Lead easily crosses the placenta;[254] cord blood lead levels are typically 85–90% of maternal blood lead levels.[255] Lead follows a U-shaped course during pregnancy; a significant drop occurs from the first to second trimesters, followed by a gradual rise until delivery. In the blood, lead occurs mostly inside red blood cells; therefore, the whole blood lead concentrations vary with changes in blood volume during pregnancy. Blood lead levels in the mother initially increase during pregnancy and then decrease after delivery. Observational studies indicate that blood lead falls more than expected from hemodilution during early pregnancy, probably as a result of the resorption of trabecular bone with presumably lower lead content compared with the cortical bone.[256] In later pregnancy, increasing resorption of cortical bone increases whole blood lead concentrations. In a study of 98 pregnant women with a geometric mean BLL of 0.42 μg/L in the second trimester, the median change in BLL from second to third trimester was 0.015 μg/L (P = 0.08) compared with 0.06 μg/L (P = <0.01).[257] Without further exposure to lead, maternal blood lead levels increase by 6–8 months postpartum.[258]

Breast Milk

Maternal diet and release of lead from bone loss are the major sources of lead in breast-milk-fed infants aged <3 months. In a study of mothers (n = 21) and their

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

breastfed infants ($n = 24$) 2–3 months postpartum, the contribution of breast milk to blood lead levels in the infants ranged 36–80% based on lead isotope ratios ($^{207}Pb/^{206}Pb$, $^{206}Pb/^{204}Pb$).[259] The mean lead concentration in breast milk for participants in the study was 0.73 ± 0.70 μg/kg. The infant can substantially reduce the body burden of lead during the first months of life in the absence of postnatal lead exposure.[260]

There are few data to indicate that lead is preferentially excreted in breast milk; breastfeeding probably does not increase the risk of lead toxicity in infants from mothers with normal blood lead concentrations.[261] The concentration of lead in breast milk is relatively low with typical maternal milk/whole blood ratios <3%,[262] even among women with relatively high lifetime exposure to lead. In a review of 11 studies analyzing lead in breast milk, the mean lead concentrations in mature milk samples ranged from 0.15–6.1 and from 0.48–14.6 ng/mL in colostrum samples. Some samples were below the limit of detection (0.1–2 ng/mL). The milk/whole blood lead ratio ranged 0.01–0.48; the heterogeneity of the data and analytic methods indicate a wide variation in study design and sample collection. In a study of the four stages of breast milk production (colostrums, transitional milk, early mature milk, mature milk), the concentrations of microelements decreased with advancing lactation stages.[263] The mean lead concentration in samples from 45 lactating women in each lactation stage ranged from 13.22 ± 3.58 ng/mL (range, 6.70–22.36 ng/mL) in colostrum samples to 2.93 ± 1.70 ng/mL (range, 0.45–7.80 ng/mL) in mature breast milk samples.

In a study of 310 lactating women in Mexico City at 1 month postpartum, the geometric mean lead concentration in breast milk was 1.1 ng/mL (range, 0.21–8.02 ng/mL).[264] The primary determinants of lead in breast milk were current lead exposure and redistribution of bone lead from past environmental exposures. In a study of mothers living in Andean Ecuadorian villages with high lead contamination, the lead concentration in breast milk from five nursing mothers ranged from 1–49 ng/mL (ppb).[265] The median lead concentration in breast milk from 37 lactating mothers living near Brazilian tin ore smelters was 11.3 ng/mL (range, 0.9–29.4 ng/mL) with 79% of the samples above the WHO limit of 5.0 ng/mL; the limit of detection for graphite furnace atomic absorption spectrometry was 0.9 ng/mL.[266] In comparison, the median lead concentration in milk samples from 45 lactating women from fishing villages was 3.5 ng/mL (range, 0.9–16.2 ng/mL). Maternal milk/plasma ratios are significantly higher than milk/whole blood ratios. In a Mexico City study of 81 lactating women providing breast milk samples 1 month postpartum, the mean milk/plasma lead ratio was 7.7 (range, 0.6–39.8).[267] The mean infant blood lead level of 60 infants at 3 months of age was 3.4 ± 2.2 μg/dL with the blood lead level increasing 1.8 μg/dL for each 1 μg/L increase in maternal milk lead.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Effects

Over 90% of absorbed lead resides in erythrocytes. Inorganic lead inhibits a number of intracellular biochemical processes that generally reduce cellular growth and disrupt cellular processes. A review of lead-interacting proteins identified 23 proteins bound by lead involving a variety of cellular processes including heme biosynthesis (e.g., δ-aminolevulinic acid dehydratase), oxidative stress/lipid peroxidation (e.g., glutathione peroxidase), calcium metabolism/pathways (e.g., calmodulin-mediated pathways, synaptotagmin, voltage-gated calcium channels), nuclear function (e.g., apurinic/apyrimidinic endonuclease 1), lead chelation (↑ metallothionein), nervous system metabolism, and receptor function (acetylcholine, NMDA).[268] The uptake of lead by the mitochondria inhibits cellular respiration, resulting in swelling, loss of crista, and disruption of oxidative phosphorylation and ion transport.[269] The precise mechanism of action of lead on cellular metabolism remains unclear despite the recognized effects of lead on porphyrin and heme biosynthesis from the inhibition of δ-aminolevulinic acid dehydratase (ALAD), δ-aminolevulinic acid synthetase (ALAS), coproporphyrinogen III oxidase, and ferrochelatase. Lead complexes with ligands (sulfhydryl groups most prominently) of enzyme systems throughout the body, leading to diffuse effects. The chemical similarity between lead and calcium suggests that lead may compete with calcium to alter critical intracellular processes (e.g., ion transport, energy production, heme-containing enzymes),[270,271] intracellular messenger systems (calmodulin, protein kinase C),[272] neurodevelopment (altered neuron migration, reduced neural cell adhesion, disruption of cellular communication, decreased synaptic plasticity from disruption of *N*-methyl-D-aspartate type of excitatory amino acid receptor-mediated calcium signaling in glutamatergic synapses),[273] and neurotransmission (blockage of calcium into nerve terminals, impaired uptake by calcium channels, reduced calcium-binding sites, impaired

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. mitochondria calcium uptake, alteration of glutamatergic, dopaminergic, and cholinergic pathways).[274]

Susceptibility

Children are more susceptible to lead toxicity than adults because of several factors including 1) increased bioavailability of lead in children, 2) increased distribution of lead to soft tissues rather than bones, 3) increased penetration of lead into the brain as a result of an immature blood–brain barrier, and 4) the presence of developing body systems.[66]

ALAD (aminolevulinate dehydratase) polymorphism may alter the susceptibility of workers to the effects of lead exposure as a result of the relative tighter binding of the ALAD2 protein to lead compared with the ALAD1 protein.[275] The ALAD2 allele is present in about 7–10% of the population. The *ALAD* genotypes do not affect heme synthesis at whole blood lead concentrations <20 μg/dL.[276] Blood samples from ALAD1 homozygotes contained increased ZPP concentrations at whole lead concentrations ranging 20–59 μg/dL and increased plasma aminolevulinic acid (ALA) concentrations at whole blood concentrations ranging 40–59 μg/dL compared with blood samples from ALAD2 homozygotes.[277] Theoretically, the relatively stronger binding of ALAD2 protein to lead may reduce the amount of biologically active lead in ALAD homozygotes, but there are few data on the clinical effect of these differences in lead workers. A cross-sectional study of middle-aged and elderly men in the Department of Veterans Affairs Normative Aging Study did not detect a significant difference in serum uric acid, serum creatinine, or estimated creatinine clearance by *ALAD* genotype; the study suggested *ALAD* genotype may modify the effect of lead on the renal excretion of uric acid after control of confounding variables.[278]

Pathological Changes

Hematopoietic System

Impaired heme biosynthesis is the most sensitive reaction to increasing blood lead levels. Lead alters the activity of at least four heme enzymes (ALAS, ALAD, coproporphyrinogen III oxidase, ferrochelatase) resulting in reduced heme production and increased urinary porphyrins, coproporphyrins, δ-aminolevulinic acid, erythrocyte protoporphyrin (EP), free erythrocyte protoporphyrin (FEP), and zinc protoporphyrin (ZPP) as outlined in Figure 16.2. The most sensitive reaction in humans occurs when lead inhibits the conversion of δ-aminolevulinic acid to porphobilinogen by forming

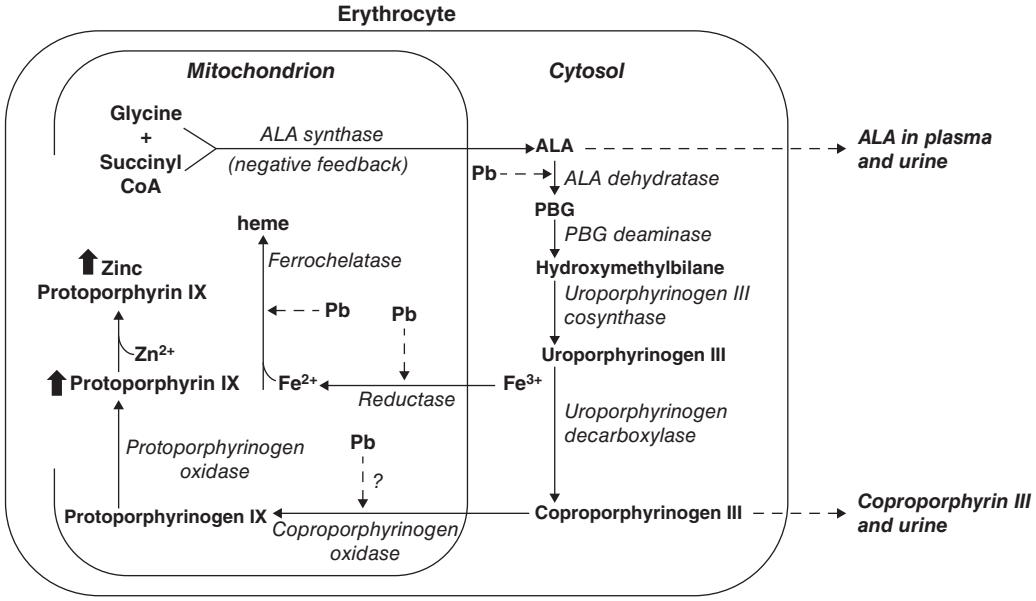

FIGURE 16.2. Schematic representation of the effects of lead on three lead-sensitive heme enzymes and resultant changes in urinary aminolevulinic acid, porphyrins, coproporphyrins, and heme production (anemia). Inhibition of ALA synthases increases plasma/urinary ALA and urinary coproporphyrin, whereas increased intracellular protoporphyrin IX increases free erythrocyte protoporphyrin and zinc protoporphyrin in the erythrocyte. *Abbreviations:* ALA = δ-aminolevulinic acid; PGB = porphobilinogen. (Redrawn from Sakai).[283]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. a mercaptide from δ-aminolevulinate dehydratase.[279] Some animals are less sensitive to the hematological effects of lead. In a rodent study, lead exposure caused a transcription-dependent induction of ALA dehydratase that potentially compensated for the lead-induced inhibition of this enzyme.[280] Porphyrinogen is the intermediate in heme biosynthesis, and coproporphyrin is a by-product of the nonenzymatic oxidation of coproporphyrinogen. Lead-induced inhibition of ferrochelatase causes an accumulation of protoporphyrin IX in bone marrow normoblasts;[281] in circulating erythrocytes, the replacement of iron by zinc in the porphyrin moiety produces ZPP. The binding of ZPP in the heme pockets of hemoglobin remains throughout the life of the erythrocyte. Zinc protoporphyrin accumulates when inadequate supplies of iron substrate limit the chelation of iron by protoporphyrin to form heme.[282] The accumulation of ZPP occurs only in erythrocytes formed primarily in the bone marrow normoblasts when lead exists during erythrocyte formation. Consequently, the erythrocyte maturation process produces a lag time between lead exposure and elevated ZPP concentration, whereas the steady state only occurs after the turnover of the entire red cell population (i.e., 120 days).

