $P_{heterogeneity}$ = 0.48) with no heterogeneity. Glyphosate exposure was not associated with follicular lymphoma, multiple myeloma, or chronic lymphocytic leukemia/small lymphocytic lymphoma. A pooled analysis of US and Canadian studies (North American Pooled Project) identified 1,690 NHL cases and 5,131 controls including proxy respondents. Comparing ever- versus never-use of glyphosate, the overall age/sex/residence/family cancer history/proxy respondent/personal protective equipment use-adjusted OR

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for NHL was statistically significant (aOR = 1.43, 95% CI: 1.11–1.83 n_{NHL} = 113 cases/244 controls); however, the OR became statistically nonsignificant after adjustment for 2,4-D, dicamba, and malathion use (aOR = 1.13, 0.84–1.51). Overall NHL risks did not increase with increasing duration of glyphosate use. Similarly, the fully adjusted odds ratios for diffuse large B cell (45 cases), follicular (28 cases), and small lymphocytic (15 cases) lymphomas were statistically nonsignificant. Cumulative measures of glyphosate exposure (e.g., >2 days/year) were also inconsistent (e.g., $P_{DLBCL\ trend}$ = 0.2).

Insecticides

Although based on only two cases, a retrospective mortality study of pesticide applicators demonstrated a SMR for non-Hodgkin lymphoma of 7.11 (95% CI: 1.78–28.42) in the group with ≥3 years of employment.[294] Exposure to specific pesticides was not well defined. Population-based case-control studies of Midwestern farmers demonstrated an ~50% increase in NHL risks for farmers using organophosphate insecticides based on proxy interviews; however, the odds ratio decreased significantly to 1.2 when direct interviews were administered.[295]

Carbamates Individual carbamate insecticides include aldicarb, carbaryl (Sevin®), carbofuran, methomyl, and pirimicarb. Table 60.16 lists results from selected case-control and cohort studies on carbaryl exposures and overall NHL risks. For carbamate insecticides, analysis of pooled data from 1,254 NHL cases in the ACRIOCOH consortium demonstrates no association between ever- and never-use of carbamate insecticides and adjusted NHL risks (aHR = 0.94, 95% CI: 0.81–1.08).[264] Additionally, the study did not detect statistically significant increases in common NHL subtype risks. Similarly, analysis of data from the US Agricultural Health Study cohort did not detect statistically significant hazard ratios for common NHL subtype risks and ever-exposure to aldicarb, carbofuran, or carbaryl.[262] Although the magnitude of some cumulative measures of carbamate exposures was positive,[296] the data did not support exposure-response relationships between overall NHL risks and cumulative carbamate exposure tertiles measured in lifetime exposure days (P_{trend} = 0.23–0.87) or intensity-weighted exposure days (P_{trend} = 0.22–0.94) using never-exposed participants as referents.

Organochlorine Organochlorine insecticides are a highly diverse group of chemicals with complex metabolic pathways that may include carcinogenic metabolites. Important organochlorine compounds include aldrin, chlordane, DDT, dieldrin, endrin, heptachlor, lindane, methoxychlor, and toxaphene. Most organochlorine insecticides were banned or severely restricted because of their extremely long half-lives (years–decades). The association between NHL lymphoma risks and overall organochlorine insecticide exposure is inconsistent with cohort studies typically reporting null or statistically nonsignificant results, whereas increased NHL risks are associated with some case-control studies. In a Cross-Canada multicenter study of 517 incident NHL cases and 1,506 population-based male controls (<10 hours/year exposure), the NHL odds ratio in the exposed group (≥10 hours/year exposure) was 1.27 (95% CI: 0.87–1.69, 50 cases/134 controls).[263] In contrast to the Cross-Canada multicenter study, analysis of pooled data from the AGRICOH Consortium cohort demonstrated an inverse association between self-reported ever- versus never-use use of organochlorine insecticides and overall NHL risks (aHR = 0.86, 95% CI: 0.74–0.99,

TABLE 60.16. Selected case-control and cohort studies on ever- versus never-use of carbaryl and overall non-Hodgkin lymphoma risks. Adjustments for multiple pesticide exposures tended to attenuate the odds ratios. Most observational studies on carbamate exposures and NHL risks report statistically nonsignificant results.

Study	Exposure Category	Odds Ratio	95% Confidence Interval	NHL Cases/Controls
Pooled Cross-Canada population-based case-control (McDuffie H, 2009)[263]	≥10 hours/year	2.11[a]	1.21–3.69	25/34

[a] Adjusted for multiple pesticide use.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

n_{NHL} = 1,254 cases).[264] The results were fully adjusted for multiple pesticide exposures. Subgroup analysis detected no significant differences in risks between common NHL subtypes and organochlorine insecticide exposures.

The IARC classifies lindane as a human carcinogen (Group 1) based on consistent evidence of an association of lindane exposure with NHL, strong mechanistic evidence (oxidative stress, immunosuppression), and sufficient evidence of carcinogenicity in experimental animals.[298] In the Cross-Canada multicenter study, the association of ever- versus never-use of lindane was associated with a statistically significant increased overall NHL risk (aHR = 2.06, 95% CI: 1.01–4.22, n_{NHL} = 15 cases/23 controls) after full adjustment for multiple pesticide exposures.[263] Analysis of pooled data from the AGRICOH Consortium yielded an inverse, statistically nonsignificant adjusted HR comparing ever- versus never-use of lindane (aHR = 0.87, 95% CI: 0.78–1.01, n_{NHL} = 953 cases).[264] Subgroup analysis detected no significant differences between common NHL subtypes and organochlorine insecticide exposures.

DDT is classified as an IARC probable human carcinogen (Group 2A) based on strong mechanistic data (modulation of receptor-mediated effects, immunosuppression, enhanced oxidative stress), sufficient evidence of carcinogenicity in experimental animals for the metabolite, DDE (but not DDT), and limited human evidence including positive studies on NHL.[299] The Cross-Canada population-based case-control study reported a statistically significant association between self-reported ever- and never-use of DDT after full adjustment, including multiple pesticide exposures (aHR = 1.73, 95% CI: 1.08–2.76, n_{NHL} = 32 cases/59 controls).[263] In contrast, analysis of pooled data from the AGRICOH Consortium cohort demonstrated no association (aHR = 0.92, 95% CI: 0.81–1.04, n_{NHL} = 976 cases), with no evidence for different NHL subtype risks.[264] In a Swedish study of 910 living, incident NHL cases (no proxies) and 1,016 age/sex-matched, national population registry controls using unconditional logistic regression and self-reported DDT exposure data (postal questionnaires, telephone interview), the odds ratio was 1.17 (95% CI: 0.62–2.22, n_{NHL} = 20 cases/19 controls) for total DDT use of ≤37 days and 1.76 (95% CI: 0.97–3.20, n_{NHL} = 30 cases/18 controls) for >37 days total DDT exposure.[265] Comparison of DDT-exposed and unexposed NHL subtypes suggests elevated risks for follicular lymphomas (aOR = 2.14, 95% CI: 1.05–4.40, n_{NHL} = 165 cases) and T cell lymphomas (aOR = 2.88, 95% CI: 1.05–7.95, n_{NHL} = 53 cases).

The IARC classifies dieldrin, and aldrin metabolized to dieldrin, as probably carcinogenic to humans (Group 2A) based on sufficient evidence of carcinogenicity in experimental animals, moderate mechanistic evidence for dieldrin (genotoxicity, oxidative stress, immunosuppression, cell proliferation), and limited evidence of carcinogenicity in humans.[300] Mechanistic evidence for carcinogenicity of aldrin is modest, and human evidence for carcinogenicity is inadequate. Conversion of aldrin to dieldrin occurs in the environment, living organisms, and presumably in humans; however, little evidence is available to determine the extent of absorption or metabolism. In the Cross-Canada Study of 517 NHL cases and 1,506 controls, the elevation of NHL risks for aldrin exposure after full adjustment including multiple pesticide exposures was statistically significant, but imprecise (aOR = 4.19, 95% CI: 1.48–11.96, n_{NHL} = 10 cases/6 controls) based on a few cases.[263] The prospective Agricultural Health Study cohort detected no significant elevated overall NHL risks for ever- versus never-use of aldrin (aRR = 0.9, 95% CI: 0.7–1.1, n_{NHL} = 116 cases/364 controls), dieldrin (aRR = 0.9, 95% CI: 0.6–1.2, n_{NHL} = 35 cases/442 controls), chlordane (aRR = 1.0, 95% CI: 0.8–1.3, n_{NHL} = 136 cases/344 controls), heptachlor (aRR = 1.0, 95% CI: 0.7–1.2, n_{NHL} = 90 cases/384 controls), or toxaphene (aRR = 1.0, 95% CI: 0.7–1.2, n_{NHL} = 79 cases/397 controls).[262] Subgroup analysis demonstrated no statistically significant elevations of common NHL subtype risks. Comparison of cumulative exposure tertiles of lifetime days and intensity-weighted days with unexposed controls detected no exposure-response trends for aldrin (P_{trend} = 0.58 and 0.74, respectively), dieldrin (P_{trend} = 0.47 and 0.84, respectively), chlordane (P_{trend} = 0.43 and 0.16, respectively), heptachlor (P_{trend} = 0.82 and 0.88, respectively), or toxaphene (P_{trend} = 0.50 and 0.38, respectively).

Organophosphorus Organophosphate (OP) insecticides are a diverse group of several hundred organophosphorus compounds with a wide range of toxicities. Major OP insecticides include chlorpyrifos, coumaphos, diazinon, dimethoate, famphur, fonofos, malathion, methidathion, ethyl/methyl parathion, phorate, terbufos, and trichlorfon. Data on NHL risks associated with specific organophosphate insecticides are limited, with inconsistent evidence of a positive association with diazinon, malathion, and terbufos. Analysis of pooled data from three US National Cancer Institute Midwestern studies on male farmers involving 748 NHL cases and 2,236 nonfarming unexposed controls reported statistically significant increased NHL risks in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

farmers ever-exposed to organophosphate insecticides (OR = 1.5, 95% CI: 1.2–1.9, n_{NHL} = 158 cases/279 controls) based on self-reported exposure (26% proxy interviews).[301] The age/residence-adjusted odds ratio was weaker and statistically nonsignificant when only direct interviews were evaluated (OR = 1.2, 95% CI: 0.9–1.6, n_{NHL} = 117 cases/224 controls) compared with only proxy interviews (OR = 3.0, 95% CI: 1.8–5.0, n_{NHL} = 41 cases/55 controls). The odds ratio was positive, but statistically nonsignificant for the highest exposure duration category (≥20 years) using direct (OR = 1.3, 95% CI: 0.8–2.1, n_{cases} = 32 exposed/49 controls) and proxy (OR = 2.4, 95% CI: 0.8–6.7, n_{cases} = 7 exposed/10 controls). Analysis of four NHL subtype risks indicated no clear association with modestly positive, but statistically nonsignificant odds ratios using direct interviews for organophosphate exposure estimates.

A meta-analysis of five cohort, four nested case-control, and one case-control studies using random effects models reported a modestly elevated, statistically significant odds ratio for ever- versus never-exposure to diazinon, malathion, or terbufos (summary OR = 1.22, 95% CI: 1.04–1.43, I^2 = 41.2%, $P_{heterogeneity}$ = 0.032) with moderate heterogeneity.[302] Subgroup analysis indicated significant differences between study designs and overall NHL risks for ever-exposure to the three organophosphate insecticides using unexposed participants as referents. The summary OR for overall NHL risks was null for cohorts (OR = 1.00, 95% CI: 0.85–1.17, $P_{significance}$ = 0.967, I^2 = 1.2%, $P_{heterogenicity}$ = 0.424), whereas NHL risks were statistically significant for case-control (OR = 1.44, 95% CI: 1.14–1.81, $P_{significance}$ = 0.002, I^2 = 29.9%, $P_{heterogenicity}$ = 0.189) and nested case-control (OR = 1.57, 95% CI: = 1.04–2.39, $P_{significance}$ = 0.033, I^2 = 0%, $P_{heterogenicity}$ = 0.571) studies. Adjusting for multiple pesticide use (OR = 1.04, 95% CI: 0.88–1.23, n = 12 studies, $P_{significance}$ = 0.620, I^2 = 14.3%, $P_{heterogenicity}$ = 0.304) and family cancer history (OR = 1.14, 95% CI: 0.89–1.47, n = 9 studies, $P_{significance}$ = 0.300, I^2 = 32.7%, $P_{heterogenicity}$ = 0.157) reduced the overall NHL risks to small, statistically nonsignificant values. Ever-exposure to these organophosphate insecticides was not associated with elevated NHL risks in women (OR = 0.85, 95% CI: 0.56–1.29, n = 3 studies, $P_{significance}$ = 0.441, I^2 = 35.4%, $P_{heterogenicity}$ = 0.213). The authors noted the difficulty in quantifying insecticide exposures based on self-reported questionnaires on ever-exposure rather than internal doses.

Observational studies have not clearly associated increased NHL risks with other organophosphate insecticides, including chlorpyrifos, dichlorvos, dimethoate, parathion, terbufos, or trichlorfon.[303] Although analysis of pooled data from three population-based case-control studies in the US Midwest suggests an elevated NHL risk comparing the ever- and never-use of chlorpyrifos based on a few cases (aOR = 3.2, 95% CI: 1.1–9.2, n_{NHL} = 7 cases/8 controls), other studies have not confirmed these findings.[262,264] In the Agricultural Health Study, the standardized mortality ratio for applicators ever- versus never-using chlorpyrifos was 0.64 (95% CI: 0.29–1.39, n_{NHL} = 10 cases/27 controls).[304] A meta-analysis of three observational studies on ever-exposure to terbufos using unexposed participants as referents and random effects models reported no association with overall NHL risks (summary OR = 1.07, 95% CI: 0.85–1.36, $P_{significance}$ = 0.550, I^2 = 0.0%, $P_{heterogeneity}$ = 0.800).[302]

DIAZINON Although several observational studies associate diazinon with NHL, the overall results are mixed and controversial, as displayed in Table 60.17. The IARC classifies diazinon as a probable human carcinogen (Group 2A) based on strong mechanistic evidence

TABLE 60.17. Odds ratios of selected case-control and cohort studies on non-Hodgkin lymphoma (NHL) risks associated with diazinon exposures.

Study	Exposure Category	Odds Ratio	95% Confidence Interval	NHL Cases/Controls
Pooled Cross-Canada population-based case-control (McDuffie H, 2001)[263]	≥10 hours/year	1.69[a]	1.26–2.27	90/167

(genotoxic, but not mutagenic, oxidative stress) and limited human evidence of carcinogenicity, with some positive studies associating diazinon exposure and NHL.[305] In a meta-analysis of seven epidemiology studies using random effects models, the summary odds ratio for NHL comparing ever- and never-use of diazinon was statistically significant with no heterogeneity (OR = 1.39, 95% CI: 1.11–1.73, $P_{\text{significance}} = 0.003$, $I^2 = 0\%$, $P_{\text{heterogenicity}} = 0.668$).[302]

MALATHION The IARC classifies malathion as probably carcinogenic to humans (Group 2A) based on strong mechanistic evidence (genotoxic, but not mutagenic, cell inflammation/proliferation, oxidative stress), sufficient evidence in experimental animals, and limited evidence of carcinogenicity in humans. Although some case-control studies report positive associations between ever- versus never-use of malathion, most of these studies demonstrate no statistically significant differences in NHL risks between exposed and unexposed groups, particularly after adjusting for multiple pesticide exposures and the use of proxy interviews, as displayed in Table 60.18. In a meta-analysis of seven observational studies on ever-exposure to malathion using unexposed participants as referents and random effects models, the odds ratio was statistically nonsignificant with high heterogeneity (summary OR = 1.17, 95% CI: 0.82–1.67, $P_{\text{significance}} = 0.390$, $I^2 = 73.2\%$, $P_{\text{heterogeneity}} = 0.001$).[302]

The odds ratios for common NHL subtypes in ever-users of malathion were not statistically significant in the AGRICOH Consortium Study[264] or the Agricultural Health Study.[262] The latter study suggested an elevated risk for diffuse large B cell lymphoma (aOR = 1.61, 95% CI: 1.16–2.22), but not follicular or small lymphocytic lymphomas. Other cohort studies have not confirmed increased risks for diffuse large B cell lymphoma or other NHL subtypes.[262,264]

Little data support an exposure-response relationship between malathion exposure and NHL risks. North American Pooled Project data suggest an elevated NHL risk for malathion exposures ≥6 years (OR = 1.57, 95% CI: 1.18–210, $P_{\text{trend}} < 0.01$) after adjustment for multiple pesticide exposures. Other observational studies have not confirmed increased NHL risks with cumulative exposure measures. In the Agricultural Health Study,[262] cumulative measures comparing NHL risks in the highest malathion exposure tertile with referents demonstrated no association of NHL risks with total malathion exposure days ($P_{\text{trend}} = 0.63$) or intensity-weighted exposure days ($P_{\text{trend}} = 0.46$).

PYRETHROIDS Pyrethroids are a diverse group of synthetic esters derived from naturally occurring pyrethrins in the Dalmatian pyrethrum plant (*Chrysanthemum cinerariifolium* (Trevir.) Vis.). Major pyrethroid compounds include deltamethrin, esfenvalerate, and permethrin. Little epidemiological data support a positive relationship between pyrethroid/pyrethrin exposures and NHL risks. In the pooled analysis of the ARICOH Consortium, the hazard ratio for ever- versus never-use of pyrethroid insecticides and overall NHL risks was 1.04 (95% CI: 0.90–1.19, $I^2 = 2\%$, $P_{\text{heterogeneity}} = 0.36$); no common NHL subtype was associated with the three pyrethroids, except deltamethrin and chronic lymphocytic leukemia/small lymphocytic lymphoma (HR = 1.48, 95% CI: 1.06–2.07, $I^2 = 0\%$, $P_{\text{heterogeneity}} = 0.35$).[264] The Agricultural Health Study reported no association between permethrin and overall NHL risks (RR = 1.1, 95% CI: 0.8–1.3, $n_{\text{NHL}} = 112$ cases/363 controls).[262] The hazard ratio for

TABLE 60.18. Odds ratios of selected case-control and cohort studies on non-Hodgkin lymphoma (NHL) risks associated with malathion exposures.

Study	Exposure Category	NHL Odds Ratio	95% Confidence Interval	NHL Cases/Controls

ever- versus never-use of permethrin and multiple myeloma (but not chronic lymphocytic leukemia/small lymphocytic lymphoma) was statistically significant (HR = 2.2, 95% CI: 1.4–3.5). The study reported no exposure-response relationship between permethrin and NHL risks; cumulative tertiles of permethrin exposure were not associated with total exposure days (P_{trend} = 0.54) or intensity-weighted exposure days (P_{trend} = 0.99). In a Swedish study of 910 NHL cases (78% participation rate) and age/sex-matched, population-based controls, the association between permethrin and overall NHL risks was modestly positive, but statistically nonsignificant (OR = 1.23, 95% CI: 0.48–3.14, n_{NHL} = 9 cases/9 controls).[265]

Solvents

Benzene

Although some rodent models develop malignant lymphomas after prolonged, high-dose benzene exposures,[306] intraspecies differences limit extrapolation to humans. Epidemiological studies report inconsistent and generally modest associations between organic solvents and NHL risks including no definitive exposure-response relationship. An IARC review classified benzene as a human carcinogen with a positive association between benzene exposure and non-Hodgkin lymphoma; however, only a small minority of the Working Group considered benzene a cause of non-Hodgkin lymphoma.[307] Most,[308] but not all,[309] mortality studies and meta-analyses report no association between benzene exposure and overall NHL risks. A meta-analysis of 308,000 petroleum workers (6.6 million person-years), with observations periods 1937–1996, detected 506 NHL deaths versus 561.68 expected. The standardized mortality ratio (SMR) was 0.90 (95% CI: 0.82–0.98).[310] In a systematic review of 11 population-based case-control, 3 nested occupation-based case-control, and 7 occupational benzene cohort studies, 2 of the 21 study groups reported statistically significant elevated NHL risks; these 2 studies involved multiple chemical exposures.[311] Overall, the summary odds ratio for NHL in these 21 groups was 1.04 (95% CI: 0.94–1.14, n_{NHL} = 390 deaths expected/404 deaths observed). Exclusion of the two studies involving multiple chemical exposures yielded a summary OR of 0.96 (95% CI: 0.86–1.06, n_{NHL} = 373.2 deaths expected/359 deaths observed).

In a meta-analysis of 16 case-control (16 incidence/0 mortality) and 6 cohort studies (1984–2007, 2 incidence/4 mortality) on benzene exposure and NHL risks using random effects models, the summary NHL relative risk was 1.23 (95% CI: 1.02–1.48, $P_{heterogeneity}$ = 0.36, I^2 = 8%).[312] Restricting the meta-analysis to 13 studies the authors considered "high exposure" without assigning a specific quantitative measure, the summary NHL RR increased to 1.49 (95% CI: 1.09–2.04, $P_{heterogeneity}$ = 0.25, I^2 = 20%). A meta-analysis of 16 case-control, 6 cohort, and 2 other designs (cancer registrations, death certificates) through fall, 2009 examined NHL risks comparing ever-benzene-exposed and never-benzene-exposed workers, primarily NHL incidence.[313] Of the 24 studies, 22 reported no association; the pooled risk estimate using a random effects model was 1.11 (95% CI: 0.94–1.30, $P_{heterogeneity}$ = 0.001, I^2 = 72.6%) with substantial heterogeneity. Restricting the analysis to six studies using historical benzene measurements, the authors reported little consistent evidence of increasing NHL risks with higher cumulative or intense (duration, peak, mean) benzene exposures. A meta-analysis of 14 case-control studies reporting benzene as an independent analytic variable and 8 cohort or nested case-control studies reporting benzene as a quantitative exposure metric through spring 2009 examined summary relative risk estimates (SRRE) and evaluated exposure-response relationships.[314] The SRRE for all studies was 1.08 (95% CI: 0.93–1.24, $P_{heterogeneity}$ = 0.360). Subgroup analysis did not support an independent association between benzene exposure and NHL, with most estimates statistically nonsignificant. Evaluation of 4 cohort and 1 case-control studies reporting data on cumulative benzene exposures >60 ppm-years yielded a SRRE of 1.08 (95% CI: 0.36–3.24, $P_{heterogeneity}$ = 0.135).

A 15-year, retrospective cohort study examined hematological neoplasm incidence and benzene exposure in 74,828 benzene-exposed Chinese workers and 35,805 nonexposed controls in the same or other Chinese factories employed from 1972–1987 in coatings, rubber, chemical, shoe, or other Chinese industries.[315] Estimation of benzene exposure was based on evaluations by local industrial hygienists and occupational health personnel using job titles, historical benzene measurements, and production information. For all benzene-exposed workers, the mean time-weighted average benzene exposure lagged 1.5 years was 22.5 ppm, with a mean duration of 9.3 years and cumulative exposure of ~698,000 person-years. The relative risk of non-Hodgkin lymphomas in all benzene-exposed workers was positive, but statistically nonsignificant and imprecise (RR = 3.0, 95% CI: 0.9–10.5, n = 16 cases). NHL cases were associated with distant benzene exposure prior to 1972 (15/16, P = 0.005). Dose-response data were difficult to interpret because of small numbers and unstable confidence intervals. Extension of follow-up to 28 years yielded an increased, statistically significant age/sex-adjusted NHL relative risk with a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

wider confidence interval (RR = 3.9, 95% CI: 1.5–13.2, n = 30 exposed cases/4 unexposed cases).[309]

Trichloroethylene

The IARC classifies trichloroethylene as a human carcinogen based primarily on increased renal cancer risks following occupational trichloroethylene (TCE) exposure. Although the IARC suggests a modestly positive association of NHL with trichloroethylene exposure may exist,[316] inconsistent study results, variable exposure measurements, lack of exposure-response relationships/statistically significant risks, and difficulty evaluating numerous NHL subtypes limit definite conclusions on causation. A meta-analysis of 12 cohort and 12 case-control studies involving occupational TCE-exposed workers reported a statistically significant summary relative NHL risk of 1.21 (95% CI: 1.06, I^2 = 35.91, $P_{\text{heterogeneity}}$ = 0.04) with substantial heterogeneity.[16] For cohort studies, the summary RR was 1.52 (95% CI: 1.29–1.79, I^2 = 7.09%, $P_{\text{heterogeneity}}$ = 0.63), whereas the summary RR for case-control studies was not statistically significant (mRR = 1.14, 95% CI: 0.93–1.40, I^2 =10.51%, $P_{\text{heterogeneity}}$ = 0.23). In a Canadian study of 215 men with NHL and 2,341 population and cancer controls, the adjusted OR for NHL in workers with any TCE exposure was not statistically significant (adjusted OR = 1.3, 95% CI: 0.5–3.4, n_{NHL} = 7 cases).[317]

A pooled analysis of four international studies including 2,348 lymphoma cases and 2,462 controls reported an increased risk of some NHL subtypes (e.g., follicular lymphoma/CLL) associated with retrospective assessment of occupational TCE exposure.[318] Overall, NHL risk did not increase by probability, duration, or frequency of TCE exposure; however, restricting analysis to high-probability TCE exposures yielded a modestly positive odds ratio (adjusted OR = 1.4, 95% CI: 0.9–2.1, n_{NHL} = 50 cases/38 controls) but statistically nonsignificant result. Analysis of TCE exposure intensity and NHL risks in a meta-analysis did not reveal any positive pattern consistent with other studies.[16] TCE exposure estimates in a US study of 1,189 NHL cases (76% participation) and 982 unexposed controls (52% participation) suggest a marginally elevated NHL risk in the highest tertile of cumulative exposure (OR = 2.3, 95% CI: 1.0–5.0, n_{NHL} = 24 cases); however, neither overall exposure duration nor intensity was positively associated with NHL.[319] In a German case-control study of 710 lymphoma cases and matched controls, the odds ratio for NHL was marginally elevated in TCE-exposed workers with >35 ppm-years TCE exposure (adjusted OR = 2.1, 95% CI: 1.0–4.8, n_{NHL} = 21 cases/9 controls); however, the trend for cumulative TCE tertiles was not statistically significant (P_{trend} = 0.14).[320] A Nordic cohort study did not detect a positive exposure-response relationship between TCE and NHL; for the high cumulative TCE exposure group, the hazard ratio was 0.95 (95% CI: 0.84–1.06, n_{NHL} = 353 cases) compared with unexposed referents.[321]

Other Solvents

Observational evidence of increased NHL risks following solvent exposures other than benzene remains limited and relatively small. In a hospital-based French study of 244 male NHL cases and 456 age/residence-matched male controls (solvent-unexposed patients in rheumatology or orthopedic wards) using unconditional logistic regression, the overall NHL risk for any lifetime solvent exposure including benzene was marginally significant statistically (OR = 1.4, 95% CI: 1.0–2.0, n_{NHL} = 140 cases/233 controls, P = 0.06) based on self-reported questionnaires and expert reviews.[322] Expert-estimated benzene exposures were usually low (e.g., 81% of 12 definite cases of <1 ppm). The NHL odds ratio was statistically marginally significant for estimated daily job frequency >35% and lifetime exposure duration >15 years, but not for lifetime high-intensity duration or high-average intensity. Subgroup analysis of petroleum, aromatics, halogenated, and oxygenated solvents for overall and intensity with NHL risks yielded a statistically marginally significant OR only for lifetime exposure duration of >15 years to petroleum solvents. The multicenter European population-based case-control Epilymph study reported slightly increased, marginally statistically significant B cell NHL odds ratios for ever-exposed to solvents (OR = 1.1, 95% CI: 1.0–1.3, n_{NHL} = 808 cases/1,009 controls, P_{trend} = 0.00019) as well as for BTX (benzene, toluene, xylene), styrene, and other solvents.[323] Elevation of follicular lymphoma risks was statistically significant for BTX, styrene, and ever-exposed to other solvents. Cumulative exposures were significantly associated with slightly increased risks for B cell NHL (P_{trend} = 0.02) and follicular lymphomas (P_{trend} = 0.02). The US multicenter, population-based National Cancer Institute-SEER study of NHL risks and occupational exposure to chlorinated solvents reported marginally statistically significant elevation of NHL risks (OR = 1.9, 95% CI: 1.00–3.6, n_{NHL} = 34 cases/16 controls, P_{trend} = 0.04) for cumulative carbon tetrachloride exposure (>520 hours) based on computer-assisted personal interviews and expert reviews of 38 job-exposure and task-exposure matrices.[324] The reported NHL risks for other chlorinated solvents (chloroform, methylene chloride, tetrachloroethylene, 1,1,1 trichloroethane) were null.

In a US study of 376 incident female NHL cases and 463 unexposed, population-based female controls

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(56% participation rate), a history of any work or home paint organic solvent exposure was not associated with statistically significant increased, adjusted NHL risks (OR = 1.29, 95% CI: 0.82–2.03) based on telephone interviews (20.5% proxy interviews).[325] None of the nine solvent exposure categories including benzene (aOR = 1.52, 95% CI: 0.41–5.70, n_{NHL} = 7 cases/5 controls) had statistically significant elevations of NHL risks. Exposure duration (P_{trend} = 0.611) and cumulative (P_{trend} = 0.596) solvent exposures were also not associated with statistically significant elevations of NHL risks. A California study of 1,591 NHL cases (72% participation rate) and 2,515 age/sex/residence-matched, population-based controls (78% participation rate) reported no association between NHL and occupational solvent exposures.[326] Using unconditional logistic regression to estimate relative risks and personal interviews (no proxy interviews), the NHL relative risks for ever-solvent exposure were 0.95 (95% CI: 0.80–1.1, n_{NHL} = 73 cases/75 controls) and 0.95 (95% CI: 0.78–1.2, n_{NHL} = 20 cases/20 controls) for medium-high solvent exposures compared with unexposed controls. Subgroup analysis for NHL subtypes demonstrated no significant differences in relative risks for solvent exposures. Investigation of NHL risks for benzene and formaldehyde exposures also yielded null results.

2,3,7,8-Tetrachlorodibenzo-p-dioxin (TCDD)

TCDD is a persistent contaminant of numerous chemical reactions involving chlorine compounds classified by the International Agency for Research on Cancer (IARC) as human carcinogens (Group 1) based on limited epidemiological evidence and upgraded by a strong mechanism of action in experimental animals.[327] Although the IARC considers TCDD a complete carcinogen capable of causing cancer in all tissue sites based on mechanistic evidence, the IARC classified epidemiological evidence for increased NHL risks after TCDD exposure as limited based on observational studies of military (e.g., Agent Orange use in Vietnam), industrial, and accidental (e.g., Seveso, Italy) exposures. Industrial cohort studies suggest a positive association between NHL mortality and TCDD exposure; however, inconsistent results across other TCDD exposure groups and the lack of clear dose-response relationships limit the classification of any TCDD association as causal.[24]

Agent Orange and Other Vietnam Herbicides

The US Institute of Medicine Committee to Review the Health Effects in Vietnam Veterans of Exposure to Herbicides (IOM Committee) evaluated available medical data on Agent Orange and other herbicide use in Vietnam, as well as background evidence on the association of herbicides and NHL. The IOM Committee determined the medical evidence was sufficient to conclude a positive statistical association existed between herbicide use and increased NHL risks in Vietnam veterans, with reasonable confidence that the association was not related to chance, bias, or confounding.[328] According to the mandate for the IOM Committee, their findings were based on a statistical rather than a strict causal association.

The prospective Air Force Health Study cohort enrolled 1,261 Operation Ranch Hand male veterans involved in aerial Agent Orange and other herbicide spraying in South Vietnam from 1962–1971 with periodic physical examinations and questionnaires from 1982–2002. Controls were 19,101 unexposed male US Air Force veterans assigned to air cargo missions in Southeast Asia during the same time. The median serum TCDD concentrations were 12.4 ppt (range, 0.0–617.7 ppt) for Ranch Hand veterans and 4.2 ppt (range, 0.0–52.8 ppt) for unexposed US Air Force veterans.[329] As of the end of 1999, no death of a TCDD-exposed Ranch Hand veteran was attributed to non-Hodgkin lymphoma.[330] The morbidity portion of the Air Force Health Study enrolled 1,197 Ranch Hand veterans and 1,855 matched controls followed through 2002. Two Ranch Hand veterans developed NHL; their estimated TCDD concentrations at the end of their Vietnam tour were ≤10 and >118.5 ppt.[331] The comparison group had six NHL cases; however, the study size was insufficient to exclude small differences between exposure groups.

The Army Chemical Corps study examined 894 veterans of the US Army Chemical Corps involved with handling, mixing, application, and storage of herbicides during the Vietnam War. Mean lipid-corrected serum TCDD concentrations were much lower than for US Army Chemical Corps members or Ranch Hand veterans ranging from 4.3 ppt (range, 0.8–85.8 ppt) in Army Chemical Corps veterans spraying herbicides in Vietnam to 2.1 ppt (range, 0.4–12.5 ppt) in unexposed veterans stationed outside Vietnam. None of the US Army Chemical Corps veterans stationed in Vietnam developed NHL. The Selected Cancers Study enrolled 1,157 incident NHL cases and 1,776 randomly selected controls using self-reported exposure information from telephone interviews.[332] Compared with Vietnam-era veterans serving outside Vietnam, NHL risk for veterans serving in Vietnam was marginally increased statistically (OR = 1.52, 95% CI: 1.00–2.32, n_{NHL} = 96 cases); however, higher NHL risks appeared in veterans (navy, marine corps, noncombat support units) with much less Agent Orange exposure. NHL risks were not increased

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(OR = 0.89, 95% CI: 0.50–1.58, n_{NHL} = 19 cases) in veterans serving in the area and time period of heaviest spraying (III Corps). No serum TCDD concentrations were available to validate self-reported Agent Orange exposures. Although these studies suggest an association between Vietnam military service and the NHL, the association with Agent Orange is much weaker. Overall, these studies demonstrated no consistent, statistically significant associations or dose-response relationships between Agent Orange or other herbicide exposures and increased NHL risks; however, some of these studies had significant limitations (small sample sizes, inadequate documentation of exposure).

Occupational Cohorts

Considerably higher serum TCDD concentrations occur in TCDD-contaminated herbicide production workers and 2,4,5-T herbicide applicators than in the general population. TCDD-contaminated herbicides primarily involve 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), pentachlorophenol, and trichlorophenol. Some mortality studies of these workers suggest elevated NHL risks; most, but not all, of these studies report statistically nonsignificant increased SMRs. A pooled analysis of 36 cohorts, including 21,863 participants from 12 countries exposed to chlorophenols, phenoxy herbicides, and dioxins, examined NHL mortality using reconstructions of TCDD exposures from company exposure questionnaires, job records, and serum/adipose dioxin concentrations.[25] An estimated 13,831 were classified as TCDD-exposed, whereas 7,553 were considered unexposed. NHL mortality for TCDD-exposed workers was modestly elevated, but statistically nonsignificant (SMR = 1.39, 95% CI: 0.89–2.06, n_{NHL} = 24 deaths) compared with 1.00 (95% CI: 0.46–1.90) for unexposed workers using national data. The SMR for workers with ≥20 years of TCDD exposure was also statistically nonsignificant (SMR = 1.21, 95% CI: 0.15–4.38, n_{NHL} = 2 deaths), with imprecise estimates from the small sample size.

In a US retrospective cohort mortality study of 2,192 Michigan chlorophenol production workers employed from 1930s–1980s, 12% of the trichlorophenol (TCP) and 20% of the pentachlorophenol (PCP) workers developed chloracne.[28] Trichlorophenol production ceased in 1979, whereas pentachlorophenol production ended in 1980. The SMR for NHL in TCP workers was 1.08 (95% CI: 0.52–1.99, n_{NHL} = 10 deaths) with no evidence of a dose-response relationship between SMR tertiles and TCDD concentrations (P_{trend} = 0.630). In a retrospective US mortality study of 2,122 pentachlorophenol (PCP) production workers using US standardized mortality rates, the increased SMR for NHL was statistically significant (SMR = 1.77, 95% CI: 1.03–2.84, n_{NHL} = 17 deaths).[281] Subcohort analysis demonstrated a statistically significant elevated SMR for NHL in 720 workers exposed to TCP *and* PCP (SMR = 2.50, 95% CI: 1.08–4.93, n_{NHL} = 8 deaths), whereas the SMR was not statistically significant for 1,402 PCP workers with no TCP production work (SMR = 1.41, 95% CI: 0.64–2.67, n_{NHL} = 9 deaths). TCP workers typically have much higher serum TCDD than with other dioxin concentrations; PCP workers usually have higher dioxin concentrations than TCDD. An uncontrolled decomposition reaction occurred in a German trichlorophenol plant during 1953, resulting in TCDD contamination of the plant.[333] During cleanup and repair processes, 254 workers were exposed to TCDD, with 56 severe and 45 less severe chloracne cases subsequently developing in these workers. Estimated TCDD doses exceeded 1 μg/kg body weight in 69 workers. No NHL cases occurred in these workers during 40 years of follow-up.

Seveso, Italy, TCDD Incident

Environmental TCDD contamination occurred in Seveso, Italy, during 1976 from a trichlorophenol production plant accident. Long-term surveillance of cancer incidence and mortality revealed some evidence of increased NHL risk in the local community during 25 years of follow-up. The most consistent finding was elevated hematopoietic and lymphoma cancer risks in men and women. The highest increase for non-Hodgkin lymphoma (RR = 2.8, 95% CI: 1.1–7.0) occurred 15 years after the accident about 30 miles north of Milan.[334] Figure 60.4 demonstrates the contamination and reference zones surrounding the accident in Seveso, Italy, with Table 60.19 listing the associated mean TCDD soil concentrations (minimum–maximum), median lipid-adjusted serum TCDD concentration in samples collected from specific zones 1976–1977, and rate ratios for NHL deaths in each zone.[27] No NHL cases occurred in the 18 Seveso residents developing chloracne after the accident (1.7 cases expected).[27]

Environmental Ionizing Radiation

Life Span Study

Initial follow-up studies of 401 NHL cases in Japanese atomic-bomb survivors suggest the possibility of a slight NHL excess (i.e., ~8 cases) in men; however, the evidence is relatively modest and absent in women. Analysis of data from atomic-bomb survivors in the Life Span Study through 2001 did not detect evidence of a statistically significant, dose-related excess non-Hodgkin

lymphoma risk overall.[121] The excess relative rate/Gy was positive in men (ERR/Gy = 0.46, 95% CI: −0.08 to 1.29), but the trend was statistically nonsignificant (P_{trend} = 0.11). In women, the ERR/Gy was near zero (ERR/Gy = 0.02, 95% CI: <−0.44 to 0.64) without evidence of a dose-response relationship (P_{trend} > 0.5).

Sun Exposure

Several case-control studies suggest total and recreational, but not occupational, sun exposure reduces NHL risks by 25–40%;[335,336] however, evidence for a causal or protective effect of sun exposure on NHL

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risks is inconsistent. A pooled analysis of data from 10 European and Australian, mostly population-based case-control studies participating in the International Lymphoma Epidemiology Consortium (InterLymph) compared the highest and lowest quartiles of cumulative total personal (recreational/occupational) and recreational sun exposures based on self-reports and questionnaires.[337] The adjusted estimated odds ratio for the highest quartile of total sun exposure was inverse, but not statistically significant (aOR = 0.87, 95% CI: 0.71–1.05, n_{NHL} = 1,087 cases/1,364 controls) using the lowest quartile as referents and random effects models. For cumulative recreational sun exposure, the comparison was statistically significantly inverse (aOR = 0.76, 95% CI: 0.63–0.91, n_{NHL} = 1,584 cases/2,019 controls). The multicenter European case-control study reported no statistically significant reduction in NHL risks comparing the highest and lowest quartiles of personal indicators of UV radiation exposure (childhood free/school days, adult free/workdays, sunlamp use), except for a modest association between NHL risks and cumulative sunlamp use in hospital-based controls.[252]

Limited data from cohort studies have not supported a protective effect of UV radiation exposure on NHL risks. The US Nurses' Health study identified 1,064 incident NHL cases from 1976–2006 in 115,482 women with follow-up by biennial questionnaires.[338] The study used UV-B flux based on current residence location as a proxy measure for personal sun exposure and dietary vitamin D intake from questionnaire data. None of the comparisons of high and low UV-B flux measurements demonstrated a statistically significant inverse relationship for NHL risks. The multivariable-adjusted relative risk for high UV areas at age 15 years was positive and marginally statistically significant (aRR = 1.21, 95% CI: 1.00–1.47, n_{NHL} = 212 cases/288 controls, P_{trend} = <0.01) using low UV areas as referents. Subgroup analysis yielded no statistical heterogeneity by NHL subtype; however, power was limited by relatively few cases. The Norwegian-Swedish Women's Lifestyle and Health Cohort Study enrolled 104,953 women and identified 158 NHL cases during ~1.6 million years of observation.[339] Using Poisson regression analysis to estimate the association between NHL risks and artificial tanning devices, bathing vacations, and sunburns, the age/residence-adjusted relative NHL risks for all three cumulative measures of sun exposure were near the null. Although several pigmentary characteristics were associated with NHL risks (e.g., ↑ brown hair, ↓ gray/green/blue eyes), the results did not support an association between cumulative sun exposure and NHL risks.

The most common hypothesis for an inverse relationship between sun exposure and NHL risks is vitamin D production; however, little evidence supports vitamin D deficiency as an etiology of NHL risks. A US study of 126 NHL cases and 139 clinic-based controls reported an inverse odds ratio of NHL risks for sunbathing of >1/week (aOR = 0.28, 95% CI: 0.10–0.79, n_{NHL} = 10 cases/98 controls) using never-sun bathers as referents and self-administered surveys for exposure data. In this study, current vitamin D deficiency as measured by radioimmunoassays was not associated with NHL (aOR = 0.86, 95% CI: 0.44–1.68, n_{NHL} = 88 cases/34 controls) or a dose-response relationship comparing high and low tertiles of vitamin D concentrations (P_{trend} = 0.35). The Nurses' Health Study also reported no association between NHL risks and dietary (P_{trend} = 0.35) or total (P_{trend} = 0.22) vitamin D intake.[338]

Lifestyle

Although studies on NHL risks and self-reported smoking, alcohol consumption, and obesity are inconsistent, observational studies have not excluded the effect of lifestyle on NHL subtype risks. Diet probably does not have a prominent role in NHL etiology. Caffeine-containing products (e.g., coffee, tea) are not consistently associated with protective or deleterious effects on NHL risks. Several Italian case-control studies report no clear association between coffee consumption and NHL risks in a country where the average annual per capita coffee consumption is ~600 cups. In a northern Italian study of 429 incident NHL cases and 1,157 hospital-based controls, the estimated relative risk for NHL comparing coffee drinkers and nondrinkers was modestly positive, but not statistically nonsignificant (aRR = 1.2, 95% CI: 0.8–1.7) after adjustment for age, sex, residence, BMI, alcohol consumption, and smoking using multiple logistic regression.[340] The study detected no statistically significant trend between NHL risks and intensity (P_{trend} = 0.11) or duration (P_{trend} = >0.90) of coffee consumption using non-coffee drinkers as referents; however, aRR for the highest quintile of coffee consumption was statistically significant (aRR = 2.2, 95% CI: 1.3–3.9, n_{NHL} = 23 cases/82 controls). The multivariate RR for tea consumption was similar (aRR = 1.2, 95% Ci: 0.9–1.6, n_{NHL} = 95 cases/216 controls) using non-tea drinkers as referents.