Anemia is the most common *hematological* manifestation of lead exposure. Decreased hemoglobin production and increased erythrocyte destruction cause hypochromic, normocytic anemia with associated reticulocytosis. Lead-induced anemia increases in frequency and severity with increasing blood lead levels; however, the anemia is rarely severe. The common hematological abnormalities involve the erythroid series (erythroid hyperplasia with ring sideroblasts) and include reticulocytosis and basophilic stippling. The latter results from aggregated RNA material from the inhibition of pyrimidine 5′-nucleotidase. In one study of children living near a smelter, 17% of children with blood lead levels >80 μg/dL had hematocrit levels <33% compared with 1.6% of children with lead levels <80 μg/dL.[284] Neither anemia nor basophilic stippling is a sensitive indicator of lead intoxication because concurrent congenital defects in heme synthesis may be required to express the anemia. A study of lead-exposed workers suggests that lead may affect erythrocyte glycolysis at the hexokinase step; however, the clinical significance of this effect is unclear.[285]

Nervous System

Peripheral Nervous System

The motor axons are the principal target of lead in the peripheral nervous system. Primary segmental demyelination followed by axonal degeneration of peripheral nerves leads to decreased motor nerve conduction velocity. In adults, peripheral neuropathy is the most common neurological manifestation of lead toxicity, whereas encephalopathy appears more frequently than peripheral neuropathy in children. Although lead affects the peripheral nervous system in several ways, a primary mechanism of toxicity involves disruption of calcium homeostasis and cell-signaling pathways including activation of protein kinase C. Many peripheral and central nervous system processes rely on the calcium-dependent protein kinase C isoenzyme family for synaptic transmission (e.g., ion channel conduction, ligand-receptor interactions, neurotransmitter synthesis, dendritic branching).[37] Lead also displaces zinc in zinc-finger proteins found in enzymes, channels, and receptors.

Central Nervous System

The encephalopathy produced by inorganic lead depends on the route of exposure, dose, and age with young children (1–4 years) particularly vulnerable. Lead appears to pass the blood–brain barrier more easily in children, resulting in disruption of mitochondrial function leading to the onset of coma and convulsions at lower blood lead levels than adults.[23] Acute cerebral and cerebellar edema with hemorrhage occurs in neonates following acute, high-dose lead exposure. Pathological findings probably result from increased microvascular permeability that causes erythrocyte leakage, microthrombosis, endothelial cell necrosis, perivascular exudation of periodic acid-Schiff (PAS) positive material and erythrocytes, and subacute endothelial proliferation.[286]

A direct neurotoxic effect of lead on neurons is equivocal,[287] but lead-induced premature activation of protein kinase C (PKC) may impair brain microvascular formation. High lead levels also produce alterations in the astrocytes and endothelial cells in the blood–brain barrier (BBB), resulting in diffusion of albumin, ions, and water intracellularly along with disruption of the BBB. As a result of the slow clearance of plasma constituents, intracranial edema and hypertension develop contributing to acute lead encephalopathy. Other pathological changes associated with lead toxicity include inflammatory changes (perivascular cuffing, granuloma formation) in the cerebral cortex and diffuse cerebral edema. Cerebral edema is a late complication of lead encephalopathy, and coma may appear in the absence of cerebral edema. Rodent studies suggest that vascular endothelial growth factor mediates the vasogenic edema associated with acute lead encephalopathy.[288]

The difference in the incidence of encephalopathy between small children and adults may result from

the maturation of the choroid plexus sink.[289] Potential mechanisms for the increased susceptibility of young children to lead neurotoxicity include the disruption of cellular migration during critical periods of CNS development secondary to interference with synaptic neurotransmission and cell adhesion molecules.[66] Lead inhibits *N*-methyl-D-aspartate receptor function, enhances background transmitter release, and stimulates background levels of the intracellular messenger protein kinase C.[290] The subsequent reduction in the synaptic signal-to-noise ratio may permanently disrupt the refinement of synaptic connections during a critical early period of postnatal development. Well-defined neuropathological findings have not been described in humans exposed to low lead levels; animal models demonstrate conflicting results.[287] Abnormalities in spatial learning and memory may result from abnormalities in dopamine, γ-aminobutyric acid, and glutamate kinetics (uptake, efflux, metabolism) in the brain, particularly long-term potentiation related to the latter neurotransmitter.[291]

Kidney

In animal models, chronic lead toxicity produces lesions in the S3 segment of the straight proximal tubule, interstitium, and loops of Henle characterized by round, eosinophilic, or acid-fast intra-nuclear inclusion bodies.[292] Lead-induced renal disease occurs in the following principal stages: 1) acute, reversible changes that produce an alteration of mitochondrial function and proximal renal tubular dysfunction, and 2) irreversible, chronic changes characterized by tubular atrophy and dilation, arteriosclerosis, and interstitial fibrosis.[293] The latter stage represents the kidney's nonspecific response to chronic disease that occurs following many types of nephrotoxins. The physiological consequences of these anatomic changes include enzymuria (e.g., ↑ urinary *N*-acetyl-β-D-glucosaminidase, retinol-binding protein), low-molecular-weight proteinuria (e.g., ↑ urinary β_2-microglobulin), high-molecular-weight proteinuria (e.g., ↑ albumin), impaired transport of organic anions and glucose, and depressed glomerular filtration rate (↑ serum creatinine, ↓ urine creatinine clearance). These changes are particularly evident following chronic lead exposure exceeding 50 μg/dL.[37,294] Although hyperuricemia is common during renal failure, gout is rare except in these patients. Lead decreases tubular secretion of uric acid, causing a higher incidence of gout,[295] but factors other than lead exposure account for most cases of end-stage renal disease in patients with gout and renal failure.[296]

Acute Toxicity

Severe, acute lead poisoning produces proximal tubular dysfunction that results in a Fanconi-like syndrome (aminoaciduria, phosphaturia, glycosuria, renal tubular acidosis). These acute tubular changes are usually reversible; the proximal tubular defects do not typically progress to interstitial nephritis following cessation of acute lead exposure.[297] Pathological changes in the proximal tubules include epithelial cell proliferation, mitochondrial swelling, loss of basilar infolding and crista, and lysosomal-like structures with dense inclusion bodies. The intranuclear inclusion bodies contain sulfhydryl-rich lead-protein complexes that probably form in the cytoplasm and migrate to the nucleus.[298] These inclusion bodies disappear after chelation and sloughing of the tubule.

Chronic Toxicity

Renal biopsies of patients with chronic lead-induced nephropathy demonstrate a chronic nephropathy that may progress to contracted kidneys with arteriosclerotic changes, interstitial and peritubular fibrosis, glomerular sclerosis, tubular atrophy, and hyaline degeneration of the renal vasculature.[299,300] Florescent microscopy of seven of eight renal specimens demonstrated glomerular and tubular immunoglobulin deposition, suggesting an autoimmune process. End-stage lead nephropathy is characterized more by chronic interstitial disease than glomerular disease. Histological changes in the kidneys are not invariably present in patients with excessive body burdens of lead. Structural mitochondrial abnormalities in renal proximal tubule cells are a consistent feature of lead-induced nephropathy.[301] The formation of intranuclear inclusion bodies in the renal proximal tubule frequently develops in patients with lead nephrotoxicity; these bodies represent a shift in lead from the cytosol to nuclear material. These inclusion bodies are not specifically associated with tubular injuries. In rodent studies, inclusion bodies were more frequent in the less severely affected S2 segment than the more severely affected S3 segment of the proximal tubule.[302] Although intranuclear eosinophilic inclusion bodies (i.e., lead–protein complexes) usually occur in the proximal tubular cells following acute renal toxicity, these pathological abnormalities may or may not occur in chronic lead-induced kidney disease.[83] In a study of 12 lead workers with reduced glomerular filtration rates, only about ½ of the renal biopsies demonstrated changes consistent with lead nephropathy including focal tubular atrophy and interstitial disease.[303] Age- and hypertension-related changes may confound the interpretation of the causal role of lead in these changes.

Endocrine

Occupational studies suggest an association between high blood lead levels (≥40–60 μg/dL) and alteration of thyroid (↓ serum thyroxine, T4; ↑ thyroid-stimulating hormone),[304] pituitary, and testicular hormones (follicle-stimulating hormone, luteinizing hormone, testosterone); however, the results are inconsistent secondary to potential confounding (e.g., age, tobacco use), design issues (e.g., small sample sizes), and differences in laboratory methods/outcomes.[305] In some occupational studies, the thyroid effects (i.e., ↓ T4 with inappropriately low TSH or poor thyrotropin-releasing hormone response) were consistent with a primary pituitary or hypothalamic insufficiency.[304,306] Positive studies reported alterations of thyroid changes following high chronic lead exposure (≥40–60 μg/dL).[307] Limited data in children does not indicate an association between lead exposure and altered thyroid hormone concentrations; these children typically have BLL lower than adults with occupational lead exposure. In a study of 68 inner city children with mean blood lead of 25 μg/dL (range, 2.0–77 μg/dL), linear regression analysis demonstrated no association between blood lead levels and either serum T4 or free T4.[308]

Disturbances of vitamin D metabolism occur both in animal models and children with moderate to marked elevations of blood lead (30–60 μg/dL). In a study of 177 children age 1–16 years with BLL ranging 12–120 μg/dL, the active form of vitamin D (1,25-dihydroxycholecalciferol, 1,25-CC, 1,25-dihydroxyvitamin D_3), was negatively associated with BLL ($r = -0.88$).[309] Sex and season were not associated with serum, 1,25-CC concentrations, whereas the serum 1,25-CC concentration was higher in children aged 11–16 than ≤10 years of age. A Midwestern US study of 105 children at ages 1 and 3 years detected no significant alterations in vitamin D metabolism or calcium and phosphorus homeostasis in children with normal nutritional status and low–moderate blood lead levels (<25 μg/dL).[310] An increase in the serum level of 1,25-dihydroxyvitamin D_3, a potent vitamin D metabolite formed in the proximal renal tubules, was detected in workers exposed to lead, primarily in those workers with blood lead levels >60 μg/dL.[311] A study of lead-exposed workers did not detect a statistically significant increase in the excretion of major catecholamine metabolites (homovanillic acid, vanillylmandelic acid).[312]

Reproductive System

Occupational studies suggest some association between high lead exposure and stillbirths, spontaneous abortions, and decreased sperm counts. In a study of lead concentrations in umbilical cord blood from 5,183 consecutive deliveries of at least 20 weeks gestation, stepwise logistic regression suggested a dose-related association between minor congenital abnormalities and cord blood lead.[313] Occupational studies suggest an association between high blood lead levels (≥30–40 μg/dL) and alteration of testicular hormones (follicle stimulating hormone, luteinizing hormone, testosterone). Although changes occurred in the serum FSH, LH, and testosterone concentrations in highly lead-exposed workers (↑ LH, ↓ testosterone),[314] there was no consistent pattern of exposure-response.[315] Potential mechanisms for the observed lead-induced reduction of stature include diminished human growth hormone secretion and inhibition of insulin-like growth factor I formation.[316]

Liver

Transient elevations in serum hepatic aminotransferase concentration occur rarely in severe lead poisoning, but impairment of liver function is not well documented in workers exposed to lead.

Cardiovascular System

Meta-analyses suggest a persistent but weak association between blood lead levels and hypertension.[317] Lead affects several hormonal and neural systems that alter heart rate, cardiac output, and regulation of peripheral vascular resistance. The mechanisms of action include the direct effect on end-arterioles by alteration of intracellular calcium and the indirect effect of renal dysfunction.[318] Potential mechanisms of toxicity are multifactorial including 1) deficiency of nitric oxide from direct (inactivation of endogenous nitric oxide) and indirect actions (downregulation of soluble guanylate cyclase by reactive oxygen species); 2) increased sympathetic activity and plasma norepinephrine with depressed vascular and elevated renal β-adrenergic receptor density; 3) elevated plasma angiotensin-converting enzyme activity, plasma renin activity, angiotensin II, and aldosterone concentrations; 4) increased kininase I and kininase II activity; 5) lead-induced increased intracellular sodium and calcium by inhibition of vascular smooth muscle Na^+-K^+ ATPase; and 6) increased endothelin and thromboxane generation.[319] Subjects from the general population with hypertensive nephropathy and nephropathy from other causes have similar body lead burdens. In a study of 40 adults with hypertensive nephropathy and 24 controls with a similar degree

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of renal dysfunction from causes other than hypertension, chelatable lead and blood lead levels were statistically similar (7.2 ± 4.7 μg/dL and 7.2 ± 4.1 μg/dL, respectively).[320]

Postmortem Examination

Diffuse cerebral edema and dilated ventricles are common pathological findings in autopsies of fatal pediatric poisoning cases.[321] In a postmortem study of 20 children with fatal lead encephalopathy, the most common histological finding following examination of the brain was dilation of the capillaries with swollen endothelial nuclei protruding into the lumen and diffuse astrocytic proliferation.[322] A 2-month-old infant developed vomiting, tonic-clonic seizures, anorexia, demyelinating neuropathy, and tarry stool from lead poisoning; she died despite chelation therapy from sepsis (organism not reported).[323] Postmortem examination demonstrated cerebral edema with subarachnoid hemorrhage, acute renal tubular necrosis, and massive liver necrosis. Histological examination revealed mild perineurial edema and focal segmental demyelination of the median nerve, focal necrosis of neurons in the cerebral cortex with reactive astrocytosis and microgliosis, and dilation of the perivascular spaces with PAS-positive exudate. A 41-year-old man died of lead oxide poisoning that was recognized posthumously.[324] On exhumation 6 months after the death, forensic analysis demonstrated the following lead concentrations (μg/g): liver, 47.6; kidney, 4.75; femur, 20.4; sacral vertebra, 103; pubic hair, 33.7; and nails, 13.6.

CLINICAL RESPONSE

The clinical presentation of lead poisoning (plumbism, saturnism) is typically nonspecific with the signs and symptoms of lead poisoning depending on blood lead concentration, age, and duration of exposure. The presence of clinical features of lead intoxication requires a careful evaluation of the potential sources of lead in the environment of the patient. High risk of lead toxicity may occur in children residing in houses, daycare centers, or preschools with old (pre-1960) chipping paint; frequent visitations to pre-1960 houses undergoing renovation; living or playing with children diagnosed with elevated lead levels; residing with adults exposed to lead (job, hobby); or living near a point source of lead (factory, hazardous waste site). Case reports associated the intravenous injections of lead and opium with the development of elevated serum hepatic aminotransferases, symptoms of acute hepatitis (general malaise, vomiting, constipation), musculoskeletal pain, and anemia.[325,326]

Acute Ingestion

Acute lead poisoning in adults is rare, typically resulting from very large intentional ingestions of lead salts, surreptitious lead salt ingestions by mentally impaired patients,[173,327] ingestion of lead objects, or intravenous administration of lead salts or lead-contaminated drugs of abuse.[328] Clinical features of acute lead poisoning typically involve abdominal pain with gastrointestinal distress, peripheral neuropathy, and less often encephalopathy (delirium, hallucinations), hepatorenal dysfunction, low-grade fever, and acute hemolytic anemia.[173,329] An acute encephalopathy following single, large ingestions of inorganic lead is relatively rare in adults; high whole blood lead concentrations may occur without clinical evidence of an acute encephalopathy that commonly develops in children at similar high blood lead concentrations.[330] In a study of 32 adults presenting with acute lead poisoning after ingesting lead-contaminated flour over ~2 weeks, clinical features involved systemic symptoms, gastrointestinal distress, anemia, and musculoskeletal complaints.[331] A few patients with the highest blood lead concentrations developed hemolytic anemia, high-output congestive heart failure with severe anemia, transient proximal renal tubular dysfunction (glucosuria, aminoaciduria, hypoproteinemia), prerenal azotemia (renal vasoconstriction, volume depletion), toxic hepatitis, gouty arthritis with hyperuricemia, and encephalopathy. The mean whole blood lead level in the 13 most severely affected patients was 102 ± 26 μg/dL. Following acute lead arsenate exposure, nausea, constipation, metallic taste, and abdominal pain occur along with vomiting of milky material resulting from the formation of lead chloride. Although lead arsenate is an acid-soluble compound, absorption is considerably slower for lead than arsenic. These patients typically present with signs of arsenic toxicity.[332]

Occupational Exposure

The vast majority of excessive chronic lead exposures in adults occur in the work environment; common sources of occupational lead exposure include the use of acetylene torches to demolish lead-containing pipes, paint, or tanks.[333] Neurasthenic symptoms (headache, generalized weakness, fatigue, lightheadedness, anorexia, arthralgias) are frequent complaints among these workers.[334,335] A case series of 47 demolition workers developed elevated BLL (mean = 59 μg/dL; range 15–99 μg/dL) following the removal of leaded tanks and pipes over 2 weeks.[336] The most common symptoms in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the group were fatigue (83%), headache (45%), sleep disturbances (40%), abdominal cramps (40%), constipation (40%), dizziness (38%), and anorexia (34%). Following improved hygiene, symptoms diminished with declining BLL. Determination of the causal relationship between specific symptoms and lead exposure is complicated by a variety of factors that contribute to the reporting of symptoms including work conditions, job satisfaction, overall health, social support, selection bias, and test conditions. Prospective studies of lead workers demonstrate a high percentage of central nervous system and musculoskeletal symptoms in both chronic lead-exposed workers and control groups (e.g., 75% vs. 60% and 65% vs. 40%, respectively).[337] Many studies use the measure of recent lead exposure (i.e., blood lead level) rather than measures of cumulative lead exposure, including bone lead, of the cumulative blood lead index (area of the BLL curve over time). The latter two cumulative measures probably better reflect chronic lead exposure in an individual than the blood lead level alone, particularly at low-dose lead exposure.[338] Burton's line is the bluish-purple discoloration of gums associated with high blood lead levels and the deposition of lead sulfide in the gum line.[339,340] Although these discolorations often occur in patients with poor oral hygiene, the condition and color of the gum are not affected directly by lead.

Gastrointestinal Tract

Clinically significant gastrointestinal symptoms typically occur at high whole blood lead levels (>70–80 μg/dL). Abdominal colic characterized by a combination of abdominal pain, constipation, cramps, nausea and vomiting, anorexia, and weight loss is a consistent, early symptom of acute and chronic lead poisoning. Diarrhea occurs less often than other gastrointestinal complaints. Histopathological evidence of lead-induced gastrointestinal damage does not usually occur;[37] therefore, gastrointestinal symptoms often resolve following decreases in the blood lead level. Case reports indicate that the gastrointestinal symptoms following the absorption of high lead dose (e.g., blood lead level >100 μg/dL) rapidly improve after chelation.[285]

Peripheral Nervous System

Currently, lead neuropathy is an infrequent form of lead toxicity that usually develops after long-term exposure to high lead levels (>70 μg Pb/dL).[341] Rarely, this abnormality results from very high blood lead levels during acute lead toxicity. The peripheral neuropathy associated with chronic lead toxicity is classically a symmetrical, painless polyneuropathy with motor weakness, particularly in the extensor muscles of the most active extremity (i.e., dominant upper extremity) with minimal sensory changes (e.g., paresthesias). The peripheral motor neuropathy is characterized by segmental demyelination and axonal degeneration that cause wrist and ankle drops in severe cases. Although weakness can occur as the only symptom of lead toxicity, most patients with lead neuropathy have other clinical evidence (e.g., abdominal colic, constipation) of lead poisoning.[342] Weakness usually develops first in the finger and wrist extensors. Muscular wasting is a conspicuous finding in early, severe lead poisoning.[343] Although an acute myopathy may occur following gasoline sniffing (organic and inorganic lead exposure), little evidence supports an association between chronic lead exposure and myopathy (acute muscle necrosis, tender muscles, myalgias, limb weakness).[344]

Some abnormalities in nerve conduction studies occur following chronic exposure to blood lead concentrations <40 μg/dL; however, the clinical significance of mild reductions in nerve conduction velocity remains unclear, especially when the findings are not consistent with the specific nerve (median, ulnar, peroneal, posterior tibial) or type of measurement (maximum nerve conduction velocity, amplitude, latency). If segmental demyelination develops, only partial improvement in the peripheral neuropathy may occur following cessation of lead exposure.

Central Nervous System

Case series associated a wide variety of neurological effects with acute onset of lead encephalopathy ranging from confusion, disorientation, irritability, and memory loss to seizures, obtundation, cerebral edema, papilledema, coma, and death.[345] Headache, nausea, vomiting, tremor, and optical neuritis occur less frequently. Dramatic neurological symptoms of inorganic lead encephalopathy are uncommon in adults. Tremor may occur in workers with blood lead concentrations >70 μg/dL.[346]

Nonspecific symptoms reported by lead-exposed workers include fatigue, arthralgias, headache, irritability, insomnia, and diminished libido, but the exact contribution of lead toxicity to these symptoms remains difficult to define because of the high prevalence of these symptoms in control groups. The evidence for subtle changes in neurological function without evidence of an encephalopathy remains somewhat controversial because of the difficulty controlling confounding variables and the validity of measures of chronic exposure. A study of 466 elderly US men (67.4 ± 6.6 years) in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the Normative Aging Study compared scores on the Mini-Mental State Examination (MMSE) at an average of 3.5 ± 1.1 years apart. A 1-interquartile range (20 μg/g bone mineral) higher patella bone lead concentration measured with K-shell X-ray was associated with a decrement of 0.24 (95% CI: −0.44 to −0.05) in the mean score after adjustment for age, smoking, education, alcohol consumption, and years between testing.[347] This difference was equivalent to ~5 years of age-related cognitive decline from the baseline MMSE score. There was no difference in the quartiles of the whole blood lead level based on 2 μg/dL increments for this cohort with lead-exposed groups similar to the general population; the association between tibial lead and MMSE scores was weak.

There are few prospective data on the effect of chronic lead exposure on adult cognitive function. A 2-year longitudinal study of 803 current and former lead workers in South Korea suggested some decrement in neurological function based on linear regression models, primarily in the domains of executive abilities and manual dexterity. These decrements were correlated to blood lead levels but not to tibial lead concentrations. Further studies are necessary to elucidate the effect of chronic lead exposure on neurological functions. A study of this South Korean cohort indicated that patellar lead did not add significant information to the study of neurobehavioral function when compared with blood lead and tibial lead.[348] A meta-analysis of nine epidemiology studies suggested an association between chronic occupational lead exposure and amyotrophic lateral sclerosis (ALS).[349] The odds ratio was 1.81 (95% CI: 1.39–2.36) with relatively low heterogeneity ($I^2 = 0.14$). Adjusting for age and sex reduced the estimated odd ratio to 1.41 (95% CI: 1.21–1.65). Because of the rarity of ALS, only two cohort studies were included in the analysis; consequently, recall bias is an unresolved issue. The estimated attributable risk of ALS resulting from occupational lead exposure was 5%.

Kidney

The chronic form of lead-induced nephropathy is a slowly progressive, clinically silent nephropathy that may progress to renal impairment following long-term, high-dose lead exposure (>50–80 μg/dL). The clinical presentation often manifests as chronically reduced glomerular filtration and interstitial fibrosis of the kidney; gout and hypertension also may occur as a result of the decreased secretion of urate.[350] Renal failure does not usually develop in workers with chronic, long-term lead exposures defined by blood lead levels <60 μg/dL.[351,352] Some population-based studies suggest that environmental lead exposure may produce slight renal impairment,[353] but the epidemiological studies to date cannot exclude the possibility that renal impairment itself may increase the body lead burden or that the small changes in renal function are clinically relevant.[354,355] A cross-sectional study of 652 Korean lead workers with mean blood lead levels of ~31 ± 17 μg/dL and mean duration of lead exposure of 10 ± 6.5 years suggested patella lead levels correlated to *N*-acetyl-β-D-glucosaminidase concentrations blood lead, and tibial lead levels.[356] The association between these lead biomarkers and measures of renal function (serum creatinine, creatinine clearance) was not statistically significant.

Hypertension

An increased incidence of hypertension and cerebrovascular disease occurred in lead workers exposed chronically to lead doses during the early 1900s.[357] A review of epidemiological studies (occupational and general population) up to the mid-1990s suggested a small dose-response (~1–2 mm Hg systolic/doubling of BLL) for BLL <30–40 μg/dL.[358] A cross-sectional study of 222 lead battery manufacturing workers with a mean blood lead level of 56.9 ± 25.5 μg/dL did not demonstrate a correlation between current blood lead levels and blood pressure based on multivariate regression analyses.[359] A meta-analysis of 12 occupational studies detected a weak association between blood lead concentrations and hypertension.[317] In this study, a 2-fold increase in the blood lead concentration was associated with a mean elevation of the systolic and diastolic blood pressure of 1.0 mm Hg and 0.6 mm Hg, respectively. Observed associations between lead exposure and blood pressure may reflect an immediate response to blood lead concentration or a persistent effect of the cumulative lead dose. A cross-sectional study of 632 current and former lead workers (BLL mean = 31.9 μg/dL) demonstrated a relationship between blood lead concentration and systolic blood pressure, but not to patellar lead, diastolic blood pressure, or hypertensive status based on linear regression analysis.[360] For BLL and patella lead, the Spearman correlation coefficient is 0.66 ($P < 0.0001$).

Environmental Exposure

Lead toxicity should be considered in the differential diagnosis of the following disorders: recurrent abdominal pain or vomiting, autism, learning disabilities or behavior disorders, developmental delay, speech and hearing deficits, encephalopathy, and convulsions.[361]

Acute Toxicity

Irritability, lethargy, and ataxia may be early signs of acute encephalopathy, whereas convulsions, cerebral edema, and coma are the hallmarks of acute encephalopathy; however, irritability, lethargy, and ataxia may precede the onset of frank encephalopathy.[362] Other symptoms of lead-induced encephalopathy may include bizarre behavior, ataxia, apathy, and memory loss. About 30% of children with encephalopathy from acute lead exposure have permanent neurological deficits.