Although epidemiological evidence regarding coffee consumption and NHL risks is limited, some data suggest a difference in NHL subtype risks. In a multicenter Italian study of 1,418 NHL cases (1,301 B

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cells, 117 T cells), the fully adjusted odds ratio was positive, but statistically nonsignificant comparing any coffee drinking with nondrinkers for diffuse large B cell lymphoma (OR = 0.95, 95% CI: 0.61–1.5, n_{NHL} = 338 cases).[341] The study reported some evidence of a dose-response for coffee drinking intensity (>4 cups daily, P_{trend} = 0.045) and duration (>4 cups daily for ≥30 years, P_{trend} = 0.001) using ≤2 cups daily coffee users as referents. Although the estimates were imprecise, any coffee drinking was not associated with statistically significant increases in unadjusted T cell lymphoma risks using nondrinkers as referents (OR = 2.3, 95% CI: 0.84–6.4, n_{NHL} = 113 cases). No significant trends were noted in T cell lymphoma risks with increasing intensity or duration of coffee use, using ≤2 cups of daily coffee as referents.

Tobacco Smoking

Findings of epidemiological studies examining tobacco smoking and NHL risks are inconsistent with slightly positive results primarily associated with follicular lymphoma and T cell subtypes in women.[342] In a meta-analysis of 41 case-control (20,143 incident NHL cases) and 9 cohort studies (5,748 incident NHL cases), the pooled-effect estimate for overall NHL risks comparing ever-smokers with nonsmoking referents was marginally significant (pooled-effect estimate = 1.05, 95% CI: 1.00–1.09), primarily reflecting the estimate for T cell NHL subtypes (pooled-effect estimate = 1.23, 95% CI: 1.09–1.38).[33] The International Lymphoma Epidemiology Consortium (InterLymph) examined tobacco smoking and NHL risks in an analysis of nine case-control studies from the United States, Europe, and Australia (6,594 cases; 8,892 controls) using unconditional logistic regression models controlling for age, sex, race, and study center.[343] In contrast to nonsmokers, ever-smokers had a self-reported lifetime history of >100 cigarettes or ≥6 months of regular smoking. The odds ratio for overall NHL in ever-smokers was marginally significant statistically (OR = 1.07, 95% CI: 1.00–1.15, n_{NHL} = 3,765 cases/3,914 controls). The trend among quartiles of cumulative smoking was statistically significant for pack-years ($OR_{\geq 36\ pack\text{-}years}$ = 1.21, 95% CI: 1.09–1.34, n_{NHL} = 1,066 cases/1,194 controls, P_{trend} = 0.01) and smoking duration ($OR_{\geq 36\ years}$ = 1.16, 95% CI: 1.05–1.28, n_{NHL} = 1,197 cases/1,349 controls, P_{trend} = 0.01). Using 2001 WHO NHL subtype classifications, the odds ratio for NHL subtypes among current smokers was statistically significant only for follicular lymphoma (OR = 1.31, 95% CI: 1.12–1.52, n_{FL} = 1,452 cases). A European study of 373 incident follicular lymphoma cases and 818 population-based controls reported a slightly positive, statistically nonsignificant odds ratio for follicular lymphoma in current smokers (OR = 1.12, 95% CI: 0.81–1.56, n_{FL} = 99 cases/177 controls, P_{trend} = 0.62).[344] For women, the magnitude of the odds ratio for follicular lymphoma was higher, but still statistically nonsignificant (OR = 1.42, 95% CI: 0.92–2.21, n_{FL} = 51 cases/112 controls, P_{trend} = 0.16). Analysis of human leukocyte antigen (HLA) class II data and follicular lymphoma risks suggested carrying two shared HLA-DRB1 haplotypes increased follicular lymphoma risks in currently smoking women (OR = 2.52, 95% CI: 1.47–4.34, 18 cases/48 controls, P_{trend} = 0.002).

The Shanghai study of 649 NHL cases (76% participation rate) and 1,298 hospital-based controls demonstrated no association between NHL risks and ever-smokers using never-smokers as referents (OR = 1.04, 95% CI: 0.81–1.35, n_{NHL} = 272 cases/537 controls) with no significant relationship for daily smoking intensity (P_{trend} = 0.36) or duration (P_{trend} = 0.69).[245] Passive smoking was not associated with NHL risks (OR = 0.93, 95% CI: 0.70–1.25, n_{NHL} = 158 cases/350 controls). The prospective Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening Trial examined NHL risks and smoking comparing ever- (≥6 months regular smoking history) and never-smokers based on baseline questionnaire data.[345] Results indicated no association between overall NHL risks or common NHL subtypes and smoking. For current smokers, the age/sex/race/education-adjusted HR for overall NHL risks in current smokers was 0.90 (95% CI: 0.73–1.11, n_{NHL} = 105 cases), whereas the HR for follicular lymphoma was 0.74 (95% CI: 0.42–1.31, n_{FL} = 14 cases). None of the hazard ratios for quartiles in cumulative measures of ever-smokers (duration, packs/day) were statistically significant, including overall NHL and follicular lymphoma risks (P_{trend} 0.365–0.964), except diffuse large B cell lymphoma duration ($HR_{>40\ years}$ = 0.79, 95% CI: 0.49–1.29, n_{DLBCL} = 20 cases). In a Japanese cohort of 1,332 HTLV-1 seropositive participants using never-smokers as referents and followed from 1990–2012, the multivariate hazard ratio for adult T cell leukemia/lymphoma (ATLL) in ever-smokers was 1.64 (95% CI: 0.45–6.06, n_{ATLL} = 10 ever-/15 never-smokers) after adjusting for age, alcohol intake, and geographical area.[346] The multivariate hazard ratios for smoking intensity were statistically significant and demonstrated an exposure-response relationship for 20 cigarettes/day (aHR_{ATLL} = 2.03, 95% CI: 1.13–3.36) and 40 pack-years smoking (aHR_{ATLL} = 2.39, 95% CI: 1.32–4.44).

Alcohol

Although some case-control[347] and cohort[348] studies on NHL risks and alcohol consumption suggest a modestly inverse relationship, epidemiological evidence is inconsistent and weaker for a dose-response relationship along with variation between NHL subtypes. In a pooled analysis of 9 US and European case-control studies involving 6,492 cases and 8,683 controls from the InterLymph Consortium, the age/sex/ethnic/socioeconomic/study center-adjusted pooled OR comparing current and non-alcohol drinkers was inversely associated with overall NHL risks (aOR = 0.73, 95% CI: 0.64–0.84, n_{NHL} = 1,601 cases/2,392 controls).[349] The NHL risks did not decrease with increased alcohol consumption (P_{trend} = 0.97) with little difference between alcohol beverage types. In current drinkers, the adjusted odds ratios were statistically significant for Burkitt's lymphoma (aOR = 0.29, 95% CI: 0.13–0.64, n_{BL} = 111 cases) and diffuse large B cell lymphoma (aOR = 0.64, 95% CI: 0.53–0.77, n_{DLBCL} = 2,126 cases), but not other common B or T cell lymphomas. A meta-analysis of 21 case-control and 8 cohort studies involving 18,759 NHL cases using random effects models reported an inverse summary relative risk for overall NHL risks comparing current- and non-drinkers (summary RR = 0.85, 95% CI: 0.79–0.91, I^2 = 56.7%) with moderate heterogeneity.[350] The summary RR was statistically significant for case-control studies (RR = 0.80, 95% CI: 0.74–0.87), but not cohort studies (RR = 0.96, 95% CI: 0.88–1.04), with significant heterogeneity between the two estimates ($P_{heterogeneity}$ = 0.001). The summary RR for NHL in heavy alcohol drinkers was inverse and marginally statistically significant (RR = 0.84, 95% CI: 0.70–1.00, n = 7 studies, I^2 = 3.1%). The summary relative risks were similar between men, women, and common NHL subtypes.

The prospective US Cancer Prevention Study II Nutrition Cohort study identified 1,991 incident NHL cases among 43,124 participants.[351] Using Cox proportional hazards regression and nondrinkers as referents, the multivariable-adjusted relative risk was statistically significant and inverse only for >2 drinks daily (RR = 0.78, 95% CI: 0.65–0.93). The study detected little difference in NHL risks between sexes ($P_{interaction}$ = 0.45) or beverage type ($P_{difference}$ = 0.22). Alcohol use and NHL risks were more closely associated with B cell (P_{trend} = 0.005) than T cell subtypes (P_{trend} = 0.76). The Shanghai hospital-based case-control study reported no association between NHL risks and ever- versus never-alcohol consumption (OR 0.92, 95% CI: 0.72–1.19, n_{NHL} = 133 cases/280 controls), with no significant difference in NHL risks between alcohol beverage types.[245] In the prospective Prostate, Lung, Colorectal, and Ovarian (PLCO) Cancer Screening cohort of older participants followed a median of 6.4 years, alcohol consumption was not associated with NHL risks comparing the highest alcohol quartile ($OR_{\geq 14\ drinks/week}$ = 0.84, 95% CI: 0.62–1.14, n_{NHL} = 68 cases, P_{trend} = 0.187) with nondrinking referents.[245] Specific alcoholic beverage consumption tertiles were also not associated with NHL risks with the P_{trend} ranging from 0.247–0.455.

Obesity

Pooled analyses of data from case-control studies suggest BMI is associated with slight increases in NHL risks, particularly for diffuse large B cell lymphoma (DLBCL); however, the results are mixed. In a pooled analysis of 18 case-control studies from the InterLymph Consortium (10,453 cases/16,507 controls) using normal weight BMI as referents (18.5–24.99 kg/m^2), the findings demonstrated no association comparing overall NHL risks with obese (BMI = 30–39.99 kg/m^2, OR = 0.97, 95% CI: 0.81–1.15, I^2 = 69.8%) or severely obese (BMI = ≥40 kg/m^2, OR = 0.99, 95% CI: 0.70–1.41, I^2 = 26.8%) participants.[45] The pooled odds ratio for DLBCL in severely obese participants was positive and statistically significant (OR = 1.80, 95% CI: 1.24–2.62, $P_{heterogeneity}$ = 0.40, I^2 = 4.4%); however, increasing 5 kg/m^2-BMI increments was not associated with DLBCL risks. A meta-analysis of 10 cohort studies and 6 case-control studies (21,720 cases) reported modestly elevated overall NHL risks in overweight (BMI = 25–<30 kg/m^2, summary RR = 1.07, 95% CI: 1.01–1.14, I^2 = 57.3%, $P_{heterogeneity}$ = <0.001) and obese (BMI ≥ 30 kg/m^2, summary RR = 1.20, 95% CI: 1.07–1.34, I^2 = 72.1%, $P_{heterogeneity}$ = <0.001) participants using normal weight participants (BMI = <25 kg/m^2) as referents.[352] The summary RR/5 kg/m^2 increase in BMI for overall NHL risks was slightly positive (RR = 1.10, 95% CI: 1.05–1.16, I^2 = 72.9%, $P_{heterogeneity}$ = <0.001). Body weight and height were measured in seven studies and self-reported in nine studies. In obese participants, DLBCL, but not follicular lymphoma, risks were positive and statistically significant (summary RR = 1.40, 95% CI:1.18–1.66, n = 6 studies, I^2 = 39.8%, $P_{heterogeneity}$ = 0.14). The prospective Prostate, Lung, Colorectal, and Ovarian Cancer Screening Trial enrolled 14,982 participants aged 55–74 years and followed them for a median of 8.8 years using baseline questionnaires to assess weight and height at age 20 years and baseline.[345] The overall NHL risk was positive and statistically significant for BMI in obese participants

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

at baseline (BMI = ≥30 kg/m^2, HR = 1.32, 95% CI: 1.13–1.54, n_{NHL} = 321 cases, P_{trend} = <0.01), particularly for DLBCL risks (HR = 1.58, 95% CI: 1.10–2.27, n_{NHL} = 63 cases, P_{trend} = 0.056). The self-reported BMI at 20 years in obese participants was slightly positive, but statistically nonsignificant (HR = 1.09, 95% CI: 0.72–1.65, n_{NHL} = 23 cases, P_{trend} = <0.001).

A meta-analysis of prospective studies reported slightly elevated overall NHL risks with 5 kg/m^2 increments of BMI in men (RR = 1.09, 95% CI: 1.04–1.14, n = 8 studies, I^2 = 0%, $P_{heterogeneity}$ = 0.69) and women (RR = 1.07, 95% CI: 1.02–1.13, n = 10 studies, I^2 = 44.1%, $P_{heterogeneity}$ = 0.07) with no statistically significant difference between male and female risks ($P_{difference}$ = 0.64).[47] The overall NHL risk for increasing 5-kg/m^2 BMI increments in men and women together was statistically marginally significant (RR = 1.06, 95% CI: 1.00–1.12, I^2 = 0%, $P_{heterogeneity}$ = 0.61). Diffuse large B cell lymphoma incidence in men and women, but not follicular lymphoma incidence, was associated with increasing 5-kg/m^2 BMI increments (RR = 1.13, 95% CI: 1.02–1.26, n = 8 studies, I^2 = 37%, $P_{heterogeneity}$ = 0.13).

The US Women's Health Initiative study identified 1,123 NHL cases in the cohort of postmenopausal women followed for a mean of 11 years using self-administered baseline questionnaires to examine anthropometric factors.[353] Comparing the highest and lowest quartiles, the hazard ratio was marginally statistically significant for height ($HR_{>166.1\,cm}$ = 1.19, 95% CI: 1.00–1.43, n = 300 cases, P_{trend} = 0.02) and statistically significant for DLBCL ($HR_{>166.1\,cm}$ = 1.43, 95% CI: 1.01–2.03, n = 85 cases, P_{trend} = 0.03). The study reported no exposure-response relationship between other anthropometric factors and NHL risks, including abdominal fat (waist circumference, P_{trend} = 0.91; hip circumference, P_{trend} = 0.64; waist-to-hip ratio, P_{trend} = 0.90) or BMI (P_{trend} = 0.77). The hazard ratio for self-reported BMI at age 18 was associated with overall NHL risks ($HR_{\geq 21.8\ kg/m^2}$ = 1.27, 95% CI: 1.01–1.59, n_{NHL} = 178 cases, P_{trend} = 0.09), but not BMI at ages 35 or 50 years. In the US Multiethnic Cohort of 87,079 men and 105,972 women, BMI at age 21 years ($HR_{\geq 30\ kg/m^2}$ = 1.86, 95% CI: 1.02–3.40, n_{NHL} = 11 cases, P_{trend} = 0.27) was a stronger predictor of NHL risks than baseline anthropometric factors, after adjusting for ethnicity, education, alcohol consumption, and baseline age.[46] The NHL incidence was lower in all ethnic groups (African Americans, Latinos, Native Hawaiians, Japanese) than Caucasians, consistent with most of the medical literature. The data suggest a stronger association between NHL risks and follicular lymphoma than DLBCL; however, the risk estimates were unstable for small sample sizes. A meta-analysis of 22 prospective studies on anthropometric factors and NHL risks supported a slightly increased NHL risk and increasing 5-kg/m^2 BMI increment in early adulthood ($HR_{BMI\ age\ 18–21\ years}$ = 1.11, 95% CI: 1.07–1.16, I^2 = 20.3%, $P_{heterogeneity}$ = 0.24) that was stronger than BMI increments reported at other adult ages.[354] Obesity (≥30 kg/m^2) was associated with modestly increased overall NHL risks (HR = 1.13, 95% CI: 1.06–1.20, I^2 = 10.8%, $P_{heterogeneity}$ = 0.328). Measures of abdominal fat (waist circumference, waist-to-hip ratio) were not associated with NHL risks. Among NHL subtypes, DLBCL had the strongest association with anthropometric factors ($HR5\text{-}kg/m^2_{BMI\ increment}$ = 1.11, 95% CI: 1.05–1.16, n = 16 studies, I^2 = 15.2%, $P_{heterogeneity}$ = 0.279).

Diet

Findings from observational studies evaluating the magnitude and consistency of an association between NHL risks and dietary factors are relatively modest and conflicting. No single dietary pattern is conclusively associated with elevated NHL risks. Although results are inconclusive, the strongest dietary factors associated with NHL are animal fat and saturated fat, with suggestive evidence for higher consumption of whole grains and vegetables. Modest alcohol intake lowered NHL risks based primarily on case-control studies.[355] In the US Multiethnic Cohort of >215,000 Caucasians, African Americans, Japanese Americans, Native Hawaiians, and Latinos aged 45–75 at baseline, 939 NHL cases occurred in 10 years of follow-up based on linkage with cancer registries.[356] None of the three dietary patterns (fat/meat, fruit/milk, vegetables) were significantly associated with NHL risks in the total population using Cox regression. Most of the NHL risks in NHL subgroups were statistically nonsignificant; however, some associations were positive (e.g., follicular lymphoma in men and fat/meat diet) based on small sample sizes.

Typically, red meat includes beef, lamb, mutton, pork, and veal, whereas processed meat includes bacon, cured/preserved meats, ham, and sausages. The US NIH-AARP Diet and Health Study enrolled 492,186 participants ($mean_{age}$ = ~62 years; range, 50–71 years) using a baseline self-administered dietary questionnaire, with a subcohort of 302,162 participants receiving a supplemental questionnaire on meat-cooking methods and doneness levels.[357] Proxy respondents and participants with prevalent cancer were excluded from the study. During a mean follow-up of 9 years, the study identified 3,611 incident NHL cases. Using multivariable Cox proportional hazards regression models to compare the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

highest and lowest consumption quintiles, overall NHL risks were not associated with total red meat (HR = 1.01, 95% CI: 0.90–1.14, n = 684 cases, P_{trend} = 0.41), total processed meat (HR = 0.99, 95% CI: 0.89–1.11, n = 691 cases, P_{trend} = 0.45), poultry (HR = 1.00, 95% CI: 0.90–1.12, n = 705 cases, P_{trend} = 0.77), or fish (HR = 1.07, 95% CI: 0.96–1.16, n = 732 cases, P_{trend} = 0.24). Overall, meat cooking and meat processing did not increase overall NHL, DLBCL, or follicular lymphoma risks.

A meta-analysis of 13 population-based case-control, 10 hospital-based case-control, and 10 cohort studies reported a modestly positive, statistically significant association between NHL risks and red meat consumption (summary RR = 1.22, 95% CI: 1.03–1.44, n = 10,149 cases/14 studies, I^2 = 35%).[52] The summary RR (sRR) did not reach statistical significance for processed meat, white meat, or fish/seafood. The sRR for overall dairy consumption was modestly positive and near statistical significance (sRR = 1.26, 95% CI: 0.99–1.60, n = 4,168 cases/6 studies, I^2 = 49%) with moderate heterogeneity. However, cheese (sRR = 1.13, 95% CI: 0.91–1.41, n = 6,969 cases/14 studies, I^2 = 32%) and milk (sRR = 1.12, 95% CI: 0.90–1.38, n = 5,120 cases/8 studies, I^2 = 61%) consumption were not clearly associated with overall NHL risks. None of the dietary factors were associated with statistically significant increased risks for DLBCL or follicular lymphoma. A meta-analysis of four population-based case-control, six hospital-based case-control, and four cohort studies reported a modestly positive, statistically significant pooled relative risk for NHL and red meat comparing the highest and lowest measures of red meat consumption (pooled RR = 1.14, 95% CI: 1.03–1.26, n = 13 studies, I^2 = 24.2%, $P_{heterogeneity}$ = 0.20).[358] Subgroup analysis indicated NHL risk for red meat depended on results from case-control studies (pooled RR = 1.19, 95% CI: 1.06–1.34) rather than cohort studies (pooled RR = 1.08, 95% CI: 0.92–1.26). The pooled RR for processed meat consumption was slightly positive, but statistically nonsignificant (pooled RR = 1.06, 95% CI: 0.98–1.15, n = 11 studies, I^2 = 3.6%, $P_{heterogeneity}$ = 0.41). Sensitivity analysis on five studies demonstrated no statistically significant associations between common NHL subtypes and meat consumption.

Reproductive

The incidence rate for most NHL subtypes is higher in men than women. Some studies suggest an inverse relationship between NHL risks and gravidity (i.e., pregnancies); however, the results are conflicting depending on the limitations of study designs evaluating rare tumors. Overall, the effect of reproductive factors and exogenous hormones on NHL risks is relatively modest.[359] In a systematic review of seven cohort, one nested case-control, eight population-based case-control, and three hospital-based case-control studies, more studies reported inverse relationships (J-shaped pattern) with NHL risks for gravidity than parity (births). The California Teachers study reported an inverse association between gravidity and B cell NHL risks.[360] The InterLymph study also reported an inverse, statistically nonsignificant relationship for follicular lymphoma and gravidity (pooled OR = 0.82, 95% CI: 0.51–1.31, n_{fl} = 117 cases), but not for overall NHL risks (pooled OR = 0.98, 95% CI: 0.75–1.28, n_{NHL} = 547 cases/885 controls, P_{trend} = 0.97).[361] For parity, the findings were null for overall NHL, follicular lymphoma, and DLBCL risks. In the Connecticut Women's case-control study, the age/family NHL history/BMI/menopausal status-adjusted odds ratio for overall NHL risks was inverse and statistically significant in the highest quartile of pregnancies ($OR_{\geq 4 \text{ vs. never}}$ = 0.6, 95% CI: 0.4–0.9, P_{trend} = 0.03) and parity ($OR_{\geq 4 \text{ vs. nulliparous}}$ = 0.6, 95% CI: 0.4–0.9, P_{trend} = 0.008),[362] whereas a UK population-based case-control study demonstrated no association between the highest parity tertile and overall NHL risks.[363] The 1-year lagged age/region-adjusted odds ratio for overall NHL in women with ≥3 births was 1.1 (95% CI: 0.8–1.5, n_{NHL} = 120 cases/112 controls). The NIH-AARP Diet and Health Study Cohort study reported no statistically significant associations between NHL, DLBCL, or follicular lymphoma and parity, age at menarche, age at first birth, or menopausal status at baseline.[359]

Medications

The use of chemotherapy for HL increases secondary NHL risks. Chemotherapeutic drugs (e.g., azathioprine, cyclosporine) associated with the treatment of autoimmune diseases and adverse immune reactions in transplant patients are confounders for assessing NHL risks in these patients. Hormone-based contraception has changed substantially over the previous decades, with high estrogen concentrations in preparations distributed in the 1960s, medium estrogen/progestin doses in the 1970s, and low doses since the 1980s. Additionally, the complex relationship between biological, sociodemographic, and reproductive factors, along with age at consumption and oophorectomy status, may affect NHL risks associated with hormone therapy. Most epidemiological studies on NHL risks

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in hormonal contraceptive users report null findings. The California Teachers Study reported a marginally lower B cell NHL risk in oral contraceptive users, particularly in women starting use at <25 years of age (multivariate-aRR = 0.72, 95% CI: 0.51–0.99); however, the study detected no exposure-response relationship with duration of use.[364] The relative risk of NHL comparing ever- and never-oral contraceptive users was close to 1 in the NIH-AARP Diet and Health Study Cohort[359] and the Connecticut Women's case-control study.[362] In general, case-control studies reported relative risks below 1, and cohort studies typically demonstrated overall null results, except for some NHL subtypes in women with surgical menopause (i.e., no endogenous estrogen).[365]

Although results associating postmenopausal hormone therapy with NHL risks are inconsistent, the overall NHL epidemiological findings are stronger for unopposed estrogen than estrogen/progestin use.[365] Several case-control studies report an inverse relationship between NHL risks and postmenopausal hormone therapy; however, the protective effect of postmenopausal hormone therapy typically is not supported by cohort studies, particularly with some common NHL subtypes (DLBCL, follicular lymphoma). The Women's Health Initiative randomized clinical trial identified 383 incident NHL cases during 13 years of follow-up while comparing conjugated equine estrogen and estrogen plus medroxyprogesterone acetate use.[366] The hazard ratios were similar and close to 1 for both arms of the trial, with no specific NHL subtypes associated with either treatment. The California Teachers Study reported null results comparing ever- versus never-use of postmenopausal hormone use and B cell NHL (RR = 1.05, 95% CI: 0.83–1.33, $n_{\text{B cell NHL}}$ = 299 cases), with no statistically significant associations with common NHL subtypes.[364] Among women with no postmenopausal hormone use and bilateral oophorectomy/hysterectomy, the B cell NHL risk was higher (RR = 3.15, 95% CI: 1.62–6.13) using participants with natural menopause as referents. The US Cancer Prevention Study II Nutrition Cohort identified 616 NHL cases in postmenopausal women during 15 years of follow-up.[367] Using extended Cox regression and never-users as referents, the HR for NHL was positive and statistically significant for ever-users of postmenopausal hormone therapy (HR = 1.29, 95% CI: 1.05–1.58, n_{NHL} = 284 cases), primarily from elevated risks for follicular lymphoma (HR = 1.98, 95% CI: 1.26–3.13, n_{FL} = 51 cases). The hazard ratio for NHL in ever-users of estrogen/progestin was null (HR = 1.02, 95% CI: 0.82–1.39, n_{NHL} = 83 cases). Duration of postmenopausal hormone use was not associated with statistically significant elevation of hazard ratios for NHL ($HR_{\text{current estrogen only use 15+ years}}$ = 1.22, 95% CI: 0.87–1.72, n_{NHL} = 54 cases).

Diseases

Altered Immunity

Immune deficiency is the most important NHL risk factor; immunocompromised patients including those with HIV/AIDS, immune suppressive therapy, immunosuppressed organ transplant patients, and congenital defects in the immune system have increased relative NHL risks ranging from 10–100-fold.[368,369] The vast majority of HIV-associated NHL neoplasms are B cell tumors with most being extranodal and high grade. In an analysis of 10 US SEER cancer registries with information on HIV status at NHL diagnosis from 1992–2009, 5.9% of 115,643 NHL cases were HIV-infected.[183] The highest percentage of HIV-infected cases in NHL subtypes were Burkitt lymphoma (26.9%), diffuse large B cell (7.8%), and peripheral T cell lymphomas (3.2%), with other subtypes containing ≤1.1% HIV-infected cases.

The strongest NHL risk factors from autoimmune diseases involve Sjögren syndrome, systemic lupus erythematosus, and rheumatoid arthritis.[180] Epidemiological data suggest substantial increased NHL risks ranging over 4-fold occur in patients with autoimmune conditions primarily from B cell activation (e.g., systemic lupus erythematosus,[370] rheumatoid arthritis,[63] psoriasis,[371] Sjögren syndrome, Hashimoto thyroiditis).[372,373] Lymphocytic infiltration of salivary and tear glands characterizes Sjögren syndrome; this autoimmune disease is associated with increased low-grade B cell NHL risks, predominately marginal zone histological types (i.e., extranodal marginal zone mucosa-associated lymphoid tissue, MALT).[374] A meta-analysis of 20 cohort studies using random effects models to evaluate autoimmune disease risk factors reported the highest NHL risks for Sjögren syndrome (mSIR = 18.8, 95% CI: 9.5–37.3), moderate risks for systemic lupus erythematosus (mSIR = 7.4, 95% CI: 3.3–17.0), and lower NHL risks for rheumatoid arthritis (mSIR = 3.9, 95% CI: 2.5–5.9).[375] The large confidence intervals reflect imprecise estimates and high heterogeneity ($I^2 > 70\%$). Results from the InterLymph Consortium indicate autoimmune disorders mediated by B cell responses were associated with increased diffuse large B cell lymphoma risks (OR = 3.11, 95% CI: 2.25–4.30, n_{DLBCL} = 70 ever/2,402 never) and marginal zone lymphoma (OR = 5.80, 95% CI: 3.82–8.80, n_{MZL} = 33 ever/500 never).[376]

An English study matched a cohort of 471,970 atopic eczema participants (median IQR = 41.1 years, IQR range = 24.9–60.7 years) with 2,239,775 nonatopic eczema individuals (median IQR = 39.8 years, IQR range = 25.9–58.4 years).[377] The hazard ratio for NHL was 1.20 (99% CI: 1.07–1.34) compared with 1.48 (99% CI: 1.07–2.04) for Hodgkin lymphoma after adjustment for confounders. For NHL, the adjusted HR increased with the severity of atopic eczema. The HR for NHL in severe atopic eczema patients was 2.08 (99% CI: 1.42–3.04) compared with nonatopic eczema participants after adjustments. The authors opined that the positive findings in diseases with different etiologies (i.e., NHL, Hodgkin lymphoma) suggest the possibility of detection bias or residual confounding related to immunosuppression. In general, existing evidence of cancer risks in atopic eczema patients is conflicting due to difficulty adjusting for important confounders.

Chronic immune stimulation and T cell dysregulation associated with autoimmune diseases contribute to increased NHL risks; however, autoimmune-associated T cell lymphomas (Crohn's disease, celiac disease) are less common than B cell lymphomas. In a pooled analysis of 8,692 NHL cases and 9,260 controls for 14 case-control studies in the International Lymphoma Epidemiology Consortium, autoimmune conditions mediated by T cell responses were associated with peripheral T cell lymphoma (OR = 2.14, 95% CI: 1.35–3.38, $n_{\text{peripheral T cell lymphoma}}$ = 26 ever/257 never).[376]

Infections

Both viral and bacterial infections are associated with NHL, as displayed in Table 60.20. Rare adult infections associated with elevated NHL subtypes primarily involve *Helicobacter pylori*/gastric mucosa-associated lymphoid tissue lymphoma (MALT)[378] and several viral infections. These infections include Epstein–Barr virus (Burkitt lymphoma, extranodal nasal natural killer/T cell lymphoma), human T cell lymphotropic virus 1 (adult T cell leukemia/lymphoma), human herpesvirus 8 (primary effusion lymphoma), and hepatitis C virus (splenic marginal zone B cell NHL, diffuse large B cell NHL, follicular lymphoma.).[379,380,381] DLBCL is the most frequent aggressive NHL subtype associated with HCV often developing from a preceding low-grade marginal zone lymphoma (MZL); other NHL subtypes associated with HCV infections include lymphoplasmacytic lymphomas, splenic MZL, and non-gastric (MALT) MZL.[382] HTLV-1 is a necessary, but not sufficient cause of adult T cell leukemia/lymphoma; only ~3% of patients infected by this virus develop this lymphoma.[383] Most pediatric infections are not associated with elevated NHL incidence. Extranodal NK- and T cell lymphomas are strongly associated with Epstein–Barr virus infection with substantial geographical variability.

HISTOLOGY

Non-Hodgkin lymphoma (NHL) is a diverse, heterogeneous disease arising from B cells (85–95%) and less commonly T cell lymphocytes (5–15%), with the histological features of each NHL subtype depending on the specific cell of origin and stage of development.[182] These tumors appear mostly in the central lymph nodes (i.e., 70–80%) with the remainder in extranodal reticuloendothelial tissues.

B Cell Lymphomas

Diffuse large B cell and follicular lymphomas are the most common adult, high-grade non-Hodgkin

TABLE 60.20. Infectious agents associated with non-Hodgkin lymphoma (NHL) subtypes. (Adapted from Skrabek et al.).[180]

Infectious Agent	NHL Subtypes
Borrelia burgdorferi (Lyme disease)	Marginal zone lymphoma
Chlamydia psittacosis (Psittacosis)	Marginal zone lymphoma
Coxiella burnetii (Q fever)	Diffuse large B cell lymphoma (DLBCL), follicular lymphoma
Epstein–Barr virus (EBV)	Burkitt lymphoma, nasal NK/T cell lymphoma, posttransplant lymphoproliferative disease
Hepatitis B virus (HBV)	Diffuse large B cell lymphoma (DLBCL) and other NHL subtypes
Hepatitis C virus (HCV)	B cell NHL (splenic marginal zone lymphoma, DLBCL)
Helicobacter pylori	Gastric mucosal-associated lymphoid tissue lymphoma (MALT)
Human herpes virus-8 (HHV-8)	Primary effusion lymphoma
Human T cell lymphotropic virus (HTLV-1)	Adult T cell leukemia/lymphoma
Plasmodium falciparum	Burkitt lymphoma

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

lymphomas accounting for ~65% of all NHL lymphomas, with an additional ~5% being marginal zone lymphomas.[384] DLBCL is a heterogeneous disease with three genetically distinct subtypes (germinal center B cell-like, activated B cell-like, unclassified origin) that are now further subclassified.[13] Marginal zone lymphoma subtypes include splenic, nodal, and mucous-associated lymphoid tissue (MALT). The latter is the most frequent marginal zone lymphoma commonly occurring in the stomach associated with t(11;18) translocations and *Helicobacter pylori* infection. Burkitt lymphoma is a highly aggressive, rapidly proliferating B cell NHL with three major morphologically and immunophenotypically similar variants; the endemic type affects young children in equatorial Africa and Papua New Guinea, where *Plasmodium falciparum* malaria is endemic along with EBV. Involvement of the central nervous system may occur. The sporadic type is worldwide, whereas the immunodeficiency-associated HIV-related type affects HIV-infected and immunosuppressed transplant patients. All three types of Burkitt lymphoma are histologically indistinguishable. Lymphoplasmacytic lymphoma is an indolent B cell tumor consisting of a wide spectrum of plasmacytic differentiation (small lymphocytes, plasmacytoid lymphocytes, plasma cells) within the bone marrow that often produce paraproteins (IgG, IgM). Waldenström macroglobulinemia is a type of lymphoplasmacytic lymphoma associated with a monoclonal IgM gammopathy and lymphoplasmacytic bone marrow infiltration.

T Cell Lymphomas

Mature T cell and natural killer (NK) lymphomas are a rare, typically clinically aggressive, very heterogeneous category of >20 subtypes ranging from indolent peripheral-cell lymphoma to more aggressive subtypes (e.g., adult T cell leukemia/lymphoma, hepatosplenic γδT cell lymphoma). Most T cell lymphomas are classified as peripheral T cell lymphomas (~10–15% of all NHL subtypes), most commonly as peripheral T cell lymphoma not otherwise specified, anaplastic large-cell lymphoma, or angioimmunoblastic T cell lymphoma.[385,386] The indolent skin subtypes include cutaneous anaplastic large cell, lymphoid papulosis, and mycosis fungoides as well as other less common T cell lymphoma subtypes. Mycosis fungoides is an indolent and common cutaneous T cell lymphoma that may progress to the more aggressive Sézary syndrome (generalized lymphadenopathy, peripheral blood involvement, erythroderma). Although these two entities previously were considered different expressions of the same disease, genome-wide analysis of cutaneous T cell lymphomas indicates they arise from different memory T cell subsets, resulting in histopathological differences between these tumors.[387]

HOST SUSCEPTIBILITY

Although NHL clusters occur in families, family history of NHL or autoimmune diseases is not a strong risk factor. In a pooled analysis of data from 17 case-control studies collected in the International Lymphoma Epidemiology Consortium (InterLymph) using unconditional logistic regression models with adjustment for confounding, self-reported NHL occurrence in a first-degree relative increased NHL risks (OR = 1.5, 95% CI: 1.2–1.9) unrelated to gender; the 10,211 NHL cases were 93% white.[388] The highest NHL risk occurred in participants having a brother with NHL (OR = 2.8, 95% CI: 1.6–4.8). The NHL risks were similar across NHL subtypes. In a Scandinavian study of 24,728 NHL cases and 55,632 population-based controls using univariate logistic and hierarchical regression models to estimate odds ratios, a personal history of systemic autoimmune disease was associated with up to a 5-fold increased NHL risk. However, the NHL odds ratio for a family history of systemic autoimmune disease was modest, but statistically nonsignificant (OR_h = 1.31, 95% CI: 0.85–2.03, n_{NHL} = 291 cases/533 controls).[389] For most autoimmune disorders, the NHL risk was greater 1–4 years after diagnosis than after 5 years.

Immune system abnormalities represent the strongest NHL risk factor. Similar to cHL (classical Hodgkin lymphoma), congenital or acquired immune deficiencies are strong risk factors for childhood NHL, including autoimmune lymphoproliferative syndrome, combined variable or severe combined immune deficiency, Wiskott–Aldrich syndrome, X-linked hyperimmunoglobulin M syndrome, and X-linked lymphoproliferative disease. Two distinct HLA class II haplotypes are associated with increased follicular lymphoma risks, whereas HLA-B*08 is strongly associated with diffuse large B cell lymphoma.[176]

CLINICAL FEATURES

NHL clinical features vary substantially from an indolent course to an aggressive malignancy depending on subtype, organ involvement, and anatomical area.[390] Consequently, NHL presents with a wide range of symptoms involving any organ in the body depending on the clinical stage. Table 60.21 separates common B cell lymphomas into indolent and aggressive NHL

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 60.21. B cell non-Hodgkin lymphoma (NHL) indolent and aggressive subtypes. Indolent NHL subtypes are slowly progressive, widespread diseases with few systemic symptoms. These NHL subtypes generally respond to initial therapy, but relapses frequently are fatal. Aggressive lymphomas typically present with rapidly expanding lymph nodes, extranodal involvement, and B symptoms (fever, night sweats, weight loss). These NHL subtypes are rapidly fatal if untreated; however, many are potentially curable. (Adapted from Ninkovic and Lambert).[390]

Indolent B Cell NHL Subtype	Aggressive B Cell NHL Subtype
Extranodal and nodal marginal zone	Burkitt
Follicular	Diffuse large B cell (activated B cell, germinal center B-type, NOS)
Lymphoplasmacytic/Waldenström macroglobulinemia	High-grade B cell, NOS
Mantle cell[a]	Large B cell
Mucosa-associated lymphoid tissue (MALT)	Mantle cell[a]
Splenic marginal zone	Primary diffuse large B cell of central nervous system, Primary mediastinal (thymic)

Abbreviation: NOS = not otherwise specified.
[a] Mantle cell lymphoma sometimes has features of indolent and aggressive B cell subtypes.

subtypes. NHL is primarily an adult cancer except for Burkitt lymphoma (one peak in childhood and the other in the seventh decade of life). The median age at diagnosis for follicular lymphoma is the sixth decade.[391] Higher-grade, indolent NHL subtypes (e.g., follicular lymphoma) typically present with painless lymphadenopathy that fluctuates in size over a long clinical course. Lymphoplasmacytic lymphoma is an indolent B cell lymphoma associated with IgM paraproteinemia (Waldenström macroglobulinemia). Clinical symptoms result from tumor infiltration (bone marrow, liver, lymph nodes, spleen), IgM paraproteinemia (cold agglutinin hemolytic anemia, cryoglobulinemia, hyperviscosity), and IgM paraprotein deposition (amyloidosis, kidney disease, neuropathy). In contrast to Hodgkin lymphoma, aggressive NHL subtypes (e.g., Burkitt lymphoma) may manifest with a rapidly enlarging mass commonly in the abdomen, head, neck, or mediastinum with bowel obstruction, tumor lysis, and/or B symptoms (fever, night sweats, fatigue, weight loss, pruritis). Diagnosis is based on an excisional biopsy of a lymph node or involved organ.

NHL survival rates are poor compared with other hematopoietic malignancies, particularly in young adults with prognosis depending on clinical stage, cell origin, sex, age, and NHL subtypes. Favorable prognosis after the administration of rituximab to anthracycline-containing chemotherapy is better for BN2 and EZB diffuse large B cell lymphoma subtypes than MCD and N1 subtypes; however, MCD and BN2 DLBCL subtypes may respond to therapeutic inhibition of "chronic active" B cell receptor signaling.[195] The prognosis is better for DLBCL subtype tumors originating in germinal centers than peripheral (activated) B cell subtypes. Most T cell lymphomas have similar outcomes with treatment.[392]

MULTIPLE MYELOMA

Abnormal clonal plasma cells in the bone marrow characterize multiple myeloma. This hematological malignancy is part of a range of monoclonal gammopathies that includes monoclonal gammopathy of undetermined significance (MGUS, asymptomatic premalignant plasma cell proliferation) and asymptomatic smoldering multiple myeloma (SMM).[393] Almost all multiple myeloma cases evolve from MGUS;[394] ~3–5% of Europeans of ≥50 years of age have detectable MGUS.[395] Worldwide, multiple myeloma is the 23rd most common cancer with an annual incidence of 160,000 and 106,000 related annual deaths.[1] The incidence varies widely (i.e., 30-fold) internationally, with generally higher rates in developed countries. The annual incidence rate has been relatively stable in the recent past; however, case numbers are increasing in the general population of developed countries due to increased survival and an aging population.[396] The US incidence of multiple myeloma increases from ~8/100,000 persons aged 50–54 years to ~50/100,000 persons aged 80–84 years, according to the Surveillance, Epidemiology, and End Results (SEER) program (https://seer.cancer.gov/statistics/). In the United States and Europe, the annual age-adjusted incidence is ~3–5/100,000 general population,[19] whereas the reported incidences in Western Africa and Southeast Asia are <1/100,000.[397] The recent 5-year trend in the annual incidence rate of multiple myeloma has increased by 2.8% in men and 1.6% in women.[398] Multiple myeloma is 2–3-fold higher in blacks than whites, with relatively lower rates in Asians and Pacific Islanders;[399,400] for African-Americans, multiple myeloma is the most common hematological

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

malignancy.[401] Approximately 35,000 new multiple myeloma cases occur in the United States annually, with a male/female ratio of 1.3/1; estimated annual deaths from multiple myeloma are ~13,000.[76] In developed countries, multiple myeloma is the second most common hematological malignancy after non-Hodgkin lymphoma, representing 10–20% of all hematological malignancies.