Central Nervous System

The most severe form of pediatric lead poisoning is an acute encephalopathy in children <30 months of age characterized by increased intracranial pressure, protracted vomiting, abdominal colic, behavioral abnormalities, ataxia, seizures, and altered mental status ranging from disorientation to coma. Vomiting and lethargy frequently occur in the week preceding the development of acute encephalopathy.

Kidney

Acute lead nephropathy manifests as a reversible, proximal renal tubular damage characterized by epithelial degenerative changes and one or more elements of the Fanconi syndrome. This form of high lead exposure causes proximal renal tubular impairment including aminoaciduria, glycosuria, and hyperphosphaturia that usually resolves after lead exposure ceases.[294] This form of lead nephropathy occurs primarily in children. Some,[363] but not all studies,[364] of children chelated for severe lead poisoning demonstrate an increased incidence of chronic nephropathy during adulthood. The positive studies suggested the persistence of a partial Fanconi syndrome (↑ aminoaciduria, ↑ glucosuria) when compared with historic controls; however, renal function as measured by serum creatinine and blood pressure remained normal.[365] A 50-year follow-up of 35 survivors of childhood lead poisoning occurring primarily in the 1930s and 22 matched (age, sex, race) controls demonstrated an increased risk of hypertension (RR = 7, 95% CI = 1.2–42.3) in the exposed cohort; however, the creatinine clearance rates in the exposed cohort were above normal.[366]

Musculoskeletal

In contrast to primary gout, the most commonly affected joint in saturnine gout is the knee rather than the first metatarsophalangeal joint; polyarthritis occurs in a minority of cases of saturnine gout.[367] The onset of saturnine gout typically occurs after other features of lead toxicity (e.g., abdominal pain, constipation, radial/peroneal nerve palsies) in a patient with high BLL (e.g., 80 μg/dL).[368]

Chronic Toxicity

Symptoms associated with chronically elevated lead levels (i.e., >15–20 μg/dL) include colic, headache, myalgias, dizziness, and paresthesias.[369] Anorexia, lethargy, vomiting, and colicky abdominal pain are the most common symptoms of lead intoxication in children. Cross-sectional studies using dentine lead levels as a surrogate for excessive lead exposure associated high dentine (>18–20 ppm Pb) levels with higher school absenteeism and drop-out rates,[370] small decrements in verbal and full IQ,[371] and school performance.[372] Some,[373,374,375] but not all,[376,377] epidemiological studies using prenatal and postnatal blood lead levels suggest low-level lead exposure has a small mean (1–3 IQ points) negative effect on intellectual performance as well as some behavioral abnormalities.[378,379] Continual exposure to lead risks permanent central nervous system damage; therefore, the lead source requires elimination.

Substantial numbers of children with elevated total body lead burdens do not display overt symptoms of lead toxicity. Subclinical lead toxicity in these children produces subtle effects on behavior, cognitive development, growth, and hearing; these effects may occur at relatively low blood lead levels (5–10 μg/dL) by historical standards. In general, the contribution of lead at blood lead levels <10 μg/dL is relatively less than other factors.[380,381] These confounding factors (e.g., environment, socioeconomic status, maternal and paternal IQ/education, genetics) complicate the quantitation of lead effects on measured outcomes (e.g., IQ) because of the relatively large effect of these confounders compared with the effect of lead.

Cognitive Deficits

There is no single neurobehavioral abnormality or a unique group of neurobehavioral abnormalities that identify lead exposure in children with no consistent effects on individual cognitive domains.[382] Confounding the effects of lead on cognitive and behavioral development include iron deficiency and permissive parenting styles.[383] Although elevated body lead burden and mild iron efficiency states often occur concurrently, the effect of iron deficiency on lead toxicity has not been well studied. Despite the effects of lead neurodevelopment and behavior problems, the presence of elevated lead concentrations does not necessarily imply that impairment will occur.

Intelligence

In the early 1990s, the US Centers for Disease Control and Prevention[81] and the US EPA[384] concluded that blood lead levels of 10–15 μg/dL present risks of developmental abnormalities in children; therefore, these agencies recommended screening children for blood lead to reduce blood lead levels below 10 μg/dL. Recently, some analyses suggest lead effects on cognition may extend below blood lead concentrations of 10 μg/dL.[36] Despite many studies on the cognitive effects of lead, a number of methodological issues complicate the interpretation of many positive studies including ascertainment bias, specificity of outcome variables (neuropsychological and development testing), multiplicity of outcome measures, control of confounding variables having a greater effect on development than blood lead, and the lack of consistency in the outcome. Most of these studies use blood lead (i.e., a measure of recent lead exposure) rather than long-term lead exposure (cumulative blood lead index, K X-ray fluorescence). Most epidemiological studies indicate a modest inverse association between lead exposure and cognitive function in children; there is general, but not unanimous, consensus that this association is causal.[385,386]

Deficit Initial studies during the 1980s and 1990s linking the effect of biomarkers of lead exposure (blood, teeth, bone) on cognitive development primarily involved intelligence testing. Several,[387,388,389] but not all,[390] epidemiological studies associated blood and bone lead concentrations with decrements in intelligence testing during childhood; some of the positive studies[387] developed hypotheses after the study outcomes were known, resulting in selected choices of statistics, models, and result reporting (i.e., harking). The effect of blood lead in these studies on cognitive development is relatively small (e.g., ~1–3 point decrease in WISC-R Full-Scale IQ with an increase in average lifetime blood lead from 10–20 μg/dL) compared with confounding variables (e.g., social factors, serum folate concentrations, home environment, family income).[391,392] Needleman et al. reported a 4-point reduction in Intelligence Quotient scores; significantly fewer children with superior Intelligence Quotient scores in a study of asymptomatic children with elevated total body lead stores as measured by lead dentine concentrations.[393] A study of nonverbal intelligence in 188 children of Ecuadorian Andean lead-glazing workers suggested a dose-related decline in visual-spatial intelligence and nonverbal reasoning of ~2 IQ points per 10 μg/dL increase in blood lead levels as measured by the Raven Colored Progressive Matrices (RCPM).[394] The mean blood lead level of the children was 29.3 μg/dL with a range of 3.5–94.3 μg/dL. Of the 47 children with blood lead levels <10 μg/dL, 30 children had RCPM standard scores $\leq 25^{th}$ percentile, whereas 97 of 141 children with blood lead levels >10 μg/dL had abnormal RCPM scores. Although lead exposure may affect performance on neurodevelopment measures, lead concentrations in children account for a relatively small portion (i.e., ~4–8% of the explained variance) compared with the child's family and personal psychosocial experiences.[395] In a study of 68 children aged 12–36 months presenting to a large urban public hospital clinic, children with capillary blood concentrations between 10–24.9 μg/dL had a mean Mental Developmental Index (Bayley Scales of Infant Development) score of 6.2 points (95% CI: 1.7–10.8) lower than children with blood lead concentrations <10 μg/dL after adjustment for confounders.[396] Regression analysis indicated that blood lead accounted for 5% of the variance in the Mental Development Index compared with 13% for cognitive stimulation in the home environment.

Cross-sectional and prospective studies associating blood lead levels of 10–25 μg/dL with a reduction in IQ (i.e., primarily verbal IQ) provide the strongest evidence available on the neurotoxicity of low-level lead exposure. Most studies show an inverse relationship between blood lead levels in this range and measures of IQ. At these lead concentrations, perceptuomotor skills appear significantly more sensitive to the effects of lead than the language-related measures of intelligence.[397] A meta-analysis of available studies indicated that the magnitude of the reduction is 0–5 points for every 10 μg/dL increment in blood lead level. Controlling for socioeconomic factors (maternal education, child-rearing environment, maternal depression) reduces the most likely range to ~1–3 points.[72] These studies adjusted for maternal IQ but not for paternal IQ.

The shape of the exposure-response curve below 10 μg/L remains controversial. Several cross-sectional observational studies suggest an inverse association between intelligence and blood lead levels at concentrations <10 μg/L;[398] this nonclassical exposure-response curve implies increasing impact of the blood lead level at concentrations <10 μg/L. Confounding factors (i.e., covariates) that vary from study to study may account for some of the differences in deficits including prenatal lead exposure, particularly in the third trimester.[399] As the blood lead level decreased over the last several decades, the frequency distribution changed from normal to exponential.[400] Several authors suggest the shape of the curve at low blood lead concentrations may reflect a statistical artifact rather than a biological effect.[401,402]

Threshold The threshold for the effect of lead on neurodevelopment is not well defined; risk models (e.g., benchmark dose analysis) suggest reductions in IQ may occur at prenatal and postnatal lead exposures <10 μg/dL.[403] To date, there is no clearly defined blood lead concentration below which cognitive performance does not decline, including blood lead concentrations <10 μg/dL based on a pooled analysis of seven cohort studies of the association between blood lead concentrations and intelligence measures.[398] Reanalysis of the Lanphear pooled-analysis data supported a nonlinear exposure-response; however, the exposure-response for decrements in IQ and blood lead concentrations <10 μg/L was linear.[404] The effects of confounding variables (maternal/paternal education, homeownership, employment status, residential mobility, insurance status, child health, maternal smoking) and the lack of precision in the neuropsychological measures limit the ability of these studies to detect a threshold effect of lead on IQ. The exact temporal relationship is unclear. Some studies suggest that blood lead levels <10 μg/dL are associated with decrements in achievement tests and IQ scores when compared with children with very low blood lead levels (i.e., 1–2 μg/L). In an analysis of data from the New England Children's Amalgam Trial, school-age children (mean age = 8 years, range 6–11.5 years) with blood lead levels of 5–10 μg/dL had lower adjusted scores in overall intelligence (Wechsler Intelligence Scale for Children), visual-spatial skills, executive function, and IQ-adjusted academic achievement when compared with children with blood lead levels <2 μg/dL.[405] The former group had adjusted scores 7.8 ± 2.4 and 6.9 ± 2.2 points lower on reading and math composite scores, respectively, compared with the low lead group ($P < 0.01$). Higher lead levels were associated with more negative effects on verbal IQ (e.g., vocabulary) than performance IQ. These scores were adjusted for age, race, socioeconomic status, and primary caregiver IQ, but there was no information on lead concentrations prior to the initiation of the study. This study did not detect cognitive effects at blood lead levels <5 μg/dL. The prospective Port Pirie study demonstrated a linear association between blood lead and developmental outcomes without definite evidence of a threshold; however, the magnitude of the effects was sufficiently small to define this curve only at a group rather than individual level.[406] The effect of lead on IQ at low lead levels is also relatively small compared with other factors. In a Swedish study of 3,176 primary school children aged 7–12 and followed to ages 16–19 years (mean BLL = 3.4 μg/dL; 90th percentile = 6.0 μg/dL), univariate analysis indicated the BLL accounted for 1.5% of the variance in IQ.[407] Other factors accounted for 19.3% of the variance; socioeconomic status did not correlate to BLL in this study.

Persistence There are limited data on the critical periods of lead exposure and the persistence of these neurobehavioral effects. The effect of lead *in utero* and the first year of life does not appear to persist into the grammar school year when lead exposure ceases and blood levels return to normal by the age of 2 years.[408,409] During preschool years, several factors are associated with the persistence of neuropsychological deficits including high prenatal exposure to lead, high postnatal lead exposure with elevated blood lead levels at the age of 2 years, and lower socioeconomic characteristics.[410] Ruff et al. reported an improvement in cognitive skills in children aged 13–87 months when blood lead concentrations were reduced.[411] The initial blood lead concentrations ranged from 25–55 μg/dL. The Port Pirie study followed children with mean blood lead levels of 21.2 μg/dL at 2 years of age; the mean lead level declined to 7.9 μg/dL at age 11–13 years.[412] The cognitive deficits associated with lead exposure in early childhood were only partially reversible after a subsequent decline in blood lead levels. Within this cohort, the cognitive skills of children with higher lead exposures changed little with age compared with children with lower exposure levels. Because very early lead exposure (i.e., perinatal period) is not correlated well to school-age IQ, the issue of reverse causality remains (i.e., do children with lower IQ eat more lead?). This prospective study indicated cumulative lead exposure across childhood and early adolescence rather than prenatal blood lead best predicted developmental outcomes, suggesting persistent rather than transient effects. The Dunedin cohort study followed 565 participants (56% participation rate) with BLL at age 11 of 10.99 ± 4.63 μg/dL until age 38 years.[413] Each 5 μg/dL increase in BLL was associated with 1.61 (95% CI: −2.48 to −0.74) decline in adult IQ driven primarily by lower scores in perceptual reasoning (IQ = −2.07, 95% CI: −3.14 to −1.01) and working memory (IQ = −1.26, 95% CI: −2.38 to −0.14). The associations were not statistically significant between BLL and verbal comprehension or processing speed. Each 5 μg/dL increased in BLL was also associated with lower socioeconomic status (IQ = −1.79, 95% CI: −3.17 to −0.40).

School Performance An observational study comparing school examination performance in Wisconsin children with moderately elevated blood lead levels (10–<20 μg/dL) before age 3 years and control children (<5 μg/dL) indicated the highest association with lead and proficiency category was language arts (OR = 1.70,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

95% CI: 1.31–2.21) and lowest for math (OR = 1.40, 95% CI: 1.08–1.81).[414] Household social status and childhood health partially explained the decreased examination scores. A study of 855 children aged 6–9 years found a 5.8-point difference on the British Ability Scales between the groups with the highest and lowest blood levels (range, 3–34 μg/dL).[415] Although there was a dose-response relationship between blood lead level and test scores, there was no evidence of a threshold effect. Retrospective cohort studies of children with early lead exposure suggest effects on academic achievement persist into elementary and junior high school, particularly for children with blood lead concentrations >10 μg/dL based on a convenience sample extracted from databases and multivariate logistic regression analysis of Michigan Educational Assessment Program scores.[416] These scores were analyzed by two categories rather than a continuous variable. Additionally, some epidemiology data suggest decrements (i.e., 10–15%) in math/reading achievement when comparing third-grade children with current BLL 5–9 and 0–4 μg/dL.[417]

Behavior Abnormalities

Although some neurobehavioral abilities appear more vulnerable to early lead exposure, current studies have not clearly identified a neurobehavioral phenotype characteristic of early lead exposure.[418] Early studies suggested an association between elevated lead levels and signs of inattention, hyperactivity, and disruptive behavior.[419] A retrospective cohort study of 850 first grade boys years as the exposure measure associated high bone lead levels as measured by tibial K X-ray fluorescence spectroscopy at age 12 with an increased clinical score for attention deficits, delinquency, and aggression as assessed by teachers and parents.[420] The study compared groups with scores in the upper 30th percentile on a self-reported antisocial behavior scale with controls matched by an equal number drawn randomly from the group with scores in the lower 70% of the distribution. A case-control study from the same group compared 194 youths aged 12–18 years, arrested and adjudicated as delinquent by a Pennsylvania Juvenile Court with 146 controls from high schools in Pittsburgh without juvenile records.[421] After adjusting for covariates (parental education/occupation, single-parent home, race, children in the home, neighborhood crime rate), bone lead concentrations >25 ppm were four times higher in adjudicated delinquent controls using logistic regression models. The study did not report blood lead levels or establish a dose-response relationship between bone lead and adjudicated delinquency. A prospective longitudinal birth cohort study of 195 urban, inner-city adolescents recruited from the Cincinnati Prospective Lead Study between 1979–1985 analyzed the relationships between prenatal/postnatal lead exposure and antisocial/delinquent behaviors.[422] The mean maternal blood lead level was 8.9 μg/dL with 35% of the cohort exceeding 25 μg/dL between birth and 5 years of age. After adjustment for co-variables, prenatal and postnatal blood lead concentrations were significantly associated with an increased frequency of parent-reported delinquent and antisocial behaviors. The study reported total scores without individual covariate analysis; maternal blood lead levels were surrogates for cord blood lead concentrations. Subsequent studies demonstrated inconsistent findings, in part because of the difficulty controlling confounding social and demographic variables (e.g., poverty, parenting practices) and design issues (lack of simple measures of neurobehavioral function, substantial individual variation, strong multifactorial causes).[423] The true associations between BLL and behavioral outcomes including criminal behavior are difficult to separate from low socioeconomic status. In a study of 553 New Zealand participants (56% participation rate) in the Dunedin Multidisciplinary Health and Development Study followed 15–38 years of age, the BLL at age 11 (10.99 ± 4.63 μg/dL) did not correlate to self-reported offenses, recidivism, convictions, or violence.[424] Although the BLL and socioeconomic status of participants in this study were similar to children in New Zealand,[425] the BLL was a poor discriminator between any conviction and no convictions (AUC = 0.58). The study did not support a dose-response relationship between BLL and criminal behavior, despite the lack of confounding of poor socioeconomic status.

Private structured interviews assessed psychopathology symptoms in the New Zealand Dunedin cohort using the Diagnostic Interview Schedule five times between ages 18–38 years evaluating 11 disorders scaled to 100 ± 15.[426] Each 5 μg/dL increase in childhood BLL at age 11 years was associated with a 1.34 (95% CI: 0.11–2.57, $P = 0.03$) increase in general psychopathology driven primarily by internalizing (depression, anxiety, fears, phobias) and thought disorders (manic, obsessive-compulsive, psychotic). As with IQ, the effect sizes associated with childhood lead exposures and adult psychopathology/personality difficulties are small ($r = 0.08$) compared with childhood maltreatment ($r = 0.21$) and family mental health illness ($r = 0.23$), suggesting childhood lead exposure is not a major etiological factor in adult psychiatric disease. In childhood, psychopathological symptoms are more often externalizing (e.g., hyperactivity) than internalizing symptoms.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Well-controlled studies demonstrate small, but significant, associations between blood lead and symptoms of hyperactivity, but evidence that lead causes attention-deficit hyperactivity disorder is inconclusive.[66,427] A study of 579 New Zealand 11-year-old children detected a statistically significant association between teacher-reported general behavioral problems and the log blood lead level after adjustment for social, background, and environmental factors. The impact of blood lead levels was small with a 10-fold increase in blood lead associated with an increase in behavioral scores of ~0.1 points. From birth, Wasserman et al. followed 379 3-year-old Yugoslavian children born in two towns, one with a smelter and one without a point source of lead.[428] The children were evaluated by the Child Behavior Checklist; the results were controlled for social and demographic factors as well as for difficult infant temperament. Multiple regression analysis demonstrated that the concurrent blood lead level explained ~1–4% of the variance on the Destructive and Withdrawn subscales. An increase in the blood lead level from 10–20 μg/dL was associated with an increase of 0.5 points on the subscale scores. A prospective observational study followed 780 urban 12–33-month-old children with blood lead concentrations of 20–44 μg/dL. The blood lead concentration at 2 years old was not associated with Conners' Parent Rating Scale-Revised scores at 5 years old or the Behavioral Assessment for Children scores at 7 years of age.[429] However, the concurrent blood lead concentration was associated with externalizing and school problems scales at 7 years of age.

Hearing

Although the exact mechanism is unclear, a cross-sectional study of children over the age of 6 years indicated an increased blood lead level of 6–18 μg/dL was associated with a 2 dB loss in hearing at all frequencies.[430] A prospective study of children in Mexico City demonstrated a significant association between maternal blood lead levels at 20 weeks gestation (GM = 7.7 μg/dL; range, 1–31 μg/dL) and brainstem auditory evoked responses in neonates, 3-month-old infants, and 5½-year-old children.[431,432] The I–V and III–V interpeak intervals data were concave upward, decreasing between BLL 1–8 μg/dL and increasing with a rise in the BLL 8–31 μg/dL. However, a cross-sectional study of 112 Andean children with high blood lead concentrations (mean = 49.25 μg/dL; range, 4.4–119.1 μg/dL) did not detect a significant correlation between blood lead concentration and the brainstem auditory evoked responses including BAEP interpeak conduction.[433]

Kidney

The proximal tubule is the most sensitive renal tissue with inhibition of the activation of vitamin D synthesis occurring near blood lead levels of 25 μg/dL.[434] Intense, short-term lead exposure in children may cause proximal renal tubular dysfunction (i.e., Fanconi syndrome) characterized by aminoaciduria, hypophosphatemia, glycosuria, renal tubular acidosis, and hyperphosphaturia. A case series of 151 young children with elevated blood lead levels (mean = 34.2 ± 22.4 μg/dL), demonstrated elevated urinary concentrations of *N*-acetyl-β-D-glucosaminidase compared with standardized control values.[435] Blood lead concentrations did not correlate to abnormalities of albumin, α-1 microglobulin, retinol-binding protein, or alanine aminopeptidase in urine samples. The study did not report measures of kidney function for children.

In a study of 744 men from the Normative Aging Study initially enrolled in Boston 1963–1968 and evaluated in 1988–1991, multivariate linear regression analysis with log-transformed BLL demonstrated a statistically significant ($P = 0.04$) association between covariant-adjusted creatinine clearance and blood lead levels.[436] The mean age of the study group was 64 years (range, 43–90 years) with a mean baseline BLL of 8.1 μg/dL (range, <4–26 μg/dL). In a similar longitudinal study of 459 enrollees, multivariate linear regression (with log-transformed BLL) demonstrated a statistically significant increase in serum creatinine after adjustment for covariates (hypertension, alcohol consumption/tobacco smoking, age, body mass index, education). The adjusted serum creatinine increased 0.08 mg/dL (95% CI: 0.02–0.13) for a 10-fold increase in BLL. In the cross-sectional Belgian Cadmibel Study of 965 males (mean = 48 years) and 1,016 females (mean = 48 years), multivariate linear regression analysis (with log-transformed BLL) demonstrated 10–13 mL/minute reduction in co-variant-adjusted creatinine clearance for a 10-fold increase in the BLL; the co-variants included diabetes mellitus, analgesic/diuretic therapy, age, body mass index, and urinary γ-glutamyltransferase activity.[437] The mean BLL in men and women were 11.4 μg/dL (range, 2.3–72.5) and 7.4 μg/dL (range, 1.7–6.0), respectively. Issues remain controversial regarding the clinical significance and reversibility of renal abnormalities as well as the contribution of renal impairment to elevated blood lead levels.

Hypertension

Collective evidence from studies of the general population indicates the association between blood lead and hypertension is relatively weak (i.e., 1–2 mm Hg elevation in systolic blood pressure/doubling of BLL)

and inconsistent.[438,439] The British Regional Heart Study demonstrated lead exposure was a minor contribution to the development of hypertension,[438] but the exact strength of the association and the dose-response characteristics were less clear. In a multivariate analysis of NHANES IV data, slight increases in systolic (+0.76 mm Hg, 95% CI: 0.38–1.13 mm Hg) and diastolic (+0.43 mm Hg, 95% CI: 0.18–0.68 mm Hg) blood pressures occurred with doubling of the BLL; however, the odds of developing hypertension were not elevated (0.95, 95% CI: 0.90–1.01; $P = 0.11$).[440] Systolic blood pressure correlated significantly with ethnicity and sex. Several epidemiological studies suggest that the effect of lead on blood pressure in the general population is modest (adjusted regression coefficient, 2–4 mm Hg/ln (μg Pb/dL)).[441] Confounding factors interacting with the effect of lead on hypertension include caffeine use, ethnicity, and amount of lead accumulation. Concern exists over the possibility that soft acid water increases lead solubility and the incidence of hypertension/cardiovascular mortality in areas with soft water supplies. Consequently, the importance of lead-induced changes in blood pressure remains controversial.

In a study of participants in NHANES II, linear regression analysis indicated an independent relationship between blood pressure and blood lead level in middle-aged men, but not women.[442] The cross-sectional study of 7,731 men (range, 40–59 years) from 24 British towns in the British Regional Heart Study demonstrated a covariate-adjusted blood pressure increase per 2-fold increased BLL of 1.45 mm Hg (95% CI: 0.47–2.43 mm Hg) systolic and 1.25 mm Hg (95% CI: 0.65–1.85 mm Hg) diastolic based on multiple regression analysis.[443] Covariates included alcohol consumption, cigarette smoking, age, body mass index, and socioeconomic factors. The median BLL was 13–16 μg/dL with 8% ≥25 μg/dL.

A meta-analysis of 58,518 subjects from the general population and 12 occupational studies detected a weak association between blood lead concentrations and hypertension.[317] In this study, a 2-fold increase in the blood lead concentration was associated with a mean increase of 1.0 mm Hg systolic and 0.6 mm Hg diastolic blood pressure. A logical regression model of hypertensive patients in a group of US veterans from the Normative Aging Study suggested that long-term accumulation of lead as measured by K X-ray fluorescence was an independent risk factor for the development of hypertension.[444] The mean BLL was 6.3 ± 4.1 μg/dL.

The relationship between blood lead and the development of hypertension in women is suggestive, but the association in epidemiological studies is weaker than with men; this relationship varies more with other factors (e.g., alcohol consumption, age).[445] A case-control study evaluated lead concentrations from 93 middle-aged (mean = 61 years) self-referred patients with hypertension chosen from the National Nurses' Health Study and 204 controls matched for age and smoking.[446] The combined (cases and controls) mean BLL was 3 μg/dL (range, <1–14 μg/dL). Although there was no statistically significant association between hypertension and mean blood or tibial lead concentrations, the odds ratio of developing hypertension was ~2 for women in the 90th percentile of patella lead values compared with women in the 10th percentile.