CARCINOGENESIS

Multiple myeloma is a malignant neoplasm of terminally differentiated, mature B cells (plasma cells) that usually develops in bone marrow and produces monoclonal immunoglobulins (paraproteins) detectable in serum and/or urine. In contrast to primary plasma cell leukemia, multiple myeloma tumor cells are dependent on the bone marrow microenvironment for survival.[402] The multistep accumulation of adverse biological features in secondary plasma cell leukemia allows the spread of malignant plasma cells into the blood. These tumors are very heterogeneous with multiple subclones characterized by distinct gene mutations that independently alter tumor progression.[403] The lack of serum or urinary monoclonal paraproteins does not exclude the diagnosis of multiple myeloma, which occurs infrequently (i.e., <3% of multiple myeloma patients).[404] The tumor cells are strongly bone marrow-dependent, with absent IgM expression and hypermutation of immunoglobulin genes. In contrast to normal plasma cells, multiple myeloma cells retain the potential to reduce their proliferation rate.[405] Almost half of MGUS and multiple myeloma tumors are the hyperdiploid biological subtype with 48−75 chromosomes, primarily 49–56 chromosomes including ≥3 odd-numbered chromosomes (e.g., 3, 5, 7, 9, 11, 15, 19, 21).[406] These tumors lack recurrent immunoglobulin gene translocations. In contrast, the immunoglobulin heavy locus (IgH) chromosome 14 translocations [t(4:14), t(14;16), t(14;20), t(6:14), t(11;14)] characterize nonhyperdiploid subtype of myeloma tumors. This latter tumor subtype has <48 and/or >75 chromosomes, a more aggressive clinical course, and shorter survival compared with the more indolent hyperdiploid subtype.[406] These biological subtypes do not usually change during the course of the disease. Upregulation and overexpression of cyclin D genes are common in hyperdiploid and nonhyperdiploid multiple myeloma tumors, as displayed in Figure 60.5. Other common genetic events in multiple myeloma tumors involve *NRAS*, *KRAS*, and *BRAF* genes, activation of NF-κB pathway, 17p deletions, and rearrangements of the *MYC* gene. The presence of t(14;16), t(14;20), t(6:14), 17p13 (tumor suppressor *P53* gene) deletions, and gains of 1q indicate a worse prognosis.[407]

Multiple myeloma tumors contain currently identified universal driver genes. The Myeloma Genome Project identified 63 apparent driver genes with 17 being potentially actionable including novel putative oncogenes (*IDH1, IDH2, PRKD2, PTPN11*) and, less commonly, putative tumor suppressor genes (*UBR5*, *HUWE1*).[408] These driver genes most often affect various pathways including MEK/ERK (50%), epigenetic regulators (24%), RNA processing (18%), NF-κB signaling (14%), and G_1/S cell-cycle transition (5%). Increasing driver gene abnormalities portends a worse

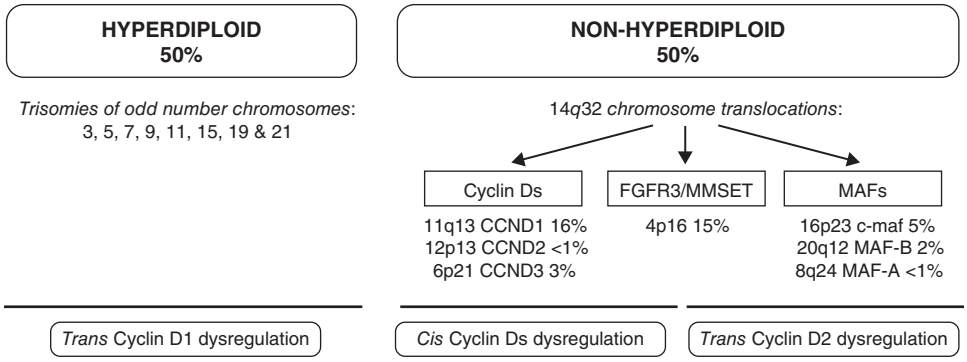

FIGURE 60.5. Cyclin $D_{1\text{-}5}$ dysregulation is common to hyperdiploid and nonhyperdiploid multiple myeloma tumors as well as monoclonal gammopathy of undetermined significance (MGUS) and smoldering multiple myeloma (SMM). Most hyperdiploid tumors have biallelic cyclin D_1 *trans*-dysregulation, whereas t(14q32) translocations affect the loci in non-hyperdiploid tumors, as displayed in the figure. The percentage indicates locus frequency. (Adapted from Chesi et al.).[407] *Abbreviations: FGFR3* = fibroblast growth factor receptor 3; *MAF* gene = MAF bZIP transcription factor functions as a transcriptional activator or repressor for several processes including T cell susceptibility to apoptosis; *MMSET* = also known as *NSD2* gene (nuclear receptor-binding SET domain protein 2) involved with normal development.

prognosis. Translocations involving the immunoglobulin heavy chain locus (IgH) are important primary events in monoclonal gammopathies, including translocation t(11;14) expression of *CCND1*(cyclin D1) important for cell-cycle progression and translocation t(4;14) producing overexpression of *NSD2* (epigenetic dysregulation) and *FGFR3* (fibroblast growth factor receptor 3) genes.[393] Other frequent genetic aberrations include MYC rearrangements and mutations of *KRAS*/*NRAS* genes. The NF-κB pathway involves a transcription factor that regulates the transcription of multiple genes involved with expression of chemokines, proinflammatory cytokines, COX-2, innate/adaptive immunity, cell proliferation, and antiapoptotic genes. Myeloma cells produce several growth factors including insulin-like growth factor 1, interleukin-6, stromal cell-derived factor-1α, and vascular endothelial growth factor that enhance cell proliferation, whereas bone marrow stromal tumor cells produce fibroblast growth factor, tumor necrosis factor-α, and tumor necrosis factor-β.[409]

EXPOSURE

The few well-established risk factors associated with multiple myeloma include older age, male gender, African American ethnicity, monoclonal gammopathy of undetermined significance, and family history of B cell lymphoproliferative disease.

Occupation

Multiple myeloma is not consistently associated with a specific occupational exposure. Low statistical power from small sample sizes and the relative rarity of multiple myeloma complicate accurate quantitation of multiple myeloma associations with specific occupations or industries. Analysis of data from 15 million Nordic residents enrolled in the nationwide registration of 2.8 million incident cancer cases reported a slight, statistically significant multiple myeloma SIR for farmers (pooled SIR = 1.07, 95% CI: 1.03–1.11, n = 2,870 cases).[19] The pooled SIR for gardeners was also slightly elevated, but marginally significant (SIR = 1.07, 95% CI: 1.00–1.16, n = 701 cases), whereas none of the SIRs for the other 52 occupations were statistically significant. A US population-based study of 180 multiple myeloma cases (50% participation rate) and 481 controls (52% participation rate) identified by random dialing used unconditional logistic regression to estimate odds ratios for 135 occupation codes and 143 industry codes.[410] At the P = 0.05 statistical significance level, 9 occupational and 13 industrial categories reached statistical significance. Multiple myeloma was not associated with agricultural occupations based on the self-reported involvement of four cases and seven controls. The odds ratios for multiple myeloma in painters, paperhangers, and plasterers were positive, but statistically nonsignificant with a wide confidence interval (OR = 3.6, 95% CI: 0.7–19, n = 3 exposed/3 control cases). Multiple myeloma was associated with a wide variety of services (e.g., health, religious organizations, transportation services/manufacturing, food/productions, insurance/securities/real estate/business services) with imprecise odds ratios and no clear exposures to carcinogens. An analysis of pooled data from 5 international case-control studies involving 1,959 multiple myeloma cases and 6,192 controls used unconditional regression to estimate odds ratio for multiple myeloma in 98 nonfarming occupations.[411] None of these odds ratios reached statistical significance. The highest reported OR occurred in metal processers (OR = 1.55, 95% CI: 0.98–2.35, n = 58 exposed/212 control cases); glass formers, potters, and related workers (OR = 1.45, 95% CI: 0.75–2.79, n = 14 exposed/39 control cases); and athletes, sportsmen, and related workers (OR = 1.43, 95% CI: 0.35–5.81, n = 6 exposed/21 control cases). A US death certificate study examined 231 industrial and 509 occupational codes in 12,148 multiple myeloma death certificates and 5 age/gender/race-matched controls per case.[412] The results yielded 23 statistically significant odds ratios in 23 occupations and 29 industries. The most consistent, statistically significant increased odds ratio for multiple myeloma occurred in elementary school teachers ($OR_{\text{white females}}$ = 1.5, 95% CI: 1.3–1.7, n = 342 exposed cases; $OR_{\text{white males}}$ = 1.5, 95% CI: 1.2–1.8, n = 140 exposed cases). The odds ratios for the categories of agriculture, forestry, fisheries, and agriculture products/crops were null.

A UK study of 409 multiple myeloma cases and 309 matched hospital controls investigated multiple myeloma risks for workers employed ≥1 year in 18 industries.[413] The relative risk of multiple myeloma was elevated in the food processing/agricultural industries (RR = 1.8, P = 0.002), whereas the RR was statistically nonsignificant for the photographic, petroleum, and painting industries. A proportional mortality ratio (PMR) study of 88,090 Iowa death certificates on white male farmers aged ≥20 years reported a slightly positive and statistically nonsignificant PMR for multiple myeloma (PMR = 1.17, 95% CI: 0.98–1.40, n = 123 cases).[414] A random effects meta-analysis of 32 peer-reviewed, mostly case-control studies of multiple myeloma in farmers reported a modestly elevated metaRR of 1.23 (95% CI: 1.14–1.32).[415] Study heterogeneity was not reported.

Chemicals

Benzene

Although early data from the Pliofilm cohort suggest a possible link between multiple myeloma and benzene exposure based on four cases, follow-up studies have not consistently reported statistically significant associations between benzene exposure and multiple myeloma.[416,417] The 28-year, retrospective cohort study of over 73,000 benzene-exposed Chinese workers ($Mean_{time\text{-}weighted\ average}$ = 22.5 ppm benzene) identified one multiple myeloma case in exposed workers and three cases in controls (RR = 0.12, 95% CI: 0.01–0.96). Multiple myeloma is a very rarely reported disease in Asia, particularly in young and middle-aged workers.[315] A historical cohort study investigated multiple myeloma risks in 27,919 Norwegian offshore (6,734 upstream operator offshore) workers employed from 1981–2003 in the upstream petroleum industry exposed to benzene in crude oil, natural gas, drilling mud, and other products using Cox proportional hazard regression modeling.[418] Referents included 366,114 non-benzene-exposed Norwegian workers matched by gender, age, and community of residence. The authors surmised that upstream operator offshore workers were the most highly benzene workers; however, quantitative data on benzene concentrations and smoking were not available. The rate ratio for multiple myeloma in these workers was elevated (RR = 2.49, 95% CI: 1.21–5.13, n = 9 operator cases/132 referent cases). All multiple myeloma cases in upstream operator offshore workers occurred in cases with first exposures prior to 1986. The median time between the first year of registered engagement and the diagnosis of multiple myeloma in upstream operators offshore included in the cohort prior to 1986 was 18 years (range, 13–20 years). Examination of cohort studies of benzene-exposed workers suggests the time from first benzene exposure until diagnosis of multiple myeloma in other studies may range up to 20 years.[419]

A meta-analysis of 26 cohort studies examining benzene-exposed workers and multiple myeloma reported a slightly positive, statistically nonsignificant metaRR for multiple myeloma (mRR = 1.12, 95% CI: 0.98–1.27, n = 284 exposed cases).[420] The metaRR for multiple myeloma was more positive for the start of follow-up after 1972 (mRR = 1.26, 95% CI: 0.92–1.71, n = 10 studies/80 exposed cases) than before 1972 (mRR = 1.07, 95% CI: 0.93–1.24, n = 16 studies/204 exposed cases). In the highest category of exposure assessment quality, the metaRR for multiple myeloma was also more positive, but statistically nonsignificant (metaRR = 1.48, 95% CI: 0.96–2.27, n = 8 studies/28 exposed cases) than poorer-quality studies using less robust exposure measures. The exposure-response relationship between benzene exposure and multiple myeloma was unclear in this study.

Chlorinated Solvents

Few studies specifically examine myeloma risks following exposure to chlorinated solvents. Most mortality and cohort studies have not reported increased multiple myeloma risks in trichloroethylene-exposed workers; however, the power of these studies is limited by relatively small case numbers.[421,422] A follow-up study of 14,455 civilian workers at the Hill Air Force Base in Utah investigated cancer mortality and exposure to organic solvents for at least 1 year from 1952–1956, particularly trichlorethylene (TCE).[423] The measures of exposure were ever- versus never-use and tertiles of cumulative TCE exposure using a Cox proportional hazards regression model to estimate relative risk; little quantitative historical data were available. The relative risk of multiple myeloma in the TCE-exposed workers was slightly positive, but statistically nonsignificant (RR = 1.35, 95% CI: 0.62–2.93, n = 25 exposed cases). Examination of tertiles of TCE exposure did not demonstrate a clear exposure-response relationship ($RR_{highest\ cumulative\ tertile}$ = 1.19, 95% CI: 0.40–3.54, n = 7 exposed cases). A population-based US study of 180 multiple myeloma cases identified from Surveillance, Epidemiology, and End Results (SEER) cancer registries in Washington State and Detroit (50% participation rate) and 481 random-dialed controls (52% participation rate) used unconditional logistic regression to estimate odds ratios.[424] Organic solvent exposure was based on job-specific questionnaires and in-person interviews, with no surrogates completing reports of solvent exposure. Comparing ever- versus never-TCE use, the odds ratio for TCE was positive, but statistically nonsignificant (OR = 1.4, 95% CI: 0.9–2.1, n = 66 exposed case/138 control cases). The results demonstrated no significant exposure-response relationship for quartiles of exposure duration (P = 0.41), cumulative exposure (P = 0.10), or cumulative exposure, 10-year lagged (P = 0.08). The study also reported positive odds ratios for 1,1,1-trichloroethane, tetrachloroethylene, and methylene chloride; however, exposure-response relationships did not support a causal association.

Agriculture

The North American Pooled Project investigated pesticide use and multiple myeloma by combining

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

data from 3 US and Canadian case-control studies involving 54 multiple myeloma cases and 2,700 age/sex/residence-matched population controls. Exposure categories included ever- versus never-use, duration, and cumulative lifetime days based on self-reports or proxies (35% cases/28% controls) for 2,4-D, captan, carbaryl, chlordane, DDT, glyphosate, lindane, malathion, and methoxychlor.[425] Comparing ever-/never-use, the age/residence/proxy respondents/allergic conditions/rheumatoid arthritis-adjusted odds ratios for chemical pesticide classes (phenoxy herbicides, organochlorine insecticides, organophosphate insecticides, carbamate insecticides) were modestly positive, but statistically nonsignificant. Excluding proxy respondents increased the organochlorine insecticide odds ratio (OR = 1.33, 95% CI: 1.01–1.75, n = 264 exposed/442 control cases); however, odds ratios for the other pesticide classes remained nonsignificant. The adjusted odds ratios of multiple myeloma for specific pesticides were elevated for carbaryl (OR = 2.02, 95 CI: 1.28–3.21, n = 29 exposed/96 control cases), captan (OR = 1.98, 95 CI: 1.04–3.77, n = 15 exposed/40 control cases), and DDT (OR = 1.44, 95 CI: 1.05–1.97, n = 66 exposed/270 control cases) with some evidence of an exposure-response relationship. The odds ratios for the other pesticides were not statistically significant. In a combined random effects and fixed-effects meta-analysis of ever-/never-use of glyphosate, the mRR was modestly positive and marginally significant (mRR = 1.4, 95% CI: 1.0–1.9, n = 4 case-control studies, I^2 = 0.0%, $P_{\text{heterogeneity}}$ = 0.63).[286] Based on an overall evaluation of the medical literature and study limitations, the authors concluded the association was not causal.

Ionizing Radiation

Although early data from the Life Span Study cohort of Japanese atomic-bomb survivors suggested excess mortality from multiple myeloma, later evaluations did not support significant excess morality and reduced point estimates. In an update following 113,011 participants for over 3.6 million person-years from 1950–2001 using Poisson regression methods, analysis of data from atomic-bomb survivors in Hiroshima and Nagasaki did not detect a statistically significant excess of multiple myeloma risks among 136 survivors with adequate data (ERR/Gy = 0.38, 95% CI: −0.23 to 1.36, $P_{\text{difference}}$ = 0.21).[119,121] The authors concluded that the study demonstrated no evidence of radiation-associated excess multiple myeloma risks. Thorotrast® was an X-ray contrast medium during the 1930s–1950s that exposed the patient to chronic α-radiation from thorium deposition in various organs.[426] The standardized mortality rate for multiple myeloma was positive and statistically significant, but imprecise for men (SMR = 9.2, 95% CI: 1.1–425, n = 6 cases); the SMR for women was noncalculable in the absence of multiple myeloma cases.

A pooled cohort of 119,195 US nuclear workers at 4 Department of Energy nuclear weapons facilities reported a mean radiation dose among the cohort of 20 mSv.[251] In contrast to the Life Span Study cohort, multiple myeloma mortality excess relative risk (ERR) was positive and statistically significant, but imprecise (ERR/10 mSv = 3.9%, 95% CI: 0.60–9.5%). Overall mortality was below expectations compared with the general population. The International Nuclear Workers study followed a cohort of 308,297 workers for a total of 8.2 million person-years; the estimated average career absorbed radiation dose to the active red bone marrow was 15.9 mGy (95% CI: 2.1–78.0 mGy).[427] The ERR/Gy for multiple myeloma and immunoproliferative diseases was not statistically significant for a fitted lag of 2 years (ERR/Gy = 1.24, 90% CI: −0.84 to 4.46, $P_{\text{heterogeneity}}$ = 0.626); this lag period represented the maximum likelihood.

Lifestyle

Alcohol consumption, tobacco smoking, and diet are not strongly associated with multiple myeloma, whereas some epidemiology data suggest obesity as defined by BMI, but not waist-to-hip ratio or abdominal girth, may modestly increase multiple myeloma risks.[397,428] Most studies on physical activity and multiple myeloma risks report null results.[429,430] Some epidemiological data suggest alcohol consumption is associated with reduced multiple myeloma risks, particularly in female wine drinkers. Observational studies on multiple myeloma and hormonal factors (hormone replacement therapy, parity, age at first birth) overall do not demonstrate a significant association.[431]

Tobacco Smoking

Most observational studies of tobacco smoking and multiple myeloma have not detected elevated multiple myeloma risks. A meta-analysis examined multiple myeloma risks by pooling data from 27 case-control (4,625 cases/21,591 controls) and 13 cohort (2,228 incident cases/1,852,763 subjects) studies using random effects models.[432] The overall odds ratio for multiple myeloma comparing ever-/never-tobacco smokers was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

null (pooled-RR = 0.92, 95% CI: 0.85–1.00, n = 22 studies, I^2 = 49.9%, $P_{\text{heterogeneity}}$ = 0.005). Similarly, current smokers (pooled-RR = 0.87, 95% CI: 0.74–1.03, n = 24 studies, I^2 = 65.3%, $P_{\text{heterogeneity}}$ = <0.001) and former smokers (pooled-RR = 1.04, 95% CI: 0.96–1.13, n = 23 studies, I^2 = 0%, $P_{\text{heterogeneity}}$ = 0.062) were not associated with increased multiple myeloma risks. A prospective cohort study of 336,381 Swedish construction workers followed for a mean of 22.2 years examined the relationship between self-reported tobacco smoking and 520 incident cases of multiple myeloma using Cox proportional hazards regression models to estimate incidence rate ratios (IRR).[433] Using never-users as referents, the age/BMI-adjusted IRR for multiple myeloma was not statistically significant for current smokers (IRR = 0.96, 95% CI: 0.77–1.20, n = 168 cases) or ex-smokers (IRR = 1.11, 95% CI: 0.86–1.43, n = 102 cases).

Alcohol

Some observational data suggest an inverse relationship between specific alcoholic beverage types and multiple myeloma risks. In a meta-analysis of 8 case-control and 10 cohort studies involving 5,694 multiple myeloma patients using random effects modeling, the relative risk of multiple myeloma comparing ever-users and non-/never-alcohol drinkers was null overall (pooled mRR = 0.97, 95% CI: 0.85–1.10) with the results similar in case-control and cohort studies.[434] Using non-alcohol drinkers as referents, dose-risk analysis indicated an ~15% reduction in multiple myeloma risks for two to four drinks daily. A meta-analysis examined multiple myeloma risks by pooling data from 16 case-control (3,921 cases/19,594 controls) and 10 cohort (3,167 incident cases/2,557,649 subjects) studies using random effects models.[435] Overall, the odds ratio for multiple myeloma comparing ever-and never-alcohol drinkers indicated a statistically significant inverse relationship (pooled-RR = 0.88, 95% CI: 0.79–0.99, n = 22 studies, I^2 = 49.9%, $P_{\text{heterogeneity}}$ = 0.005) with moderate heterogeneity. The pooled RR was stronger for wine drinkers and women, whereas the results for men, beer, and liquor were null.

Obesity

Several epidemiology studies suggest self-reported obesity (BMI = ≥30 kg/m^2) modestly increases multiple myeloma risks. The National Institutes of Health-AARP Diet and Health Study examined multiple myeloma risk using baseline questionnaires from 485,049 participants aged 50–71 years (no proxy respondents) on self-reported height and weight along with state cancer registries to identify multiple myeloma cases.[430] Compared with referents (BMI = 18.5–22.49 kg/m^2), the trend for increasing weight quartiles was statistically significant for baseline weight (P_{trend} = 0.008) and 50 years (P_{trend} = 0.04). The hazard ratios as estimated by Cox proportional hazards regression models were statistically significant for the severely obese category (≥35 kg/m^2) at baseline (HR = 1.55, 95% CI: 1.01–2.39, n = 34 cases) and 50 years (HR = 1.77, 95% CI: 1.05–2.99, n = 18 cases), but not for the overweight categories (25–29.9 kg/m^2). Modeling BMI as a continuous variable with multiple myeloma risks, the hazard ratio/5-kg/m^2 increment in BMI was marginally statistically significant ($HR_{\text{continuous}}$ = 1.10, 95% CI: 1.00–1.22). Waist size and waist-to-hip ratios did not demonstrate a statistically significant relationship with multiple myeloma risks. A Swedish/Finnish cohort study of 70,067 twins used Cox proportional hazards models to estimate hazard ratios for obese (BMI = ≥30 kg/m^2) and overweight participants (BMI = 25–29.99 kg/m^2), with normal weight participants as referents (BMI = 18.50–24.99 kg/m^2).[436] The sex/age/country-adjusted hazard ratio was statistically significant for obese participants (HR = 2.1, 95% CI: 1.1–3.7, n = 13 cases), but not for overweight participants (HR = 1.0, 95% CI: 0.7–1.5, n = 45 cases).

A meta-analysis of 15 cohort studies on multiple myeloma risks reported modestly elevated risks for overweight (summary RR = 1.12, 95% CI: 1.07–1.18, I^2 = 0%, $P_{\text{heterogeneity}}$ = 0.73) and obese participants (summary RR = 1.21, 95% CI: 1.08–1.35, I^2 = 34.1%, $P_{\text{heterogeneity}}$ = 0.07). On a continuous scale, a 5-kg/m^2 increment in BMI was associated with a statistically significant increased multiple myeloma risk ($HR_{\text{continuous}}$ = 1.12, 95% CI: 1.08–1.17, n = 15 studies, $P_{\text{heterogeneity}}$ = 0.41).

Diet

Epidemiology studies on the relationship between diet and multiple myeloma risks are conflicting, with some suggestions of modest inverse effects for fruit, vegetable, and fish consumptions; however, the results are inconclusive.[397] The European Prospective Investigation into Cancer and Nutrition (EPIC) study used Cox proportional hazards regression to estimate the relationship between quartiles of vegetable/fruit intake and multiple myeloma risks based on self-administered dietary assessment instruments covering their diet over the previous 12 months.[437] The hazard ratio for multiple myeloma comparing the highest and lowest quartile of total fruit intake was inverse and statistically significant (HR = 0.60, 95% CI: 0.37–0.98, n = 52

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cases); trends for all other vegetable/fruit categories were statistically nonsignificant including total vegetables (P_{trend} = 0.85), leafy vegetables (P_{trend} = 0.36), onions/garlic (P_{trend} = 0.83), citrus fruits (P_{trend} = 0.15), and hard fruits (P_{trend} = 0.44). Using multivariate analysis, tobacco smoking/ethanol consumption/energy intake/education-adjusted hazard ratios per 100 g of intake were statistically nonsignificant for total vegetable intake (HR = 1.03, 95% CI: 0.90–1.18) and total fruit intake (HR = 0.93, 95% CI: 0.83–1.03). A meta-analysis of four hospital-based case-control, three population-based case-control, and four cohort studies evaluated multiple myeloma risks using random effects models to estimate summary relative risks.[52] The summary relative risk for fish/seafood consumption was marginally inverse (summary RR = 0.71, 95% CI: 0.51–1.00, n = 6 studies/2,238 cases, I^2 = 82%) with high heterogeneity. The result for white meat was null with little heterogeneity, whereas the summary RR for red and processed meats was positive, but statistically nonsignificant with high heterogeneity. For dairy products, the RR was close to null for cheese (RR = 0.94, 95% CI: 0.36–2.41, n = 3 studies/571 cases, I^2 = 67%) and milk (RR = 1.08, 95% CI: 0.46–2.54, n = 3 studies/571 cases, I^2 = 64%).

Diseases

The association of multiple myeloma with autoimmune diseases is inconsistent and relatively modest.[438] A retrospective cohort study of 4,501,578 US veterans used Poisson regression to estimate age/race/latency-adjusted, multiple myeloma relative risks for veterans with autoimmune diseases.[439] The RR was slightly positive and statistically significant (RR = 1.15, 95% CI: 1.02–1.28, n = 362 cases); however, subgroup analysis limiting the cohort to follow-up of ≥10 years reduced the aRR to a statistically nonsignificant value (RR = 1.07, 95% CI: 0.90–1.26, n = 152 cases). In a systematic review and pooled analysis of data from 31 observational studies, the relative risk for multiple myeloma in cases with any autoimmune condition was statistically significant (pooled RR = 1.13, 95% CI: 1.04–1.22, I^2 = 43%, $P_{heterogeneity}$ = ≤0.001) with mild heterogeneity and evidence of publication bias (P_{Egger} = 0.02).[440] The results were driven primarily by statistically significant associations with autoimmune hemolytic anemia (pooled RR = 2.80, 95% CI: 1.37–5.74, n = 3 studies, I^2 = 40.8%, $P_{heterogeneity}$ = 0.18) and pernicious anemia (pooled RR = 1.50, 95% CI: 1.25–1.80, n = 6 studies, I^2 = 27.8%, $P_{heterogeneity}$ = 0.23). The associations between all other autoimmune conditions and multiple myeloma were statistically nonsignificant.

Although to a lesser extent than HL and NHL, severe immune suppression (e.g., HIV, organ transplantation) increases multiple myeloma risks. In a meta-analysis of six cohort studies, the meta-SIR for multiple myeloma was 2.71 (95% CI: 2.13–3.44, n_{MM} = 76 cases, $P_{heterogeneity}$ = 0.78) and 3.12 (95% CI: 2.13–4.57, n_{MM} = 31 cases, $P_{heterogeneity}$ = 0.67) for multiple myeloma in three cohorts of transplant patients.[441] Analysis of data from 98,336 people with AIDS and a population-based cancer registry in the United States and Puerto Rico containing 1,125,098 subjects with cancer aged <70 years investigated multiple myeloma risks.[442] The post-AIDS trend for the relative risk of multiple myeloma was statistically significant (P = 0.01) and the RR was positive, but imprecise and statistically nonsignificant (RR = 4.5, 95% CI: 0·9–13.2). Observational studies on multiple myeloma risks associated with hepatitis C (HCV) are conflicting. A meta-analysis of 6 population-based and 11 hospital-based case-control studies consisting of 11,697 cases and 344,521 controls using random effects models reported a positive, statistically significant pooled odds ratio for multiple myeloma (pooled OR = 2.67, 95% CI: 1.35–5.26; I^2 = 88.1%, $P_{heterogeneity}$ = 0.000) with high heterogeneity.[443] Subgroup analysis indicated the positive odds ratios depended on study design, quality, and HCV prevalence. The multiple myeloma pooled OR was statistically significant for hospital-based case-control studies (pooled OR = 2.17, 95% CI: 1.45–3.24, P = <0.001, I^2 = 49.6%, $P_{heterogeneity}$ = 0.031), but not for population-based case-control studies (pooled OR = 3.17, 95% CI: 0.92–10.87, P = <0.067, I^2 = 95.4%, $P_{heterogeneity}$ = 0.031). Similarly, the pooled OR was statistically significant for multiple myeloma in high- but not moderate- or low-prevalence countries. An earlier meta-analysis of six cohort studies reported statistically significant positive meta-SIRs for HIV/AIDS (SIR = 2.71, 95% CI: 2.13–3.44, n = 6 studies/76 cases, $P_{heterogeneity}$ = 0.76) and immunosuppressed transplant patients (SIR = 3.12, 95% CI: 2.13–4.57, n = 3 studies/31 cases, $P_{heterogeneity}$ = 0.67).[441] The meta-analysis detected no publication bias.

HISTOLOGY

Multiple myeloma is a mature B cell neoplasm derived from plasma cells that consists of two major subtypes (i.e., hyperdiploid, non-hyperdiploid) associated with unique molecular and genetic features. The two major biological classifications of multiple myeloma tumors are morphologically similar; however, these genetic subtypes have unique clinicopathological features

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and different outcomes. The multiple myeloma tumor consists of innate and adaptive immune cells (e.g., regulatory T cells, dendritic cells), bone marrow stromal cells, vascular endothelial cells, osteoclasts, and osteoblasts. The morphological features of plasma cell leukemia and multiple myeloma are similar in the bone marrow, with increased monoclonal plasma cells of variable maturity and diffuse infiltration. The round nucleus is eccentrically located with pyramidal blocks of chromatin arranged against the nuclear membrane creating a characteristic "cartwheel" appearance.[444]

HOST SUSCEPTIBILITY

The relatively frequent occurrence of multiple myeloma in families suggests a family history of B cell lymphoproliferative diseases predisposes to multiple myeloma, particularly among blacks compared with whites.[445,446] In an analysis of 218 multiple myeloma cases in the Icelandic cancer registry, the occurrence of multiple myeloma in a first-degree relative increased the risk of developing multiple myeloma (OR = 2.33, 95% CI: 1.12–4.26, n = 10 cases).[447] Analysis of pooled data from 11 mostly population-based case-control studies in the International Multiple Myeloma Consortium used unconditional logistic regression models to estimate multiple myeloma risks in participants self-reporting 1st-degree relatives with multiple myeloma.[448] The sex/age/education-adjusted odds ratios for multiple myeloma in participants with first-degree relatives were elevated (aOR = 1.90, 95% CI: 1.26–2.87, n = 45 cases/60 controls), particularly for men (aOR = 4.13, 95% CI: 2.17–7.85, n = 25 cases/20 controls). The adjusted odds ratio for African American/black cases was substantially elevated but unstable compared with European American/white cases. A population-based registry linkage study evaluated familial multiple myeloma risks in 8,406 Swedish multiple myeloma cases, 22,490 first-degree relatives, and 16,543 controls.[438] The relative risk of multiple myeloma increased significantly in first-degree relatives of multiple myeloma patients (RR = 1.67, 95% CI: 1.02–2.73, n = 29 cases), particularly in relatives ≥65 years of age at diagnosis (RR = 2.50, 95% CI: 1.19–5.27, n = 17 cases).

CLINICAL FEATURES

Multiple myeloma is an age-related disease primarily of the elderly being rare in young adults (<2% less than 40 years of age) and extremely uncommon (<0.02%) in childhood.[449] The median age at diagnosis of this neoplasm is ~69 years, with only ~25% of cases presenting less than 55 years of age.[450]

Monoclonal gammopathy of undetermined significance (MGUS) is a premalignant B cell disorder that precedes the development of almost all multiple myeloma tumors; however, only ~15% of MGUS cases eventually progress to multiple myeloma.[393,451] Plasma cells (MGUS) are age-dependent, appearing in ~4% of individuals >50 years old. MGUS is typically asymptomatic with no end-organ damage and fewer mutated mononuclear immunoglobulins (mIg)/mononuclear bone marrow cells than multiple myeloma. However, some MGUS patients develop primary amyloidosis from the deposition of pathological mIg light chains in various tissues.[405] Smoldering multiple myeloma (SMM) also has no detectable end-organ damage, but the bone marrow mononuclear cell counts and serum mIg concentrations are higher than MGUS. SMM progresses to multiple myeloma in ~10% of cases annually during the first 5 years after diagnosis, then ~5% annually in the next 5 years, and 1% annually after 10 years.[452] Extramedullary multiple myeloma can present with a leukemic phase (plasma cell leukemia). This very aggressive and rare form of plasma cell dyscrasia is classified as *de novo* primary diagnosed at presentation or secondary to relapse/refractory multiple myeloma. Plasma cell leukemia is defined by >20% plasma cells in peripheral blood and $>2\times10^9$ plasma cells/L, with diagnosis occurring ~10 years earlier (median age = 52–65 years) than multiple myeloma or secondary plasma cell leukemia.[453]

The proliferation of protein-producing myeloma cells produces lytic lesions (pathological fractures), bone pain, anemia, renal dysfunction, hypercalcemia, free urinary light chains, and bloodstream hyperviscosity. The most common clinical features of multiple myeloma include anemia, lytic/osteopenic bone disease, hypercalcemia, infections, amyloid deposition in various tissues, and renal failure from obstructing casts of light-chain immunoglobulins; however, some myeloma patients present incidentally without symptoms. Back pain or anemia without a specific cause in an elderly patient suggests the possibility of multiple myeloma. More aggressive multiple myeloma tumors may metastasize to extramedullary locations (e.g., extracellular spaces, liver, spleen) and progress to plasma cell leukemia.

Multiple myeloma is mostly incurable; however, the survival rate has increased substantially over the last few decades.[454] Recent advances in multiple myeloma treatment (proteasome inhibitors, immunomodulatory drugs) resulted in 5-year survival rates of at least 40–50%.[398,455] The introduction of proteasome inhibitors (e.g., bortezomib, carfilzomib, ixazomib), histone deacetylase (HDAC) inhibitors

(panobinostat), monoclonal antibodies (daratumumab, elotuzumab), and immunomodulating agents (lenalidomide, pomalidomide) along with hemopoietic stem cell transplantation and CAR T cell therapy within the last 15 years has improved median overall survival rate after diagnosis of multiple myeloma from ~3 to up to 8–10 years.[456] Survival after the diagnosis of plasma cell leukemia is short. Historically, the median survival is <1 year with an overall 5-year survival rate of <10% in most studies.[457]

Chapter 61

SKIN

Excessive UV radiation is the primary risk factor associated with basal cell and squamous cell carcinomas among fair-skinned persons; both UVA and UVB are established carcinogens producing reactive oxygen species, DNA damage, and immunosuppression (↑inflammatory cytokines).[1,2] These two skin cancers arise from epidermal keratinocytes. Although nonmelanoma skin cancer traditionally refers to these two skin cancers, keratinocyte carcinoma is a more accurate term that separates these two cancers from other, relatively rare nonmelanoma cutaneous cancers (adnexal carcinoma, dermatofibrosarcoma protuberans, highly aggressive Merkel cell neuroendocrine carcinoma, primary cutaneous B cell lymphoma, Kaposi sarcoma). Despite many similarities between basal cell and squamous cell carcinomas, high-risk squamous cell carcinoma is a biologically and clinically distinct tumor.[3] Keratinocyte carcinomas are the most common malignancies in the United States, with basal cell carcinomas of the skin 3–4-fold more common than cutaneous squamous cell carcinomas depending on sex, age, skin pigment, and sun-related exposure.[4,5] The exact incidence of keratinocyte carcinomas is unclear because many cancer registries do not include these cancers in local cancer registries, including the US National Cancer Institute's/Surveillance, Epidemiology, and End Results (SEER) program. Both basal and squamous cell carcinomas are more common in sun-exposed areas of the skin.

UV radiation exposure produces an increased risk of squamous cell carcinomas, basal cell carcinomas, and the premalignant lesions of actinic keratosis.[6] Intermittent, excessive sun exposure (lifetime sunburn, childhood sunburn) is a more important risk factor for basal cell carcinoma than squamous cell carcinoma, whereas a high cumulative UV radiation dose (lifetime sun exposure) is a more important risk factor for squamous than basal cell carcinoma.[7] Promoting agents include nonspecific skin irritation (burn scars, decubitus ulcers, chronic sinus tracts), phototoxic agents (8-methoxypsoralen), and chemicals (croton oil, phorbol esters, *n*-dodecane). Radiotherapy-induced skin tumors are uncommon today after recognition of the limited cutaneous carcinogenic risks associated with small fractional radiation doses totaling <1,000 R (9.33 Sv).[8] Table 61.1 lists agents and chemicals classified by the International Agency for Research on Cancer (IARC) as melanoma and keratinocyte carcinoma carcinogens.

BASAL CELL CARCINOMAS

Basal cell carcinoma is the most common worldwide cancer in light-skinned races, with incidence rates continuing to increase as the population ages and lifestyle changes (e.g., clothing, tanning equipment), particularly in young European and US fair-skinned women.[10] Basal cell carcinomas account for >70–80% of epithelial skin tumors, with a propensity for head (e.g., ears) and neck skin in patients of >50 years of age, with an average lifetime basal cell carcinoma risk for white-skinned individuals of ~30%.[11] Together with squamous cell carcinoma, these two keratinocyte carcinomas account for

TABLE 61.1. International Agency for Research on Cancer (IARC) Classification of cutaneous cancer sites by sufficient and limited evidence of human carcinogenicity. (Adapted from IARC).[9]

Anatomical Site	Carcinogen with *Sufficient* Human Evidence (Group 1)	Carcinogen with *Limited* Human Evidence (Group 2A or 2B)
Melanoma	Polychlorinated biphenyls, solar radiation, ultraviolet-emitting tanning devices, polychlorinated biphenyls	Firefighting (occupation), petroleum refining (occupation)
Keratinocyte carcinomas	Arsenic and inorganic arsenic compounds, azathioprine, coal-tar distillation, coal-tar pitch, cyclosporine, methoxsalen plus ultraviolet A radiation, mineral oils, untreated or mildly treated, shale oils, solar radiation, soot chimney sweep occupation, X- and γ-ray radiation	Creosotes, human immunodeficiency virus type 1 infection, human papillomavirus types 5 and 8 (associated with epidermodysplasia verruciformis), hydrochlorothiazide, nitrogen mustard, (occupational exposures), petroleum refining, ultraviolet-emitting tanning devices, Merkel cell polyomavirus (MCVyP)

~95% of malignant skin cancers.[12] Basal cell carcinoma incident rates vary from >1,000/100,000 person-years in Australia to much lower rates in South America, Asia, and Africa (<1/100,000 person-years). These rates are strongly correlated with geographical latitude and inhabitant pigment status.[13] Basal cell carcinoma incidence varies geographically over 10–25-fold in Caucasians reflecting differences in the annual mean ambient UV radiation dose related to geographical areas (i.e., latitude). The highest incidence occurs closest to the equator.[14] For men of ≥80 years of age, the basal cell carcinoma incidence varied from 475/100,000 ($\text{Mean}_{\text{annual ambient UVR}} = 0.8\,\text{kJ/m}^2$) to 14,173/100,000 ($\text{Mean}_{\text{annual mean ambient UVR}} = 1.8\,\text{kJ/m}^2$).[15] The exact incidence and distribution of basal cell carcinomas are unclear because many basal cell carcinomas are diagnosed clinically without histological confirmation. Many national/regional cancer registries do not include this tumor because of its high prevalence and little to no increased mortality.[16]

CARCINOGENESIS

Basal cell carcinoma is a complex epithelial skin cancer resulting from the interaction of ultraviolet radiation, UVR-sensitive phenotypes, and somatic/germline gene mutations. The major drivers of basal cell carcinoma involve mutations that activate the Sonic Hedgehog signaling pathway (organogenesis, stem-cell maintenance) and involve tumor suppressor genes (patched 1, *PTCH1*; tumor protein p53, *TP53*) with much smaller contributions from mutations in the *SUFU* gene (SUFU-negative regulator of hedgehog signaling). In a genetic profiling study of 293 basal cell carcinomas, additional, more infrequent drivers included mutations in *MYCN* (*MYCN* proto-oncogene, bHLH transcription factor), *PPP6C* (protein phosphatase 6 catalytic subunit), *STK19* (serine/threonine kinase 19), *LATS1* (large tumor suppressor kinase 1), *ERBB2* (erb-b2 receptor tyrosine kinase 2), and *PIK3CA* (phosphatidylinositol-4,5-bisphosphate 3-kinase catalytic subunit alpha) genes.[17] Mutations in *MYCN*, *PTPN14*, and *LATS1* genes upregulate the Hippo-YAP pathway involved with cell proliferation, organogenesis, repair, apoptosis, and homeostasis.[18]

The *PATCH1* gene (chromosome 9q22) encodes a protein receptor associated with the upregulation of the Sonic Hedgehog signaling pathway and the development of embryonic structures as well as tumors.[19] Patched-1 and Sonic Hedgehog pathways influence cell growth, cell specialization, and the shape of the developing body (patterning).[20] The absence of Sonic Hedgehog signaling activation and patched-1 protein prevents cell proliferation and division. Somatic PCTH1 mutations occur in the vast majority (i.e., ~90%) of sporadic basal cell carcinomas, with the lack of inhibitor patched-1 protein producing uncontrolled activation of smoothened gene (*SMO*, chromosome 7q32), resulting in resistance of keratinocytes to apoptosis.[21] The cellular translocation of *SMO* interferes with the patched protein and prevents normal inhibition by patched or smoothened (*SMO*). Approximately 30–40% of sporadic basal cell carcinomas contain the PTCH tumor suppressor gene mutation, whereas ~20% contain the SMO (smoothened, frizzled class G-protein-coupled receptor) mutation.[22]

TP53 (chromosome 17p13) gene encodes the tumor suppressor protein p53 involved with DNA repair, cell-cycle arrest, senescence, and apoptosis; somatic mutations in *TP53* occur in a majority of sporadic basal cell carcinomas.[23] Basal cell carcinomas on the head/neck (i.e., more sun-exposed skin areas) more commonly express *TP53* than basal cell carcinomas in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

other sites on the body.[24] In addition to causing genetic mutations, solar radiation induces immunosuppression by altering cytokine expression (IL-3, IL-4, IL-6, IL-8, IL-10, tumor necrosis factor-α, and epidermal dendritic Langerhans cells, CD1a+) along with the formation of reactive oxygen species.[25]

EXPOSURE

Basal cell carcinomas arise from the complex interaction of genetic abnormalities (mutations, signal nucleotide polymorphisms), phenotypic expression (age, light pigment status, tanning ability, personal skin cancer history, childhood sunburn/actinic skin damage), environmental risk factors (intense youth UV radiation exposure, sunbed use, arsenic exposure), and certain medical therapies (immunosuppression, ionizing radiation, PUVA/UVB therapy). The strongest risk factor for basal cell carcinoma is ultraviolet (UV) light, with the risk depending on dose, pattern, sub-types, and age at exposure along with susceptibility factors.[6,26] Compared with UV radiation, all other predisposing risk factors produce small effect sizes including light skin type, immunosuppression, and rare genetic disorders (e.g., albinism, Gorlin syndrome, xeroderma pigmentosum). Little epidemiology data support the substantial influence of dietary factors on basal cell carcinoma risks, including protective effects of carotenoids, selenium, and vitamins.[27]

Ionizing Radiation

Ultraviolet

UV light refers to the portion of the light spectrum wavelength between the visible blue section and soft X-rays and Grenz rays; 6.8% of solar radiation lies in the UV spectrum compared with 54.3% in near-infrared wavelengths and 38.9% in the visible light range (400–760 nm).[28] UVA is the portion of the light UV band between 315 and 400 nm that usually produces photosensitivity reactions rather than malignant tumors. Oxygen and ozone in the stratosphere absorb 77% of UV radiation including all UVC (100–280 nm) and >90% of UVB radiation (280–315 nm). Consequently, >95% of UV solar radiation reaching the earth's surface is UVA capable of inducing mutations in *TP53* in basal keratinocytes.[29] UVB exposure represents 1–5% of solar radiation at the earth's surface, usually accounting for sunburns and oncogenic mutations in epidermal keratinocytes. UVC (200–290 nm) potentially may cause cutaneous erythema and tumors, but this portion of UV radiation seldom penetrates the ozone layer. The development of skin cancer depends on the total UV radiation dose, the UV fractionation dose (i.e., divided UV radiation doses more effectively induce skin cancer),[30] the amount of melanin pigment present in the skin, and the competency of the immune system with the contribution probably greater from the higher energy in UVB than the lower energy in UVA. Absorption of the former occurs primarily in the epidermal area containing DNA and proteins, whereas UVA penetrates the epidermis depositing the UVA radiation mostly in the basal epidermis and dermal fibroblasts. Hence, UVB causes direct effects on DNA and proteins, whereas UVA causes indirect effects involving the generation of reactive oxygen species.[31] UV radiation accounts for most cutaneous damage predisposing white-skinned individuals to basal cell carcinoma, particularly UVB.

Solar

In contrast to the more direct association between squamous cell carcinoma risks and cumulative UVB radiation exposure, the association between solar UV exposure and basal cell carcinoma is more complex and less consistent. Observational studies suggest solar UV radiation will increase basal cell carcinoma risks more when delivered in infrequent, intense increments (i.e., sunburn) than a similar dose delivered continuously over the same total time period, particularly in young individuals.[32,33] Although sun exposure is a very important basal carcinoma risk factor, multiple risk factors (e.g., red/light hair color, light eye color, sunburn sensitivity, sunburn history, north European ancestry) influence the effect of solar radiation on basal cell carcinoma incidence rates. Some observational studies do not support a strong association between various types of solar radiation and basal cell carcinoma. A US population-based, cross-sectional study of 808 white watermen over the age of 30 years (~70% participation rate) and age-matched controls examined the prevalence of basal cell carcinoma and average UVB exposure based on personal interviews, field measurements, and expert analysis.[34] The average annual UVB exposure was similar in 33 watermen with basal cell carcinoma and controls in contrast to the higher UVB radiation exposure in 35 watermen with squamous cell carcinoma. Using logistic-regression models and comparing estimated cumulative UVB exposure to age 60 years between the highest and other UVB exposure quartiles, the prevalence of squamous cell cancer (OR = 2.53, 95% CI: 1.18–5.40), but not basal cell carcinoma, exposure (OR = 1.11, 95% CI: 0.50–2.44) was statistically significant. Using mean daily, erythemal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

weighted ambient UV radiation levels derived from satellite measurements of column ozone, age/sex/study year-adjusted incidence data from 40 selected studies, and Poisson distribution regression analysis to model estimates of basal cell carcinoma incidence, these variables *together* explained 82% of the variability in basal cell carcinoma incidence among adolescent and adult Caucasians.[35] The mean daily UV radiation alone accounted for 37% of the variability.

An Italian hospital-based study of a convenience sample consisting of 166 basal cell carcinoma cases and 158 controls suggests an association between basal cell carcinomas and early, intense, intermittent solar radiation exposure. The multivariate-adjusted basal cell carcinoma risk for the highest tertile of early recreational sun exposure (>8 weeks yearly before age 20 years) was elevated and statistically significant (aOR = 4.5, 95% CI: 1.9–10.5, $n = 53$ cases/30 controls, $P_{\text{trend}} = 0.01$).[36] The wide confidence interval suggests imprecise risk estimates. This and other[37] studies indicate increased basal cell carcinoma risks occur in areas containing sun-induced skin damage (actinic keratoses, solar lentigines), particularly in an individual with a genetic predisposition to sunburn. Approximately 20% of basal cell carcinoma cases occur in non-sun-exposed skin areas of the body.

Artificial UV Sources

The UVA/UVB ratio and intensity differ in tanning beds compared with solar UV radiation. Pre-1980s, mercury sunlamps emitted UVB and UVC wavelengths, whereas tanning beds distributed in the 1980s emitted predominantly UVA radiation (95% UVA/1% UVB).[38] During the 1990s, high-intensity, high-speed devices increased the UVB portion by up to 5%.[39] UVA radiation exposure from tanning devices may exceed midday solar sun UVA exposure depending on the device, with basal cell carcinoma risks being dependent on frequency, duration, and age at use, along with host susceptibility factors.[40]

Several observational studies suggest indoor tanning contributes to basal cell carcinoma risks; however, variation in tanning-bed usage patterns/spectral output over time, control of confounding factors (e.g., solar UV radiation, skin type, tanning ability), and study design issues (e.g., recall bias, small sample sizes, insufficient lag times) complicate the determination of causation. In a meta-analysis of 10 mostly case-control studies using random effects models and never-users as referents, the summary RR for ever-users of indoor tanning was modestly elevated and statistically significant (sRR = 1.29, 95% CI: 1.08–1.53, $I^2 = 36.8\%$, $P_{\text{heterogeneity}} = 0.14$).[41] Other than sunbed use and solar UV exposure, limited epidemiology data suggest lifestyle factors do not strongly influence basal cell carcinoma risks.

Non-ultraviolet

Ionizing radiation increases basal cell carcinoma risks at the irradiation site from medical radiation (e.g., ankylosing spondylitis, acne, *Tinea capitis*, brain tumors), atomic bomb survivors,[42] and radiological technologists. In a US population-based study of 592 basal cell carcinomas identified through a statewide surveillance system and 536 age/sex-matched unexposed controls, the basal cell carcinoma risk in the radiation site comparing ever- versus never-receiving therapeutic radiation was elevated and statistically significant (OR = 3.3, 95% CI: 1.60–6.81), particularly in patients exposed prior to 20 years of age.[43] A US cohort study of 65,304 white, mostly female radiology technologists estimated relative risks for basal cell carcinomas based on baseline mailed questionnaires and Cox proportional hazard models. After a mean follow-up of 10.2 years, a subsequent questionnaire examined skin cancer history and associated risk factors.[44] Approximately one-half of the follow-up questionnaires were confirmed by medical record reviews. Adjusted factors included age, sex, skin complexion, eye and hair color, and self-reported childhood and adult UV exposure. The adjusted RR was categorized by decade using cases first working after 1959 as referents. Table 61.2 displays the results by decade first worked as a radiology technologist.

Occupation

Persons in outdoor occupations (farmers, sailors, gardeners) have a higher incidence of skin cancer compared with persons engaged in indoor occupations.[45] A study of Czechoslovakian uranium miners

TABLE 61.2. Adjusted relative risks for basal cell carcinoma by decade first worked as radiology technologist using ≥1960 basal cell carcinoma incidence as reference.[44] The P_{trend} for the difference between decades and references was statistically significant ($P_{\text{trend}} = <0.001$). Presumably, ionizing radiation doses for the workers were higher in earlier decades; however, the duration of work did not correlate with basal cell carcinoma risks. (Data adapted from Yoshinaga et al.).[44]

Decade	Adjusted Relative Risk	95% CI	Cases in Decade
<1940s	2.16	1.14–4.09	18
1940s	2.04	1.44–2.88	131
1950s	1.42	1.12–1.80	303
≥1960s	1.0[a]		868

Abbreviation: CI = Confidence Interval.
[a] referents.

detected an increased incidence of basal cell carcinomas predominantly in the cheek and forehead of these workers that, according to the authors, resulted from excessive alpha particle radiation;[46] however, this study has not been replicated in other uranium workers.

Arsenic

Arsenic (As) is a natural constituent of well water in some areas of Bangladesh, India, China, Southwest Taiwan, Northern Chile, and Argentina. Keratinocyte skin cancers (basal cell/squamous cell carcinomas) are well-recognized causes of chronically ingesting high arsenic doses (>100 μg/L) from arsenic-contaminated artesian (tube) well water and medicinal arsenicals.[47] Melanoma is not clearly associated with these arsenic exposures.[48] The threshold for As-induced skin cancer remains controversial in part because of the difficulty in excluding confounders (genetic predisposition, metabolic polymorphisms, UV radiation, socioeconomic status).[49] Skin cancer is the most common neoplasm associated with As ingestion. In a retrospective nationwide population-based survey of keratinocyte cancers, the age-standardized incidence rate of cutaneous basal cell carcinoma was 3–4-fold higher in black foot disease-endemic areas with very high As-contaminated well water than other areas in Taiwan.[50] These rates have decreased in the last several decades due to public health efforts to reduce As contamination. In contrast to UV-induced skin cancers, arsenic-induced basal cell carcinomas typically develop in multiple sites within areas protected from sun exposure.[51]

Occupational As exposure occurs in a variety of industries including mining, manufacturing (agricultural products, electronic semiconductors, glass/pigment production, animal feed additives), and metal smelting. Although As commonly contaminates industrial discharges (metal smelting, coal-fired power generation), epidemiology studies on occupational arsenic exposure and basal cell carcinomas are inconsistent.[52] A multinational European study of 618 incident keratinocyte carcinomas and 527 hospital-based controls examined basal cell carcinoma risks comparing self-reported and expert reviews of ever- versus never-arsenic exposure in the workplace. The age/sex/residence/family history/sun sensitivity/As drinking water-adjusted odds ratio for basal cell cancer was modestly positive and statistically nonsignificant (aOR = 1.22, 95% CI: 0.84–1.75, $n = 113$ cases/80 controls). Basal cell carcinoma risk for the highest tertile of cumulative lifetime was positive and statistically nonsignificant (aOR = 1.47, 95% CI: 0.83–2.58, $n = 39$ cases/25 controls).

Lifestyle

Tobacco Smoking

Current epidemiology data do not associate tobacco smoking with increased basal cell carcinoma risks. Some, but not all, observational studies suggest an inverse relationship between basal cell carcinoma risks and tobacco smoking.[53] An analysis of data from a large UK primary care database (Clinical Practice Research Datalink) compared basal cell carcinoma risks in 6,999 current smokers with 28,058 age/sex-matched nonsmoking controls.[54] The basal cell carcinoma risk for current smokers was inverse and statistically significant (aOR = 0.77, 95% CI: 0.74–0.80). The Australian prospective Nambour Skin Study identified 281 basal cell carcinomas in 1,277 participants with no prior basal cell carcinoma history. Smoking history was assessed at baseline and during updates over 16 years of follow-up. After adjustment for multiple confounders (age, sex, education, occupational sun exposure, sunscreen/β-carotene treatment, country of birth, skin color), the adjusted relative risk was modestly inverse and statistically nonsignificant for current smokers (aRR = 0.69, 95% CI: 0.45–1.05) and minimally positive and nonsignificant for former smokers (aRR = 1.05, 95% CI: 0.84–1.31) using never-smokers as referents.[55] Tobacco-smoking duration and intensity were not clearly associated with basal cell carcinoma risks. In a meta-analysis of 14 studies using random effects models, the odds ratio for basal cell carcinomas was consistent with null results and moderate heterogeneity (OR = 0.95, 95% CI: 0.82–1.09, $I^2 = 59\%$).[56]

Alcohol

Some epidemiology studies suggest alcohol consumption may modestly increase basal cell carcinoma risks;[57] however, observational studies are inconsistent without support for a strong dose-response relationship or a clear mechanism of toxicity.[58,59] Analysis of data from the large UK primary care database (Clinical Practice Research Datalink) reported the smoking-adjusted odds ratio for basal cell carcinoma comparing never- and current-alcohol use was slightly elevated and statistically significant (aOR = 1.19, 95% CI: 1.15–1.23). The data demonstrated no clear dose-response relationships, with the odds ratio for ex-alcohol users being consistent with the null (aOR = 0.96, 95% CI: 0.87–1.05).[54] The Australian Nambour Skin Cancer Study identified basal cell carcinoma risks in 1,360 participants during 11 years of follow-up using alcohol abstainers as referents.[60] The study reported no association between the highest

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

category of alcohol consumption (median = 26.3 g/day) and multivariable-adjusted basal cell carcinoma relative risks (maRR = 1.05, 95% CI: 0.65–1.65, $P_{trend} = 0.84$). Specific beverage types in the moderate and high categories of alcohol consumption were not associated with statistically significant elevations of basal cell carcinoma risks ($P_{trend} = 0.16$–0.93). Multivariate adjustment included age, sex, β-carotene use, skin color, smoking, sun exposure, and skin cancer history.

An analysis of data from three prospective cohort studies included 75,209 women in the Nurses' Health Study (1984–2010), 92,556 women in the Nurses' Health Study II (1991–2011), and 43,697 men in the Health Professionals Follow-Up Study (1986–2010).[61] Using Cox proportional hazard models and alcohol abstainers as referents, the multivariable-adjusted basal cell carcinoma risk for the highest quartile of alcohol consumption (≥ 30 g/day) was modestly elevated and statistically significant (aRR = 1.22, 95% CI: 1.15–1.30, $n = 2{,}015$ cases, $P_{heterogeneity} = 0.10$, $P_{trend} = <0.0001$). The elevated risk/daily 10-g increase in alcohol consumption was slight (aRR = 1.06, 95% CI: 1.03–1.10). In a meta-analysis of two hospital-based case-control and four prospective cohort studies using random effects models, the summary relative risk (sRR)/daily 10-g increase in alcohol consumption for basal cell carcinoma compared with alcohol abstainers was slightly elevated and statistically significant (sRR = 1.07, 95% CI: 1.04–1.09, $I^2 = 61.1\%$, $P_{heterogeneity} = 0.008$) with moderate heterogeneity. The risks were higher in the cohort than in case-control studies.[62] The dose-response curve was nonlinear, with the curve flattening above 9-g daily alcohol consumption. The authors suggest a cautious interpretation of the results because of the potential residual confounding.

Caffeine

Some observational studies[36,59] but not all case-control studies,[63,64] suggest caffeine reduces basal cell carcinoma risks in Caucasians; however, the contribution of caffeine or other constituents of coffee to basal cell carcinoma risks is conflicting. An 11-year prospective study on 1,325 randomly selected adult residents of subtropical Australia with mostly fair to medium skin color examined basal cell carcinoma risks in coffee drinkers based on self-reported food-frequency questionnaires administered every 3 years during follow-up using Poisson and negative binomial regression modeling.[65] The fully adjusted basal cell carcinoma relative risk was not associated with total caffeine intake (aRR = 0.96, 95% CI: 0.87–1.05) or tertiles of caffeine intake ($P_{trend} = 0.20$); however, participants with a prior skin cancer history had a statistically significant reduction in basal cell carcinoma risks comparing the highest (four cups daily) and lowest tertiles of caffeine intake (aRR = 0.75, 95% CI: 0.57–0.97, $n = 427$ participants, $P_{trend} = 0.025$). Adjusted confounders included age, sex, skin cancer history, tanning ability, back freckling, treatment allocation, and neck elastosis.

Obesity

Limited data indicate obesity is not a significant independent risk factor for basal cell carcinoma, with some conflicting results from case-control studies.[66] Analysis of data from the large UK primary care database (Clinical Practice Research Datalink) containing 57,123 incident basal cell carcinomas and 57,123 basal cell carcinoma-free controls suggests an inverse association between obesity and basal cell carcinoma risks using normal weight BMI (18.5–24.9 kg/m^2) as referents.[54] The age/sex/alcohol/smoking-adjusted odds ratio for basal cell carcinoma in obese participants (30.0–60.0 kg/m^2) was inverse and statistically significant (aOR = 0.73, 95% CI: 0.70–0.75). The authors opined that the inverse relationship may result from confounding (e.g., lack of outdoor activity, decreased UV radiation exposure). An analysis of pooled data from two large US cohorts (Health Professionals Follow-Up Study, Nurses' Health Study) reported a combined age- and multivariate-adjusted hazard ratio for basal cell carcinoma of 0.75 (95% CI: 0.67–0.83, $n = 509$ cases) for overweight participants (BMI = 25–29.9 kg/m^2) using normal weight participants (BMI = 18.5–24.9 kg/m^2) as controls ($n = 1{,}254$ cases) and controlling for gender.[67] For very obese participants (≥ 35 kg/m^2), the age- and multivariate-adjusted HR was 0.56 (95% CI: 0.36–0.88, $n = 20$ cases, $P_{trend} = <0.0001$).

Medications

Patients with severe psoriasis may receive >100–200 treatments of psoralen plus a portion of UVA radiation (PUVA) or narrow-band UVB (primarily 311–313 nm) treatments. The prospective Psoralen Ultraviolet A Follow-Up Study used univariate and multivariate Poisson regression, negative binomial regression, and Cox proportional hazard models to estimate basal cell cancer risks in 1,380 psoriasis patients receiving PUVA therapy during ~30 years of follow-up.[68] The mean number of PUVA treatments in the 84% receiving UVB radiation was 206 ± 195; the mean age was 44 ± 16 years, with 29% having skin type I/II. Biopsy-proven basal cell cancer occurred in 330 participants (24%), with most developing multiple tumors (1,729 tumors). After adjusting for age/gender/identified confounders and using patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with <50 PUVA treatments as referents, the univariate incidence rate ratio for developing ≥1 basal cell carcinoma per year in participants within the highest quintile (>450 PUVA treatments) was elevated and statistically significant (IRR = 3.09, 95% CI: 2.36–4.6). The multivariate incidence rate ratio for basal cell carcinoma in participants receiving >300 UVB treatments was modestly elevated (IRR = 1.40, 95% CI: 1.21–1.63) using participants with <100 treatments as referents. Limited data suggest self-reported use of some photosensitizing medications (e.g., tetracyclines, thiazide diuretics, nonsteroidal anti-inflammatory drugs) may increase basal cell carcinoma risks;[69,70] however, the results are inconsistent and lack dose-response relationships.

Diseases

Several observational studies suggest diseases associated with chronic immunosuppression (e.g., organ transplant patients/immunosuppressive agents) increase basal cell carcinoma risks.[71,72] In an Italian, partially retrospective cohort study of 1,476 renal and 458 heart transplant recipients, 91 patients (4.7%) developed basal cell carcinoma within a median of 6.8 years after transplantation.[73] Approximately 2% (41 with 1st basal cell carcinoma) developed a 2nd basal cell carcinoma; the occurrence of the 2nd basal cell carcinoma was not associated with age at transplantation, transplanted organ type, or immunosuppressive therapy. A New Zealand cohort of 384 renal transplant patients was followed for 35 years (1972–2007).[74] Approximately 4.4% (17 patients) developed basal cell carcinomas as the 1st keratinocyte carcinoma, whereas 18.5% (71 patients) developed squamous cell carcinomas or squamous cell carcinoma *in situ*. The median time to first keratinocyte carcinoma was 18.3 years (95% CI: 14.2–22.9 years). The average number of keratinocyte carcinomas excised per patient was 14 (range, 1–208). Beginning in 1998, immunosuppression regimens mostly included prednisone, azathioprine, and cyclosporine or prednisone, mycophenolate mofetil, and cyclosporine.

Most observation studies have not reported a clear association between basal cell carcinomas and human papillomaviruses (HPV) in immunocompetent patients.[75] In a US population-based study of 525 patients with basal cell carcinomas and 461 control subjects, HPV seropositivity was not associated with basal cell carcinomas (OR = 0.8, 95% CI: 0.6–1.1).[76] A large prospective European study identified 1,990 basal cell carcinoma cases by linking data on serum donors to national cancer registries.[77] The presence of baseline HPV seropositivity did not increase basal cell carcinoma risks for HPV 16 (OR = 1.0, 95% CI: 0.8–1.3, $n_{positive}$ = 159 cases/153 controls) or HPV 18 (OR = 0.9, 95% CI: 0.7–1.1, $n_{positive}$ = 132 cases/147 controls).

HISTOLOGY

Basal cell carcinomas arise from stem cells in the hair follicle infundibulum and adjacent interfollicular mechanosensory touch-dome epithelia. This tumor does not develop from precursor lesion.[78] Both basal and squamous cell carcinomas are more common in sun-exposed skin. The vast majority (95%) of these tumors develop after the age of 40 years, with up to 85% appearing on the head and neck;[79,80] up to 1/3 occur on areas of the head without high sun exposure. In the prospective Psoralen Ultraviolet A Follow-Up Study containing 566 participants with basal cell carcinomas (1,741 total tumors), 54% developed on the trunk, whereas 29% occurred on the trunk/buttocks, 10% on the lower extremities, 7% on the upper extremities, and 0.002% on the genitalia.[68] The four histological subtypes of basal cell carcinoma vary with tumor location. In a retrospective study of 13,457 cases of basal cell carcinoma in 10,245 patients with a mean age of 65 years, the approximate distribution of histological subtypes was nodular (40–70%, translucent, pink or shiny aised lesion), superficial (20–30%, red, flat. scaly lesions with well-defined margins), and morpheaform (5–10%, flat or depressed, light pink or white, sometimes pigmented lesions).[81] The head was the main location for nodular (90%) and morpheaform (95%) subtypes, whereas the trunk was the most common location for the superficial type (46%).

Basal cell carcinomas contain uniform cells with oval/round eosinophilic nuclei, large/dark nuclei, and infrequent atypia. The most common type is nodular basal cell carcinoma with solid, well-defined, irregular, lobulated nests of tumor cells surrounded by dense stroma fibroblasts and mucinous material (mostly hyaluronic acid). Empty peritumoral clefts produce characteristic stromal retractions.[82] The clinical appearance of nodular types includes raised margins, pearly sheen, central ulcerations, and a cystic, pearly sheen, whereas superficial basal cell carcinomas are usually multiple, erythematous macules or plaques with central erosions and bleeding. Sclerosing basal cell carcinomas typically have an atrophic, white appearance. Table 61.3 lists the histology of major basal cell carcinoma histological types.

HOST SUSCEPTIBILITY

Phenotypic risk factors for basal cell cancer include light hair (OR ≈ 1.5–2.5),[83] skin predisposed to sunburns (i.e.,

TABLE 61.3. Major basal cell carcinoma histological types. (Adapted from Mackiewicz-Wysocka et al.).[82]

Basal Cell Carcinoma Type	Histology
Nodular	Aggregates of basaloid cells have well-defined borders and peripheral cellular palisading with typical clefts. Central necrosis may occur with eosinophilia, granules, and mucin (primarily hyaluronic acid). Aggressive tumors may display mitotic activity; otherwise, mitotic activity is limited. Micronodular subtype is an aggressive subtype with plaque-like shape, well-defined border, myxoid stroma, minimal palisading, skin/grayish color often without ulcerations. Pigmented subtypes of nodular basal cell carcinoma occur predominantly in dark-skinned individuals.
Superficial	Erythematous, well-circumscribed macule with few scales. Painless papules mimic psoriasis or eczema. Nests of basaloid cells extending from epidermis with prominent peripheral palisading and well-demarcated tumor islands. Neoplastic cells resemble primordial germ cells.
Morpheaform/sclerosing	Depressed skin-tone plaque is similar in appearance to scar tissue. Thin, elongated tumor islands without peripheral palisading or stromal retractions. May involve fat and cutaneous annexes with poorly defined borders and non-painful destruction of surrounding tissues.
Metatypical	Mixed histology with more than one type in the neoplasm (e.g., basal and squamous cell carcinomas).

Fitzpatrick skin types I and II, OR ≈ 1.5–4), especially during childhood,[84] excessive chronic sun-induced skin damage (freckles, actinic keratoses, solar elastosis/lentigines), light hair/eye colors (OR ≈ 1.5–2),[85] personal history of a basal cell carcinoma, and age, particularly in men. Persons of Celtic descent are especially susceptible to sun-induced cancers, whereas skin cancer is rare in deeply pigmented races.[86] The melanocortin 1 receptor (*MC1R* gene) is the major determinant of skin pigmentation/hair color expressing eumelanin via binding of α-melanocyte-stimulating hormone. The highly polymorphic *MC1R* gene variants are important risk factors for keratinocyte carcinoma including basal cell carcinoma. Single-stranded conformation polymorphism analysis was followed by sequencing of unknown variants from 153 subjects with squamous cell carcinoma, 284 with nodular basal cell carcinoma, 142 with superficial multifocal basal cell carcinoma, and 385 controls. The study identified 27 *MC1R* variants with the strongest relationship between the *MC1R* variants associated with red hair and light skin. Stratification by skin type and hair color indicates the *MC1R* variates enhance basal cell carcinoma risks independent of other risk factors including phenotype (e.g., hair/skin color).[87,88]

Patients with an abnormal immune system (immunosuppressive therapy, hematological malignancies, acquired immunodeficiency syndrome) are at increased risk of developing primary cutaneous tumors, especially in sun-exposed skin areas. Genetic syndromes predisposed to the early development of basal cell carcinomas include the multisystem, autosomal-dominant basal cell carcinoma syndrome (Gorlin–Goltz syndrome, basal cell nevus syndrome), X-linked-dominant Bazex–Dupre–Christol syndrome, autosomal-dominant Rombo syndrome, albinism, and autosomal-recessive xeroderma pigmentosum (multiple skin cancers).

CLINICAL PRESENTATION

Basal cell carcinomas typically display slow growth and minimal soft tissue invasion. The most common presentation is a smooth, raised pink lesion or a pink to red, flat lesion. The rate of metastasis for basal cell carcinomas is <0.5%. A patient may develop multiple basal cell carcinomas over years or decades, with a typical latent period between UV damage and diagnosis of basal cell carcinoma of 20–50 years.[89] The male/female ratio is ~1.7–2/1.[5] Although the biological behavior and clinical presentation depend on the basal cell carcinoma subtype, this malignant tumor rarely metastasizes (i.e., <0.1–0.5%).[90] Pooled analysis of data from 19 observational studies reported that ~1/3 of patients with an initial basal cell carcinoma later develop another basal cell carcinoma and <5% develop a subsequent squamous cell carcinoma depending on geographical location and UV radiation exposure.[91] Mortality from basal cell carcinoma is extremely low, with little effect on overall cancer mortality or reduced survival.[92] A qualitative review of 12 observational studies did not detect a significant difference in all-cause mortality in patients with basal cell carcinoma, with all studies demonstrating inverse or null results.[93] Using random effects modeling, the authors' meta-analysis of four large retrospective cohort studies detected no increased all-cause mortality in the basal cell carcinoma patients (mRR = 0.92, 95% CI: 0.83–1.02, $I^2 = 99.4\%$, $P_{\text{heterogeneity}} = 0.000\%$) with very high heterogeneity.

The US Preventive Services Task Force recommends counseling children, adolescents, and young adults (<24 years) with fair skin about minimizing UV radiation exposure to reduce skin cancer risks (benefit, moderate to substantial).[94] The expected benefit

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for adults over 24 years of age was considered small. A Cochrane review concluded that available epidemiological data were insufficient to determine if daily sunscreen reduces basal or squamous cell cancer risks.[12] The authors opined that the only random clinical trial reporting no difference in basal or squamous cell carcinoma risks between daily and discretionary sunscreen use was low quality due to a lack of histopathological confirmation and potential confounding. Although sunscreen use may reduce basal cell carcinoma risks from UV radiation exposure, multiple factors limit the prevention of keratinocyte carcinoma, including susceptible skin coverage, appearance of lesions in non-sun-exposed skin areas, previous sun exposure/skin damage history, and age at use. The preventative effects appear stronger for squamous than basal cell carcinomas.[95] The standard measurement of sunscreen protection from UV radiation exposure (sun-protection factor, SPF) assesses UVB rather than UVA protection; consequently, protection against UVA using SPF can be variable.[96]

SQUAMOUS CELL CARCINOMA

The lifetime incidence of squamous cell carcinoma in the United States is ~7–11%, with the rate continuing to increase as the Caucasian population ages and skin cancer screening increases.[97,98] In Europe, the age-standardized squamous cell carcinoma incidence ranges from 9–96/100,000 in men and 5–68/100,000 in women.[99] The rates are up to 499/100,000 for Australian men and 291/100,000 for Australian women.[100] Overall, cutaneous squamous cell carcinoma incidence varies geographically by >10–25-fold in Caucasians, reflecting in part differences in the annual mean ambient UV radiation dose as well as pigmentation. For men ≥80 years of age, the squamous cell carcinoma incidence varied from 79/100,000 ($\text{Mean}_{\text{annual ambient UVR}} = 0.7\,\text{kJ/m}^2$) to 12,149/100,000 ($\text{Mean}_{\text{annual mean ambient UVR}} = 1.8\,\text{kJ/m}^2$).[15,101] Although squamous cell carcinoma is uncommon in dark-skinned individuals, this keratinocyte cancer is the most common skin cancer in African-Americans, Hispanics, and Asians, often occurring in non-sun-exposed areas of the body.

CARCINOGENESIS

Squamous cell carcinoma is an epithelial skin cancer that contains more mutations than most other common malignancies (e.g., lung).[102] UV radiation-induced mutations in *TP53* loss-of-function are the most common tumor suppressor gene mutations in primary and metastatic squamous cell carcinoma, usually with a classic UV signature (CC-TT). These mutations occur early in tumor formation. The mutation rates in the *TP53* gene vary widely, and many other background mutations exist in these tumors. Other potential drivers include Notch pathway (*NOTCH1*/*NOTCH2* genes), *CDKN2A* (cyclin-dependent kinase inhibitor 2A involved with cell-cycle control), and *KNSTRN* (kinetochore gene important for mitotic spindle involved with chromosome segregation and progression of cell cycle into anaphase) genes as well as *HRAS* proto-oncogene (alters GTPase activity important for cellular signal transduction pathways) and *KMT2* methyltransferase family of epigenetic regulators.[103,104] Mutations in *TP53*, *CDKN2A*, and *RAS* are early UV radiation-induced abnormalities; however, other mutations are necessary for tumor formation and expansion. Small noncoding RNAs (microRNAs, MiRs) may contribute to tumor formation by upregulating oncogenic MiRs (e.g., MiR-21) and downregulating tumor suppressor MiRs (MiR-1).[105]

EXPOSURE

Solar radiation and immunosuppression are the primary risk factors for squamous cell carcinomas; other important risk factors include age and fair skin (Fitzpatrick skin types I/II). Less-common, established risk factors include high-dose arsenic and therapeutic radiation exposures along with congenital skin disorders. Less-established risk factors include smoking and HPV infections.

Ionizing Radiation

Ultraviolet

The primary cause of cutaneous squamous cell carcinoma is cumulative sun exposure, whereas the association between basal cell carcinoma and UV radiation is more complex, as reflected in the relatively high occurrence of the latter skin cancer in typically non-sun-exposed areas of the skin.[106] Using mean daily, erythema-weighted ambient UV radiation levels derived from satellite measurements of column ozone, age/sex/study year-adjusted incidence data from 40 selected studies, and Poisson distribution regression analysis to model estimates of cutaneous squamous cell carcinoma incidence, these variables *together* explained 85% of the variability in squamous cell carcinoma

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

incidence among adolescent and adult Caucasians.[35] The mean daily UV radiation alone accounted for 40% of the variability. In a meta-analysis of 10 mostly case-control studies using random effects models and never-users as referents, the summary RR for squamous cell carcinomas in ever-users of indoor tanning was modestly elevated and statistically significant (sRR = 1.67, 95% CI: 1.29–2.17, $I^2 = 47.1\%$, $P_{\text{heterogeneity}} = 0.09$) with slight to moderate heterogeneity.[41]

Non-ultraviolet

Soon after the discovery of X-rays in 1895, the association between skin cancer and radiation-induced dermatitis from excessive local ionizing radiation doses became apparent. Most of the early radiation-induced skin cancers were squamous cell carcinomas developing quickly after exposure to very high local cutaneous radiation doses.[107] The association with therapeutic radiation is weaker for squamous cell carcinomas than basal cell carcinomas.[42] A US cohort study of 65,304 white, mostly female radiology technologists estimated relative risks for squamous cell carcinomas comparing ever- versus never-receiving therapeutic radiation based on baseline mailed questionnaires and Cox proportional hazard models.[44] Squamous cell carcinoma was not associated with the decade of first exposure or duration of radiation exposure consistent with the lack of a clear association between squamous cell carcinoma and radiation exposure in the atomic bomb survivor cohort, as displayed in Table 61.4.

In a population-based study of 289 squamous cell carcinomas identified through a statewide surveillance system and 536 age/sex-matched unexposed controls, the squamous cell carcinoma risk in cutaneous radiation sites comparing ever- versus never-receiving therapeutic radiation was elevated and statistically significant (OR = 2.94, 95% CI: 1.30–6.67).[43] The elevated squamous cell carcinoma risk occurred only in irradiated skin, primarily in sun-sensitive phenotypes. The Skin Cancer Prevention Study enrolled 1,690 participants (32% participation rate), with 118 participants developing 179 incident squamous cell carcinomas during an average follow-up of 4 years.[108] Self-reported therapeutic radiation was not associated with an increased rate ratio for squamous cell carcinoma (RR = 1.0, 95% CI: 0.6–1.7). The Life Span Study did not establish a clear dose-response relationship between ionizing radiation exposure and squamous cell carcinomas with a marked difference between squamous cell cancer rates and the two major sites of the atomic bomb survivors, primarily reflecting differences in histological classifications for squamous cell carcinoma *in situ*.[42] Skin cancer is uncommon in Japan.

TABLE 61.4. Adjusted relative risks for squamous cell carcinoma by decade first worked as radiological technologist using ≥1960 squamous cell carcinoma incidence as reference.[44] The P_{trend} for the difference between decades and references was not statistically significant ($P_{\text{trend}} = 0.678$). Presumably, ionizing radiation doses for the workers were higher in earlier decades; the duration of work did not correlate with basal cell carcinoma risks. (Data adapted from Yoshinaga et al.).[44]

Decade	Adjusted Relative Risk	95% CI	Cases per Decade
<1940s	0.69	0.23–2.10	5
1940s	0.81	0.44–1.51	33
1950s	1.52	0.94–2.43	86
≥1960s	1.0[a]		139

Abbreviation: CI = Confidence Interval.
[a] referents.

Occupation

Limited data are available to determine the contribution of occupation to squamous cell carcinoma risks including UV radiation. The Nordic Occupational Cancer Study project linked self-reported occupational information from the censuses in five Nordic countries to cancer registries containing 12.9 million persons born between 1896–1960 and 87,619 incident primary cutaneous squamous cell carcinoma cases.[109] The standardized incidence ratios were increased and statistically significant in 15 of 53 occupations, with outdoor occupations being inconsistently associated with squamous cell carcinoma risks compared with the general working-age population. Generally, the positive risks were relatively weak, as displayed in Table 61.5.

A Canadian study of 180 squamous cell carcinoma cases (80% participation rate) and 406 age-matched controls (71% participation rate) examined squamous cell carcinoma risks using self-reported answers to a standardized questionnaire administered by a trained interviewer.[110] Comparing the highest exposure category with never-exposed controls, the squamous cell carcinoma risks were elevated for insecticides, herbicides, fungicides, petroleum products, grease, diesel fumes, and coal dust. However, the authors opined that the results should be interpreted with caution because of potential selection/information bias in the retrospective data. A German population-based study examined cancer risks in 408 squamous cell carcinoma cases, 224 actinic keratosis class III/Bowen disease cases, and 996 age/sex/phototype/nonoccupational

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 61.5. Statistically significant elevated squamous cell carcinoma risks in male workers of >50 years of age after categorizing the workers into 53 occupations based on Nordic census data. The association with outdoor work was inconsistent. Occupations associated with outdoor work include seamen, gardeners, fishermen, and woodworkers, whereas mixed indoor/outdoor occupations include transport workers, postal workers, building caretakers, and military personnel. (Data adapted from Alfonso et al.).[109]

Category	Standardized Incidence Ratio	95% CI
Physicians	1.75	1.57–1.95
Assistant nurses	1.36	1.04–1.75
Administrators	1.32	1.27–1.37
Dentists	1.30	1.08–1.56
Military personnel	1.29	1.17–1.41
Religious workers	1.27	1.19–1.36
Public safety workers	1.25	1.16–1.34
Seamen	1.23	1.14–1.32
Teachers	1.20	1.13–1.26
Clerical workers	1.18	1.13–1.23
Sales agents	1.16	1.11–1.20
Technical workers	1.13	1.09–1.16
Printers	1.13	1.02–1.24
Transport workers	1.10	1.03–1.16

Abbreviation: CI = Confidence Interval.

UV exposure-adjusted odds ratios. Total occupation and recreational UV exposure were estimated by the Wittlich algorithm that adjusts for exposure duration, intensity, seasonality, geographic region, reflection, and lifetime skin-exposure areas. Using a standardized erythema dose (SED) of <40th percentile as the referent (<12.6 SED), the squamous cell carcinoma risk in the top 10% of SED (≥6,834.8) was increased and statistically significant (aOR = 1.95, 95% CI: 1.19–3.18, $n = 85$ cases, 41 controls). The estimated nonoccupational UV exposure using <20th percentile (9,136.8 SED) as the referent was not statistically significant (aOR = 1.11, 95% CI: 0.66–1.87, $n = 64$ cases/62 controls).[111]

Polycyclic Aromatic Hydrocarbons and Scrotal Cancer

Complex mixtures of polycyclic aromatic hydrocarbons are well-known skin carcinogens. In 1775, Sir Percival Pott first associated the development of scrotal cancer with exposure to coal soot in chimney sweeps. Scrotal cancer is a rare cancer with a long latent period and mixed histology as reported from small, single-institutional series. The rarity of scrotal cancer significantly limits establishing occupational risk factors for this neoplasm.[112] Analysis of US Surveillance, Epidemiology, and End Results (SEER) cancer registry data identified 471 cancers from 1973–2002, with an age-adjusted incidence rate for scrotal cancer in 2002 of 1/1,000,000 men.[113] Squamous cell carcinoma was the most common histological type (32%), followed by extramammary Paget's disease (21%), basal cell carcinoma (18%), and sarcoma (18%). Squamous cell carcinoma was more common in black than white men, with mortality rates being higher for squamous than other scrotal histological types.

Increases in scrotal cancer incidence occur in patent-fuel workers exposed to coal tar and coal-tar pitches.[114] Creosotes are classified as Group 2A (probable) carcinogens by the IARC, and case reports suggest an increased incidence of scrotal cancer in workers handling creosote-treated timber. Untreated or mildly treated mineral oils are human carcinogens, and exposure to mineral oils (metal machining, jute processing, cotton mule-spinning) produces an increased squamous cell carcinoma incidence, particularly on the scrotum. A case series of 344 scrotal cancers reported that 62% of the cases were exposed to mineral oils with a mean latent period of 34.4 ± 12.1 years.[112] Unprocessed petroleum-based lubricating oils are less carcinogenic than coal tar; solvent refining processes can remove the carcinogenic fraction from petroleum-based oils.[115] More recent studies suggest occupational risk factors do not contribute significantly to squamous cell scrotal cancer incidence. A follow-up study of Scottish shale-oil industry workers employed between 1950 and 1962 demonstrated a significant squamous cell carcinoma excess, primarily of the scrotum.[116] Although the evidence for the association between exposure to shale oil and the development of skin cancer is substantial, a cohort study of 325 workers at a shale-oil demonstration plant did not detect an excess incidence of skin cancer.[117] A downward trend in the incidence of scrotal cancer began in the 1970s, perhaps as a result of improved industrial hygiene.[118]

Petroleum Industry

A prospective Norwegian study of 24,917 male offshore petroleum workers identified 63 squamous cell carcinomas during 13.5 years of follow-up.[119] Although the study reported elevated hazard ratios for crude oil, benzene, and mineral oil comparing unexposed and exposed workers, none of the hazard ratios were statistically significant with very wide confidence intervals. Some measures of dose-response relationships (duration, cumulative) were positive for benzene and crude oil on potentially exposed areas (hand/forearm); however, the findings were inconsistent with unstable confidence intervals.

Arsenic

Arsenic is a well-recognized human skin carcinogen from the ingestion of arsenic-contaminated well water (e.g., Bangladesh, India, China, Chile, Southwest Taiwan)[120] and arsenic-containing medicines (Chinese proprietary medicine, Fowler's solution, arsenicals) based on observational studies,[121] particularly in areas where black foot disease is endemic. Animal models of As-induced skin cancer have not replicated observational results.[122] Case reports from Chile associate the daily ingestion of 1–1.2-mg arsenic (8-g arsenic total dose) in the drinking water with the development of skin cancers.[123] The latent period was 20–23 years; all patients had palmar hyperkeratosis.

Inorganic trivalent arsenic exposure (e.g., medicinal use of Fowler's solution) is associated with the induction of multiple skin tumor types in non-sun-exposed areas beside squamous cell carcinomas, including intraepidermal carcinomas (Bowen's disease), multiple superficial basal cell carcinomas, and mixed tumors.[124] The English physician Thomas Fowler introduced arsenic as a medicinal agent (Fowler's solution, 1% potassium arsenite) in 1786; subsequently, medicinal applications included the treatment of syphilis, malaria, acute myeloid leukemia, and psoriasis. In 1887, Sir Jonathan Hutchison first associated arsenicals with skin cancer when he reported a case series of skin cancer patients chronically ingesting arsenicals; the carcinomas were all preceded by keratotic lesions.[125] In a retrospective, nationwide, population-based survey of keratinocyte skin cancers, the age-standardized incidence rate of cutaneous basal cell carcinoma was 4–6-fold higher in black foot disease-endemic areas, with very high As-contaminated well water than other areas in Taiwan.[50] Arsenic-induced squamous cell carcinomas develop *de novo* or evolve from areas of Bowen's disease (intraepithelial carcinoma/carcinoma *in situ*) and premalignant skin lesions (hyperpigmentation, hyperkeratosis, depigmentation).[126]

Occupational As exposure is not clearly associated with increased squamous cell carcinoma risks. A multinational European study of 618 incident keratinocyte skin cancers and 527 hospital-based controls comparing ever- versus never-arsenic occupational As exposure reported a positive and statistically nonsignificant odds ratio for squamous cell carcinoma (aOR = 1.54, 95% CI: 0.78–3.02, $n = 23$ cases/80 controls).[52] The odds ratio was adjusted for age, sex, residence, family history, sun sensitivity, and As drinking water exposure. Squamous cell carcinoma risk for the highest tertile of cumulative lifetime was positive and statistically nonsignificant (aOR = 1.54, 95% CI: 0.49–4.85, $n = 5$ cases/25 controls).