In an analysis of 2,563 males (mean = 47.5 years) and 2,394 females (mean = 47.7) without a history of treated hypertension from the Health Survey for England, HSE, the covariate-adjusted diastolic blood pressure increased with increasing BLL in men but not in women based on multivariate linear regression (with log-transformed BLL).[447] Systolic blood pressure was not correlated to the BLL in men or women. Covariates included in the above model were region of residence, socioeconomic status, alcohol consumption, tobacco smoking, age, and body mass index. The geometric mean BLLs in men and women were 3.7 μg/dL and 2.6 μg/dL, respectively. An 8-year prospective cohort study of 728 people aged 20–82 found no consistent association between change in blood pressure and blood lead levels <30 μg/dL.[448] The risk ratio for developing hypertension given a doubling of the initial blood lead level was 1.2 (95% confidence interval, 0.7–2.0). The blood lead level did not predict the development of hypertension in the 47 patients in this study.

Reproductive Abnormalities

Increased fetal mortality in the offspring of women exposed to high lead concentrations (>40–60 μg/dL) is an unfortunate part of the Industrial Revolution.[449] Sterility, miscarriages, stillbirths, premature births, and low birth weight were recognized complications of high lead exposure in female workers and wives of husbands working in the lead industry.[450] Current data do not suggest lead causes major congenital abnormalities. Pica increases the risk of maternal blood lead concentrations >45 μg/dL. In a study of New York City Health Department data on 491 cases of lead-poisoned pregnant women, the odds ratio for BLL >45 μg/dL was 3.3 (95% CI: 1.25–8.68) in women with pica compared with women without reported pica.[65] The mean BLL for pregnant women with pica was 29.5 μg/dL.

Pregnancy Outcomes

Issues regarding the timing and maternal BLL necessary to cause adverse effects of lead on pregnancy outcomes (low birth weight, preterm delivery, small-for-gestational-age) at maternal BLL <25 μg/dL complicate the interpretation of limited data on the possibility of a specific no-adverse-effect threshold.[451] Some, but not all, epidemiological studies reveal a dose-response effect of preterm delivery and maternal blood lead concentrations >10–15 μg/dL. Lead exposure at this concentration probably does not cause an increased risk of premature rupture of membranes, miscarriages, or stillbirths.[451,452] In a study of 262 mother–infant pairs reported to California lead surveillance agencies for elevated BLL from various clinical laboratories, an increased risk of adverse pregnancy outcomes (preterm delivery, small-for-gestational-age) was associated with maximum maternal BLL >10 μg/dL when compared with maximum maternal BLL <10 μg/dL.[453] The reason for the referrals was not available, limiting the extrapolation of the data to all pregnant women. Additionally, women with maximum BLL <5 μg/dL tended to deliver smaller infants (mean = 3401 g) than women in the range of 6–9 μg/dL (mean = 3571 g), suggesting the presence of confounding variables.

In a nested case-control study of 668 Mexican women seeking prenatal care in Mexico City, the odds ratio for spontaneous abortion after multivariant adjustment was 1.8 (95% CI: 1.1–3.1) for every 5 μg/dL increase in blood lead level.[454] The mean BLLs in cases and controls were 12.0 μg/dL and 10.1 μg/dL, respectively. A study of 304 Yugoslavian women living near a lead smelter (mid-pregnancy mean BLL = ~16 μg/dL) did not detect a positive association between low lead levels and the rate of spontaneous abortion when compared with 335 pregnant women living >25 km away (mid-pregnancy mean BLL = ~5 μg/dL).[455] A higher incidence of premature delivery (13% vs. 3%, respectively) and early membrane rupture (17% vs. 0.41%, respectively) occurred in 253 women living near Missouri mines compared with 249 women from a different area of Missouri.[456] The prospective Australian Port Pirie study compared women in a lead smelter community in South Australia with women in surrounding rural areas and neighboring towns; the mean mid-pregnancy maternal blood lead levels in 851 pregnant women from Port Pirie and surrounding community controls were 10.6 μg/dL (n = 531) and 7.6 μg/dL (n = 171), respectively.[457,458] The study demonstrated no association between spontaneous abortions and BLL, whereas preterm delivery correlated to maternal lead levels at delivery. The risk of preterm delivery at maternal blood lead levels of 14 μg/dL was 8.7 times greater than maternal blood levels <8 μg/dL. Other investigators have not detected a statistically significant relationship between maternal or fetal lead levels and preterm delivery.[459,460,461] In a convenient sample of 121 Finnish women occupationally exposed to lead and categorized with BLL <10 μg/dL, 10–19 μg/dL, and ≥20 μg/dL, time-to-pregnancy was not associated with BLL when compared with low lead exposure.[462]

A review of nine studies on lead exposure and gestational hypertension or preeclampsia indicated a positive association in six of the studies.[463] The mean whole blood lead concentration in most of the studies was <10 μg/L as measured during a range of time from the last trimester to the postpartum period. Interpretation of these studies and the association between gestational hypertension is complicated by a lack of control of confounding variables (e.g., calcium supplementation, body mass index) and inadequate exposure measures (e.g., plasma lead is probably a better measure of the lead available to diffuse into the placenta than whole blood lead).

Congenital Abnormalities

Currently, few data associate increased blood lead levels and major malformations following exposure to low lead levels; the data on the pattern of minor congenital abnormalities and BLL is inconsistent. A case report associated the VACTERL association (*V*ertebral anomalies, *A*nal atresia with/without fistula, *C*ardiac defect commonly with ventricular septal defect, *T*racheoesophageal fistula, *R*enal anomalies, *L*imb anomalies) with a maternal blood lead level of 62 μg/dL at 8 weeks gestation.[464] In a retrospective study, Needleman et al. found a statistically significant association between cord blood lead levels and the occurrence of minor malformations (e.g., hemangiomas, hydrocele, undescended testes, lymphangiomas) as a whole; however, no single malformation demonstrated a statistically significant correlation with cord blood lead levels.[313] Other studies (Port Pirie,[458] Cleveland[465]) found no association between congenital anomalies and lead exposure at the blood lead concentrations present in the women. The mean venous blood lead concentration at delivery for 248 Port Pirie women was 11.2 ± 0.21 μg/dL compared with 6.48 ± 1.88 μg/dL (2.7–11.8 μg/dL) in whole blood at delivery for 185 Cleveland women.

Fetal/Infant Physical Development

The association between lead levels <25 μg/dL and early development is less clear; data on physical development

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

are conflicting. A study of 305 lower socioeconomic status women residing in predesignated lead-hazardous areas of Cincinnati reported a statistically significant association between maternal blood lead levels between 6–28 weeks of gestation and birth weight; all maternal blood lead levels were <30 μg/dL.[379] Infant development rather than birth weight was the primary outcome of this study. A cross-sectional study of 165 pregnant women living in a rural area and 19 pregnant women living in an urban area demonstrated no association between maternal blood lead levels in early pregnancy and fetal development at 6 days of age (Guthrie test).[466]

Some, but not all, epidemiological studies reveal a dose–response effect of maternal blood lead concentrations >15 μg/dL on some measures of fetal growth and development. An analysis of the National Health and Nutrition Examination Survey 1976–1980 data on ~2,700 children aged 0.5–7 years suggested that blood lead levels of 10–35 μg/dL were inversely correlated to stature (height, weight, chest circumference).[467] In a prospective study of 260 infants followed from birth, covariate-adjusted growth rates in stature were negatively correlated to the mean infant BLL at 3–15 months only when prenatal (maternal) blood lead levels were >7.7 μg/dL.[468] An increase in the postnatal blood lead concentration of 10 μg/dL was associated with a 2 cm decrease in height compared with an infant having a stable blood lead concentration.

Male Reproduction

In male workers, very high chronic lead exposure may produce decreased libido, impotence, abnormalities in the formation of sperm, and reduced fertility. Chronic lead exposure (blood lead levels >45–55 μg/dL) results in a progressive decline of the total sperm counts along with abnormal sperm motility and morphology, particularly when the blood lead levels exceed 60–70 μg/dL.[469,470,471] European cross-sectional studies of lead-exposed workers indicate adverse lead effects on sperm concentration and susceptibility to acid-induced denaturation of sperm chromatin are unlikely following chronic lead exposure below whole blood lead levels of 45 μg/dL.[472] Total sperm count and sperm concentration are the most sensitive measures of semen quality in men exposed to lead.[473] Follow-up studies on cohorts of lead-exposed workers suggest that lead-related changes in sperm quality are at least partially reversible following a reduction in lead exposure.[474] Although these studies indicate chronically high lead exposures adversely affect sperm quality, a cohort of 229 French battery workers aged 20–60 years with mean annual BLL of 46.3 ± 15.2 μg/dL and followed a mean of 4.1 years did not demonstrate a consistent association between measures of lead exposure or a dose-related reduction in fertility based on the annual occurrence of live births.[475] The 125 non-lead exposed workers were not evaluated for BLL. Similarly, a cross-sectional study of 97 South African lead battery workers with mean whole blood lead levels of 53.8 ± 11.2 μg/dL reported no consistent association between lead exposure and measures of fertility or procreation.[476] The study did not include a control population. Together, these studies suggest the reduction in semen quality at these blood lead levels is not sufficient (i.e., sperm concentration $<5 \times 10^{-6}$/mL) to cause a reduction in the fertility rate of these workers.

Although the evidence for reduced fertility is inconclusive, current data suggest the threshold for fertility in men begins in the BLL range of 30–40 μg/dL. A study of Taiwanese lead workers indicated that increasing the whole blood lead concentration by 1 μg/dL increased the time to pregnancy by 0.15 cycles in workers with BLL ≥30 μg/dL; there were no statistically significant reductions in fertility below these lead concentrations.[477] A retrospective study of Finnish lead workers did not detect reduced time to pregnancy or decreased fecundability in workers exposed to whole blood lead levels up to 50 μg/dL.[478] In a group of 74 Belgian lead battery workers with a mean BLL of 46.3 μg/dL, the logistic regression model demonstrated a significant reduction in fertility (OR = 0.65, 95% CI: 0.43–0.98) during the period of exposure to lead, cadmium, and manganese when compared with 138 controls (mean BLL = 10.4 μg/dL). The mean duration of lead exposure was 10.7 years; the duration of lead exposure correlated to the decrease in fertility.

Studies on the effects of lead on male endocrine function are conflicting. A study of 122 current lead workers (mean BLL = 35 μg/dL, range 9.6–77.4 μg/dL) demonstrated a moderate increase in plasma luteinizing hormone and plasma follicle stimulating hormone at blood concentrations 10–40 μg Pb/dL; however, these hormone levels reached a plateau or decline at higher blood lead levels.[315] Another study of lead workers with BLL 17–77 μg/dL demonstrated a subclinical increase in follicle-stimulating hormone only at blood lead levels >47 μg/dL.[479] Neither study detected a change in plasma testosterone levels. A case-control study of Finnish lead workers did not demonstrate a statistically significant relationship between the incidence of spontaneous abortions and paternal lead exposure.[480] None of the adjusted odds ratios for the categories of paternal lead exposure during spermatogenesis (i.e., 80 days before conception) reached statistical significance including the highest category (BLL = ≥39.3 μg/dL; OR = 1.6, 95%

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

CI: 0.6–4.2). Adjusted confounders included maternal organic solvent/mercury exposure, parity, contraception, previous spontaneous abortion, paternal cadmium/mercury exposure, and alcohol use. A retrospective case-control study of estimated paternal lead exposure and strabismus suggested a weak but statistically nonsignificant association (RR = 2.6, 95% CI: 0.4–27) between paternal lead exposure and strabismus.[481] Three industrial hygienists estimated the blood lead exposure during conception through infant age of 9 months or age at diagnosis; no blood lead levels were available for confirmation of estimated lead exposure. The unadjusted odds ratio for the highest paternal lead exposure category was 1.2 (95% CI: 0.4–3.3). Multivariate adjustments did not affect the exposure odds ratios.

Carcinogenesis

The National Toxicology Program lists lead and lead compounds as reasonably anticipated to be human carcinogens; the International Agency for Research on Cancer determined inorganic lead was Group 2A carcinogen (probably carcinogenic to humans) and organic lead was Group 3 (not classifiable). Overall, there is small, but consistent increased incidence of some cancers following long-term inorganic lead exposure in occupational cohorts. The strongest epidemiological evidence involves stomach and lung cancers.[482] The IARC determined inorganic lead was a Group 2A (probable) human carcinogen based on limited epidemiological data in workers and an excess of renal tumors and gliomas in rodents administered lead acetate and lead subacetate. The US National Toxicology Program lists lead and lead compounds as substances reasonably anticipated to be carcinogens with limited epidemiological evidence of carcinogenicity in humans.[483] Almost all epidemiological studies of lead workers have design flaws that limit the validity of conclusions regarding the carcinogenicity of lead.[37] Several cohort studies suggest small excesses (i.e., RR = 1.3–1.5) of stomach cancer, but the effect of confounding variables (dietary habits, ethnicity, *Helicobacter pylori* infection, socioeconomic status) could not be excluded; a nested case-control study of stomach cancer suggested causes other than lead for the elevated SMR of stomach cancer.[484] The risk of lung cancer appears relatively small with possible confounding by exposure to arsenic and smoking. The association between occupational lead exposure and other cancers (e.g., brain, bladder, kidney) is equivocal. There are few data on the carcinogenic effect of metallic lead in animals, in part because of the difficulty of administering these relatively less soluble lead compounds compared with lead acetate.