Lifestyle

The major causes of squamous cell carcinomas in fair-skinned individuals are solar radiation (sun exposure, sunbed use) and immunosuppression (solid-organ transplant recipients, specific genetic disorders, medical conditions including HIV, chronic lymphocytic leukemia).[127] The association between squamous cell carcinoma and physical activity or dietary factors is relatively weak. Limited epidemiology data suggest dietary factors as significant factors for cutaneous squamous cell carcinoma, including protective effects of carotenoids, selenium, and vitamins.[128]

Tobacco Smoking

The association of smoking with increased squamous cell carcinomas is conflicting with some[53] but not all,[129] studies reporting modest increases in squamous cell carcinoma risks for current smokers. Most of these studies do not report clear dose-response relationships. In a meta-analysis of six studies using random effects models, the odds ratio for squamous cell carcinomas for current smokers was elevated and statistically significant with moderate heterogeneity (OR = 1.52, 95% CI: 1.15–2.01, $I^2 = 64\%$); former smokers exhibited the smallest effect sizes for squamous cell carcinoma (OR = 1.21, 95% CI: 0.94–1.56; $I^2 = 28\%$).[56] An Australian prospective study of 43,794 randomly selected residents of Queensland identified 193 squamous cell carcinomas during 3 years of follow-up.[130] Using Cox proportional hazards models with adjustment for confounders (age, sex, private health insurance, education, skin color, tanning ability, freckles, sunburn (painful, blistering) history, cumulative sun exposure) and never-smokers as referents, the squamous cell carcinoma risk in current smokers was increased and statistically significant (aHR = 2.30, 95% CI: 1.46–3.62). For ever-smokers, the aHR was modestly increased and statistically nonsignificant (aHR = 1.6, 95% CI: 0.92–1.73) based on self-reported baseline questionnaires. The squamous cell carcinoma risks were close to the null for ex-smokers (aHR = 1.05, 95% CI: 0.74–1.48). The data demonstrated no clear dose-response relationship with quartiles of smoking duration ($P_{trend} = 0.117$), intensity in cigarettes/day ($P_{trend} = 0.546$), or cumulative pack-years ($P_{trend} = 0.053$). The authors opined that the results in current smokers should be interpreted with caution because of the lack of elevated risks in ex-smokers, no dose-response relationships, and the absence of a compelling biological mechanism.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Alcohol

The Australian Nambour Skin Cancer Study reported no significant increased squamous cell carcinoma risks for alcohol users in 1,360 mostly fair-to-medium-skinned participants during 11 years of follow-up with alcohol abstainers as referents.[60] The multivariate-adjusted relative risk for squamous cell carcinoma in the highest alcohol consumption category (26.3 g/day) was consistent with the null (maRR = 0.94, 95% CI: 0.49–1.80, $P_{trend} = 0.38$). Specific beverage types in the moderate and high alcohol consumption categories were not associated with statistically significant elevations of squamous cell carcinoma risks ($P_{trend} = 0.17$–0.97). In a meta-analysis of three prospective cohort studies using random effects models, the summary RR/daily 10-g increase in alcohol consumption for squamous cell carcinoma compared with alcohol abstainers was slightly elevated and statistically significant (sRR = 1.11, 95% CI: 1.06–1.16, $I^2 = 18.8\%$, $P_{heterogeneity} = 0.291$).[62] The small number of studies prevented the evaluation of nonlinearity in the dose-response curve.

Caffeine

Most observational studies do not associate caffeine consumption with the alteration of squamous cell carcinoma risks.[64,65] In a meta-analysis of several cohort and case-control studies, the summary relative risk was close to the null with moderate heterogeneity (sRR = 0.93, 95% CI: 0.68–1.27, $I^2 = 50\%$).[131] These studies demonstrated no clear dose-response relationship between total caffeine or tea consumption and squamous cell carcinoma risks.

Obesity

The association between obesity and squamous cell carcinoma risk is relatively weak. Analysis of pooled data from the US Nurses' Health Study and the Health Professionals Follow-Up Study examined squamous cell carcinoma risks prospectively using normal BMI as referents.[67] The combined, multivariate-adjusted hazard ratio was inverse and statistically significant for mildly obese (BMI = 30–34.9 kg/m^2), mostly Caucasian participants (maHR = 0.68, 95% CI: 0.57–0.80, $n = 178$ cases), and severely obese (BMI $\geq$ 35 kg/m^2) participants (maHR = 0.63, 95% CI: 0.48–0.82, $n = 40$ cases, $P_{trend} = <0.0001$). Multivariate-adjusted variables included gender, sunburn reaction, melanoma family history, severe sunburns, moles, hair color, sun exposure at different age intervals, UV index at residence at different ages, quintiles of physical activity, and history of cardiovascular diseases, type 2 diabetes, and cancer. A 16-year, prospective community-based study of 1,171 Australians reported quartiles of height ($P_{trend} = 0.017$) but not BMI ($P_{trend} = 0.456$) in men, were associated with increased multivariate-adjusted squamous cell carcinoma risks.[132] In women, neither quartiles of height ($P_{trend} = 0.432$) nor BMI ($P_{trend} = 0.492$) were associated with increased risks. The model adjusted for age (years), treatment allocation, squamous cell carcinoma history, elastosis of the neck, freckling of the back, and smoking status.

Medications

PUVA Therapy/Immunomodulation

Long-term immunotherapy in solid-organ transplant patients produces very significant increased squamous cell carcinoma risks compared with immunocompetent persons, as well as increased metastases and mortality rates.[133] Basal and squamous cell carcinoma risks differ substantially in psoriasis patients receiving PUVA therapy, with the incidence being much higher in the latter than in the former. In the prospective Psoralen Ultraviolet A Follow-Up Study using patients with <50 PUVA treatments as referents and Poisson regression, 351 of 1,380 (25%) cohort patients developed 2,973 biopsy-proven squamous cell carcinomas during the 30 years of follow-up.[68] The age/gender/identified confounder-adjusted multivariate incidence rate ratio for developing ≥1 squamous cell carcinoma per year in participants within the highest quintile (>450 PUVA treatments) was elevated and statistically significant (IRR = 9.57, 95% CI: 7.13–12.83). Using participants with <100 UVB treatments as referents, the multivariate incidence rate ratio for squamous cell carcinoma in participants receiving >300 UVB treatments was modestly elevated (IRR = 1.49, 95% CI: 1.32–1.68), similar to the rates for basal cell carcinomas.

Vitamin A

Vitamin A consists of a large number of retinoids (e.g., retinal retinol, retinoic acid); animal-based foods contain preformed vitamin A (retinoic acid), whereas plant-based foods contain provitamin A carotenoids (e.g., α- or β-carotene, β-cryptoxanthin) capable of conversion to retinol and non-provitamin A carotenoids (e.g., lutein, lycopene, zeaxanthin). Animal studies suggest a potential role for vitamin A in chemoprevention of keratinocyte-associated carcinomas including squamous cell carcinoma; however, some clinical studies using retinoids or carotenoids report significant adverse

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. effects (liver dysfunction, myalgias/arthralgias, alopecia, headache, hypercholesteremia).[134] A prospective cohort study identified 3,978 squamous cell carcinoma cases in 75,170 women from the Nurses' Health Study and 48,400 men from the Health Professionals Follow-Up Study.[135] Using Cox proportional hazards regression models based on biennial questionnaires and the lowest quintile of dietary vitamin A as the reference, the adjusted pooled multivariable hazard ratio for squamous cell carcinoma in the highest quintile was inverse and statistically significant (HR = 0.86, 95% CI: 0.78–0.96, P_{trend} = <0.001). The results for the second and third quintiles were consistent with the null, whereas the result for the 4th quintile was inverse and statistically nonsignificant. The authors opined that the results indicated future studies are needed to determine the role of vitamin A supplementation on squamous cell carcinoma risks.

Diseases

Immunosuppression

Similar to basal cell carcinomas, several observational studies suggest diseases associated with chronic immunosuppression (e.g., organ transplant patients/immunosuppressive agents, HIV, chronic lymphocyte leukemia)[136] increase squamous cell carcinoma risks. Squamous cell carcinoma/squamous cell carcinoma *in situ* are more common than basal cell carcinomas in these patients.[137,138] In an Italian cohort of 1,934 solid-organ transplant patients, 109 patients (5.6%) developed squamous cell carcinoma within a median of 6.8 years after transplantation.[73] In comparison to squamous cell carcinoma, ~2.6% (50 with 1st basal cell carcinoma) developed a 2nd basal cell carcinoma unrelated to age at transplantation, transplanted organ type, or immunosuppressive therapy. In a New Zealand cohort of 384 renal transplant patients followed for 35 years, squamous cell carcinoma and squamous cell carcinoma *in situ* were ~4-fold more common than basal cell carcinomas.[74] Older age at the first transplant was a predictor of the 1st keratinocyte carcinoma. Low CD4 counts and high viral loads increase squamous cell carcinoma risks in HIV patients compared with HIV-negative persons. In a US observational study of 6,560 HIV+ and 36,821 HIV− non-Hispanic white adults using HIV− participants as referents, the adjusted rate ratio for squamous cell carcinoma in HIV+ participants was 2.6 (95% CI: 2.1–3.2, n = 386 cases HIV+/1,682 cases HIV−) compared with 2.1 (95% CI: 1.8–2.3, n = 136 cases HIV+/479 cases HIV−) for basal cell carcinoma.[139]

Human Papillomavirus

Human papillomavirus (HPV) types consist of five genera (α, β, γ, μ, ν). The association between HPV and squamous cell carcinoma is strongest for β-HPV genus in the external genitalia, perianal area, and nail regions; however, the association is relatively weak and conflicting with an unclear mechanism of action in immunocompetent individuals. Although some data suggest HPV5 and HPV8 may influence the early development of squamous cell carcinomas (e.g., epidermodysplasia verruciformis disorder),[140] current data indicate the presence of the β-HPV genome and E6/7 oncoproteins is not required for tumor promotion or maintenance.[141] In an article by Wang and Aldabagh et al. describing a meta-analysis of 17 case-control studies using inverse variance, random effects modeling, and normal-appearing skin in immunocompetent participants as controls, the pooled effect size for HPV in squamous cell tumors was positive and statistically significant (pooled ES = 2.43, 95% CI: 1.97–5.98, $P_{difference}$ = <0.0001) with little publishing bias (P_{Egger} = 0.23) and high heterogeneity from variation in sampling methods and viral detection techniques. For immunosuppressed patients, the pooled effect size for HPV in cutaneous squamous cell tumors was also positive and statistically significant (pooled ES = 3.01, 95% CI: 2.00–4.52, $P_{difference}$ = <0.0001, n = 12 studies) with mild heterogeneity and no publication bias (P_{Egger} = 0.78). Although the study suggested an association between HPV and squamous cell carcinomas, the authors opined that the study did not imply causality.

In a US population-based study of 252 patients with squamous cell carcinomas and 461 control subjects, the squamous cell carcinoma risk in patients within the β-HPV genus was marginally significant (OR = 1.5, 95% CI: 1.0–2.1), particularly in sun-exposed areas of patients with HPV5 (OR = 1.8, 95% CI: 1.0–3.1).[76] A small portion of squamous cell carcinomas contain high-risk genital human papillomaviruses (HPV), including HPV16 and HPV18. A large, prospective European study identified 633 squamous cell carcinoma cases by linking data on serum donors to national cancer registries.[77] The presence of baseline seropositivity increased cutaneous squamous cell carcinoma risks for HPV16 (OR = 1.6, 95% CI: 1.1–2.6, $n_{positive}$ = 57 cases/37 controls) and HPV18 (OR = 1.7, 95% CI: 1.1–2.5, $n_{positive}$ = 65 cases/41 controls). Only 4 of 79 tumor blocks contained HPV16 DNA, and no HPV18 DNA was detected. The authors opined that the lack of HPV DNA indicated confounding with genital HPV infections accounting for the positive DNA results. HPV is not transcriptionally active in squamous cell carcinomas. Hence, HPV may contribute to the induction but probably not maintenance of these tumors.[142]

HISTOLOGY

Squamous cell carcinomas develop from the malignant transformation of epidermal keratinocytes or adnexal structures (e.g., pilosebaceous units, eccrine glands). These tumors usually arise from sun-damaged skin or preexisting cutaneous lesions (e.g., scars, ulcers, discoid lupus, chronic radiodermatitis). Squamous cell carcinomas are much more common on the extremities than head or neck in contrast to basal cell carcinomas. In the prospective Psoralen Ultraviolet A Follow-Up Study containing 566 participants with squamous cell carcinomas (2,973 total tumors), 62% developed on the lower extremities and 16% on the upper extremities, whereas 11% occurred on the trunk/buttocks, 9% on the head/neck, and 1% on the genitalia.[68] Squamous cell carcinoma histological types include acantholytic, conventional, lymphoepithelioma-like, spindle-cell, and verrucous, as displayed in Table 61.6.[143]

Keratoacanthoma is a common skin neoplasm in fair-skinned individuals characterized by early proliferation, stabilization, and occasional spontaneous regression; this neoplasm displays characteristics between a benign and malignant tumor.[144] Keratoacanthomas are frequently mislabeled as cutaneous squamous cell carcinomas.

HOST SUSCEPTIBILITY

Inherited skin conditions associated with squamous cell carcinomas include albinism (congenital defect in melanin formation), Bloom syndrome (chromosomal instability), dyskeratosis congenita (telomere maintenance/trafficking), Huriez syndrome, multiple self-healing squamous epithelioma (*TGF*-b signal transduction), epidermodysplasia verruciformis (signal transduction in endoplasmic reticulum), Rothmund–Thomson syndrome (chromosomal instability, telomere maintenance/trafficking), and xeroderma pigmentosum (autosomal-recessive deficiency in DNA nucleotide excision repair).[145] Low-to-moderate-risk susceptibility genes associated with pigment characteristics include genes producing melanocortin 1 receptor (*MC1R*), interferon regulatory factor 4 (*IRF4*), and tyrosinase (*TYR*).[127]

CLINICAL PRESENTATION

The clinical presentation of squamous cell carcinoma depends on tumor location and subtype (e.g., degree of differentiation). The most common presentation is scaly, flat red lesion (*in situ*) or a firm, raised red lesion with erosion or scale (invasive). Actinic keratosis, the precursor lesion, is a scaly, flesh- to pink-colored papule or plaque with an erythematous base that progresses an estimated ~1/200–1/1,000 lesions to squamous cell carcinoma; however, reliable data on monitoring these lesions over time are extremely limited.[146] Bowen's disease (squamous cell carcinoma *in situ*) is an erythematous, well-defined, scaly plaque that is usually asymptomatic; larger lesions may produce pain, tenderness, and/or bleeding. Invasive squamous cell carcinoma usually presents with a persistent ulcer or nonhealing wound that may occur as an indurated or ulcerated lesion (Marjolin ulcer) in a preexisting scar or ulcer. Limited case reports associate squamous cell carcinomas with chronic inflammation in tattoo-induced scars, particularly with red pigment (mercuric sulfide).[147] HPV-induced squamous cell carcinoma typically

TABLE 61.6. Major squamous cell carcinoma histological types. (Adapted from Paolino et al.).[143]

Squamous Cell Carcinoma Type	Histology
Acantholytic	Adenoacanthoma has adenoid pattern with many dyskeratotic cells, often developing in areas of previous radiotherapy.
Conventional	Atypical dermal cells with enlarged, pleomorphic nuclei and atypical mitotic activity. Ulcerated lesions with inflammation (neutrophils, lymphocytes, plasma cells). Aggregates of moderate or poorly differentiated keratinocytes with surrounding desmoplastic stroma may be present.
Lymphoepithelioma-like	Scattered nests of poorly differentiated tumor cells with diffuse lymphocytic infiltrate between epithelial nests. Mainly polygonal in shaped tumor cells with an eosinophilic cytoplasm, containing vesicular nuclei, prominent atypia, numerous mitoses, diffuse lymphoplasmacytic infiltrate surrounding the epithelial nests, and an infiltrating tumor margin.
Spindle-cell	Associated with post-traumatic ulcerated lesions characterized by whorls of spindle cells in the dermis with myxoid stroma and pleomorphic giant cells with atypical mitoses.
Verrucous	Well-differentiated exophytic squamous proliferation with marked papillomatosis, koilocyte-like changes, and little atypia. Rare tumor.

presents as a new or enlarging warty growth on the anus, vulva, penis, or periungual region. The average age at diagnosis for squamous cell carcinoma is the mid-sixth decade of life, with a predilection for men.[148] Latency for arsenic-induced squamous cell carcinomas may extend to 20–40 years.[149]

Squamous cell carcinomas are usually spread by local invasion rather than distant metastasis via the lymphatic system. The rate of metastasis for squamous cell carcinoma is <2%. The propensity of squamous cell carcinomas to metastasize depends on the location, size (>2 cm), depth of invasion (>2 mm), perineural/lymphovascular involvement (>0.1 mm), and location (ear, temple). Typically, the metastatic rate is ~4–5%, with several-fold higher risk among immunosuppressed patients.[150] In a case series of 264 patients presenting to a Danish dermatology institute during the 1950s with cutaneous squamous cell carcinoma and followed to 1976, 3.3% of 153 patients developed metastases compared with 11% of 55 patients with labial squamous cell carcinoma.[151] The incidence of metastasis in patients with cutaneous squamous cell carcinoma from inflammation and degenerative processes ranged from 10–30%. The parotid gland is the most common site of metastasis.

In-office surgical excision or curettage is the typical treatment for keratinocyte carcinomas with low risk of recurrence. For higher risk lesions, Mohs surgery is usually recommended. This technique involves removing the tumor in stages guided by pathological evaluation of the surgical margins under a microscope to ensure entire removal of the lesion. The recurrence rate after Mohs surgery is ≈3%. These patients have a high risk of addition keratinocyte carcinomas (i.e., 40% over 5 years).

In contrast to basal cell carcinoma, squamous cell carcinoma-associated mortality is significant in elderly and immunosuppressed patients. A quantitative systematic review of 10 mostly retrospective cohort studies suggests squamous cell carcinomas are associated with reduced all-cause mortality.[93] Using random effects modeling and data from four large retrospective cohort studies, the authors reported a statistically significant increased summary relative risk for all-cause mortality in squamous cell carcinoma participants (sRR = 1.25, 95% CI: 1.17–1.32, $I^2 = 98.8\%$, $P_{\text{heterogeneity}} = 0.000$) with very high heterogeneity. In the New Hampshire Skin Cancer Study of 1,125 cases and 1,416 population-based controls followed for an average of 9.5–9.8 years, all-cause mortality was increased in patients with squamous cell carcinoma (aHR = 1.25, 95% CI: 1.01–1.54, $n = 189$ deaths) after adjustment for age, sex, smoking, and nonskin cancer occurrence.[152] The primary means of preventing squamous cell carcinomas in fair-skinned individuals involve the consistent use of sunscreen (SPF 15–SPF 30) along with avoidance of excessive sun exposure. A literature review suggests the addition of DNA repair enzymes or antioxidants may reduce risks.[153] Little data from randomized clinical trials support efficacy of these substances in reducing squamous cell carcinoma risks. Other possible chemopreventive agents include vitamin B_3, nonsteroidal anti-inflammatory drugs, and difluoromethylornithine.

MELANOMA

Melanoma is a multifactorial disease with a variety of genetic and epigenetic causes and heterogenous clinical presentations, resulting in differing origins, UV radiation sensitivity, anatomic site, and mutational profile for melanoma histological subtypes.[154] Worldwide, cutaneous melanoma varies widely accounting for ~230,000 incident cases and ~55,000 deaths annually depending in part on access to primary care and early detection as well as pigmentation and sun exposure. The lowest reported melanoma incidence rates occur in Southeast Asia, whereas the highest rates occur in Caucasian residents of New Zealand and Australia, as displayed in Table 61.7.[155] European melanoma rates are intermediate between these two areas. For the last several decades, melanoma incidence has increased ~3% annually, with some evidence of plateauing in Caucasian population in New Zealand and Australia, particularly in Queensland.[156] Beside geographical location, the age-standardized incidence and body site for melanomas vary between men and women (e.g., ↑ head, neck, and trunk in men; lower ↑ extremities in women).[157] An analysis of 2018 GLOBOCAN data from 185 countries reported age-standardized male/female melanoma incidence rate ratios ranging from 0.68 (95% CI: 0.63–0.73) in Denmark and 0.68 (95% CI: 0.63–0.72) in Belgium to 1.35 (95% CI: 1.33–1.37) in the United States and 1.47 (95% CI: 1.42–1.52) in Australia.[158]

In the United States, melanoma is the fifth most common cause of cancer. Melanoma incidence increases linearly after the age of 25 years before peaking at 50 years and then declining, particularly in women.[159] The incidence of melanoma has decreased recently in adolescents and young adults in contrast to the increased incidence in older populations. Analysis of data from the National Program of Cancer Registries and the Surveillance Epidemiology and End Results

TABLE 61.7. Estimated age-standardized rate/100,000 population for melanoma incidence and mortality by gender and region. The reported incidence and mortality rates are usually higher in men than women and higher in more-developed than less-developed countries. (Adapted from Torre et al.).[155]

Region	Incidence-Men	Incidence-Women	Mortality-Men	Mortality-Women
World	3.3	2.8	0.9	0.6
More developed	10.2	9.3	2.0	1.2
Less developed	0.8	0.7	0.4	0.3
Africa	1.0	1.1	0.5	0.7
Northern	0.3	0.4	0.2	0.2
Southern	5.0	3.7	1.6	0.8
North America	16.1	12.2	2.6	1.2
South America	2.9	2.2	1.0	0.6
Asia	0.5	0.4	0.3	0.2
Eastern	0.6	0.5	0.4	0.3
Western	1.8	1.6	0.6	0.5
Europe	8.6	8.9	2.0	1.3
Northern	14.0	15.4	2.5	1.6
Southern	8.1	8.3	1.6	1.0
Australia/New Zealand	40.3	30.5	5.9	2.4

(SEER) US Cancer Statistic database reported an increased overall melanoma incidence rate from 200.1 to 229.1/1,000,000 person-years between 2006–2015.[160] The annual percentage change (APC) during that interval increased in men >40 years of age (APC = 1.8%, 95% CI: 1.4–2.1%) and women (APC = 1.8%, 95% CI: 1.4–2.2%). The melanoma incidence decreased for male (APC = −4.4%, 95% CI: −1.7 to −7.0%) and female (APC = −5.4%, 95% CI: −3.3 to −7.4%) adolescents, as well as for male (APC = −3.7%, 95% CI: −2.5 to −4.8%) and female (APC = −3.6%, 95% CI: −2.8 to −4.5%) young adults 20–29 years.

In the United States, the cutaneous melanoma-related death rate accounts for a majority (i.e., ~62–72%) of non-keratinocyte-related skin cancer deaths.[161] However, mortality from melanoma has declined dramatically over the past decade, primarily as a result of more effective screening and effective treatments for advanced disease. In white-skinned races, the cutaneous melanoma incidence is increasing faster than any other malignant tumor, except for lung cancer in women.[162] There is no clear increase in mortality from melanomas in dark-skinned populations. The melanoma risk for young adult women was about twofold higher than that for young adult men. There is no clear increase in mortality from melanomas in dark-skinned populations.

CARCINOGENESIS

Normal melanocytes rarely divide (i.e., <2 times/year); however, melanomas progressively grow in size as point mutations and copy-number alterations increase, resulting in a very high somatic mutational load.[163,164] Cutaneous melanomas usually contain classic ultraviolet-signature mutations including UVA-induced G→T and UVB-induced C→T transitions.[165] Although skin cancers in chronic sun-damaged areas of skin including melanomas, mutate more than almost all other human cancers, all cutaneous melanomas do not contain a unique universal driver.[166,167] The BRAF V600E mutation occurs early in the progression of melanomas. Benign nevi frequently may contain this mutation (i.e., ~80%). In contrast to melanomas, a growth-arrest phase follows transient activation of cell-proliferation by the BRAF-MAPK pathway in benign nevi.[168,169] The latter pathway is a central driver of cell proliferation, differentiation, and survival. About 40–60% of cutaneous melanomas contain the BRAF mutation, and 15–30% contain the NRAS mutation. Although the latter usually occurs in sun-damaged body sites, neither mutation type contains classical UV signature mutations.[170] Progression to precursor lesions (melanocytic nevi, intermediate lesions, melanomas *in situ*) involves the telomerase reverse-transcriptase

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(*TERT* promoter) gene in about ¾ of these tumors, along with tertiary mutations in cell-cycle control genes *CDKN2A* (cyclin-dependent kinase-inhibitor 2A) and/or chromatin remodeling (*ARID1A/1B/D2*, AT-rich interaction domain).[164] Telomere length is positively associated with the nevus count; however, patients with cutaneous melanoma have consistently longer telomeres than healthy persons.[171] Later stages of melanoma metastasis typically include tumor suppressor mutations in *TP53* and *PTEN* (phosphatase-and-tensin homolog, cell-cycle progression control) genes. In a majority of melanomas, these mutations produce overstimulation of several cellular pathways, including MAPK (mitogen-activated protein kinase), PI3K (phosphoinositide 3-kinase, AKT serine-threonine protein kinase family), β-catenin-mediated Wnt signaling, and mTOR (mammalian target of rapamycin) pathways. *BRAF* and *NRAS* are oncogenes within the MAPK pathway, whereas the tumor suppressor gene *NF1* alters regulation of *RAS* (most commonly *NRAS* and less often *KRAS* and *HRAS* genes).[172] Other less-common mutated oncogenes include *RAC1*, *PREX2*, and *ERBB4*. Melanoma cells evade immune checkpoints by alterations of the interferon receptor via Janus-kinase (JAK) and signal-transducer-and-activator-of-transcription (STAT) pathways, resulting in disruption of the programmed-cell-death-protein-1 (PD-1) immune checkpoint.[173] The number of mutations and copy-number alterations varies significantly with melanoma histological type. Dysregulation of the nuclear factor (NF)-κB pathways alters the tumor microenvironment by degrading the extracellular matrix through overexpression of matrix metalloproteinases (e.g., MMP-2, MMP-9); subsequent changes enhance tumor cell invasion and metastasis via the blood.[174]

EXPOSURE

Established risk factors for melanoma include ultraviolet radiation (sun/sunbed exposures, particularly <35 years of age with sunburn), numerous dysplastic/melanocytic nevi, susceptible phenotypes (blue eyes, red/blond hair, fair skin, freckling), 1° family/personal melanoma history, and high socioeconomic status.[175,176] Similar to squamous cell carcinomas, high sunburn frequency throughout life increases melanoma risks. No other environmental risk factor is clearly associated with increased melanoma risks.[177] Although melanomas are more frequent in patients with light skin, most melanomas do not occur on sun-exposed parts of the body. The predominant locations of melanomas are areas exposed to intermittent, intense sunlight (i.e., backs of men, legs of women) rather than skin receiving more constant sun exposure (i.e., face, dorsum of hands). Malignant epithelial tumors (e.g., basal cell, squamous cell carcinomas) occur in the latter areas. Table 61.8 lists the major predisposing factors for developing melanomas. High-risk populations include individuals with red (3-fold ↑ risk) or blond (60% ↑ risk) hair, fair complexion (2-fold risk), and multiple nevi (>20 nevi → 3-fold ↑ risk).[178] Lifestyle (e.g., sun exposure, sunbed use) and genetic and physiological (e.g., immune function) factors determine the number of nevi; increasing the number of nevi, sizes, and types elevates melanoma risks.[179]

TABLE 61.8. Estimated relative risk factors for melanoma. (Adapted from Williams et al.).[179]

Factor	Estimated Relative Risk[a]
Changing pigmentation	Very high
Xeroderma pigmentosum	500
Family history of FAMM[b]	
Previous melanoma	500
Atypical nevi without melanoma history	150
Numerous common nevi	5–65
Atypical nevi	7–20
Giant congenital nevus	5–15
Previous melanoma	9
Lentigo maligna	5–10
Immunosuppressive therapy	4–7
Sun sensitivity	2–3
Excessive sun exposures	2–4
Melanoma in first-degree relative	6–15
Few or no common nevi	0.3
Hispanic or African American	0.0–0.15
Age <15 years	0.01

[a] Average risk = 1. [b] Familial atypical mole or melanoma syndrome.

Ionizing Radiation

Ultraviolet

UV radiation is the major environmental risk factor for melanoma, accounting for up to 70–75% of these tumors, particularly with higher energy UVB producing more DNA damage than oxidative damage (i.e., reactive oxygen species).[180,181] The epidermis absorbs most UVB radiation, with 9–15% of UVB reaching the melanocytes in the basal layer compared with ~50% of UVA radiation.[182] Melanoma risk probably increases with the addition of UVA radiation; however, the exact contribution of these two portions of the UV spectrum remains controversial.[11,183] Although

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

UV radiation causes similar types of mutations at the DNA nucleotide level (i.e., UV-signature mutations) in melanoma and keratinocyte skin cancers, the target mutations are different. Epidemiological and molecular genetic data support two distinct types of cutaneous responses to ultraviolet radiation, depending on the delivered dose.[184,185] Early, intense, intermittent sun or sunbed exposure in susceptible phenotypes (multiple nevi, light-skin types) promotes the *BRAF* proto-oncogene serine/threonine kinase (BRAF) pathway and the spreading melanoma subtype.[186,187] About 25–33% of cutaneous melanomas arise from a benign, melanocytic nevus, whereas this percentage increases up to ~50–55% in patients with many nevi.[188] The clinical presentation includes young age at diagnosis, often in axial skin areas and the trunk without evidence of chronic sun damage. Age, skin type, hair color, and melanoma thickness do not influence the presentation of nevi-associated melanomas. The other distinct melanoma type involves *de novo* formation from cumulative sun exposure-induced *NRAS* proto-oncogene GTPase NRAS mutations in chronic sun-related skin-damaged areas with no relation to nevi count. These tumors have a high mutation burden with later age at diagnosis typically occurring on the head and neck.[189] In contrast to cutaneous superficial spreading melanoma, nodular and mucosal melanomas are probably not associated with UV radiation.[154] Superficial spreading melanoma is usually associated with cumulative, low intensity sun damage, whereas lentigo maligna is associated with cumulative, high intensity sun damage (i.e., sunburn).

Non-solar Ultraviolet

Indoor tanning beds now primarily emit UVA radiation (320–400 mm) in contrast to UVB radiation in early models before the 1980s. The International Agency for Research on Cancer classifies the whole ultraviolet spectrum and indoor tanning devices as human carcinogens (Group 1), as noted in Table 61.1. Duration of use and initial use at a younger age modestly increase melanoma risks.[190] Analysis of data from 141,045 women followed a mean of 13.7 years in the prospective Norwegian Women and Cancer Study, which identified 861 women with melanoma.[191] Using Poisson regression to estimate relative risks of melanoma in the highest tertile of indoor tanning use compared with never-users use, the adjusted RR was modestly elevated and statistically significant (aRR = 1.32, 95% CI: 1.08–1.63, $P_{trend} = 0.006$). The adjusted RR for initiation of indoor tanning use before age 30 years was also modestly elevated and statistically significant (aRR = 1.31, 95% CI: 1.07–1.59) using linear regression and never-users as referents. A meta-analysis of 27 case-control (12 population-base, 15 hospital-based), 1 nested case-control, 1 cross-sectional, and 2 prospective cohort studies consisting of 14,956 melanoma cases and 233,106 controls used inverse variance methods with a random effects model to estimate odds ratios.[192] With never-users as referents, the odds ratio for ever-users of indoor tanning was small but statistically significant (OR = 1.16, 95% CI: 1.05–1.28, $I^2 = 52\%$) with moderate heterogeneity. The odds ratios for studies published after 1999 and before 2000 were not statistically significant, suggesting newer tanning technology was not associated with decreased melanoma risks. Evidence for a dose-response relationship was marginal. Comparison of indoor tanning use of >10 times and never-users yielded a modestly increased odds ratio (OR = 1.34, 95% CI: 1.05–1.71, $n = 10$ studies, $I^2 = 66\%$) with moderate heterogeneity. Only three of these studies achieved statistical significance. The melanoma odds ratio for indoor tanning use of 1–10 times was not statistically significant (OR = 1.07, 95% CI: 0.90–1.26, $n = 10$ studies, $I^2 = 43\%$). The authors reported that the quality of the evidence ranged from poor to mediocre.

Occupation

For most malignant melanoma cases, recognized risk factors (UV radiation, genetic susceptibility, skin characteristics) are much more important melanoma risk factors than occupational exposures. Industries with some positive studies include agriculture, airline, electrical, healthcare, research, nuclear, oil, pulp, tannery, and teaching; however, observational studies on melanoma incidence and mortality in these occupations and industries report inconsistent results.[175] Overall, the industries with positive studies lack a common occupational agent, similar ultraviolet radiation exposures, or control for socioeconomic class. Some occupations with substantial outdoor exposure (e.g., farmers, fishermen) do not have consistently elevated malignant melanoma rates. For other occupations, these rates are lower in general than office worker populations.[193] The importance of occupational exposure to chemicals as a cause of malignant melanoma appears small.[194,195]

A mortality study demonstrated elevated proportional mortality ratios for managers and owners, accountants, architects, chemical engineers, gardeners, and nursery workers; however, the lack of an obvious chemical carcinogen in all but the last group limits conclusions regarding causation.[196] Retrospective cohort studies of workers in a chemical plant,[197]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

printing industries,[198] and oil refineries[199] demonstrated increased melanoma risks (i.e., RR < 2). In an Italian study of 100 incident melanoma cases and 200 age/sex/ethnicity/location-matched population controls using logistic-regression models, outdoor occupational sun exposure was associated with a statistically significant elevation of cutaneous melanoma (OR = 2.573, 95% CI: 1.399–4.732).[200] The significance of these studies is limited by the small number of cases, the lack of exposure data, and poor control of confounding variables (e.g., pigmentation). A cohort study of 323,860 Swedish men in the construction industry reported no increased melanoma risks, except for a positive but statistically nonsignificant, increased cutaneous melanoma risk on the head, face, and neck in the high-sun-exposure group (RR = 2.0, 95% CI: 0.8–5.2).[201] An analysis of population-based Bavarian cancer registry calculated the age-adjusted Mantel–Haenszel-type estimates of relative risks in workers classified into outdoor, mixed indoor/outdoor, and indoor categories based on job titles.[202] Using indoor workers as referents, the cutaneous melanoma risk in outdoor male workers was positive but statistically nonsignificant (aRR = 1.5, 95% CI: 0.9–2.5) and close to the null in female outdoor workers (aRR = 1.1, 95% CI: 0.4–3.6).

Lifestyle

UV radiation exposure and skin phenotypic characteristics (e.g., skin color, hair/eye color, freckle density), rather than lifestyle factors, are the major nongenetic risk factors for cutaneous melanomas. Overall, large between-study heterogeneity, small-study effects, and excess significance bias complicate interpretation of the mostly retrospective case-control studies evaluating the influence of lifestyle on cutaneous melanoma risks.[203] Skin color is the main phenotypic melanoma determinate, whereas blue/green/hazel/gray eye and red/blonde hair color are proxies for skin color (i.e., pigmentation) because all three depend on melanin content.[204] Few data support a reduction in melanoma risks with increased physical activity. In a Canadian study of 103 incident melanoma cases in men and 533 population-based controls, the melanoma risk for often engaging in recreational sports and outdoor activities was positive but statistically nonsignificant (OR = 1.24, 95% CI: 0.73–2.12, $n = 54$ cases) compared with referents never or not often engaging in recreational physical activity.[205]

Higher socioeconomic status is consistently associated with increased cutaneous melanoma incidence, particularly in the well-educated. Presentation at the late stage of disease and greater mortality are associated with lower socioeconomic status.[175] Even though blue-collar jobs theoretically involve more sun exposure, melanoma incidence usually occurs more frequently in the higher socioeconomic classes (white-collar, urban, highly educated). Analysis of data from the US population-based cancer registry data (Surveillance, Epidemiology, and End Results Program) at the National Cancer Institute indicated the age-adjusted melanoma rate in Caucasian families with income of >$50,000 (i.e., highest quintile) was 20.54/100,000 compared with 9.19/100,000 in the lowest quintile of Caucasian families (<$12,000).[206] The association may apply only to higher socioeconomic status in later life. A cohort study of 1,824,064 Swedish residents born in 1944–1960 examined the association of early-life socioeconomic position with adult cause-specific mortality using Cox proportional hazards regression models to compare manual and nonmanual social class in early life (0–16 years).[207] The reported age-adjusted hazard ratios demonstrated no evidence of a positive association in men ($aHR_{males} = 1.04$, 95% CI: 0.87–1.25) or women ($aHR_{females} = 0.95$, 95% CI: 0.77–1.16), with no significant differences between the sexes ($P_{difference} = 0.5$). The association with higher socioeconomic status may involve differences in healthcare access (tobacco bias), early diagnosis with thinner tumors, and/or greater recreational UV exposure (solar, sunbeds).

Tobacco

Evidence for an association between smoking and cutaneous melanoma is suggestive of an inverse relationship;[203] however, the association is relatively weak and complex with conflicting data.[175,208] The QSkin Sun and Health Study prospectively enrolled 43,794 residents of Queensland, Australia, aged 40–69 years using a self-reported smoking history in baseline questionnaire.[209] The study identified 247 incident invasive melanoma cases during an average follow-up of 3.5 years. Compared with never-smokers, the fully adjusted hazard ratio for invasive melanoma was inverse and statistically nonsignificant in ever-smokers (aHR = 0.80, 95% CI: 0.62–1.05) and null in current smokers (aHR = 1.01, 95% CI: 0.64–1.61). The inverse association was statistically significant for smoking intensity in cigarettes/day ($P_{trend} = 0.001$), cumulative smoking in pack-years ($P_{trend} = 0.02$), and years since quitting ($P_{trend} = 0.044$), but not duration of smoking ($P_{trend} = 0.1$). The multivariate model adjusted for age, sex, natural skin color, tanning tendency, moles at the age of 21 years, previous excised skin cancers

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. and treatment, family melanoma history, childhood sunburn, and cumulative lifetime sun exposure.

Alcohol

Some, primarily case-control, studies suggest alcohol consumption slightly increases cutaneous melanoma risks; however, the data are inconsistent. Several cohort studies reported positive, but statistically nonsignificant, increases in cutaneous melanoma risks.[210,211] A meta-analysis of 14 case-control and 2 cohort studies used random effects models to compare no/light alcohol (≤1 drink/daily) and moderate to heavy drinking (>1 drink daily).[212] The pooled relative risk for cutaneous melanoma for any alcohol consumption using no/occasional drinking as the referent was modestly increased and statistically significant (RR = 1.20, 95% CI: 1.06–1.37, I^2 = 55.6%, $P_{\text{heterogeneity}}$ = 0.003) with moderate heterogeneity. The pooled RR became statistically nonsignificant after adjustment for sun exposure (aRR = 1.15, 95% CI: 0.94–1.41).

Caffeine

The association of coffee with cutaneous melanoma risks remains unclear with conflicting results, whereas most data on tea and decaffeinated coffee consumption and melanoma risks are consistent with null effects.[213,214] In a meta-analysis of 8 cohort and 4 case-control studies involving 832,956 participants using random effects modeling, the pooled relative risk of cutaneous melanoma was inverse and statistically significant for total coffee consumption (pooled RR = 0.80, 95% CI: 0.69–0.93, n = 7,140 cases, I^2 = 53%, $P_{\text{heterogeneity}}$ = 0.014) and marginally significant for caffeinated coffee consumption (pooled RR = 0.85, 95% CI: 0.71–1.01, n = 4,459 cases/5 studies, I^2 = 65%, $P_{\text{heterogeneity}}$ = 0.022) with moderate heterogeneity.[215] Decaffeinated coffee was not associated with statistically significant inverse melanoma risks (pooled RR = 0.92, 95% CI: 0.81–1.05, n = 4,183 cases/6 studies, I^2 = 0.0%, $P_{\text{heterogeneity}}$ = 0.967). The US National Institutes of Health-AARP prospective cohort study identified 2,904 incident cases of malignant melanoma among 447,357 non-Hispanic whites during a median follow-up of 10.5 years.[216] Coffee consumption was self-reported in baseline questionnaires. Using multivariable-adjusted Cox proportional hazard models and non-coffee drinkers as referents, malignant melanoma risk was inverse and statistically significant for the highest total coffee intake category of ≥4 cups daily (HR = 0.80, 95% CI: 0.68–0.93, P_{trend} = 0.01) and caffeinated coffee (HR = 0.75, 95% CI: 0.64–0.89, P_{trend} = 0.01) but not for decaffeinated coffee intake (HR = 0.95, 95% CI: 0.76–1.18, P_{trend} = 0.55). The European Prospective Investigation into Cancer and Nutrition (EPIC) study enrolled 521,324 participants aged 25–70 years; during a median follow-up of 14.9 years, the study identified 2,712 malignant melanomas (93.4% cutaneous melanomas).[213] Coffee categories were based on self-reported consumption in the 12 months preceding enrollment using a validated country-specific dietary questionnaire. Comparing the highest quartile of coffee intake with non-coffee drinkers, the multivariable-adjusted hazard ratio was inverse and statistically significant in men (aHR = 0.47, 95% CI: 0.23–0.94, n = 148 cases, P_{trend} = 0.001) but not women (aHR = 1.10, 95% CI: 0.70–1.72, n = 357 cases, P_{trend} = 0.598). Decaffeinated coffee and tea were not associated with melanoma risks.

The Swedish prospective, population based Västerbotten Intervention Project identified 190 malignant melanomas in 64,603 participants during a median follow-up of 6 years.[217] Using multivariate Cox regression, malignant melanoma risks were not associated with total coffee consumption. Comparing the highest (≥4 cups daily) and lowest (<1 cup daily) coffee-consumption categories, the multivariate hazard ratio for malignant melanoma was 0.97 (95% CI: 0.50–1.89, n = 37 cases, P = 0.939). In the Women's Health Initiative-Observational Study cohort of 66,484 postmenopausal women followed for a mean of 7.7 years, coffee consumption was evaluated by self-administered questionnaires at baseline and the third year of follow-up.[213] Using Cox proportional hazard models adjusted for covariates and nondaily coffee drinkers as referents, melanoma risks were not associated with daily coffee consumption (HR = 0.87, 95% CI: 0.68–1.12) or with increasing coffee consumption (P_{trend} = 0.38).

Obesity

Although some observation studies suggest an association between obesity and cutaneous melanoma,[203] the data are modest and sometimes conflicting, particularly between men and women. A meta-analysis of eight case-control and seven cohort studies in men used BMI = <25 kg/m^2 as referents, BMI = ≥25–<30 kg/m^2 as overweight, BMI = ≥30 kg/m^2 as obese, and fixed effects models unless the data demonstrated substantial heterogeneity ($P_{\text{heterogeneity}}$ = <0.1) to estimate the pooled effect estimate for cutaneous melanoma.[218] The results were similarly elevated for overweight males (pooled effect estimate = 1.31, 95% CI: 1.18–1.45, I^2 = 0.0%, $P_{\text{heterogeneity}}$ = 0.525) and obese males (pooled effect estimate = 1.31, 95% CI: 1.19–1.44, I^2 = 23.2%,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

$P_{heterogeneity}$ = 0.197). For 10 case-control and 6 cohort studies in women, the results demonstrate no significant association between cutaneous melanoma and overweight (pooled effect estimate = 0.98, 95% CI: 0.92–1.05, I^2 = 14.3%, $P_{heterogeneity}$ = 0.789) or obese women (pooled effect estimate = 0.99, 95% CI: 0.83–1.18, I^2 = 40.1%, $P_{heterogeneity}$ = 0.045). The latter analysis applied random effects models with much lower pooled effect estimates for cohort than case-control studies. The authors opined that UV radiation exposure may have confounded the results in women. In a meta-analysis of six studies, the risk ratio per 5 kg/m^2 increase in BMI was weak but positive and statistically significant for malignant melanoma (RR = 1.17, 95% CI: 1.05–1.30, I^2 = 44%, $P_{heterogeneity}$ = 0.004) with slight to moderate heterogeneity.[219] The results indicated no association between obesity and malignant melanoma in women.

Diet

Diet is not strongly associated with cutaneous melanoma risks. Some observational studies suggest the consumption of citrus fruit may increase cutaneous melanoma risks, particularly fruits containing psoralens and other furocoumarins (e.g., grapefruit); however, results are inconclusive.[220] Analysis of data from the US Nurses' Health Study (63,810 women) and the Health Professionals Follow-Up Study (41,622 men) identified 1,840 incident melanomas during 24–26 years of follow-up.[221] Using Cox proportional hazards models to estimate hazard ratios and multivariable analyses to adjust for known melanoma risk factors and potential confounders, the pooled multivariable hazard ratio for melanoma was positive and statistically significant in the highest grapefruit intake category of ≥3 times weekly (aHR = 1.41, 95% CI: 1.10–1.82, n = 125 cases, P_{trend} = <0.001) but not for grapefruit juice (P_{trend} = 0.79). The trend for orange consumption and melanoma risks was not statistically significant (P_{trend} = 0.81) in contrast to orange juice intake (P_{trend} = <0.001). A hospital-based study of 304 cases of cutaneous melanoma and 305 frequency-matched controls used unconditional logistic regression and the lowest intake category as referents.[222] Dietary exposure categories were based on self-reported structured questionnaires, interviews, and a clinical examination for pigmented lesions. The adjusted odds ratio for cutaneous melanoma risks in the highest tertile of citrus fruit consumption category (>5 times weekly) was inverse and statistically significant (aOR = 0.51, 95% CI: 0.32–0.80, P_{trend} = 0.003). The odds ratio was adjusted for age, sex, education, hair color, skin types, nevi, childhood freckles, and childhood sunburns.

Medications

The preponderance of the evidence does not support an increased melanoma risk in women using oral contraceptives or hormone replacement therapy.[223,224] In a meta-analysis of 6 cohort, 12 population-based, and 5 hospital-based case-control studies involving 5,626 histologically confirmed cutaneous melanoma cases, exogenous hormone use was not associated with increased cutaneous melanoma risks.[225] Using random effects models and never-users as referents, the summary relative risks of cutaneous melanoma for ever-users of oral contraceptives were 1.04 (95% CI: 0.92–1.18, I^2 = 42%, $P_{heterogeneity}$ = 0.03) and 1.16 (95% CI: 0.93–1.44, I^2 = 47%, $P_{heterogeneity}$ = 0.05). Dose-response models indicated no significant increase in cutaneous melanoma risk for oral contraceptives or hormone replacement therapy. Cutaneous melanoma risks were not related to age at first use of oral contraceptives or time since first/last use.

Diseases

Melanomas occur more frequently in immunosuppressed patients (solid-organ transplants, hematological malignancies, HIV infections) and chronic inflammatory diseases (e.g., inflammatory bowel disease, psoriasis, rheumatoid arthritis). The small number of cases and large between-study heterogeneity limit definitive conclusions regarding causation.

Parkinson Disease

Although some retrospective studies suggest increased cutaneous melanoma risks in patients with Parkinson disease (levodopa is an intermediary product in melanin synthesis), the data are inconclusive with limited power and very large between-study heterogeneity. A systematic review and meta-analysis of the association between melanoma and Parkinson disease identified 12 publications with only 2 designed explicitly to assess the relationship between melanoma and Parkinson disease; 8 of the eligible studies had <10 cases.[226] Overall, the pooled odds ratio for Parkinson disease in melanoma patients was positive and statistically significant (OR = 2.11, 95% CI: 1.26–3.54, I^2 = 85.4%, $P_{heterogeneity}$ = 0.000%) with very high heterogeneity. In Parkinson disease patients, melanoma risks were positive and statistically significant

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(OR = 3.61, 95% CI: 1.49–8.77, $n = 6$ studies, $I^2 = 89.6\%$, $P_{\text{heterogeneity}} = 0.000\%$) compared with patients without Parkinson disease. The risk of melanoma and Parkinson disease is lower in women than in men. The overall melanoma risk in men in this study was positive and statistically significant (OR = 2.04, 95% CI: 1.55–2.69, $n = 6$ studies, $I^2 = 0.0\%$, $P_{\text{heterogeneity}} = 0.539$), whereas melanoma risks were positive but statistically nonsignificant in women (OR = 1.52, 95% CI: 0.85–2.75, $n = 5$ studies, $I^2 = 54.5\%$, $P_{\text{heterogeneity}} = 0.067$). A retrospective cohort study (Rochester Epidemiology Project) in Olmsted County, Minnesota, identified 974 Caucasian patients with Parkinson disease; all these patients were treated with carbidopa–levodopa.[227] Within this cohort, 32 melanomas occurred (29 cutaneous, 3 choroidal melanomas) with only 6 cutaneous melanomas diagnosed after their Parkinson disease. Compared with age/sex-(but not lifestyle)-matched controls, the likelihood of a Parkinson patient having a preexisting melanoma was increased 3.8-fold (95% CI: 2.1–6.8, $P = <0.001$). The melanoma cohort had a similar elevation of Parkinson disease (i.e., 4.2-fold). Using Kaplan–Meier analysis and a log-rank test, melanoma patients had a 35-year cumulative Parkinson disease risk of 11.8% (95% CI: 4.0–19.6%) compared with 2.6% (95% CI: 0.4–4.8%) in controls. The difference was statistically significant ($P = <0.001$). No single unifying mechanism explains this association. Both Parkinson disease and cutaneous melanoma patients accumulate the presynaptic protein, α-synuclein, the main constituent of intraneuronal inclusions (Lewy bodies) in Parkinson disease. This posttranslationally phosphorylated protein occurs in 90% of Parkinsonian brains compared with 4% of normal brains.[228]

Immunosuppression

Melanoma-induced immunosuppression is a complex and heterogeneous process involving several mechanisms, including malignant mutations, downregulation of surface antigens (e.g., histocompatibility complex class I), suppression of the antitumor response by depressing activation and proliferation of regulatory CD4+/CD25+ T cells, blockage of natural killer cell function,[229] and secretion of immunosuppressive cytokines (e.g., indolamine 2,3-dioxygenase, interleukin 10, transforming growth factor β) into the tumor microenvironment.[230,231] These cytokines suppress regulatory T cells and dendritic cells involved with peripheral tolerance.

Compared with the general population, observational studies suggest melanoma incidence increases in several types of immunosuppressed patients, including human immunodeficiency virus infection/AIDS, lymphoproliferative disorders (i.e., chronic lymphocytic leukemia, non-Hodgkin disease), and solid-organ transplant recipients. The latter patients have an increased incidence of many cancers, particularly skin cancers with the risk being much lower for melanoma than keratinocyte cancers. In a review of 17 observation studies on *de novo* melanoma incidence in solid-organ transplant recipients, 8 of the studies reported statistically significant elevated melanoma risks with the relative risk/standardized incidence ratio ranging from 2.14–3.4.[230] Most of the other studies had positive, but statistically nonsignificant, results. Ten patients in the Oxford renal transplant service develop melanomas out of a total of 1,874 transplant patients during 11,942.2 recipient-years of follow-up.[232] The melanoma incidence was ~8 times higher in transplant recipients than the general population, with a mean interval between transplant and melanoma diagnosis of 11 years (median = 8.5 years). For chronic lymphocytic leukemia and non-Hodgkin lymphoma patients, the relative risk/standardized incidence ratio in nine observational studies reporting statistically significantly increased *de novo* melanoma risks ranged from 1.75–6.17.[230] In general, standardized rate ratio for all-cancer incidence in HIV-infected patients increases by 1.5–2-fold. The standardized rate ratio for melanoma in a prospective cohort study of 54,780 HIV-infected persons (Adult and Adolescent Spectrum of HIV Disease Project) was 2.6 (95% CI: 1.9–3.6, $n = 39$ cases).[233]

Reproductive Factors

Malignant melanoma was the most common cancer in women aged 25–29 years, and during pregnancy in a Swedish register-based study on data collected 1963–2007;[234,235] ~1/3 of melanomas occurring in women develop during childbearing years.[236] Although some evidence suggests pregnancy reduces tumor surveillance and melanotic lesions may contain estrogen-sensitive receptors, the clinical relevance of these potential changes is unclear, particularly when most studies indicate pregnancy does not enhance melanoma progression or reduce survival.[237] Observational studies on reproductive factors influencing endogenous hormonal factors (e.g., parity, age at menarche/menopause, age at first birth) report mixed results. In a clinic-based study of 318 cutaneous melanomas and 395 age/race/residence-matched controls, melanoma risks in parous women were positive and marginally significant using nulliparous women as referents

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(aOR = 1.7, 95% CI: 1.00–2.6, $n = 259$ cases/278 controls), particularly in women of <55 years at melanoma diagnosis (aOR = 1.9, 95% CI: 1.2–3.3, $n = 176$ cases/163 controls).[223] Increasing parity was associated with increased melanoma risks ($aOR_{\geq 3\ births} = 2.5$, 95% CI: 1.5–4.3, $n = 108$ cases/98 controls, $P_{trend} = <0.001$) using women with no live births as referents. The odds ratios were adjusted for age, education, study location, dysplastic nevi, freckling, and exogenous hormone use.

A meta-analysis of 14 case-control, 3 nested case-control, and 7 cohort studies involving 16,787 cutaneous melanoma cases reported a slightly increased, statistically significant association between cutaneous melanoma risk and age at first pregnancy (summary RR = 1.011, 95% CI: 1.008–1.013, $n = 8$ studies, $I^2 = 51\%$, $P_{heterogeneity} = 0.06$).[225] Although some summary RR for other reproductive factors were also slightly positive (e.g., fertility drug use, menopausal status), none of the other summary RR for cutaneous melanoma and reproductive factors were statistically significant, including parity, menopausal status, fertility drug use, and age at menarche/menopause. The authors opined that socioeconomic differences may account for excess risks associated with age at first pregnancy.

HISTOLOGY

The epidermis consists of the stratum basale (basal stem cells), spinosum, granulosum, and corneum with melanocytes confined to the stratum basale; cutaneous melanomas arise from melanocytes in the basal epidermal layer. Variation in skin color results from melanocyte activity and melanin production rather than the number of melanocytes. Histological features of pigmented lesions characteristic of cutaneous melanoma include asymmetry, border irregularity, color variegation, recent onset, and diameter of ≥6 mm.[238] Malignant melanomas originate from the transformation of dendritic melanocytes in skin, eye (choroidal layer), leptomeninges, and mucosal epithelia. Although these tumors usually occur in the skin, melanomas can develop in any of these melanocyte-containing tissues. The more common histological categories of melanomas based on their growth patterns are: 1) superficially spreading melanoma (SSM, ≈70%); 2) nodular melanoma (NM, ≈5%); 3) lentigo maligna melanoma (LMM, ≈15%); and 4) desmoplastic melanoma (≈4%). Less common subtypes include amelanotic (2–8%), spitzoid (<2%), and acral (≈1%). Each of these melanoma subtypes can arise from different precursor lesions, gene mutations, and stages of transformation. Superficial spreading melanomas are the most common and slowest-growing (1–5 years) melanomas in Caucasians, comprising ~70% of melanomas. These tumors occur at any age after puberty on any part of the body. Nodular melanomas are the second most common melanoma subtype (15–30%); these tumors display vertical (invasive) growth early, frequently demonstrating nonclassical histological characteristics. Although more common after the age of 50 years, these tumors can occur at any age. Nodular melanomas usually begin on any portion of the skin's surface, whereas superficial spreading melanomas often arise in preexisting nevi.[239] Lentigo maligna melanomas account for ~14% of the melanomas typically appearing on the faces of older Caucasian women as large flat lesions. In contrast to superficial spreading and nodular melanomas, lentigo maligna melanomas occur primarily in sun-exposed areas where sun-related skin damage develops.[240] These melanomas existed in sunlight-exposed areas for many years before becoming deeply invasive. Acral lentiginous melanomas usually appear on the palms, soles, or nail-bed matrix in non-sun-exposed areas of older, dark-skinned patients. These tumors account for only 2–8% of the melanomas in Caucasians compared with ~70% of melanomas in African Americans.[241,242]

HOST SUSCEPTIBILITY

Family/Personal History

A positive family or personal history of melanoma increases melanoma risks and tumor development at younger ages in non-sun-exposed areas. Approximately 6–15% of melanomas occur in patients with a family history of melanoma.[243,244] Many of these patients have dysplastic nevi. In a case series of 102 patients from 49 families presenting with familial cutaneous melanoma to the Massachusetts General Hospital Pigmented Lesion Clinic during an 8-year period, 82% had a personal and/or family history of dysplastic nevi.[245] Analysis of data from the Swedish Family-Cancer Database indicates ~9% of incident melanoma cases have a family history of melanoma.[246] The relative risk of melanoma increased from ~2.5 in individuals with a history of one 1st-degree relative with melanoma to 6.5 for two 1st-degree relatives. The most common family-associated melanoma is familial atypical multiple mole-melanoma (FAMMM) syndrome along with the variant, melanoma-astrocytoma syndrome. The most frequent germline mutation in these patients occurs in *CDKN2A* (cyclin-dependent kinase inhibitor 2A, protein $p16^{INK4A}/p14^{ARF}$) and less often in *CDK4* (cyclin-dependent kinase 4) and *BAP1*

TABLE 61.9. Meta-analysis results for pooled estimates of proportion and standardized incidence ratios for the occurrence of a subsequent melanoma in a patient previously diagnosed with a melanoma tumor with subgroup analyses on study design and quality. (Modified from van der Leest et al.).[249]

Study Estimate Type	Study Number	Study Result	95% CI
Pooled Proportion Estimates			
Proportion, total studies	47	3.8%	3.3–4.4%
Population-based	11	2.6%	1.9–3.5%
Hospital-based	36	4.3%	3.7–5.2%
Newcastle–Ottawa scale ≥5	13	3.8%	2.9–4.9%
Newcastle–Ottawa scale <5	34	3.8%	3.2–4.6%
Pooled Estimate Standardized Rate Ratio			
Proportion, total studies	12	10.4	8.5–12.3
Population-based	7	7.9	5.7–10.1
Hospital-based	5	17.8	14.1–21.7
Newcastle–Ottawa scale ≥5	7	8.7	6.3–11.0
Newcastle–Ottawa scale <5	5	14.1	10.7–17.5

Abbreviation: CI = Confidence Interval.

(*BRCA1*-associated protein 1) genes.[247] The penetrance of CDKN2A mutation varies in high-risk families geographically ranging from 20% in Australia to 45% in North America and 57% in Europe.[248] Other genetic conditions associated with increased melanoma risks include xeroderma pigmentosum, Lynch syndrome type II, Li–Fraumeni cancer syndrome, and familial retinoblastoma.[243] Pooled analysis of data from 19 observational studies reported the occurrence of subsequent melanomas in patients with an initial basal cell carcinoma of <0.5–1%.[91] Keratinocyte skin cancers are the most common other cancers occurring in familial cutaneous melanoma patients, with pancreatic and breast cancer developing more often in these melanoma-susceptible patients than the general population.

In a meta-analysis of 47 mostly retrospective cohort studies using random effects modeling to calculate estimates, the pooled proportion of subsequent melanomas after an initial incident melanoma case was 3.8% (95% CI: 3.3–4.4%); subgroup analysis indicated a higher difference in hospital-based than population-based studies but no significant difference between higher (Newcastle–Ottawa scale ≥5) and lower quality studies (Newcastle–Ottawa scale of <5), as displayed in Table 61.9.[249]

Compared with the general population, the estimated standardized incidence ratio for a subsequent melanoma was increased to ~10-fold in patients with a prior melanoma (pooled estimate = 10.4, 95% CI: 8.5–12.3, $n = 12$ studies); subgroup analysis indicated differences between hospital-based and population-based studies as well as study quality, as displayed in Table 61.9.

Nevi

Approximately 25–33% of melanoma tumors arise from preexisting atypical (dysplastic) nevi; these nevi may remain indolent for decades from host immune surveillance until they acquire subsequent mutations in driver genes (e.g., *TERT*, *CDKN2A*).[250,251] Patients with multiple dysplastic nevi (i.e., flat, irregular borders; variegated colors) are particularly susceptible to melanoma transformation. These patients account for a majority of primary cutaneous melanoma patients (52–67%).[252] In a US study of 716 consecutive patients with newly diagnosed melanoma and 1,014 clinic-based controls, the melanoma risk was correlated with the number of small nevi (>2–<5 mm), the presence of large nondysplastic nevi (>5 mm), and the occurrence of dysplastic nevi.[253] The age/sex/center/small nevi-adjusted melanoma RR increased with the number of dysplastic nevi. Melanoma relative risk for the occurrence of one dysplastic nevus was 2.3 (95% CI: 1.4–3.6, $n = 64$ cases/50 controls), whereas the presence of ≥10 was associated with an adjusted melanoma RR of 12 (95% CI: 4.4–31, $n = 55$ cases/6 controls) based on imprecise estimates. Using patients with <25 small nevi as controls, the adjusted melanoma relative risk ranged from 1.8 (1.3–2.5, $n = 163$ cases/190 controls) for patients with 25–49 small nevi to 3.4 (95% CI:

TABLE 61.10. Anatomical sites of melanomas by gender, with median age at diagnosis in the German Central Malignant Melanoma Registry, 2012. Melanoma was most likely to occur on the trunk in men and the lower extremity in women. Melanomas on the trunk presented at an earlier age in women than men. Approximately 80% of melanomas in patients ≥80 years of age were on the head or neck. Differences in anatomical location and associated sun patterns are consistent with two separate causal pathways for early, intermittent/intense (sunburns) and cumulative, sun-damaging-associated exposures. (Adapted from Leiter et al.).[11]

Anatomical Site	Percentage (%) Men	Percentage (%) Women	Median Age Men at Diagnosis (Years)	Median Age Women at Diagnosis (Years)
Face	7.9	9.7	65	68
Scalp	7.7	2.8	64	67
Neck	2.6	1.8	58	53
Anterior trunk	15.0	7.8	54	41
Posterior trunk	38.1	18.1	57	47
Genital region	0.2	0.5	75	63
Upper extremity	11.6	19.4	57	53
Lower extremity	16.9	39.8	53	50

2.0–5.7, $n = 123$ cases/43 controls) for ≥100 small nevi. The adjusted melanoma RR for congenital nevi was consistent with null results. The sensitivity of specific melanoma histological types varies with different risk factors. The number of nevi appears to be more closely associated with SSM and NM types compared with LLM, whereas total sun exposure and skin type are more important risk factors for LLM than SSM or NM subtypes.[254]

CLINICAL PRESENTATION

Melanomas are malignant tumors of melanocytes that occur primarily in white-skinned races and tend to metastasize early. The overall median age ranges from 57–64 years. The highest melanoma rates occur in older men (>44 years), whereas melanomas usually affect younger women (<45 years) more than younger men, with the peak difference between women and men occurring at age 20–24 years (RR = 2.01, 95% CI: 1.21–3.33).[255] The anatomical site varies with gender; the most common site is the trunk in men and the lower extremity in women, as displayed in Table 61.10. The most common complaint is a new or changing skin lesion.

Melanoma accounts for most skin cancer-related deaths and has a historically poor prognosis for patients with metastases. Relative survival represents the ratio of the overall survival rate for cancer patients to the expected survival of a comparable group of cancer-free individuals. Relative survival depends on the clinical stage of presentation, with the survival rate decreasing with age and being higher in women than men. The difference in rates reflects earlier presentation of melanoma (58 and 65 years, respectively), more localized stage, and dissimilar UV exposure in women than men.[256] Tumor thickness is the most important prognostic factor for primary melanoma.[257] Higher survival rates occur in patients with thin tumors (<1 mm).[258] The stages for melanoma include stage 0 (melanoma *in situ*), stage IA-IIA (localized melanoma), stage IIB/IIC (increased thickness and or ulcerations), stage III (localized spread), and stage IV (distant metastasis). In the United States, the 5-year melanoma-specific survival rate for Stage I (<1-mm thickness, no lymph node involvement, no metastasis) is 98% and 95% for Stage II (1–2-mm thickness, no lymph node involvement, no metastasis). The overall 10-year relative survival rate ranges from approximately 98% for stage IA to 94% for stage IB, 88% for stage IIA to 75% for stage IIC, 88% for stage IIIA to 60 for stage IIIC, and 24% for stage IIID. About 84% of cutaneous melanomas are localized (stages I–II). Treatment with multiple checkpoint inhibitors (programmed cell death protein 1, PD-1), cytotoxic T cell-associated antigen 4, CTLA-4), and multiple tyrosine kinase inhibitors (e.g., BRAF inhibitors targeting the *BRAF* proto-oncogene serine/threonine protein kinases and mitogen-activated protein kinase MAPK signaling) dramatically improved survival in higher melanoma stages.[259] The use of PD-1-based agents and chemotherapy aimed at $BRAF^{V600+}$ melanomas increased overall 5-year survival rates for metastatic melanoma from <10% to 40–50%.[260]

Chapter 62

SOFT TISSUE AND BONE SARCOMAS

Sarcomas are rare, malignant tumors that originate in mesenchymal tissues within any part of the body, including bones, cartilage, or organs.[1] The dozens of histological types, multiple genetic mutations, and various anatomic sites of this heterogeneous cancer group result in complex interactions between somatic mutations, histology, and clinical courses. For sarcomas, the prognosis of similar histological subtypes varies with location on the body; different sarcoma subtypes in the same location also have variable prognoses. The rarity of these tumors and the many histological subtypes complicate understanding of these interactions.

Sarcomas account for ~1% of adult malignant neoplasms. The rates are relatively higher in younger populations, particularly Ewing sarcomas and osteosarcomas, whereas the median age at presentation for soft tissue sarcomas is the seventh decade. Racial differences also exist in younger populations with relatively higher rates of fibromatous sarcomas in African Americans, liposarcomas in Hispanics, and synovial sarcomas in Caucasians.[2] The annual overall sarcoma age-standardized incidence is ~5/100,000 inhabitants in developed countries, with modest variation between countries; soft tissue sarcomas are ~5–6-fold more common than bone sarcomas. In an analysis of data from the European RARECARE project, the annual age-standardized soft tissue sarcoma incidence was 4.2/100,000 inhabitants ranging from 3.3/100,000 inhabitants of Eastern Europe to 4.7/100,000 in Northern Europe; the overall age-adjusted rate for bone sarcomas was 0.8/100,000.[3] Table 62.1 lists the age-standardized incidence rates by site for soft tissue sarcomas and by histological type for bone sarcomas, along with overall rates in descending order with the most common first.

Most sarcomas are sporadic; ionizing radiation (i.e., therapeutic radiation,[4] atomic bomb survivors[5]) is the only well-recognized risk factor with limited evidence for occupational and environmental causes (e.g., chlorophenols). Epidemiology studies on phenoxyacetic acids[6,7] and chlorophenols[8,9] are inconsistent based on self-reported use and few environmental measurements. Evidence for a causal relationship between specific viruses and sarcomas overall is weak, with the exception of Kaposi sarcoma-associated human herpesvirus (HHV8) and Kaposi sarcoma, particularly in immunosuppressed patients (AIDS, organ transplant chemotherapy).[10] Table 62.2 lists agents and chemicals classified by the International Agency for Research on Cancer (IARC) soft tissue and bone carcinogens.[11]

Sarcomas comprise a heterogeneous group of about 70 uncommon subtypes that include genomically simple tumors with recurrent genetic alterations and genomically complex tumors with extensive genomical rearrangements. Overall, the mutational burden usually is low. Several familial syndromes are associated with increased sarcoma risks, including inherited retinoblastoma (RB mutation, RB transcriptional corepressor 1; certain soft tissue sarcomas, osteosarcoma), Li–Fraumeni syndrome (TP53 mutations, tumor protein p53; certain soft tissue sarcomas, osteosarcoma), and neurofibromatosis 1 (nerve sheath tumors; mutations of *NF1* neurofibromin 1) gene. Epidemiological evidence indicates older adult patients with Paget disease are susceptible to the development of primary and secondary osteosarcomas. Other very

TABLE 62.1. Annual age-standardized incidence rates per 100,000 inhabitants for soft tissue sarcomas by site and bone cancers by histological type in the Surveillance of Rare Cancers in Europe (RARECARE) project.[3] The rates are listed in descending order of the absolute number of incident cases for each site or histological type. (Data adapted from Stiller et al.).[3]

Site or Histological Type	Age-Standardized Incidence/100,000	Standard Error
Soft Tissue Sarcomas		
Overall soft tissue sarcomas	4.2	<0.1
Limbs	0.9	<0.1
Uterus	0.5	<0.1
Viscera	0.4	<0.1
Superficial trunk	0.4	<0.1
Skin	0.3	<0.1
Retroperitoneum	0.3	<0.1
Head and neck	0.2	<0.1
Central nervous system	0.2	<0.1
Other genitourinary tract soft tissue sarcomas	0.2	<0.1
Breast	0.2	<0.1
Ewing soft tissue sarcoma	0.1	<0.1
Bone Sarcomas		
Overall bone sarcomas	0.8	<0.1
Chondrogenic sarcoma	0.2	<0.1
Osteosarcoma	0.2	<0.1
Ewing bone sarcomas	0.1	<0.1
Gastrointestinal stromal sarcoma	0.1	<0.1

TABLE 62.2. International Agency for Research on Cancer (IARC) Classification of cutaneous cancer sites by sufficient and limited evidence of human carcinogenicity. (Adapted from IARC[11] and Cogliano et al.).[15]

Anatomic Site	Carcinogen with *Sufficient* Human Evidence (Group 1)	Carcinogen with *Limited* Human Evidence (Group 2A or 2B)
Bone	Plutonium, radium-224 and its decay products, radium-226 and its decay products, radium-228 and its decay products, X-radiation, gamma radiation	Iodine radionuclides including ^{131}I
Soft tissue		Polychlorophenols or sodium salts (combined exposures), iodine radionuclides including ^{131}I, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin
Endothelium (Kaposi sarcoma)	Human immunodeficiency virus type 1, Kaposi sarcoma herpesvirus

rare syndromes associated with increased osteosarcoma risks include Rothmund–Thomson syndrome (RECQL4 mutation, RecQ-like helicase 4),[12] Bloom syndrome (BLM mutation, BLM RecQ-like helicase), Werner syndrome (*WRN* mutation, Werner syndrome RecQ-like helicase),[13] and McCune–Albright syndrome (GNAS mutation, GNAS complex locus).[14]

SOFT TISSUE SARCOMAS

Soft (connective)-tissue sarcomas arise from primitive mesenchymal cells in any part of the body (head, neck, trunk, internal organs, retroperitoneum, arms, legs) including muscle, fibrous tissue, fat, lymph vessels, blood, and cartilage, with each histological type developing separate characteristics (e.g., risk factors, survival).[7] The reported incidence of these tumors has increased in men; however, the actual incidence and etiology of soft tissue sarcomas are difficult to study because of their low incidence, changing classification, and histological misclassification.[16] The US age-standardized rate (US-ASR) for soft tissue sarcomas in the Surveillance, Epidemiology, and End Results program, excluding Kaposi sarcoma, was 5.49/100,000 person-years for men and 4.60/100,000 person-years for women.[17] In an Austrian study of 5,333 cases collected from 1984–2004, the age-standardized rate was 2.4/100,000 with a male/female ratio of 0.8.[18] The study did not confirm an increase in the soft tissue cancer rate. The international rate varies by ~1.8–5.0 cases/100,000 inhabitants.

CARCINOGENESIS

Soft tissue sarcomas represent a large, complex, heterogeneous group of tumors that arise sporadically, often without specific genetic drivers or chromosomal abnormalities. About 1/3 of soft tissue sarcomas contain specific translocations (e.g., alveolar rhabdomyosarcoma), whereas some have specific mutations (e.g., gastrointestinal stromal tumors) and others lack specific genetic signatures (e.g., leiomyosarcoma, pleomorphic liposarcoma, undifferentiated pleomorphic sarcoma).[19,20] Epigenetic changes in soft tissue sarcomas include DNA methylation (e.g., hypermethylation of *PTEN* promoter region in alveolar rhabdomyosarcoma), histone modification (e.g., upregulation of Jumonji-type histone demethylases by PAX3-FOXO1 fusion gene in alveolar rhabdomyosarcoma), and noncoding RNAs (dysregulation of muscle differentiation transcription factors miRNA-133-1b and miRNA-206 in rhabdomyosarcomas).[21]

EXPOSURE

Ionizing Radiation

The history of primary cancer increases subsequent cancer risks; limited data exist on the exact contribution of radiotherapy to the increased soft tissue sarcoma risks resulting from the susceptibility to secondary cancers and chemotherapy use.

Radiotherapy

Radiation-associated cancers may occur in patients receiving high-dose radiotherapy (i.e., >8–9 Gy). A US study of 565 sarcoma patients with second malignancies identified 160 patients with radiation-associated sarcomas, including 100 soft tissue, 39 osteogenic, and 21 unclassified sarcomas.[22] The median radiation dose was 50 Gy, with malignant fibrous histiocytoma, angiosarcoma/lymphangiosarcoma, and spindle cell sarcoma representing the most common histological types using older classification categories. Given the rarity of soft tissue sarcomas, the overall absolute risk is very small, even with very high radiation doses. A retrospective US study of medical records from 22,306 radiotherapy patients from 1934–1983 identified 18 soft tissue sarcomas in previously radiated patients receiving a radiation dose ranging from 25–70 Gy.[23]

A Finnish study identified 12 soft tissue sarcomas from data in the Finnish Cancer Registry 1953–2000 covering 1.5 million person-years in a cohort of 295,712 primary cancer patients; 75% of these patients were ≥55 years of age.[24] Table 62.3 displays the standardized incidence ratios for soft tissue sarcomas for Finnish primary cancer patients with and without radiotherapy based on age and sex. The standardized incidence ratio for patients with and without radiotherapy was statistically nonsignificant, except soft tissue sarcomas in men ($n = 7$) and women <55 years of age ($n = 34$).

Japanese Atomic Bomb Survivors

The Life Span Study cohort of 80,180 Japanese atomic bomb survivors identified 104 soft tissue sarcomas with a mean latency period between exposure and diagnosis of 36.8 years. The most common histological types were leiomyosarcoma (37 cases) and malignant fibrous histiocytoma (11 cases, now classified as undifferentiated/unclassified).[25] The data suggested a doubling of soft tissue sarcoma risks using a linear dose-response model *above* 1 Gy. The excess relative risk was 1.01/Gy (95% CI: 0.13–2.46, $P = 0.019$) with an excess annual absolute risk of 4.3/100,000 population (95% CI: 1.1–8.9, $P = 0.001$).

TABLE 62.3. Standardized incidence ratios (SIRs) of bone and soft tissue sarcomas in a Finnish cohort of 295,712 patients with primary cancer diagnosed from 1953–2000.[24] Most of the SIRs in sarcoma patients with a history of radiotherapy were not statistically different than primary cancer patients without a history of radiotherapy. (Data adapted from Virtanen et al.).[24]

Age at Diagnosis (Sex)	Standardized Incidence Ratio	95% CI	Cases
	Soft Tissue Sarcoma		
<55 years (male)	10.0	4.0–20.6[a]	7
≥55 years (male)	1.0	0.2–3.0	3
<55 years (female)	3.1	2.2–4.4[a]	34
≥55 years (female)	1.2	0.7–1.9	18
	Bone Sarcoma		
<55 years (male)	3.6	0.1–19.1	1
≥55 years (male)	0	0.0–5.8	0
<55 years (female)	3.0	1.2–6.1[a]	7
≥55 years (female)	1.4	0.4–3.7	4

[a] Statistically significant at $p = <0.05$. *Abbreviation*: CI = Confidence Interval.

Occupation

An exploratory study analyzed data from the US Selected Cancers Study 1984–1988 and identified 521 incident sarcoma cases and 1,910 age-matched controls.[7] Using self-reported occupational exposures and exact conditional logistic-regression models, the odds ratios for sarcomas classified as dermatofibrosarcoma protuberans ($n = 46$), liposarcoma ($n = 53$), and skeletal sarcoma ($n = 51$) were statistically nonsignificant. Out of the 15 suspected carcinogens, the odds ratio was statistically significant for leiomyosarcoma patients ($n = 67$) exposed to plywood (OR = 2.21, 95% CI: 1.25–3.86) and wood or sawdust (OR = 2.41, 95% CI: 1.38–4.16). The only other statistically significant occupational exposure was herbicide use on a farm 5 years before the study (OR = 2.94, 95% CI: 1.07–7.32). The total number of comparisons was 60.

Human epidemiology evidence for increased soft tissue sarcoma risks following exposure to phenoxy herbicides (2,4-dichlorophenoxyacetic acid, 2,4-D; 2,4,5-trichlorophenoxyacetic acid, 2,4,5-T; 2-methyl-4-chlorophenoxyacetic acid, MCPA, methylchlorophenoxypropionic acid, MCPP, and/or 2,3,7,8-tetrachlorodibenzo-*p*-dioxin, TCDD) is limited and inconsistent without strong support for causation.[26,27] A systematic review of 13 cohort and 27 case-control studies reported mostly weak or modest and statistically nonsignificant risks for soft tissue sarcomas in phenoxy herbicide-exposed workers consistent with other reviews.[28] The authors opined that the absolute soft tissue sarcoma risks must be small if there is a true hazard. In a nested case-control study of 4,093 deaths after employment in 5 UK factories manufacturing phenoxy herbicides for a contract spray business, the highest odds ratio for soft tissue sarcoma risks in men working ≥1 year in potentially phenoxy herbicide-exposed jobs was 1.30 (95% CI: 0.30–5.62, $n = 6$ exposed cases/45 exposed controls).[29]

HISTOLOGY

Sarcomas are rare, aggressive tumors with mesenchymal differentiation categorized according to morphology and location in the body. Soft tissue sarcomas are classified according to the normal tissue they resemble. Consequently, sarcomas represent a large, heterogeneous group of >50 distinct histological types in variable locations throughout the body.[30] The World Health Organization (WHO) classifies soft tissue sarcomas as tumors of the extremities, trunk wall, and retroperitoneum rather than internal organs; the latter are considered visceral sarcomas attributable to the organ of origin. The 2013 WHO edition has 11 soft tissue histological subgroups; this WHO classification added gastrointestinal stromal and nerve sheath tumors previously associated with other organs to the soft tissue sarcoma section, along with a new undifferentiated/unclassified sarcoma section.[31] The latter soft tissue tumors now include the tumors previously classified as malignant fibrous histiocytomas (MFH).

A European study of ~13 million inhabitants identified 1,660 sarcomas (968 soft tissue sarcomas, excluding Kaposi sarcoma; 590 visceral sarcomas, including gastrointestinal and endometrial stromal tumors).[32] The newly classified gastrointestinal stromal tumors were

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

not included in the study statistics. The most common soft tissue sarcomas were liposarcomas ($n = 254$), leiomyosarcomas ($n = 156$), dermatofibrosarcoma protuberans ($n = 98$), and Kaposi sarcomas ($n = 95$). In an Austrian study evaluating 5,333 soft tissue cancer cases from 1984–2004, the most common subtypes were not otherwise specified (36%), leiomyosarcoma (24%), liposarcoma (12%), malignant fibrous histiocytoma (9%, now classified as undifferentiated/unclassified), and fibrosarcoma (5%).[18] The histological type changes with age; rhabdomyosarcomas are particularly common in the pediatric age group (median age, <20 years), whereas Kaposi sarcoma, fibrohistiocytic tumors, and leiomyosarcoma are more prevalent in adults.[33]

HOST SUSCEPTIBILITY

A small portion of soft tissue tumors are attributed to familial risks, including Li–Fraumeni syndrome, hereditary retinoblastoma, neurofibromatosis type I, Gardner syndrome, and Werner syndrome. Analysis of adjusted standardized incidence ratios (SIR) using data from the nationwide Swedish Family Cancer Database suggests familial soft tissue sarcoma risks are limited to certain histological subtypes.[34] The study identified 17 offspring–parent pairs with concordant soft tissue sarcomas; the SIR was increased and statistically nonsignificant (SIR = 1.60, 95% CI: 0.93–2.56). Most relationships between offspring soft tissue sarcoma subtypes and parental cancers were statistically nonsignificant, except for liposarcoma in offspring with parental bladder cancer and leiomyosarcoma in offspring with parental breast cancer.

CLINICAL PRESENTATION

Although the incidence of soft tissue sarcomas increases exponentially with age, these tumors become a less common portion of total cancers as age progresses, representing ~3% of tumors in the fourth decade of life compared with ~7% of pediatric cancers. Consequently, soft tissue sarcomas are relatively more common during adolescence and young adulthood. In the European study of ~13 million inhabitants, the most common locations for sarcomas (including visceral sarcomas and excluding Kaposi sarcomas) based on the US age-standardized rate per 100,000 person-years were the lower extremity (1.02), trunk wall (0.67), retroperitoneum (0.63), and stomach (0.61).[32] In a retrospective study of 2.6 million insured patients in the German federal state of Saxony, the 1-year relative survival proportion for soft tissue sarcomas was ~88% (95% CI: 80–93%, $n = 1{,}468$ cases) and ~66% (95% CI: 56–76) for relative 5-year survival.[35]

KAPOSI SARCOMA

Kaposi sarcoma is a malignant, cutaneous, or oral mucosal mesenchymal tumor affecting blood and lymphatic vessels. This Kaposi sarcoma herpesvirus-associated (previously known as human herpesvirus type 8, HHV8) tumor manifests most commonly as pink, red, purple, or brown-black skin lesions. Rarely, this cancer develops in the digestive or respiratory systems (i.e., <4%).[36] Originally, this tumor was a rare, indolent disease of elderly Mediterranean and Eastern European descendants in Greece, Italy, and the Middle East, usually with a family history of susceptibility (classic Kaposi sarcoma). Kaposi sarcoma was endemic in South Africa and portions of Sub-Saharan Africa, particularly in men (endemic Kaposi sarcoma).[37] With the onset of AIDS in Western countries, this disease was one of the initial AIDS-defining clinical illnesses along with *Pneumocystis carinii* pneumonia, esophageal/pulmonary candidiasis, tuberculosis, and toxoplasmosis.[38] Currently, most cases are associated with immunosuppression (HIV, solid-organ transplant patients).

In an analysis of data from the European RARECARE project, the age-adjusted annual incidence of Kaposi sarcoma was 0.3/100,000 inhabitants, with the highest incidence in Southern Europe (0.8/100,000).[36] Kaposi sarcoma is the most common malignancy associated with HIV infection. Although HIV infection is neither a necessary nor sufficient condition for the development of Kaposi sarcoma, the presence of HIV increases the incidence and clinical aggressiveness of this tumor.[39]

CARCINOGENESIS

Hyperplasic polyclonal lesions composed primarily of spindle cells from lymphoid endothelia develop from the stimulation of proinflammatory cytokines and growth factors (e.g., basic fibroblast growth factor, interleukin 6, tumor necrosis factor α, vascular endothelial growth factor). Viral oncogenes contribute to the proliferation of these lesions, particularly HHV8, which has a tropism for endothelial cells, keratinocytes, and lymphocytes. Although the presence of this virus is relatively low (i.e., ~10%) in early Kaposi sarcoma, ~90% of the spindles of endothelial cells in the nodular stage contain HHV8 DNA or RNA.[40,41] Immune dysregulation produces various cytokines and growth factors that promote tumor

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

growth, including FGF2 (fibroblast growth factor 2), interleukin 6, platelet-derived growth factor, oncostatin M, platelet-derived growth factor, transforming growth factor-β, tumor necrosis factor α, and VEGF (vascular endothelial growth factor).[39]

EXPOSURE

The most important conditions for the development of Kaposi sarcoma involve viral oncogenesis by the Kaposi sarcoma-associated herpesvirus (human herpesvirus-8, HHV8) and cytokine-induced inflammation/proliferation along with some immune suppression. The prevalence of HHV8 infection is high in homosexual men depending on the number of sexual partners; Kaposi sarcoma is independently associated with HHV8.[42] This tumor occurs infrequently in Western women correlating with the relative rarity of HHV8 infections, whereas the male/female ratio is similar in Africa, where HIV is primarily a heterosexually transmitted disease. The incidence of Kaposi sarcoma has declined substantially in Western countries with the advent of highly active antiretroviral therapy.[43]

Several case-control studies suggest BMI may influence soft tissue carcinoma risks. In an Italian study of 217 incident soft tissue sarcomas and 1,297 hospital controls, the soft tissue sarcoma risk for BMI $\geq 30\,kg/m^2$ was increased (OR = 3.28, 95% CI: 1.61–6.69, $n = 33$ cases/172 control cases) using BMI $\leq 20\,kg/m^2$ as controls.[44] The potential for misclassification with self-reported weight, the lack of cohort studies, and the use of hospital controls limit conclusions regarding causation.

HISTOLOGY

The primary histological process in the formation of Kaposi sarcomas is the symmetric, multicentric proliferation of atypical lymphatic and blood vessels. The patch stage is the initial pattern that manifests as a macular lesion consisting of small, irregular endothelium-lined spaces surrounding normal dermal vessels along with an inflammatory lymphocytic infiltrate.[45] Expansion of spindle-cell vascular processes during the plaque stage produces irregular, cleft-like vascular channels containing erythrocytes and hemosiderin deposits along with a perivascular inflammatory infiltrate. As sheets of spindle cells with cytological atypia expand into a network of slit-like vascular spaces, nodules appear during the nodular stage.