Occupational Exposure

The results of cancer mortality studies of lead workers are inconsistent. Some mortality studies of lead workers suggest the possibility of an association between respiratory or stomach cancers and lead exposure,[485,486] but the small size of the studies, potential confounding factors, and the lack of a clear trend between exposure (duration, intensity) and the incidence of cancer limit conclusions about a definite causal relationship. In a cohort study of 4,518 lead battery workers and 2,300 lead smelter workers, there was a statistically significant increased mortality from lung cancer (SMR = 116, 95% CI: 104–130), stomach cancer (SMR = 147, 95% CI: 112–190), and cancer of the thyroid and other endocrine glands (SMR = 308, 95% CI: 133–607).[484] Except in some lung cancer studies, the lack of an exposure-response relationship suggested that the increased incidence of cancer was not related to lead exposure. A review of the blood lead concentrations of these workers suggested that the lead exposure exceeded current biological exposure limits. About 69% of the lead battery workers and ~39% of the lead smelter workers were employed for at least 20 years. The lack of exposure data and the presence of confounding variables (arsenic, nickel, smoking) complicate the interpretation of the data on lead and cancer.

A meta-analysis of cancer studies of workers exposed to lead suggested increased relative risk ratios for developing lung cancer (RR = 1.29, 95% CI: 1.2–1.5), stomach cancer (RR = 1.33, 95% CI: 1.18–1.49), and bladder cancer (RR = 1.41, 95% CI: 1.16–1.71).[487] However, the authors noted that most of the studies did not account for confounding variables (e.g., smoking). A mortality study of 1,388 Italian workers at a lead-smelting plant did not demonstrate an elevated rate of digestive, nervous system, or lung cancer using standardized mortality ratios.[488] Although Poisson regression analysis indicated the risks of kidney and genitourinary cancers increased with the duration of employment, the SMR of these cancers was not elevated when compared with national mortality rates. There were no data on exposure, smoking, or the histological type of these cancers. A study of 3,979 Swedish workers at a lead smelter revealed an increased mortality rate (SIR = 2.8, 95% CI: 2.1–3.8) from lung cancer for the group of long-term lead workers when compared with cancer rates of the general population in the surrounding county.[489] The cancer rates of all other malignancies were comparable to those of the general population. Several factors suggested a possible interaction between lead and other carcinogens including the lack of a significant relationship between cumulative lead exposure index and lung cancer rates.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The small number of cases and the presence of several confounding variables (smoking, arsenic, nickel) limited definitive conclusions about the carcinogenicity of lead. A subsequent nested case-referent study of this Swedish cohort of primary smelter workers did not support a causal relationship between occupational exposure to inorganic lead or lead compounds and lung cancer.[490] A Canadian case-control study of histologically confirmed cases of lung cancer did not find an excess risk of lung cancer associated with occupational exposure to inorganic lead (engine emissions or other sources) based on a blinded expert-based assessment of lifetime occupational exposure and adjustment for smoking and sociodemographic characteristics.[491] Comparing ever- to never-exposed subjects, the odds ratios were 0.89 (95% CI: 0.72–1.09) for inorganic lead from engine emissions and 0.99 (95% CI: 0.76–1.29) for inorganic lead from other sources.

Some,[492,493] but not all,[484,494] hypothesis-generating studies of workers exposed to inorganic lead suggest an association between brain cancer and lead exposure. A nested case-referent study of neurological cancers revealed a 2-fold increase in the odds ratio of nervous system cancer in workers with blood lead >30 μg Pb/dL compared with workers with BLL <15 μg Pb/dL.[495] The small number of cases and the wide confidence interval limit any conclusions. All the confidence intervals included 1; therefore, the increased ratios were not statistically significant. A meta-analysis of six occupational cohorts provided little evidence of an association between occupational lead exposure and brain cancer.[482] The overall relative risk of brain cancer in these cohorts was 1.06 (95% CI: 0.8–1.4, 69 cases observed), using meta-analysis techniques.

Environmental Exposure

In a study of the US general population, there was no clear relationship between blood lead concentrations and all cancer mortality using data from the National Health and Nutrition Examination Survey II (NHANES II 1976–1980) Mortality Study.[496] The median blood lead level for the highest quartile of the US population in this study was ~20 μg/dL compared with ~7 μg/dL for the lowest quartile of lead exposure. Blood lead levels declined dramatically from NHANES II to NHANES III (1988–1994), when few adults had BLL exceeding 20 μg/dL. Statistical analysis of mortality data from NHANES III suggests BLL as low as 5 μg/dL is associated with an increased risk of death from all causes. In a study of 9,757 participants ≥40 years of age followed a median of 8.55 years with a single BLL measurement at the time of examination, the participants were divided into the following three groups: BLL <5 μg/dL (referent), BLL 5–9 μg/dL, and BLL ≥10 μg/dL.[497] Table 16.7 lists the relative risk of all cause, cancer, and major cardiovascular disease mortality as identified by ICD-10 codes in these two groups compared with the referent group.

Another statistical study of mortality rates in participants in NHANES III also detected a slight increase in mortality rates in the highest tertile (BLL ≥3.62 μg/dL), when compared to the lowest tertile (BLL <1.94 μg/dL).[498] In contrast to the former study, the increased mortality resulted from increased mortality rates from cardiovascular disease; the mortality rates for cancer were similar in both groups. In general, the hazard ratios were <2; therefore, inadequate control of confounding and exposure misclassification (i.e., single BLL) can account for the statistical differences between these groups. In a prospective cohort study of 533 women aged 65–87 years enrolled in the Study of Osteoporotic Fractures from 1986–1988, the risk of multivariate-adjusted all-cause mortality increased 59% (hazard ratio = 1.59, 95% CI: 1.02–2.49, $P = 0.041$) based on the a priori categorization of women into blood lead concentrations above and below 8 μg/dL, respectively.[499] Coronary heart disease accounted for

TABLE 16.7. Relative risk of mortality in NHANES III participants categorized by blood lead level (BLL). (Data from Schober et al.).[497]

	BLL <5 μg/dL (Referent Group)	BLL 5–9 μg/dL	BLL ≥10 μg/dL
Participants	6,608	2,532	617
Deaths	1,402	828	255
All-cause mortality	1	1.24 (1.05–1.48)[a]	1.59 (1.28–1.98)[a]
Cancer mortality	1	1.44 (1.12–1.86)[a]	1.69 (1.14–2.52)[a]
Major cardiovascular disease mortality	1	1.20 (0.93–1.55)[a]	1.55 (1.16–2.07)[a]

Abbreviation: BLL = blood lead level.

[a] Relative risk (95% confidence limit) compared with referent group (BLL <5 μg/dL).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

most of the increased mortality (HR = 3.08, 95% CI: 1.23–7.70, $P = 0.016$) in the women with blood lead concentrations ≥8 μg/dL; there was no association between blood lead and cancer, stroke, or non-cardiovascular deaths. In the population-based Shanghai Women's (n = 73,363) and Men's (n = 61,379) Health Studies, lead exposure was estimated for each participant based on a job-exposure matrix as developed by expert analysis of self-reported job history; the referents were the participants with no reported lead exposure. The cohort-specific relative hazard rate ratios were elevated for meningioma (RR = 2.4, 95% CI: 1.1–5.0) for women ever exposed; no meningiomas occurred in men ever exposed to lead.[500] The rate ratios were above 1 for kidney (RR = 1.4, 95% CI: 0.9–2.3) and brain (RR = 1.8, 95% CI: 0.7–4.8) cancers in the ever-exposed group, but the value was not statistically significant. There was no association between ever-exposed to lead and lung or stomach cancers.

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/dL = 0.0483 μmol/L = 48.3 nmol/L
1 μmol/L = 20.7 μg/dL = 207 μg/L
1 nmol/L = 0.207 μg/L
1.77 μmol ZPP/L = 110.81 μg ZPP/dL

Analytic Methods

Biological Samples

Techniques for the analysis of lead in biological media include anode stripping voltammetry (ASV), flame atomic absorption spectrometry (AAS), graphite furnace atomic absorption spectrometry (GFAAS),[501] inductively coupled plasma/atomic emission spectrometry (ICP/AES),[502] and inductively coupled plasma/mass spectrometry (ICP/MS). The latter allows the analysis of multiple trace metals from a single sample with low detection limits; however, the cost is substantially higher than GFAAS. Limits of detection for flameless/atomic absorption spectrometry and graphite furnace/atomic absorption spectrometry are ~0.1 μg/dL and 0.005 μg/dL, respectively.[503] Comparison of lead results from samples of blood and food by GFAAS and ICP/MS indicates the latter results are ~10–20% lower than GFAAS results.[504] Specialized methods for analyzing lead in biological samples include neutron activation analysis, X-ray fluorescence spectroscopy, and isotope dilution mass spectrometry. The latter method is highly sensitive for the detection of lead. Some, but not all, methods involve digestion of the sample by wet ashing with strong acid and heat, followed by the conversion of all lead species to the same lead compound by redissolving the residue in dilute acid.

US proficiency standards allow blood lead testing to operate within a total allowable error of ±4 μg/dL or ±10% whichever is greater; however, the evaluation of blood lead concentration <10 μg/dL requires better precision (i.e., ±2 μg/dL).[395] Most common commercial laboratories lack sufficient accuracy to distinguish between a BLL of 3.5 and 5.0 μg/dL. Common clinical laboratory tests reliably detect the biological effects of lead including coproporphyrin, δ-aminolevulinic acid (ALA), ALA dehydratase activity, and erythrocyte protoporphyrin concentrations; however, these tests are not specific for lead.

Protoporphyrins

Measurement of free erythrocyte protoporphyrin and erythrocyte zinc protoporphyrin are less susceptible to environmental contamination than whole blood lead analysis. Older extraction techniques did not separate protoporphyrins including zinc protoporphyrin, but contemporary technology directly measures zinc protoporphyrin concentrations in whole blood using liquid chromatography. The normal ratio between free erythrocyte protoporphyrin and zinc protoporphyrin is ~10/9.[505] ZPP concentrations vary depending on the specific analytical technique. The ZPP concentrations measured by hemato-fluorometer are consistently higher (i.e., ~1/3) compared with analysis by HPLC.[506] Contemporary assays directly measure ZPP concentrations, whereas older extraction methods converted ZPP to FEP by removing the zinc.

Bone Lead

Methods for the determination of lead in bone include ^{57}Co K X-rays in the second phalanx of the index finger (primarily cortical bone) using a germanium silicon detector,[507] ^{109}Cd K X-rays of the tibia (midshaft cortical bone) and calcaneus/patella (trabecular bone),[508] L X-rays of the tibia produced using an X-ray generator, and *in vivo* bone K X-ray fluorescence.[509] The most reliable technique is K X-rays as a result of deeper penetration (i.e., 2 cm) into cortical bone than the lower energy L X-rays; the latter technique penetrates the outer 0.5 cm of periosteal bone, detecting high bone lead concentration only at the surface.[510] Thus, K X-rays better analyze the average lead content over the entire bone thickness (i.e., cumulative lead dose) than L

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

X-ray methods.[511,512] Precision of X-ray fluorescence techniques depends on bone mass; therefore, greater measurement errors occur during the analysis of relatively thin pediatric bones compared with the mature bones of adults.

K-shell X-ray Fluorescence

Although K-shell X-ray fluorescence (K-XRF) determines the average lead concentrations in the first 2–4 cm of cortical bone, the measurement is weighted primarily at the surface. The clinical application of K-XRF is limited by its restricted availability and experimental imprecision at low bone lead concentrations. The minimum detectable bone lead level is 3–15 μg/g bone mineral; uncertainty in bone lead measurements ranges from ~3–30 μg Pb/g bone mineral.[513] Because of photon scattering by overlying tissue, imprecision is problematic in obese patients and young children. Bone lead levels based on K-XRF correlate well with age. A little increase in bone lead concentration occurs before the age of 20 years; then, the bone lead level increases linearly in persons without definite exposure to lead.[514] The lead level correlates better with the intensity and chronicity of exposure to lead in the tibia than in the phalanx, calcaneus, ulna, or sternum.[515] Although this technique is reliable, lead contamination may cause inaccurate results in samples from active lead workers.[516] The maximum skin dose of radiation to the tibia from K-XRF is small (0.45 mSv) compared with a chest X-ray.[517]

Bone lead levels measured by K-XRF correlate to cumulative blood lead levels rather than recent blood levels in both workers and children. A cross-sectional study of members of a construction trade union with relatively low exposure (mean = 8.3 μg Pb/dL blood) found a negative correlation between patellar lead levels using K-XRF and the hemoglobin levels;[518] however, the explanatory power of the final model after adjustment for confounding variables was relatively weak ($R^2 < 0.1$). At these low lead levels, no correlation was found between bone lead levels and blood pressure or serum creatinine.