CLINICAL PRESENTATION

The clinical course of Kaposi sarcoma is highly variable, ranging from a single indolent lesion to an aggressive, multifocal systemic disease producing widespread hemorrhage and/or organ dysfunction, particularly in AIDS or immunosuppressed solid-organ transplant patients.[46] Classic Kaposi sarcoma is a chronic disease that most commonly affects elderly Mediterranean, European, or Jewish men (10–15 men/1 women, 6th decade of life); the tumor manifests as multiple firm reddish-brown and purple plaques and nodules on the lower extremities, sometimes associated with lymphedema and hyperkeratosis. The clinical course of endemic African, iatrogenic, immunosuppressive, and AIDS-related Kaposi sarcoma is much more variable, ranging from chronic nodular cutaneous lesions to fulminant lymphadenopathic disease rapidly disseminating to visceral organs.[39] Spontaneous remission may occur in iatrogenic Kaposi sarcoma following the cessation of immunosuppressive therapy. Kaposi sarcoma has a relatively good prognosis depending on location, age, and comorbidity; the overall 5-year relative survival rate for all sites in the European RARECARE project was 75% ($n = 1{,}795$ tumors) compared with 25.3% ± 17.1% ($n = 27$ tumors) for digestive system Kaposi sarcomas.[36] The survival rate has improved significantly with the advent of highly active antiretroviral therapy.

LEIOMYOSARCOMA

Leiomyosarcomas are a relatively common type of soft tissue sarcoma that occurs throughout the body; however, the most common are leiomyosarcomas of the uterus. Uterine leiomyosarcomas appear genetically distinct from tumors in other locations.[47,48] Most uterine neoplasms are benign leiomyomas, with leiomyosarcomas representing ~0.1–1% of uterine neoplasms. The annual incidence of uterine leiomyomas is ~0.35/100,000 women, with the incidence about 2-fold higher in black than white women.[17]

CARCINOGENESIS

Leiomyosarcomas usually display complex karyotypes with numerous chromosomal losses and gains.[49] Currently, no single driver gene has been identified. Leiomyosarcomas display a highly heterogeneous genomic landscape with frequent abnormalities in tumor suppressor (*TP53*, *RB1*, *PTEN*) and early development (*ATRX*, *MED12*) genes. Overall, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mutational load is relatively low in leiomyosarcomas. The most common genetic changes involve alteration of *TP53* and *MDM2* expression (minichromosome maintenance complex component 2, regulation of helicase activity and genome replication), enhancement of *CDKN2A* (cyclin-dependent kinase inhibitor 2A, p16), and inhibition of λ-smooth muscle isoactin expression.[50] Consistent chromosomal losses include the *PTEN* tumor suppressor via deletions at chromosome 10q23, resulting in hyperactivation of phosphatidylinositol 3-kinase/AKT pathway involved with cell-cycle and apoptosis regulation.[51] Although overexpression of cell-cycle regulatory and apoptotic genes occurs in leiomyosarcoma tumors, other signaling pathways may be important in tumor progression, including the interferon-γ pathway and mutations of the *PSMB9* gene (proteasome 20S subunit beta 9).[52]

EXPOSURE

Leiomyosarcomas are primarily sporadic with no clearly established risk factors reflecting the rarity of these tumors and the difficulty in identifying risk factors in very rare cancers. A pooled analysis of data collected from the Epidemiology of Endometrial Cancer Consortium identified 82 leiomyosarcomas and 28,829 controls.[53] Using polytomous logistic-regression models adjusted for age, race, BMI, menarche, menopausal status, estrogen/progesterone use, smoking, and diabetes, none of the estimated odds ratios for studied risk factors reached statistical significance, including BMI ($P_{trend} = 0.26$), age at menarche ($P_{trend} = 0.44$), or parity ($P_{trend} = 0.12$). The highest odds ratios were reported for diabetic history (OR = 1.91, 95% CI: 0.77–4.77, $n = 10$ cases/1,583 controls, $P_{heterogeneity} = 0.65$), estrogen-only menopausal therapy (OR = 1.63, 95% CI: 0.18–14.95, $n = 6$ cases/2,878 controls, $P_{heterogeneity} = 0.97$), and obesity ≥30 kg/m^2 (OR = 1.56, 95% CI: 0.88–2.77, $n = 23$ cases/4,932 controls, $P_{heterogeneity} = 0.39$). Firm conclusions on causality are restricted by large confidence intervals and limited power. Very rare case reports associate radiotherapy with the subsequent occurrence of leiomyosarcoma;[54] these tumors are too rare to detect elevated risks in the Life Span Study of atomic bomb survivors.

HISTOLOGY

Although most leiomyosarcomas are sporadic, occasional case reports suggest leiomyosarcomas may develop in initially benign leiomyomas; however, distinguishing benign leiomyomas from leiomyosarcomas may be difficult because no single clinical or imaging criterion separates the two neoplasms.[55] These tumors display distinct features of smooth muscle cells. Leiomyosarcomas characteristically are large, soft intramural masses with infiltrative borders, atypical/elongated nuclei, multiple mitotic figures, abundant eosinophilic cytoplasm, and areas of necrosis.

CLINICAL PRESENTATION

Common locations for leiomyosarcomas include the abdomen, retroperitoneum, large blood vessels, and the uterus, with the latter accounting for the majority of these tumors. Overall, leiomyosarcoma incidence increases with age peaking in the seventh decade, whereas most uterine leiomyosarcomas appear in women over 40 years of age with the incidence rapidly increasing over the age of 50 years.[56] The typical uterine leiomyosarcoma patients present with vaginal bleeding, uterine pain/pressure, and a palpable pelvic mass; rarely, hypercalcemia and eosinophilia occur.[57] These aggressive tumors are relatively chemotherapy- and radiotherapy-resistant, resulting in poor survival in advanced stages of the disease. Prognosis depends on tumor size/depth, histological type, and clinical stage. In a follow-up study (median = 9 years) of 71 patients with histologically proven uterine leiomyosarcoma, the overall survival rate was 65%, ranging from 75% for International Federation of Obstetrics and Gynecology (FIGO) Stage I to 14% for Stage II, and 0% for Stages III–IV.[58]

LIPOSARCOMA

Liposarcomas are the most common soft tissue histological type representing ~1/5 of all soft tissue sarcomas with five main subtypes involving: 1) atypical lipomatous tumors/well-differentiated; 2) dedifferentiated; 3) myxoid/round-cell; 4) pleomorphic; and 5) mixed-type. The first two subtypes account for 40–50% of liposarcomas. Well-differentiated and dedifferentiated liposarcomas occur primarily in the retroperitoneum, whereas the extremities are the main location for myxoid and pleomorphic liposarcomas. Well-differentiated and myxoid liposarcomas are low-grade tumors; high-grade tumors include dedifferentiated and pleomorphic liposarcomas.

An analysis of the genomic landscape using SNP arrays and whole-exome sequencing identified known amplified genes (*CDK4*, *HMGA2 MDM2*) and novel genes (*CPM*, *ERBB3*, *IGF1R*, *IGF2*, *LAMA4*, *MIR557*,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

UAP1) along with deletions of chromosome 1p (*RUNX3*, *ARID1A*), chromosome 11q (*ATM*, *CHEK1*), and chromosome 13q14.2 (*MIR15A*, *MIR16-1*).[59] Affected signaling pathways include ErbB, JAK-STAT, MAPK, and Wnt, involving axon development, apoptosis, cell-cycle regulation, and DNA damage repair. Most myxoid and round-cell liposarcomas contain t(12;16) or t(12:22) translocations that produce fusion proteins affecting adipocyte differentiation via the PPARγ (peroxisome proliferator-activated receptor γ) and CEBP proteins (CCAAT-enhancer-binding proteins).[60]

RHABDOMYOSARCOMA

Rhabdomyosarcomas are the most common soft tissue tumors in children and young adults; these tumors are usually high-grade, locally invasive, commonly metastasizing tumors, resulting in poor survival without chemotherapy.[61] These tumors represent 1 of the 10 most common childhood malignancies, with an annual incidence for children and adolescents (< 20 years of age) of 0.004.3 cases/100,000 young population in the United States (i.e., ~350 incident cases/year).[62]

CARCINOGENESIS

Rhabdomyosarcoma is a heterogeneous disease with genetic alterations varying with histological type and age (i.e., children vs. adults). A majority of childhood tumors have the t(2;13)(q35;q14) translocation that fuses the *PAX3* gene (paired box 3) with the *FOXO1A* gene; the former is a transcriptional regulator of embryonic neuromuscular development, whereas the latter is a transcription factor from the forkhead family involved with myogenic growth and differentiation. A less frequent translocation is t(1;13)(p36;q14) that fuses *PAX7* gene (paired box 7) with *FOXO1A* gene; the former is a tumor suppressor involved with fetal development, regulating muscle precursor cell proliferation.[63] The presence of reciprocal translocations and associated fusion genes characterizes the alveolar rhabdomyosarcoma subtype, whereas embryonal rhabdomyosarcomas typically contain gene mutations, copy number changes (chromosomal losses/gains), and allelic losses frequently activating the RAS signaling pathway.[64] Approximately ¼ of childhood alveolar rhabdomyosarcomas contain no translocations.

Common pathways implicated in rhabdomyosarcoma development include nuclear factor-kappa B (NF-κB), YAP (Yes-associated protein 1) transcriptional coactivator, and Hippo, Notch, Wnt, and MEK/ERK signaling pathways.[65] The YAP and Hippo signaling pathways maintain tumor proliferation and antidifferentiation in embryonal rhabdomyosarcomas, while upregulation of Notch signaling and crosstalk with Hedgehog, Hippo, TGF-β, and Wnt pathways inhibit differentiation and promote self-renewing tumor cells.[66,67] In alveolar rhabdomyosarcoma, PAX3/7-FOXO1 fusion genes promote tumorigenesis by suppressing the Hippo signaling pathway and inhibiting myogenic differentiation of tumor cells.[68] Epigenetic changes include deregulation of the NFκB-YY1-induced downregulation of miR-29 tumor suppressor activity.[69]

EXPOSURE

Rhabdomyosarcomas are primarily sporadic with no established risk factors; however, a few rare familial syndromes predispose family members to developing rhabdomyosarcomas. The rarity of these tumors limits studies on environmental, occupational, and lifestyle risk factors.

HISTOLOGY

Although the precise cell of origin is unknown, rhabdomyosarcomas arise from primitive progenitor cells of striated skeletal muscle resembling small, round, blue-cell tumors (desmoplastic, small round-cell, lymphoma, Ewing sarcomas) characteristic of embryonic myogenesis.[1] Rhabdomyosarcomas occur in a variety of anatomical sites other than skeletal muscle. A substantial majority of these tumors stain positive for myoglobin, muscle-specific actin, and polyclonal desmin.[70] Subtype classifications of rhabdomyosarcoma include embryonal, alveolar, botryoid, pleomorphic, and anaplastic; the former two subtypes account for the vast majority of rhabdomyosarcomas in children, whereas the latter three are primarily adult tumors.[65] Embryonal rhabdomyosarcoma displays no distinct architecture, with sheets/nests of typical rhabdomyoblasts and occasional fusiform cells usually appearing in the head, neck, and urogenital regions of infants and young children. The alveolar subtype resembles pulmonary alveoli with fibrovascular septae lined with densely packed tumor cells separated by pseudoalveolar spaces; the latter histological subtype typically occurs in the extremities and parameningeal sites of adolescents.[64] Botryoid rhabdomyosarcomas form hypercellular subepithelial tissue in grape-like polypoid masses lined by epithelium of hollow viscera, usually in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. young children; pleomorphic rhabdomyosarcomas contain intersecting storiform whorls of large spindle cells with irregular, hyperchromatic nuclei and prominent nucleoli.

HOST SUSCEPTIBILITY

Noonan syndrome and related disorders, Costello syndrome, and cardiofaciocutaneous syndrome are a group of developmental malformation syndromes resulting from dysregulation of the RAS/mitogen-activated protein kinase (MAPK) signaling pathway. This pathway mediates early and late developmental processes by controlling cell proliferation, differentiation, senescence, and apoptosis. In a review of 77 peer-reviewed articles reporting 84 cancer patients with these syndromes, 42 patients had Noonan syndrome and 31 had Costello syndrome.[71] Rhabdomyosarcoma was the most common cancer accounting for 1/3 of malignant tumors, primarily Costello syndrome (22 cases) and Noonan syndrome (5 cases).

CLINICAL PRESENTATION

Most children with rhabdomyosarcoma present with local disease manifested by a painless mass surrounded by erythema.[72] Metastatic disease most frequently occurs in the lungs and bones. Although rhabdomyosarcomas can occur in any part of the body, the most common sites include the head and neck (35–40%), genitourinary tract (25%), and extremities (20%). Survival depends on clinical stage, age, site of origin, and histological subtype. The overall 5-year survival rate for rhabdomyosarcoma in children is relatively good (i.e., ~70%) compared with adults (i.e., <18%).[73] In an analysis of prognostic factors for nonmetastatic rhabdomyosarcoma from the Intergroup Rhabdomyosarcoma Studies III/IV, the 5-year failure-free survival rate ranged from 90% for embryonal RMS Stage 1 or 2, group I (localized disease, completely resected) or group IIa (resected tumor with microscopic residual) to 43% in stage 2 or 3 and group III (incomplete resection with gross residual disease) extremity primary tumors.[74] The 5-year survival rate for stage 4 (distant metastatic disease present at onset) is ~30% similar to group III alveolar or undifferentiated sarcoma subtype of rhabdomyosarcoma.[1] In general, the alveolar subtype with the PAX3–FOXO1 fusion genes is more aggressive and at higher risk with a poor prognosis,[75] whereas the embryonal subtype has an intermediate prognosis and the botryoid subtype has a relatively good prognosis.[76]

UNCOMMON SOFT TISSUE SARCOMAS

AGGRESSIVE FIBROMATOSIS

Aggressive fibromatosis (dermoid tumor) is a monoclonal, collagen-forming neoplasm consisting of myofibroblast-like cells. This tumor is locally invasive and occasionally multifocal but rarely metastatic. Although these tumors are rare, aggressive fibromatosis occurs much more commonly in patients with familial adenomatous polyposis;[77] susceptibility to this tumor in patients with familial adenomatous polyposis is associated with an inactivating germline APC gene mutation on chromosome 5q21–q22. Gardner syndrome is a variant of this inherited disease characterized by epidermal cysts, fibromas, intestinal polyposis, osteomas, and sebaceous cysts. Estrogen-related conditions (pregnancy, oral contraceptives) and trauma are suggested risk factors; however, epidemiological evidence of an association is weak and conflicting.[78,79] The most common genetic abnormality in aggressive fibromatosis is a somatic mutation in *CTNNB1* (catenin β1, chromosome 3p21) gene associated with the Wnt/β-catenin signaling pathway affecting cell adhesion and intercellular communication.

Fibrosarcomas are classified as superficial and deep (aggressive or desmoid) types. Superficial fibromatosis neoplasms are smaller, indolent, and lack the somatic β-catenin or mutation in gene *APC*; they develop in knuckles, palm, sole, and penis of predominately Caucasian adult males. Deep (aggressive, desmoid) fibrosarcomas occur in any anatomical location with distinct subsets in the abdominal wall and abdomen (mesentery, retroperitoneum). Extra-abdominal aggressive fibromatosis develops in the proximal extremities, thigh muscles, chest wall, and head and neck of young adults, particularly women.[80] Histologically, the tumor consists of long fascicles of myofibroblasts in parallel with uniform spacing and a hypocellular collagenous stroma; pleomorphism and necrosis are lacking. The typical clinical presentation is a slow-growing, painless plaque or firm, discrete mass with pressure-like symptoms depending on the location. Prognosis is generally good following complete excision of the tumor; however, recurrence may occur.

DERMATOFIBROSARCOMA PROTUBERANS

Dermatofibrosarcoma protuberans is a malignant fibroblastic skin cancer that is the most common

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. cutaneous sarcoma.[81] The overall annual incidence is 0.004/100,000 inhabitants with a similar incidence between men and women; the incidence is ~2-fold higher in blacks than whites.[82] These rare tumors typically present as an asymptomatic, indurated, slowly growing plaque that may be flesh-colored or hyperpigmented.[83] Histological examination at this stage demonstrates minimal nuclear atypia, low cellularity, and rare mitotic figures. The subsequent nodular stage consists of firm, brown to reddish-blue or violaceous nodules formed by storiform islands of bland spindle cells, myxomatous areas, less-differentiated foci, and hyperchromatic, deeply lobulated nuclei. Over 90% of these tumors contain t(17;22)(q21;q13) translocations resulting in PDGFB (platelet-derived growth factor subunit B)–COL1A1 (collagen type I alpha 1 chain) fusion gene. This genetic alteration enhances the production of platelet-derived growth factors and the activation of multiple signaling pathways affecting cell differentiation, movement, and proliferation. The absence of the PDGFB–COL1A1 fusion gene in ~8% of these tumors suggests other abnormalities may be involved, including epigenetic (e.g., miRNA-205 downregulation)[84] and genomic alterations (e.g., overexpression of p-ERK, p-STAT3, and thrombospondin-1 proteins).[85] Although dermatofibrosarcoma protuberans can present at any age, the peak incidence occurs between 25–45 years of age on the trunk (40–50%), proximal extremities (30–40%), and head/neck (10–15%).[81] Although this low-grade tumor is locally aggressive and may recur after incision, metastasis is rare. Survival is excellent after complete removal with a 2-year survival rate of 97% and a 5-year survival rate of 92%.[86]

GASTROINTESTINAL STROMAL TUMORS

Gastrointestinal stromal tumors (GIST) are the most common mesenchymal tumor of the gastrointestinal tract, with an annual incidence of ~0.015/100,000 inhabitants and a similar incidence between men and women. GIST comprise ~20% of soft tissue sarcomas.[87] In 2001, these tumors were the first neoplasms targeted by a cell surface tyrosine kinase receptor inhibitor (i.e., imatinib mesylate) to block the main initiating driver gene mutations KIT and PDGFRA.

CARCINOGENESIS

Early genomic changes in the vast majority (i.e., 75–90%) of gastrointestinal stromal tumors (GIST) involve KIT mutations (*KIT* proto-oncogene receptor tyrosine kinase, chromosome 4q12-exon 11 juxtamembrane domain). The remaining 10–25% of GIST are KIT-negative; overall, up to ~5–7% of GIST have mutations in *PDGFRA* (platelet-derived growth factor receptor α, chromosome 4q12) without KIT mutations, particularly in children with GIST.[88,89] Mutations in *KIT* and *PDGFRA* genes are mutually exclusive. Figure 62.1 displays the chromosomal location of sporadic, hereditary, and secondary gene mutations in GIST. KIT gene mutations produce a protein that activates downstream proliferative and antiapoptotic signaling pathways (mitogen-activated protein kinase, MAK; phosphoinositide-3-kinase, PI3K) without requiring binding to the stem cell factor protein. These pathways increase cell growth, survival of interstitial cells of Cajal, and GIST formation; however, the presence of mutations in *KIT* genes in up to 1/3 of healthy patients without progression to malignancy indicates KIT mutations alone are not sufficient to produce malignant cells.[90] Additionally, a relatively large pool of micro-GIST exists in the general population, providing a reservoir for the development of more advanced neoplasms.[87]

The wild-type, triple-negative tumors (*KIT*/*PDGFRA*/*SDH*-negative) are a heterogeneous group with some tumor development driven by oncogenic mutations downstream of receptor kinases. Alternative potential oncogenic events include activation of mutations in *BRAF* or *RAS*-family genes (*HRAS*, *KRAS*, *NRAS*) along with inactivation of tumor suppressor *NF1* gene (neurofibromin 1). The wild-type GIST (children/adults) usually contains succinate dehydrogenase (SDH) deficiency from inactivation of *SDHA/B/C/D* genes, particularly in younger patients with Carney triad or Carney–Stratakis syndrome.[87] Whole-exome sequencing suggests advanced GIST samples contain a low mutation tumor burden with genomic aberrations mostly affecting tumor suppressor *CDKN2A/B*, *RB1*, and *TP53* genes and copy loss involved with cell-cycle regulation.[91] This study also suggested that a minority of advanced GIST contain mutations in spliceosome-regulating genes (*PRPF18*, *RBMX*, *RBMXL3*, *SF3A2*, *SNRP200*, *U2AF2*). Chromosomal alterations associated with the progression of malignant GIST include deletions of 1p, 9p (*CDKN2A* gene, 9p21.3), 14q, and 22q, particularly tumor suppressors in chromosome 9p, whereas gains in chromosomes 8q and 17q are associated with increased metastasis.[92]

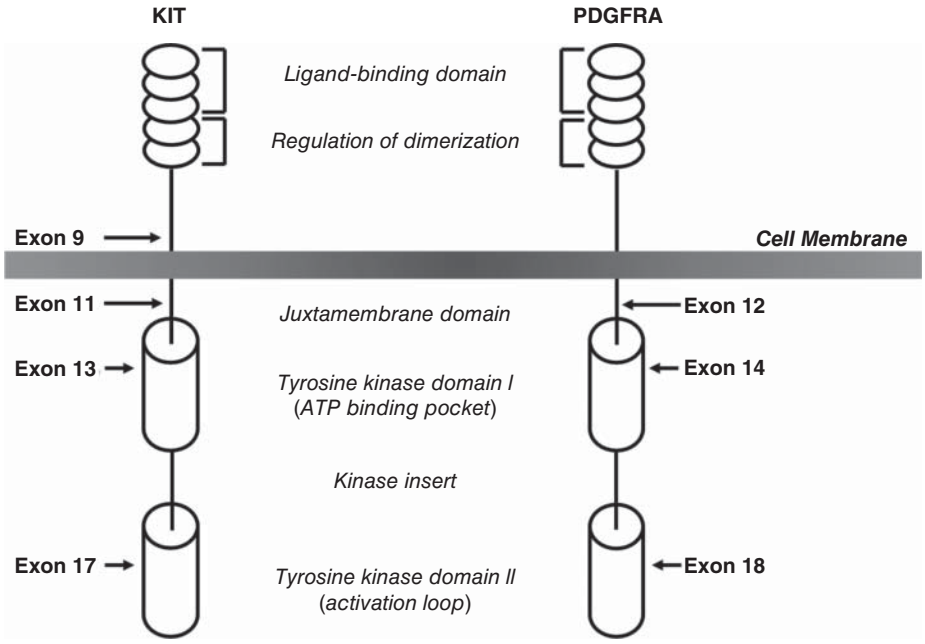

FIGURE 62.1. Schematic view of the locations of mutations in *KIT* (*KIT* proto-oncogene receptor tyrosine kinase) and *PDGFRA* (platelet-derived growth factor receptor alpha) genes in gastrointestinal stromal tumors (GIST). These mutations are mutually exclusive in GIST. The vast majority of GIST contains more of the former than the latter. KIT mutations with PDGFA mutations are much less frequent. Some mutations are sporadic (*PDGFRA* exon 12/18, *KIT* exon 11), whereas a few are hereditary (*PDGFRA* exon 12, *KIT* exon 8/11) or some secondary (*KIT* exon 9/13/14/15/16/17, *PDGFRA* exon 14/18). (Adapted from Joensuu et al.).[87]

EXPOSURE

GIST are primarily sporadic with no established risk factors; however, a few rare familial syndromes predispose family members to the development of GIST. The rarity of these tumors limits study power sufficient to identify environmental, occupational, and lifestyle risk factors.

HISTOLOGY

Most GIST probably originate or share common stem cells with interstitial cells of Cajal located in the outer surface of the gut; these c-*KIT*-positive fibroblast-like cells between intramural neurons and smooth muscle cells regulate peristalsis and the gastrointestinal autonomic nerve system.[88] Previously, these tumors were included with gastrointestinal leiomyosarcomas and schwannomas. Over one-half of GIST occurs in the stomach, ~1/3 in the small intestine, and the remainder in other portions of the gastrointestinal tract (colon and rectum, <5%; esophagus, <1%) and intra-abdominal soft tissue (e.g., retroperitoneum).[93] GIST display diverse histology ranging from small intramural or serosal nodules to large masses with hypocellularity to highly hypercellularity.[94] Histological subtypes include spindle cell, epithelioid, and mixed spindle-epithelioid with a large majority being spindle cell.[95] GIST with mutations in the *PDGFRA* gene typically develop in gastric and omental locations; the neoplasms display cystic, hemorrhagic tumors containing pleomorphic, low-mitotic count epithelioid/plasmacytoid cells with peripheral nuclei in myxoid stroma.[96] GIST with SDH mutations are multinodular/dumbbell-shaped tumors with mucosal ulcerations; histologically, these neoplasms contain fibrous bands in nodules of epithelioid or mixed cells usually with lymphovascular invasion and lymph node metastases.

HOST SUSCEPTIBILITY

Familial GIST results from hereditary mutations in *KIT*/*PDGFRA* genes; rare syndromes include Carney triad (gastric GIST, paraganglioma, pulmonary chondroma), Carney–Stratakis syndrome, and neurofibromatosis type 1 (von Recklinghausen's neurofibromatosis). Heritable mutations occur in *KIT* exon 8, 11, 13, or 17, resulting in increased susceptibility to gastric and small bowel GIST in young adults, whereas germline mutations in *PDGFRA* exon 12 predispose family members to GIST and stomach/small bowel inflammatory fibroid polyps. Patients with Carney's

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

triad or Carney–Stratakis syndrome do not have mutations in *KIT* or *PDGFRA* genes. Germline mutations in these patients involve subunits of tumor suppressor succinate dehydrogenase genes (*SDHA*, *SDHB*, *SDHC*, *SDHD*) important in the Krebs cycle and oxidative phosphorylation.[97] Succinate is an intracellular oxygen sensor that stabilizes hypoxia-inducible factor (HIF) and stimulates cell growth in low-oxygen environments. Von Recklinghausen's neurofibromatosis patients with GIST typically are KIT-negative, with <10% of these patients developing GIST.[98,99] Familial GIST accounts for an estimated <0.1% of GIST.[94]

CLINICAL PRESENTATION

Although GIST may develop at any age, the vast majority (i.e., >80%) of cases present over the age of 50 years, with the peak incidence occurring in the sixth to seventh decades of life (median = 60–65 years).[94,100] Clinical manifestations of GIST are diverse, with the clinical course varying from small, indolent nodules to metastatic, life-threatening sarcomas depending on location, type, and stage. Overall, gastrointestinal bleeding and gastric discomfort are the most common features reflecting the stomach as the most common GIST location. Intestinal obstruction, perforated bowel, and hemoperitoneum are rare presenting signs of GIST.[101] Occasional nonspecific symptoms include constipation, diarrhea, dyspepsia, nausea/vomiting, polyuria, and fatigue. Up to ~1/3 of GIST are discovered incidentally during imaging or surgical procedures.[88] GIST have variable malignant potential with prognosis depending on tumor size, mitotic rate, and location. The metastatic risk of small gastric GIST (<5 cm) with low mitotic count is small (3–5%) with a good prognosis. However, the metastatic risk is high for large, intestinal GIST with high mitotic rates. The most common metastases develop in the liver, omentum, and peritoneum, with extra-abdominal metastasis being uncommon.[102]

SYNOVIAL SARCOMAS

Synovial sarcomas are high-grade tumors usually affecting pediatric and young adult patients. The peak incidence occurs in the third decade with 90% appearing before 60 years of age.[103] Although unrelated to synovium, the name of these tumors reflects their resemblance to synovial cells. Histologically, synovial sarcomas display a wide, heterogeneous histological spectrum, characteristics of epithelial cells. Monophasic synovial sarcomas are pure spindle cell tumors, whereas biphasic synovial sarcomas contain spindle cells and epithelioid morphologies. The vast majority of synovial sarcomas have the t(X;18)(p11.2;q11.2) translocation producing the *SS18-SSX* fusion oncogene that inhibits SSX family-induced transcriptional repression. Affected signaling pathways are not well defined.

Synovial sarcomas occur predominantly in older children and young adults at a variety of anatomic sites including viscera. These tumors frequently present as large masses in deep soft tissue associated with local pain/tenderness in extremities, particularly the proximal or middle portions of the lower extremities; cutaneous lesions are rare.[104] Synovial sarcoma is usually a high-grade, aggressive sarcoma with an overall 5-year survival of ~60% and 10-year survival of ~50%.[105]

BONE SARCOMAS

Bone and articular cartilage cancers are rare, accounting for ~0.5% of all human cancers; these tumors may arise from any bone, cartilage, soft tissue, or organ. A retrospective study of 2.6 million insured patients in the German federal state of Saxony identified 671 bone sarcoma cases with approximately equivalent distribution of cases between males and females.[35] The age-adjusted annual bone sarcoma incidence was 2.1/100,000 (95% CI: 0.8–4.8) with ~48% over 50 years of age. Although the incidence of these cancers remains relatively stable, mortality from these tumors has increased in the last few decades. The three main bone neoplasms are osteosarcomas, Ewing sarcomas, and chondrosarcomas. Ewing sarcoma is a disease of childhood and adolescence, whereas osteosarcoma has a bimodal peak in childhood and the eighth decade of life. Chondrosarcoma is primarily a disease of the elderly; these tumors are a heterogeneous group of neoplasms that develop in benign cartilage abnormalities (e.g., enchondroma, osteochondroma). Ollier disease and Maffucci syndrome are rare, nonhereditary disorders associated with the development of multiple, benign enchondromas and susceptibility to the transformation of these neoplasms into chondrosarcomas.[106]

With the exception of Ewing sarcoma, ionizing radiation is the strongest risk factor, particularly bone-seeking radionucleotides (e.g., cesium, plutonium, radium). The attributable incidence of bone sarcomas in the workplace is essentially zero because of the rarity and limited potency of this tumor at typical occupational exposures.[107] A Finnish study identified 20 bone sarcomas from data in the Finnish Cancer Registry 1953–2000

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

covering 1.5 million person-years in a cohort of 295,712 primary cancer patients, mostly in patients ≥55 years of age.[24] The only statistically significant increase in SIR for bone sarcoma in radiotherapy patients was in women <55 years of age (SIR = 3.0, 95% CI: 1.2–6.1, $n = 7$ cases), as displayed in Table 62.3; however, the comparison of radiotherapy and non-radiotherapy patients for this subgroup was not statistically significant. The Life Span Study cohort of 80,180 Japanese atomic bomb survivors identified 19 bone-tissue sarcomas with a mean bone marrow radiation dose of 0.43 Gy and a mean latency period between exposure and diagnosis of 29.2 years.[108] Using a linear dose-response model to estimate bone sarcoma risks, the excess relative risk was 7.5/Gy (95% CI: 1.34–23.14) above the threshold dose of 0.85 Gy; the excess absolute risk was 5.75/Gy above the threshold based on an annual incidence of 0.9/100,000 person-years. Rare, hereditary disorders associated with increased bone sarcomas include Mendelian-dominant Li–Fraumeni Syndrome (mutations) in *TP53* autosomal-dominant Retinoblastoma Syndrome (mutations in *RB*), and autosomal-recessive Werner Syndrome (WRN mutation, Werner syndrome RecQ-like helicase).[109] Osteosarcomas and Ewing sarcoma are relatively more common during the second and third decades of life, whereas the incidence of chondrosarcomas increases steadily with age. In a retrospective German study of 2.6 million insured patients in Saxony, the 1-year relative survival proportion for bone sarcomas was ~92% (95% CI: 81–99%, $n = 671$ cases) and ~53% (95% CI: 36–69) for relative 5-year survival.[35]

OSTEOSARCOMA

Osteosarcoma is the most common primary malignant bone tumor, affecting primarily children and adolescents and representing ~5% of childhood cancers (i.e., ~400 US cases/year).[110] The age-adjusted incidence of this rare, high-grade tumor is ~0.005/100,000 population, with half the cases occurring in 10–24-year-old patients.[111] The bimodal distribution peaks in adolescence, followed by a plateau at 25–60 years of age and then a small peak in elderly individuals.[112] Overall, ~900 incident osteosarcoma cases occur in the United States annually. Osteosarcoma varies little with race or gender; the overall male/female ratio is ~1.4:1, except in patients over 60 years when the ratio is near unity.[110] Worldwide, osteosarcoma incidence rates are generally stable.[113]

CARCINOGENESIS

The mutational landscape of osteosarcomas is highly complex; the highly disorganized osteosarcoma genome contains extensive intratumoral heterogeneity with a high rate of somatic mutations (1.2 mutations/megabase) compared with other pediatric tumors. Characteristic features of osteosarcomas include copy number losses/gains, structural variation, increased mutation numbers, and genomic instability. In contrast to Ewing sarcoma, these tumors have no consistent pattern of specific chromosomal translocations, single driver genes, or molecular defects.

Commonly mutated genes in osteosarcomas include the *TP53* and *RB1* tumor suppressor genes along with genes associated with the Notch (*HEY1*, *HES1*, *NOTCH2*), Wnt/β-catenin, and PI3K-mTOR signaling pathways. Notch proteins are important for angiogenesis and normal bone development/homeostasis, whereas the Wnt/β-catenin pathway affects cell growth, normal bone development, and carcinogenesis. The PI3K family of serine/threonine protein kinases regulates the cell cycle, growth, and development. These three pathways are upregulated in osteosarcomas.[112] Long telomeres are common in osteosarcoma; altered lengthening of telomeres that prevents telomere shortening and induces senescence may enhance genomic instability.[114] Epigenetic changes (promotor DNA hypermethylation/hypomethylation, histone modification, long/micro noncoding RNAs) associated with osteosarcomas occur, but the role of these alterations in promoting osteosarcoma formation is not well defined.[115,116]

EXPOSURE

Although most osteosarcomas are sporadic, a few risk factors increase osteosarcoma risks, including radiotherapy, anthracyclines, and alkylating chemotherapeutic agents (e.g., cyclophosphamide, nitrogen mustards). Overall, reproductive risk factors, tobacco smoking, chemicals, diet, and bone trauma are not associated with increased osteosarcoma risks, with the possible exception of early onset of puberty and tall stature;[117] the association between the latter and osteosarcoma is conflicting.[118,119]

Ionizing Radiation

Exposure to ^{226}Ra and ^{228}Ra radionuclides is a well-established cause of osteosarcoma, beginning

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with US female watch dial workers in the 1920s and continuing through the regrowth of the luminous dial industry leading up to World War II.[120] The intravenous diagnostic radiocontrast agent, Thorotrast® (^{232}Th) available from 1930–1955, was also causally associated with osteosarcoma.[121] High-dose therapeutic radiation including treatment of tuberculosis arthritis in the 1920s (e.g., total doses, 50 Gy).[118] The very low radiation doses used in medical imaging (e.g., chest X-rays, CT scans) are not associated with increased osteosarcoma risks.[122]

Occupation

Limited data support an association specifically between farming and osteosarcomas. A retrospective Norwegian study of data on 323,292 offspring followed by 17 years examined incident cancers based on the national agricultural census; bone cancer was not significantly increased in the offspring of farmers (SIR = 122, 95% CI: 83–172, $n = 32$ cases) compared with the total rural population (SIR = 113, 95% CI: 84–149, $n = 51$).[123] Exposure classification was based on information obtained during the agricultural census. A positive association not suspected *a priori* was between parental chicken farming and osteosarcoma in offspring (aRR = 2.90, 95% CI: 1.38–6.11, $n = 12$ cases). Adjustment included birth and calendar year. The specific exposure associated with chicken farming was not identified.

Environmental

Although several ecological studies suggest osteosarcomas are associated with drinking water fluoride concentrations,[124] observational studies are inconsistent and relatively weak.[125,126] A New York study estimated lifetime fluoride exposure from tablets, mouth rinses, toothpaste, dental treatments, and drinking water based on self-reports and population-based estimates of tap water intake.[127] Using the lowest quartile of fluoride intake as referents, childhood osteosarcoma risk in the highest quartile of total fluoride intake was inverse and statistically nonsignificant (OR = 0.41, 95% CI: 0.14–1.22, $n = 27$ cases/17 controls). Comparing the highest tertile of fluorinated water intake with nonexposed referents, the childhood osteosarcoma risk in the highest tertile was consistent with the null (OR = 0.93, 95% CI: 0.31–2.83, $n = 16$ cases/21 controls, $P_{trend} = 0.62$).

Diseases

Several benign conditions that increase bone turnover are associated with increased osteosarcoma risks, including Paget disease, osteochondroma, enchondroma, fibrous dysplasia, and chronic osteomyelitis. Older adults with Paget disease are particularly susceptible to osteosarcoma. An analysis of data from the National Cancer Institute's population-based Surveillance, Epidemiology, and End Results (SEER) Program identified 3,482 incident osteosarcoma cases from 1973–2004.[128] Of 653 osteosarcoma patients in the 60 years and older category, Paget disease patients represented 34% (62 primary tumors, 159 secondary tumors) of the 653 elderly osteosarcoma patients compared with 12% (4 primary tumors, 115 secondary tumors) of the 974 osteosarcoma patients in the 25–59-year-old category and 4% (1 primary tumor, 70 secondary tumors) of the osteosarcoma patients in the ≤24-year-old category.

HISTOLOGY

Osteosarcomas arise from primitive bone-forming mesenchymal cells that produce a broad spectrum of histological appearances. Classic osteosarcoma subtypes include chondroblastic, fibroblastic, and osteoblastic, reflecting the predominant type of matrix present in the tumor; these three subtypes account for ~70–80% of osteosarcomas. The remaining histological variants are very rare, including low- and high-grade surface, parosteal and periosteal, small cell, and telangiectatic osteosarcomas.

HOST SUSCEPTIBILITY

Certain rare genetic disorders predispose patients to osteosarcomas; however, primary bone cancer is not strongly associated with germline mutations or increased familial risks. A small percentage of osteosarcomas result from germline mutations of important tumor suppressor and helicase genes. Rare genetic conditions with germline mutations associated with increased osteosarcoma risks include Li–Fraumeni syndrome (tumor suppressor TP53 mutations), hereditary retinoblastoma, the autosomal-recessive Bloom and Werner syndromes (BLM mutations, BLM RecQ-like helicase), autosomal-recessive Rothmund–Thomson syndrome (RECQL4 mutation, RecQ-like helicase 4), and nonhereditary McCune–Albright syndrome (GNAS1 somatic mutation, GNAS complex

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

locus).[129,130] For the highly penetrant, autosomal dominant Li–Fraumeni syndrome, osteosarcoma is a sentinel cancer, with ~70% of Li–Fraumeni syndrome families with a strong history harboring a pathogenic variant of the *TP53* tumor suppressor gene.[131] The cumulative incidence of osteosarcoma in individuals with a germline *TP53* pathogenic variant ranges from 5–11%.[132] A Swedish study of histology-specific bone cancer familial risks in offspring using parental or sibling probands identified 1,327 offspring bone cancers.[133] Only two parent–offspring pairs and one sibling pair had concordant bone cancer; however, the standardized incidence ratios were not statistically significant. The risk of developing osteosarcoma prior to 25 years of age was increased in mothers with melanoma and breast cancer, suggesting Li–Fraumeni syndrome may partly account for the familial association.

CLINICAL PRESENTATION

Osteosarcoma has a bimodal age distribution with the first peak appearing in 10–14-year-olds during the pubertal growth spurt and the second peak in older adults (>65 years). The latter peak commonly occurs in patients with Paget disease or in the transformation of other benign bone lesions.[134] The peak age for these osteosarcomas is the eighth decade. Malignant bone tumors rarely occur prior to 5 years of age. Patients typically present with indolent course of several months of localized bone pain often following trauma; anorexia, fatigue, and weight loss are uncommon. Some osteosarcoma patients have localized swelling and reduced range of motion in the affected extremity; however, few have pathological fractures at the time of presentation.[135] The most common tumor sites are long bones (i.e., ~75%) near metaphyseal growth plates, including the distal femur (knee), proximal tibia, and less frequently the proximal humerus. The tendency to affect extremity bones decreases with increasing age.[136] Metastasis at presentation occurs in ~10–20% of osteosarcoma patients; however, recurrence rates are high (i.e., ≥80%) in patients with localized disease at diagnosis and no subsequent chemotherapy.[137] The lungs are the most common site of metastasis, with involvement of lymph nodes and bone much less frequent.[138] The overall 5-year survival rate is ~60–70%, with complete local resection and multi-agent chemotherapy depending on age, clinical stage, anatomical site, and osteosarcoma subtype, whereas the presence of metastasis at diagnosis is associated with an ~30% 5-year survival.[139] Prior to the 1970s, when surgical resection was the primary treatment, the overall 5-year survival rate was ~20%.[140]

EWING SARCOMA

Ewing sarcomas are very rare and highly malignant, most common bone sarcomas, affecting predominately adolescent and young adult Caucasians. The incidence is higher in males than females; however, the tumor can occur at any age and develop in soft tissue. The overall incidence of Ewing sarcomas is ~0.13/100,000 with little change during the last several decades.[141] Significant differences exist in the pattern of Ewing sarcoma between races; the highest incidence occurs in Caucasians with a 2-fold lower incidence in Asians/Pacific Islanders and a 9-fold lower incidence in African Americans. The estimated age-standardized incidence among children from 1988–1997 was similar for boys and girls aged 0–14 years (0.005–0.006/100,000 population).[142] Among adolescents aged 15–19 years, males had a higher incidence (~0.02/100,000 population) than females (ratio = 1.8/1). An estimated 390 Ewing bone sarcomas and 170 Ewing soft tissue sarcomas occur annually in the United States.[143]

CARCINOGENESIS

This heterogenous tumor has characteristic translocations that produce fusion genes between the *TET*/*FET* (*TLS*/*FUS*, *EWSR1*, *TAF15*) and the *ETS* (E26 transformation-specific) gene families, as demonstrated in Figure 62.2. Typically, fusion genes contain a DNA-binding domain combined with a transcription or growth factor.[144] The vast majority (85–90%) of Ewing sarcomas contain the reciprocal translocation t(11;22)(q22;q12) between *EWSR1* gene (EWS RNA binding protein 1; chromosome 22q12.2) and *FLI1* gene (*FLI-1* proto-oncogene, ETS transcription factor; chromosome 11q24.3); together they produce the EWSR1/FLI1 fusion protein. This fusion protein possesses DNA-binding function of the FLI protein and the transcription regulatory function of the EWS protein. The remaining tumors contain translocations that fuse the *EWSR1* gene with other genes, including the *ETS* gene (*ETS* proto-oncogene family of DNA-binding transcription factors; chromosome 11q24.3), the *FEV* gene (FEV transcription factor, ETS family member; chromosome 2q35), and the *ERG* gene (ETS transcription factor ERG; chromosome 21q22.2). These fusion genes may promote stem cell development, cell senescence, and tumor proliferation; however, the exact function of these fusion genes is not well established. The frequency of mutations in the *TP53* gene is low. Epigenetic changes in Ewing sarcomas

include *SIRT1* (sirtuin 1)-induced suppression of Notch signaling.

EXPOSURE

Most Ewing sarcomas are sporadic. Small sample sizes limit evaluation of risk factors associated with a rare tumor-like Ewing sarcoma; most studies are case-control, ecological, or descriptive with self-reported exposures. Large cohort studies are difficult to conduct.

Occupation

Several small case-control studies suggest the parental occupation of farming is associated with Ewing sarcomas in offspring; however, the results are inconsistent with imprecise risk estimates. A study of pooled data from 3 case-control studies identified 199 Ewing sarcoma family of tumor (ESFT) cases and 1,451 population-based controls. The odds ratio was positive and statistically significant for a paternal occupation in agriculture (farm owner or laborer) and ESFT in the offspring (OR = 2.3, 95% CI: 1.3–4.1, $n = 19$ cases/61 controls). Although the trend for duration of paternal farming was statistically significant ($P_{\text{trend}} = 0.01$), paternal farming for 1–9 years was not associated with increased ESFT risks (OR = 0.9, 95% CI: 0.4–1.9, $n = 8$ cases/46 controls). The adjusted odds ratio for maternal farming and ESFT in offspring was also positive (aOR = 3.9, 95% CI: 1.6–9.9, $n = 8$ cases/16 controls). Adjustment for the odds ratio included maternal occupation, age, maternal education, and study site.

Environmental

Little epidemiological evidence associates fluoride concentration in water with increased Ewing sarcoma risks. A UK ecological study on water fluoridation and data on Ewing sarcoma risks from population-based cancer registries in England, Scotland, and Wales in 1980–2005 identified 1,650 Ewing sarcoma cases in inhabitants aged ≤49 years. After adjustment for covariates and using negative binomial regression, Ewing sarcoma was not associated with drinking water fluoride concentrations ($P = 0.503$). The relative risk for Ewing sarcoma following a 1-ppm increased fluoride concentration in drinking water was 0.929 (90% CI: 0.773–1.115). The geographical variation in fluoride concentrations did not correlate with Ewing sarcoma risks. A systematic review of water fluoridation and bone cancer risks identified 9 studies comprising 20 separate analyses of bone cancers.[145] Only one study reported excess bone cancers; however, the heterogeneity of outcome measures prevented pooling of the data for meta-analysis.

HISTOLOGY

Subtypes of the Ewing sarcoma family include Ewing sarcoma of bone, extraosseous Ewing sarcoma, peripheral primitive neuroectodermal tumor, and Askin tumor (Ewing sarcoma of chest wall). Classic Ewing sarcoma is a malignant, small, round cell bone tumor that comprises diffuse sheets or rosettes of uniform cells with round nuclei, fine chromatin, and inconspicuous nucleoli along with scanty, indistinct cytoplasm and occasional necrotic areas; morphological variants include spindled, sclerosing, and clear cell/anaplastic subtypes.[146,147] The cells are round to oval, closely packed, small, undifferentiated cells.

HOST SUSCEPTIBILITY

Familial syndromes are not strongly associated with Ewing sarcomas. In a study of data on 1,327 offspring bone cancers in the nationwide Swedish Family-Cancer Database, Ewing sarcoma was not associated with increased familial risks.[133] Using parents as probands, the SIR for childhood Ewing sarcoma was 1.0 (95% CI: 0.6–1.5, $n = 20$ cases). The SIR for Ewing sarcoma in parents with kidney cancer was positive but statistically nonsignificant (SIR = 2.2, 95% CI: 0.7–5.2, $n = 5$ cases).

CLINICAL PRESENTATION

Ewing sarcoma is a group of highly aggressive tumors primarily of the long bones (i.e., ~80%) and much less of soft tissue tumors in other organs, occurring predominantly in adolescents and young adults; cure rates are low with metastatic potential high for spread to lung and other bones and organs.[148] The peak incidence occurs in 10–20-year-olds, with the rare occurrence of this tumor in patients over 35 years of age. The most common presenting symptom is bone pain for several months and, less commonly, soft tissue swelling and fever. These tumors usually develop in long bones in the lower extremities (femur, tibia) and less commonly in the pelvis, humerus, and ribs. Most cases have localized disease at diagnosis; however, recurrence is common without chemotherapy. Prognosis depends on clinical stage (i.e., metastasis at diagnosis), tumor size (≥8 cm/≥200 mL), and location (i.e., axial vs. appendicular skeleton).[149] A study of 1,631 Ewing sarcoma cases from the US Surveillance, Epidemiology, and End Results (SEER) database reported an overall disease-specific survival rate of 55% at 5 years and 53% at 10 years.[141] Analysis of the SEER database 1991–2010 indicated the 10-year cause-specific survival was ~67% for local disease at diagnosis compared with 28% for patients with metastatic disease.[139]

Chapter 63

THYROID

In the United States, thyroid cancer is the 6th most common cancer in women and 14th most common in men, with a current total annual estimated incidence of ~52,000 cases.[1] The overall annual thyroid cancer incidence almost tripled (~3% annually) from 4.9 to 14.3/100,000 individuals during the last 2 decades of the 20th century and the 1st decade of the 21st century.[2,3] In a cross-sectional study of individuals below 20 years of age using data from the US Surveillance Epidemiology and End Results (SEER) database, the average percentage increase for overall thyroid cancer incidence in this pediatric age group from 1973–2006 was 1.11% (95% CI: 0.56–1.67%) and 9.56% (95% CI: 5.09–14.22%) for 2006–2013.[4] These differences in incident rates were primarily driven by increased diagnostic imaging and surveillance, particularly papillary thyroid cancer.[5,6] Since then, some evidence suggests the rates are currently stabilizing.[7] Based on data from the US Surveillance Epidemiology and End Results (SEER) Program, the 5-year age-standardized incidence rate for thyroid cancer is ~2.5–3-fold higher in women (21.6/100,000) than men (7.3/100,000).[1,8]

Globally, thyroid cancer is the most pervasive endocrine tumor, with ~255,000 incident cases and ~41,000 deaths in 2017 based on epidemiological data gathered by the Global Health Data Exchange query tool covering 195 countries.[9] In this cross-sectional study, the estimated annual percentage change in age-standardized thyroid cancer incidence for the preceding 27 years was 1.59% (95% CI: 1.51–1.67%). Females accounted for 70% of the age-standardized incidence of thyroid cancer. In the United States, the prevalence of thyroid cancer (i.e., ~900,000 cases) is much higher than the incidence, reflecting the excellent prognosis for this cancer.[10] Worldwide, the mortality rate from thyroid cancer has remained stable for the last four decades.[11] This tumor is the most common endocrine tumor representing over 90% of endocrine cancers and 3.4% of cancers diagnosed annually worldwide. In the United States the 5-year survival rates for thyroid cancer exceed 98%.

CARCINOGENESIS

Substantial differences exist in the genetic alterations associated with the various histological types of thyroid cancer, particularly between follicular and medullary thyroid cancers. The mutation in the *BRAF* gene (*BRAF* proto-oncogene) and the mutant $BRAF^{v600E}$ serine/threonine kinase gene appear during the initiation of 50–70% of papillary thyroid cancers (PTC) and papillary-derived anaplastic thyroid cancers. Mutations of the *RAS* family of oncogenes more frequently occur in follicular than papillary or anaplastic thyroid tumors, as displayed in Table 63.1.[12,13] The *BRAF* oncogene is part of the RAS–MAPK pathway that relays signals downstream to regulate the expression of genes responsible for cell proliferation, differentiation, and apoptosis. Mutations in the *BRAF* gene are mutually exclusive with RET/PTC rearrangements and most other common genetic alterations.[14] The mutations in *BRAF* genes are associated with genetic instability and a poorer prognosis (local recurrence, metastasis,

TABLE 63.1. Common somatic gene mutations and rearrangements in histological types of thyroid follicle-derived tumors listed as a percentage of total tumor samples from various pathology case series. (Adapted from Carling and Udelsman).[19]

Genetic Alteration	Papillary (%)	Follicular (%)	Poorly Differentiated (%)	Anaplastic (%)
		Mutations		
BRAF	29–70	0	0–13	0–12
CTNNB1	0	0	0–25	66
RAS	0–21	40–53	18–27	20–60
TP53	0–5	0–9	17–38	67–88
		Rearrangements		
NTRK1	5–13	—	—	—
PPARG	0	25–63	0	0
RET/PTC	13–36	0	0–13	0

Abbreviations: BRAF = B-type Raf kinase; *CTNNB1* = β-catenin 1; *NTRK1* = neurotrophic receptor tyrosine kinase 1; *PPARG* = peroxisome proliferator-activated receptor γ; *PTC* = papillary thyroid cancer; *RET* = *RET* proto-oncogene.

advanced clinical stage).[15] All thyroid tumors with mutations in $BRAF^{V600E}$ are considered malignant.[16] RET/PTC is an interchromosomal rearrangement of an oncogene common in papillary thyroid cancer that produces an activated serine/threonine kinase, resulting in stimulation of the RAS–RAF–MAPK signaling cascade.[17] In a mutational analysis of 72 papillary thyroid carcinomas, mutations in $BRAF^{V660E}$ occurred in 38 (44.4%) of the tumors compared with 26 (36.1%) with RET/PTC rearrangements; 22 (30.5%) contained neither genetic alteration.[18] These chimeric oncoproteins develop almost exclusively in papillary thyroid cancers.

The *RAS* family of GTP-binding proteins regulates cell growth via the MAPK and PI3K–AKT pathways. The most frequent mutations in *RAS* genes in order of the most common are first *NRAS*, *HRAS*, and *KRAS*, primarily occurring in poorly differentiated, anaplastic, and medullary thyroid cancers. Mutations in *NRAS* genes preferentially activate the PI3K–AKT pathway, whereas mutations in *KRAS* genes are preferential activators of the MAPK pathway. Mutations in *RAS* act upstream of mutations in *BRAF* genes; the two mutations are usually mutually exclusive.[14] Mutations in *RAS* genes and PAX8/PPARγ (PPARG) rearrangements are mutually exclusive and the primary oncogenic drivers in follicular thyroid cancers.[16] These two genetic alterations are not specific and occur in both follicular thyroid carcinomas and adenomas, although at a lower rate in the latter.[12]

Most early thyroid cancer mutations affect three main signaling pathways: 1) RAS–RAF–MEK–MAPK (mitogen-activated protein kinase) pathway that helps regulate cell proliferation by transmitting growth signals from the plasma membrane to the nucleus; 2) calcium–calmodulin pathway that produces an important component of calcium-mediated cellular signal transduction; and 3) the PI3K–AKT–mTOR pathway that is essential for protein synthesis, development, cell proliferation, and cell survival.[20] Most of the mutations in oncocytic thyroid carcinoma (Hürthle cell carcinoma) involve the mTOR signaling pathway. RAS mutations and RET/PTC rearrangements also stimulate the growth of benign thyroid nodules without excess transformation into malignant neoplasms;[21,22] these benign thyroid nodules grow faster with than without these genetic alterations.[23]

Novel fusion oncogenes occurring during the initial stage include the *PAX8*-peroxisome proliferator-activated receptor λ (PPARλ) translocation in follicular thyroid tumors and the RET (*RET* proto-oncogene) chromosomal rearrangement in papillary thyroid carcinomas.[24] Although most thyroid cancers harbor mutations in *BRAF* genes remain indolent, the presence of a mutation in *BRAF* gene is associated with a more advanced tumor stage at diagnosis and worse prognosis (higher recurrence/mortality).[25] More aggressive tumors also develop alterations of the PI3K–AKT–mTOR pathway associated with cell development, cell proliferation, and survival; inactivation of the TP53 tumor suppressor pathway; and antiapoptotic mutations in *TERT* genes causing reactivation of telomerase reverse transcriptase.[26,27] The latter is a catalytic protein subunit of telomerase

important for maintenance of chromosomal integrity and genomic stability. Mutations in *TERT* promoter genes typically do not occur in benign thyroid nodules and are uncommon in papillary thyroid cancers, whereas the prevalence of these mutations in poorly differentiated and anaplastic thyroid cancers usually exceeds 40%.[28]

MiRNAs are a group of >2,000 small, noncoding RNAs that have key roles in posttranscription gene regulation by repressing or degrading mRNA in the cytosol and altering gene expression. Most alterations of miRNAs involve downregulation rather than upregulation, which is usually associated with a less differentiated state.[29] Compared with normal thyroid tissues, overexpression of miRNAs-146b, miRNA-221, and miRNA-222 is associated with increased papillary thyroid tumor progression (local recurrence, metastasis, $BRAF^{V600E}$ mutation).[30,31] In a Chinese study of 36 papillary thyroid cancer tumors and 15 benign thyroid nodular goiter samples, the presence of miRNA-30-3p, miRNA-146b-5p, and miRNA-199b-5p was statistically different in the two tissues.[32] MiRNA-30-3p was downregulated, whereas the other two miRNAs were upregulated. The genes associated with these miRNAs remain unclear.

EXPOSURE

The main risk factor for thyroid cancer is ionizing radiation, particularly papillary thyroid cancer in children exposed to high-dose therapeutic or external radiation at doses from 0.1–60 Gy.[33] Other risk factors include benign thyroid diseases, iodine deficiency, and family history of thyroid cancer. Currently, epidemiological studies indicate electromagnetic field exposures and cell phone use are not associated with increased thyroid cancer risks. In a US study of 462 thyroid cancer cases and 498 population-based controls using multivariate unconditional logistic regression to estimate odds ratios, the OR for thyroid cancer in cell phone users was 1.05 (95% CI: 0.74–1.48) using nonusers as referents. The study reported no statistically significant association with cumulative cell phone use.[34] A Swedish study of ~3 million workers followed for 19 years reported no association between extremely low-frequency magnetic fields and thyroid cancer based on three job-exposure matrices.[35] Few epidemiological data indicate lifestyle is a significant risk factor for thyroid cancer; several studies suggest a modest positive association between BMI and thyroid cancer risks and an inverse association with smoking. Current smoking produces a modest dose-dependent reduction in thyroid cancer risks, particularly for papillary thyroid cancer, with the risk in former smokers approaching never-smoker risks within several years of cessation.[36,37]

Ionizing Radiation

Ionizing radiation is a well-established cause of thyroid cancer from radioactive fallout (e.g., post-Chernobyl radioiodine release, Japanese atomic bomb survivors) and high-dose cervical radiotherapy, particularly following radiation exposure during childhood. Thyroid cancer was the first solid tumor associated with an increased incidence among Japanese atomic bomb survivors.[38] Analysis of pooled data from 5 cohort (Japanese atomic bomb survivors, children treated for *Tinea capitis*, enlarged tonsils or thymus) and 2 case-control (cervical cancer, childhood cancer) studies involving ~120,000 participants covering ~3 million person-years identified almost 700 incident thyroid cancers.[39] For children of <15 years of age, the best fit for the data was a linear dose-response curve down to 0.1 Gy, with the curve beginning to level off at >10 Gy based on limited data at the high doses. The excess relative risk/Gy for thyroid cancer in these children was 7.7 (95% CI: 2.1–28.7) reflecting small sample sizes and imprecise estimates. Although the excess risk persisted for 30–40 years, the risk was small 20 years after exposure and depended strongly on the age at exposure. Only two cases occurred within 5 years of initial radiation exposure. Similarly, the minimum latency period for diagnosis of thyroid cancers following the Chernobyl accident was 4–5 years; however, minimum latency postradiation time periods in most studies are 5–10 years with the highest risks in the 10–15-year time period and diminishing risks after 20 years' postexposure.[33]

Radiotherapy

A pooled analysis of thyroid cancer incidence in 2 cohort and 2 nested case-control studies involving radiotherapy for 16,757 patients treated for childhood cancers identified 187 incident primary thyroid cancers.[40] The excessive relative risk of thyroid cancer followed a linear exponential model through 10 Gy, then leveled before declining at >30 Gy. The peak estimated RR was 14.9 (95% CI: 8.2–24.5) at 15.9 Gy. The estimated RR at 1 Gy was 3.2 (95% CI: 2.2–5.3) compared with 8.7 (95% CI: 3.1–29.7) at 1 Gy in the Ron et al. study.[39] The Childhood Cancer Survivor Study identified 119 subsequent thyroid cancers in cancer patients living at least 5 years after treatment.[40] The dose-response relationship

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

between a second primary thyroid cancer and radiation dose followed a linear exponential quadratic model with the relative risk peaking at ~20 Gy before declining; the peak RR was 14.6 (95% CI: 6.8–31.5). Sex (risk ↑ in females), time since exposure, and age at exposure (risk ↑ with younger age at exposure) were significant modifiers of radiation-induced thyroid cancer risks. The overall mean initial radiation dose was 11.3 Gy (range, 0–67.3 Gy). Chemotherapy administration did not confound the association between radiation and subsequent primary thyroid cancer risks.

A Portuguese study followed children receiving radiation therapy for *Tinea capitis* from 1950–1963 until 2012.[41] For children administered radiation doses of 3.25–4.75 Gy (325–475 R), the SIR for subsequent thyroid cancer was 2.93 (95% CI: 2.13–3.94, $n = 36$ female/8 male cases) compared with 4.05 (95% CI: 1.09–10.4, $n = 4$ female/0 male cases) for children receiving ≥6.3 Gy (630 R). An Israeli study examined thyroid cancer risks in 10,834 children receiving relatively low radiation doses (mean = 0.093 Gy; range, 0.0045–0.495 Gy) for *T. capitis*. During a median follow-up of 46 years (range, 1–54 years), the study identified 159 thyroid cancers. The peak ERR/Gy was 20.2 (95% CI: 11.8–32.3) with the value increasing during the second decade after exposure, peaking during the third decade, and decreasing dramatically during the fourth decade after exposure.

Environment

Chernobyl Nuclear Power Plant

The Chernobyl nuclear power plant accident produced the largest, uncontrolled environmental release of radioactive material by a civilian operation; the explosion and fire affected Southern Belarus, four oblasts (states) of the Russian Federation, and Northern Ukraine. High thyroid doses resulted from the ingestion of short-lived ($t^{½} = 8$ days) ^{131}I-contaminated milk among children;[42] external environmental radiation exposure was relatively low except for cleanup and emergency workers. The first thyroid cancer cases presented 4–5 years postexposure, primarily in children exposed at age ≤10 years. By 2005, over 6,800 cases of thyroid cancer were reported by UNSCEAR (United Nations Scientific Committee on the Effects of Atomic Radiation) in children from contaminated areas under 18 years of age, with most of these children being under 14 years of age; 15 fatalities were associated with these cases.[43] Little epidemiological evidence supports an increased thyroid cancer incidence in adults or children born after the Chernobyl accident. Although initially these mostly (i.e., 95%) papillary thyroid tumors were considered more aggressive than sporadic cases, subsequent studies indicated the high rates of recurrence (30%) and metastases (60–70% cervical lymph nodes, 10–15% distant) with low mortality (<1%) reflecting age at onset and solid papillary thyroid cancer histology rather than radiation-induced effects.[44,45]

Some studies suggest the genetic alterations in radiation-induced and sporadic thyroid cancer differ. In targeted next-generation sequencing and RNA-Seq on 65 papillary thyroid cancers from the Ukrainian-American cohort of children exposed at <18 years of age, driver mutations consisted of 26.2% point mutations and 70.8% fusion genes.[46] Novel driver fusion genes included POR-BRAF (cytochrome p450 oxidoreductase-*BRAF* proto-oncogene, serine/threonine kinase) and *STRN-ALK* (striatin-ALK receptor tyrosine kinase) alterations. The point mutations appeared at lower radiation doses (mean = 0.2 Gy; range, 0.013–1.05 Gy) than fusion genes (mean = 1.4 Gy; range, 0.009–6.15 Gy). The percentage of fusion genes increased to 87.8% in tumors receiving radiation doses of ≥0.3 Gy. In contrast, sporadic papillary thyroid cancers are driven primarily by point mutations. Chromosomal rearrangements are not unique to radiation-induced papillary cancers.

Fukushima Daiichi

The Japanese Fukushima Daiichi Nuclear Power Plant accidentally released 900 pBq of radiation (500 pBq ^{131}I, 10 pBq ^{137}Cs) from March 10–13, 2011; these doses represent 10% and 30% of the radiation doses released during the Chernobyl nuclear reactor explosion and fire, respectively.[47] The 2013 UNSCEAR report estimated the absorbed thyroid dose in Fukushima residents ranged from 0.047–0.083 Gy and higher in non-evacuated residents (0.036–0.795 Gy),[48] whereas the 2012 WHO report estimated a range of 0.1–0.2 Gy.[49] Although an ecological study done on 2-phase screening of 300,476 (81.7% participation rate) Fukushima residents of ≤18 years of age between October 2011 and March 2014 and a 2nd round of 270,489 (70.9% participation rate) residents between May 2014 and March 2016 suggests an increased thyroid cancer incidence,[50] further studies are necessary because of insufficient follow-up times (minimum latency: 4–5 years) and the difficulty separating prevalence and incidence.

Marshall Islands BRAVO Atmospheric Nuclear Test

On March 1, 1954, a 15-megaton nuclear weapons test heavily contaminated the inhabitants of four atolls east

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of Bikini Island in the northern Pacific Ocean with nuclear fallout from radioactive iodides (^{131}I, ^{131}I isotopes) and external γ radiation. Thyroid cancer risks and radiation exposure estimates are uncertain; however, the fallout delivered high-dose radiation based on the high incidence of acute radiation sickness in residents of Rongelap Atoll and the subsequent high incidence of thyroid nodules in Marshall islanders followed from 1954–1985.[51] Almost all Marshall islanders had thyroidectomies in the United States; hence, the true thyroid cancer incidence is unclear. Ecological studies of fallout from the Nevada Test Site have not associated the relatively low radiation doses with elevated thyroid cancer risks.[52]

Occupation

Occupations potentially exposed to ionizing radiation include radiologists and radiology technologists, particularly interventional radiologists, nuclear industry and disaster cleanup workers, military personnel in weapon production and testing, underground miners, plutonium and reactor fuel manufacturing workers, airline pilots (UV radiation), and radium-dial painting (historical). Although childhood ionizing radiation exposure is a well-recognized thyroid cancer risk factor, the association of thyroid cancer with low–moderate occupational ionizing radiation exposures in adults is less clear.

Chernobyl cleanup workers (liquidators) received external radiation exposure from radioactive materials deposited on the ground and building surfaces, particularly in the 30-km Chernobyl zone in 1986. These mostly male workers represented approximately half of the recovery workers during 1986–1991. A study of a Ukrainian cohort of 150,813 male liquidators identified 196 incident thyroid cancer cases; the mean age at exposure was the early 30s.[53] The overall SIR was 3.50 (95% CI: 3.04–4.03) compared with 3.86 (95% CI: 3.26–4.57) for liquidators' first cleaning in the Chernobyl zone in 1986.

The Nordic Occupational Cancer Project collected occupational data and 2.8 million incident cancer cases from 15 million inhabitants from Denmark, Finland, Iceland, Norway, and Sweden aged 30–64 years based on self-administered census information from 1960–1990 and follow-up for 45 years.[54] Thyroid cancer risks in various occupations were modest and inconsistent. These risks were highest in Iceland and were attributed in part to differences in diagnostic criteria. Table 63.2 lists the statistically significant increases in the standardized incidence ratio for thyroid cancer in specific occupations based on the census data; none of the comparisons

TABLE 63.2. Statistically significant standardized incident ratios (SIRs) for thyroid cancer in occupations of 15 million men and women covered by the Nordic Occupational Cancer Project (NOCP). For comparison, the SIRs for both men and women in occupations with statistically significant increases were included; none of the comparisons in the same occupations were positive and statistically significant for both men and women. (Adapted from Pukkala et al.).[54]

Occupation (Sex)	Standardized Incidence Ratio	95% CI	Observed Thyroid Cases
Fishermen (male)	1.32[a]	1.07–1.62	93
Fishermen (female)	1.22[a]	0.33–3.12	4
Public safety workers (male)	1.25[a]	1.04–1.50	112
Public safety workers (female)	0.71	0.34–1.30	10
Clerical workers (male)	1.20[a]	1.06–1.35	264
Clerical workers (female)	0.92	0.88–0.97	1,538
Farmers (male)	0.95	0.88–1.02	639
Farmers (female)	1.18[a]	1.07–1.30	420
Teachers (male)	1.15[b]	1.00–1.32	199
Teachers (female)	0.99	0.91–1.07	566
Building caretakers (male)	1.10	0.87–1.38	75
Building caretakers (female)	1.08[a]	1.01–1.15	827

[a] Statistically significant. [b] Marginally significant statistically. *Abbreviation*: CI = Confidence Interval.

between men and women for the same occupation were both positive and statistically significant. In a review of 30 studies including thyroid cancer risks in various occupations, the most consistent associations existed between thyroid cancer and radiation-exposed workers or healthcare occupations (primarily direct interaction with X-ray technology). The associations with pesticide-exposed workers and agricultural occupations were suggestive but inconsistent.[55] Exposure classifications were generally subject to misclassification and wide estimates based on small sample sizes and exposures based on self-reports, occupational categories, or generic job-exposure matrices. Most of the statistically significant associations in the Nordic study were not supported by the review; the Nordic study did not report any increased thyroid cancer risks in healthcare occupations.

In the US Radiologic Technologists cohort of 89,897 members following a mean of 21 years, the mean cumulative occupational thyroid radiation dose was 0.057 Gy (range, 0–1.6 Gy) based on self-reports, historical data, and individual film badge measurements when available.[56] Using Poisson regression to estimate excess relative thyroid cancer risks, the adjusted ERR/0.1 Gy was −0.05 (95% CI: <−0.10 to 0.34, $n = 476$ cases). Adjustments included age, sex, birth year, body mass index, and pack-year smoking. Similarly, the US Radiologic Technologists Study did not report a significant association between thyroid cancer incidence and fluoroscopically guided interventional procedures.[57] Using Cox proportional hazard models and never-working with these procedures as referents, the adjusted hazard ratio for thyroid cancer was 0.91 (95% CI: 0.61–1.38, $n = 32$ ever/96 never cases).

Reproduction

The several-fold higher risk of thyroid cancer in women and the excess thyroid cancer risk during reproductive years suggest reproductive history, menstruation, and/or estrogen status may affect thyroid cancer risks; however, epidemiological studies do not support a strong role for these factors in the etiology of thyroid cancer. The European Prospective Investigation into Cancer and Nutrition (EPIC) study reported no association between differentiated thyroid cancer risks and age at menarche or menopause, menopausal status, breastfeeding, or parity.[58] Although a positive Cox proportional hazards regression model indicated a positive association between thyroid cancer risks and infertility problems, a recent pregnancy, and surgical vs. natural menopause, the authors opined that enhanced surveillance may account for some or all of the increased risks. The Japan Public Health Center-Based Prospective Study of 54,776 women aged 40–69 years identified 187 incident thyroid cancers.[59] Using Cox proportional hazard regression modeling, analysis indicated an inverse association between age at menarche and thyroid cancer risks for premenopausal women (HR = 0.83/1-year increase, 95% CI: 0.70–0.98, $P_{trend} = 0.03$), but not postmenopausal women. The association was positive for surgical vs. natural menopause (HR = 2.34, 95% CI: 1.43–3.84). In a meta-analysis of 24 prospective studies including 5,434 thyroid cancer cases, thyroid cancer was not associated with age at menarche, oral contraceptive use, or parity.[60] Surgical menopause (summary RR = 1.43, 95% CI: 1.15–1.78) and increasing age at first pregnancy/birth (sRR = 1.56, 95% CI: 1.01–2.42) were positively associated with thyroid cancer risks.

Obesity

Some case-control and prospective studies suggest a modest positive association between obesity and differentiated thyroid carcinomas, primarily papillary thyroid cancer in women.[61,62] The European Prospective Investigation into Cancer and Nutrition (EPIC) cohort of ~370,000 women and ~150,00 men aged 35–69 years followed for 5.4 million person-years used Cox proportional hazard models to estimate hazard ratios and BMI of 18.5–24.9 kg/m^2 as referents.[63] The HR for differentiated thyroid cancer in obese participants (BMI ≥ 30 kg/m^2) was modestly positive but statistically nonsignificant in women (HR = 1.19, 95% CI: 0.89–1.59, $n = 66$ cases, $P_{trend} = 0.057$) and unrelated (HR = 0.40, 95% CI: 0.13–1.19, $n = 4$ cases, $P_{trend} = 0.449$) in men. Comparisons of tertiles of waist circumference and waist-to-hip ratio were similar to the BMI values in women (positive, nonsignificant) and men (no association). In a pooled analysis of 5 US prospective studies involving 413,979 women and 434,953 men followed for a mean of 10.3 years, the study identified 768 thyroid cancers in women and 388 thyroid cancers in men.[64] The hazard ratio for obese men and women combined was 1.53 (95% CI: 1.31–1.79) using normal weight (18.5–24.9 kg/m^2) as referents. BMI was positively associated with baseline age in women but not in men. The multivariable-adjusted HR for thyroid cancer per 5-kg/m^2 increase in BMI was positive and nonsignificant in men (aHR = 1.21, 95% CI: 0.97–1.49, $I^2 = 54.3\%$, $P_{heterogeneity} = 0.09$) and positive and significant in women (aHR = 1.16, 95% CI: 1.08–1.24, $I^2 = 0\%$, $P_{heterogeneity} = 0.48$).

Medications

Interpretation of epidemiology studies on the association of thyroid cancer with chemotherapy use is complicated by the frequent use of combined chemotherapy, the attenuation of chemotherapy-associated risks with increasing radiation doses and conflicting results. In a pooled analysis of data from two cohort and two case-control studies on thyroid cancer in childhood cancer survivors using patients without chemotherapy or radiation treatment as referents, the overall RR for developing thyroid cancer in patients treated with chemotherapy was positive but statistically nonsignificant (RR = 2.4, 95% CI: 0.5–12.3); the estimated RR was imprecise.[40] Similarly, the RR for thyroid cancer following the use of alkylating agents was 3.2 (95% CI: 0.8–12.8) and 3.1 (95% CI: 0.9–10.9) for bleomycin. The RR for anthracyclines was positive and statistically significant (RR = 4.5, 95% CI: 1.3–15.7) but imprecise. The P_{trend} for increasing quartiles of 5-Gy radiation doses on decreasing thyroid cancer risks in chemotherapy patients was statistically significant for alkylating agents ($P_{\text{trend}} = 0.01$) and bleomycin ($P_{\text{trend}} = 0.11$) but not for overall chemotherapy ($P_{\text{trend}} = 0.01$) or anthracyclines ($P_{\text{trend}} = 0.12$).

HISTOLOGY

Most thyroid nodules are small, nonpalpable nodules often identified during routine imaging studies. Over 90–95% of these nodules do not progress to cancer.[65] The histological classification of thyroid cancer consists of a heterogeneous group of three well-differentiated subtypes (papillary, follicular, medullary), poorly differentiated, and anaplastic.[66] Papillary, follicular, and some anaplastic subtypes arise from follicular cells, whereas medullary thyroid cancer is a rare neuroendocrine tumor originating in parafollicular C cells. The latter produces calcitonin rather than thyroid hormones. Traditionally, Hürthle cell carcinoma was considered a variant of follicular thyroid cancer and included with follicular thyroid cancer in studies; however, recent evidence suggests the biological behavior and genetic alteration of the two tumors differ.[67] The World Health Organization (WHO) now classifies Hürthle cell carcinoma (oncocytic thyroid carcinoma) and follicular thyroid cancer separately.[68] In countries with sufficient dietary iodine, the papillary subtype accounts for ~92% of thyroid cancer cases compared with ~6% for follicular, ~0.1–2% for medullary, and ~0.075% for anaplastic.[11]

The histology of papillary thyroid cancer is relatively straightforward, whereas follicular thyroid cancer histology is much more complicated; the latter lacks the cellular and nuclear atypia (e.g., nuclear enlargement/overlap, irregular/elongated nuclear contours, optically clear nucleoplasm) present in papillary thyroid cancers. Papillary thyroid carcinomas characteristically demonstrate papillae; however, some variants are follicular variants with no papillary areas.[19] Rare but aggressive papillary thyroid variants include tall-cell, columnar-cell, diffuse sclerosing, solid, Hob-mail, and follicular variants.[69] These tumors display irregular borders invading thyroid parenchyma and lymphatic spaces, resulting in microscopic multimodal lesions and regional lymph-node metastases. Stromal reactions include desmoplasia, myxoid areas, elastosis, fibromatosis-like changes, and amyloid formation.[66]

Follicular adenomas and carcinomas appear similar cytologically, with the difference being capsular or vascular invasion on histological slides; both neoplasms contain somatic mutations in *RAS* genes and PAX8/PPARλ rearrangements.[70] Follicular thyroid carcinomas are more common in iodine-deficient areas than nonendemic goiter areas, with the incidence ratio of papillary/follicular thyroid cancers being relatively lower in iodine-deficient countries.[71] Excessive Hürthle cells (polygonal cells with abundant eosinophilic granular cytoplasm) do not increase malignancy risks except in the presence of Hashimoto thyroiditis. Anaplastic carcinomas are the most heterogeneous, highly aggressive subtype of thyroid cancer consisting of a mixture of epithelioid, pleomorphic giant, and spindle cells with variable combinations of desmoplastic, hyalinized, and sclerotic stoma.[66] Medullary thyroid cancer is typically well differentiated, monoclonal, and not encapsulated; however, papillary and medullary thyroid cancer may develop concurrently, particularly in patients with familial medullary carcinoma and multiple endocrine neoplasia syndrome.

HOST SUSCEPTIBILITY

Hereditary thyroid neoplasms arising from calcitonin-producing C cells are called familial medullary thyroid carcinomas, whereas familial thyroid cancers developing from follicular cells are known as familial nonmedullary thyroid carcinoma or familial follicular cell-derived carcinoma. Familial medullary thyroid cancers are part of the autosomal-dominant multiple endocrine neoplasia syndrome; ~1/4 of medullary thyroid tumors occur in patients with this inherited syndrome.[72] Germline mutations in *RET* genes predispose patients with multiple endocrine neoplasia type 2A or 2B syndrome to medullary thyroid cancer.[73] Of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

all cancer sites, the familial risk of thyroid cancer is one of the highest, with increased risks extending beyond the immediate family, particularly medullary thyroid carcinomas.[74]

At least 5% of follicular cell-derived, papillary, and follicular thyroid carcinomas have a thyroid cancer family history. In a population-based Nordic cohort of 63,495 1st-degree relatives of 11,206 nonmedullary thyroid cancer patients, the overall thyroid cancer risk in individuals with a parent, child, or singleton sibling with papillary thyroid cancer increased by ~3-fold over the general population.[75] The risk increased significantly for individuals with multiple affected relatives or twin siblings. The lifetime cumulative thyroid cancer risk (0–84 years) in close female relatives of a papillary thyroid cancer patient was 2.1% (95% CI: 1.73–2.49%, $n = 146$ cases) and 0.8% (95% CI: 0.53–1.00%, $n = 51$ cases) in male relatives.

Familial nonmedullary thyroid cancers consist of two categories of rare hereditary cancer syndromes involving: 1) prominence of non-thyroid tumors; or 2) prominence of nonmedullary thyroid tumors.[76] The former category includes: autosomal-dominant Carney complex (germline mutation in *PRKAR1α* genes); autosomal-dominant Cowden syndrome from germline mutations in multiple genes (*AKT1*, *KLLN*, *PTEN*, *PIK3CA*, *SDH*, *SEC23B*); autosomal-recessive Werner syndrome (germline mutation in *WRN*); McCune–Albright syndrome (germline mutation in *GNAS*); autosomal-dominant DICER1 syndrome (germline mutation in *DICER1*); Pendred syndrome; and autosomal-dominant familial adenomatous polyposis (germline mutation in *APC*). The latter category includes familial papillary thyroid carcinoma with papillary renal cell carcinoma (germline mutation in *PRN*), autosomal-dominant familial papillary carcinoma with multinodular goiter from germline mutations in *MNG1* and *PTCSC3*, and autosomal-dominant familial papillary thyroid carcinoma with (Hürthle cell) or without oxyphilic staining. Germline alterations in Cowden syndrome with follicular thyroid cancer also involve mutations in *RASAL1* (RAS protein activator like 1) from the GAP1 family of GTPase-activating proteins.[77] Most familial thyroid cancers are more aggressive than sporadic thyroid tumors, manifested by extrathyroidal invasion, lymph-node metastasis, and earlier age at onset.

TABLE 63.3. Prevalence, clinical features, and genetic alterations associated with specific histological subtypes. Percentages are approximations based on estimates of the range of values in the medical literature. The genetic changes are listed in order of most common to least common. The epidemiology of follicular thyroid cancer is more difficult to study than papillary cancer because of the changing diagnostic criteria over time; hence, the estimates in the table for follicular thyroid cancer are wide. (Adapted from Forte et al.).[29]

Features	Papillary	Follicular	Poorly Differentiated	Undifferentiated	Medullary
Prevalence	75–80%	10–15%	<7%	2%	<5%

CLINICAL PRESENTATION

Most well-differentiated thyroid cancer are asymptomatic on presentation with the diagnosis resulting from incidental findings on diagnostic imaging or physical examination. The clinical course of thyroid cancer varies widely; most papillary and follicular subtypes display an indolent course with low mortality, whereas anaplastic thyroid cancers are usually aggressive malignancies unresponsive to iodine radiotherapy. Medullary thyroid cancer typically presents as a solitary nodule in the fourth to sixth decade of life, often with metastasis to cervical lymph nodes. Symptoms may include diarrhea and flushing; hyperthyroidism occurs rarely in follicular thyroid carcinoma.[16] Anaplastic thyroid cancer is a rare neoplasm that typically presents as a rapidly growing, firm, 8–9-cm neck mass with or without cervical adenopathy; symptoms include dysphagia, dyspnea, and hoarseness.[78] This thyroid subtype may present as a *de novo* tumor or coexist with differentiated thyroid cancer. Distant metastatic sites include the lungs and less commonly bone and brain. Metastases outside the neck and mediastinum occur in 1–2% of papillary thyroid cancer patients and 2–5% of follicular thyroid cancer cases.[79] In contrast to papillary thyroid cancer, recurrence of follicular thyroid cancer is usually associated with distant rather than lymph-node metastases.[80]

Papillary thyroid cancer has an excellent prognosis; however, ~25% of these patients develop local recurrence during long-term follow-up. In a retrospective review of 269 patients with papillary thyroid cancer, 11% of the recurrences appeared >20 years after the initial diagnosis.[81] Follicular thyroid cancer including Hürthle cell carcinoma and poorly differentiated thyroid cancers are high-risk tumors because of their tendency to metastasize through the blood, particularly to the lungs and bone.

Survival depends on tumor histology, age at diagnosis, and clinical stage. The overall 5-year survival rate for papillary thyroid cancer is extremely high (men, 99%; women, 99.8%), whereas the 5-year survival rate for anaplastic thyroid cancer is much lower (i.e., <10%).[8] In contrast to most solid cancers, regional lymph-node metastasis in well-differentiated thyroid tumors correlates with local recurrence but not strongly with overall survival.[82] Table 63.3 displays approximate percentages of prevalence, clinical features (lymph-node/distant metastases), 5-year survival, and common genetic alterations associated with thyroid cancer histological types based on an analysis by Forte et al.[29] Total thyroidectomy with or without radioactive iodine is curative in most cases of well-differentiated thyroid cancer.

  Office of Health Assessment and Translation (OHAT). **179**
Utah Cancer Registry 352
Uterine cancer *61*
Uterine cervix cancer **392**
Uterine corpus tumors
  World Health Organization (WHO) classification **410**
Uterine leiomyosarcomas 672, 673
Uterus cancer 403–416
  cervical cancers 403–409
  epithelial endometrial carcinoma 409–416
Uveal melanoma 467, **468**
  age-adjusted 471
  atypical (dysplastic) nevi and 469
  gene mutations in 467, **468**
UV radiation 469, 646–647

Vaginal cancers **392**, 404
Validity 97
Vapor pressure 173
Variation characterization 196
Vascular endothelial (VE)-cadherin 34
Vascular endothelial growth factor (VEGF) 222
Vascular endothelial growth factor receptor (VEGFR) 34, 222
Vasectomy cancer 374
Vegetables intake 103, 104–105, **106**
  consumption 105
  pickled 107–108
Vegetarian diets 367
Vesicular schwannoma 443
Vietnam herbicides 589–590
Vinyl chloride 209, 223, 304–305
Vinyl chloride polymerization 456
Viral oncogenes 671
Virtually safe dose (VSD) 189
Visceral adipose tissue (VAT) 291
Vitamin A (retinol) 108, 641–642
Vitamin D 108
Vitamin E 108, 109
Vitamins 108–109
Vitamins and Lifestyle (VITAL) study 338

Volatilization, of chemicals 175
Volunteer and/or nonrespondent bias 98
von Hippel–Lindau (VHL) syndrome 337, 341, **447**
von Recklinghausen's neurofibromatosis 513
Vulva cancers **392**, 404

Waist-to-hip ratio 312, 411
Waldenström macroglobulinemia 558, **569**, 599
Warty squamous cell carcinoma 381
Water solubility 173
Weibull distribution 189
Weight-of-evidence approach 158, 162, 164, 165, **166**, 170, 171, 173, 178, 183
  of carcinogenic potential 184
Well-designed cohort studies 88
Werner syndrome 669, 671
Wheat bran 104
Whole-exome sequencing 301, 673, 676
Wiskott–Aldrich syndrome **502**, 552
Wnt/β-catenin signaling 410
Wolf-Hirschhorn syndrome 300
Women/Female
  adenocarcinoma 115
  BMI for 102
  breast cancer 62, 101, 109, 122. *See also* Breast cancer
  cancer incident rates in 59
  cancer mortality in 62
  cancer-related deaths in 62, 391
  colorectal cancers in 62
  in leukemias 483
  lung cancer incidence in 114
  occupational exposures in 64, 407

Women/Female (*cont'd*)
odds ratio (OR) in 311
PAP test for cervical cancer in 204
small cell carcinoma 223
smokers 115
Women's Antioxidant Cardiovascular Study 108
Wood dust exposure 244–245
World Cancer Research Fund/American Institute for Cancer Research (WCRF) 101–102, **102**, 104, 105, **106**
World Health Organization (WHO) classification 171, 287
CNS **459–462**
gliomas 458
laryngeal cancer 253
of lung tumors **234**
of lymphoid neoplasms **540–543**
mesothelioma 241
of myeloid and histiocytic/dendritic neoplasms **486–488**
of pituitary adenomas **466**
uterine corpus tumors **410**
Xenobiotics 21, 75
Xeroderma pigmentosum 27
X-linked hyperimmunoglobulin M syndrome 599
X-ray exposure 114

Yes-associated protein 1 (YAP) 674
Yolk sac tumor **377**

Zinc-dependent proteolytic enzymes 37