L-shell X-ray Fluorescence

L-shell X-ray (L-XRF) fluorescence detects lead in the first 1–2 mm of bone just below the periosteum using ^{125}I. Unlike K-XRF, L-XRF is sensitive to slight variations in the thickness of skin overlying the bone and movement. These two types of techniques sample different lead pools with L X-ray fluorescence and EDTA-chelatable lead correlating well to recently deposited lead, whereas K X-ray fluorescence techniques sample a much larger lead pool more reflective of chronic lead exposure.[519] The detection limit on L-XRF is 7 μg Pb/g tissue, but the K-XRF technique has several methodological advantages over the L-XRF technique in studying the chronic effects of lead in epidemiological studies.[520] A 3–5-day course of EDTA chelation does not affect the measured bone lead level.[521,522] The effective dose equivalent of L-XRF is small (2.5 μSv).[523] K-XRF is a more widely accepted technique because of the requirements for minimal movement during the L-XRF procedure.

Environmental Samples

The most common methods to determine the content of lead in inanimate objects (dust, soil, paint chips) are inductively coupled plasma/atomic emission spectrometry (ICP/AES), graphite furnace/atomic absorption spectrometry (GFAAS), flame atomic absorption spectrometry, anode stripping voltammetry (ASV), and inductively coupled plasma/mass spectrometry (ICP/MS).[503] These methods detect lead concentrations in the range of 0.24–1.5 μg/dL (2.4–15 ppb) with sensitivity in air in the low μg/m^3 range (0.1–20 μg/m^3).[37] Analysis of environmental samples for lead by ICP/MS displays high sensitivity and easy sample preparation. Although the cost is relatively high compared with ICP/AES, the sensitivity of ICP/MS is many times greater (i.e., three orders of magnitude) than that of ICP/AES. Similar to biological matrices, isotope dilution mass spectrometry is the definitive technique for determining lead with precision, sensitivity, and accuracy; however, technical expertise and high costs limit the availability of this method.

The use of X-ray dispersive electron microscopy allows the determination of metal composition in tissues and powder residues on the skin including lead; these results help establish the distance of the gun from the surface of the skin.[524] Measurements of lead isotope ratios by ICP/MS allow the identification of specific sources of childhood lead poisoning and the relative importance of various environmental sources (soil, water, air).[525,526] Common methods for sample preparation involve microwave and hot plate techniques. For lead concentrations commonly present in the environment, interlaboratory variability ranges up to ~10–15%.[527] Because lead is ubiquitous in the environment, contamination of biological samples may produce false-positive values. Special collection tubes designed for the analysis of trace metals are the preferred containers for the collection of biological samples.

Storage

Whole venous blood lead testing requires careful skin preparation, stainless-steel needles, and special lead-free (tan top) or trace element-free (dark blue top) containers (e.g., Vacutainer, Becton Dickinson Co.). The lead-free Vacutainer tubes should be used unless the batch of Vacutainer tubes is tested for lead contamination. Accurate measures of blood lead levels are labor-intensive and expensive. An alternative is rapid microblood lead method,[528] but the accuracy of this method as a screening procedure remains unclear because of its high false-positive rates (>50%).[529] Contamination of capillary specimens may result from lead-soiled fingertips; falsely low values also may occur. Compared with venous blood samples, capillary lead sampling is usually slightly less sensitive but comparably specific when standard techniques prevent contamination.[530] The difference between venous blood lead levels and capillary-venous lead levels is typically relatively small (<1 μg/dL);[531] however, elevated capillary-venous lead concentrations should be confirmed with an analysis of a venous blood sample.[395] The preferred anticoagulant is EDTA rather than heparin. Urine should be collected in acid-washed (nitric acid) propylene bottles washed thoroughly in ultrapure water.

Biomarkers

Blood

Whole blood lead level is the principal biomarker of lead exposure available in clinical laboratories. Whole blood remains the best practical biomarker to discriminate between individuals with different mean lead concentrations.[532] Blood lead is a biomarker of recent exposure (i.e., the last few months); the elimination half-life of lead in whole blood is ~1 month.[72] Time-integrated blood lead concentrations and K X-ray fluorescence are better measures of lead accumulation in the body compared with the blood lead level.[533] Blood lead does not necessarily distinguish between high acute lead exposure and low-level intermediate or chronic high-level lead exposure as a result of the variation of blood lead in response to recent lead exposure. Epidemiological studies document the release of lead from the skeleton and elevations of the blood lead levels in several physiological states including pregnancy, postmenopause, osteoporosis, and lactation.[534]

Erythrocytes contain ~95% of the lead in whole blood.[535] Venous blood is preferable to fingerstick blood because of potential contamination by environmental lead during the latter procedure. Although the whole blood lead concentration is a sensitive index of absolute changes in lead exposure at low blood lead concentrations, the relationship between whole blood lead and lead uptake by the lungs and gastrointestinal tract at high lead concentrations is nonlinear probably as a result of the saturation of lead binding in erythrocytes.[536] The relationship between serum and whole blood lead concentrations is also nonlinear. Basophilic stippling occurs in acute and chronic lead poisoning.

Whole Blood

Whole blood lead is a biomarker of recent exposure (i.e., the last few months), reflecting the exchangeable lead pool, primarily between blood and soft tissues; in the very young, a small, highly mobile bone lead compartment links blood lead and soft tissue lead concentrations.[537] There is substantial interindividual variation in the mobilization of lead from these compartments. Whole blood is an indirect marker of body lead burden in adults as a result of the storage of >90–95% of the total lead body burden in bones and teeth.[538] The slow release of long-term lead stores from the bones and saturation of erythrocytes lead binding sites by increasing blood lead levels produce a curvilinear relationship between bone lead stores and whole blood lead levels.

General Population Whole blood lead concentrations in infants begin increasing in late infancy with a peak of 18–36 months; blood lead levels decline as the age of the child increases.[395,539] Substantial elevations of blood lead levels may occur in children following immobilization as a result of the release of lead from stores in bone.[540,541] The blood lead concentration is relatively labile in young children compared with adults. In a hospital-based study of routine lead screening in Washington, DC, during 2001–2002, the upper limit (97.5%) of lead concentrations in blood samples from female and male infants aged 0–12 months was 4.7 μg/dL and 4.9 μg/dL, respectively, compared with 5.2 μg/dL and 5.6 μg/dL, respectively, for female and male children aged 1–2 years.[542] The mean blood lead concentration decreased in this study for children >10 years of age (4.4 μg/dL) compared with young children <2 years of age. Part of the stabilization with age results from the larger bone stores in adults that contribute relatively larger portions of the blood lead than external

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sources.[543,544] In urban children, the blood lead concentration is ~1–2 μg/dL higher in summer than winter, depending on the amount of lead in the environment.[545] The peak blood lead levels in the summer months usually result from outdoor activity linked to the ingestion of soil contaminated with flaking exterior paint.[546]

Blood lead concentrations in the general population including children have declined exponentially over the last several decades including the prevalence of elevated blood lead concentrations that exceed current recommendations (i.e., ≥5 μg/dL) for reducing the risk of neurobehavioral, cognitive, and developmental effects. The geometric median of blood lead concentrations in children aged 1–5 years based on the NHANES III 1999–2004 data was 1.9 μg/dL (95% CI: 1.8–2.0 μg/dL).[547] The prevalence of children with blood lead concentrations exceeding 10 μg/dL was 1.4%, an 84% decline since 1988–1991. In the United States NHANES IV study, the geometric mean lead concentration in the general US population declined from 1.66 μg/dL (95% CI: 1.60–1.72 μg/dL) in 1999–2000 (US NHANES III) to 1.12 μg/dL (95% CI: 1.08–1.16 μg/dL) in 2009–2010 (US NHANES IV).[35] The 95% CI of blood lead in children aged 1–5 years was 3.37 μg/dL (95% CI: 2.63–4.11 μg/dL) in 2009–2010 with 2.6% of the children >5 μg/dL.

In the general population, the whole blood lead concentration is higher in smokers than nonsmokers.[548] The use of alcohol is associated with blood lead concentrations above the mean concentration in the general population. Case reports suggest lead mobilization during periods of increased bone turnover may increase blood lead levels in adults with thyrotoxicosis[549] and women during menopause[550] or pregnancy.[534,551] A 12-year-old girl developed a peak blood lead level of 32 μg/dL during a period of rapid growth (10.42 cm over preceding 15 months).[552] Her BLL at the beginning of that growth spurt was 10 μg/dL. The bone turnover biomarker, osteocalcin, was elevated at 212 ng/mL (reference, 9–42 ng/mL) at presentation. No external lead source was discovered with all family members having normal BLL. She had a prior history of a BLL of 36 μg/dL at age 6 when she lived in a dwelling built in 1910.

Toxicity Biochemical effects usually occur sooner in children (e.g., ↓ δ-ALAD activity BLL <5–10 μg/dL) than adults with children more susceptible to lead encephalopathy at lower blood lead concentrations (e.g., BLL >80 μg/dL) than adults (BLL >100–150 μg/dL). Obvious clinical symptoms do not usually occur until blood lead concentrations exceed 60 μg/dL in children and 80 μg/dL in adults. Table 16.8 demonstrates the acute clinical effects commonly associated with specific blood lead concentrations in children; the correlation between blood lead levels and symptoms is approximate.

Table 16.9 lists adult symptoms frequently associated with chronic lead poisoning correlated to ranges of whole blood lead concentrations. Nonspecific subjective symptoms (e.g., fatigue, headache, sleep disturbances, constipation, abdominal pain) do not correlate well to elevated blood lead levels in workers.[553] The dominant clinical pattern of adults with chronic lead intoxication and whole blood lead levels >75–80 μg/dL involves gastrointestinal and musculoskeletal effects, whereas whole blood lead levels >100–120 μg/dL are associated with neurological dysfunction (depression, personality changes, confusion, seizures, mental status changes). Acute lead ingestion by adults may produce extremely high lead concentrations with primarily gastrointestinal symptoms. The acute onset of encephalopathy following chronic lead exposure does not usually occur in adults unless the blood lead concentration exceeds 100–120 μg/dL, primarily following blood lead levels >150 μg/dL.[37]

A 45-year-old schizophrenic developed abdominal pain, anemia, and gastrointestinal bleeding after ingestion of over 200 lead bullets.[63] The first serum blood lead concentration drawn 8 days after ingestion and before chelation was 391 μg/dL. A 23-month-old child died from acute lead encephalopathy and cerebral edema ~1 month after ingesting a leaded curtain weight; the BLL shortly before her death was 283 μg/dL.[362] A

TABLE 16.8. Clinical features associated with grades of acute lead toxicity in children.

Severity	BLL (μg/dL)	Age	Clinical Features
Mild	<50		Lethargy, irritability, behavioral changes, impaired cognition, mild fatigue, abdominal discomfort, anorexia, myalgias, paresthesias, poor coordination, reduced hearing
Moderate	50–70	1–5 years	Fatigue, decreased focus headache, tremor, arthralgias, muscle weakness, apathy, abdominal pain, nausea/vomiting, constipation, weight loss
Severe	>70–100	12–30 months	Altered consciousness (encephalopathy), seizures, coma, paresis, paralysis, colic (severe, intermittent abdominal cramps), blue-black discoloration of gingiva (lead lines)

Abbreviation: BLL = blood lead level.

TABLE 16.9. Clinical manifestations of chronic lead toxicity in adults correlated to blood lead levels. Although most studies use the blood lead level, this test measures recent exposure; therefore, the ranges are approximate. Better measures of cumulative lead exposure include bone lead and cumulative blood lead index.

Clinical Severity	Adverse Effects	Blood Lead Level (μg/dL)
Mild	Mild fatigue, lethargy, irritability, moodiness, abdominal discomfort, sleep disturbances, apathy, decreased interest in leisure activities, reduced sperm count, myalgias, subclinical reduction in nerve conduction	>40–50
Moderate	Headache, insomnia, memory disturbances, metallic taste, abdominal pain, anorexia, constipation, anorexia, weight loss, myalgias/arthralgias, muscle weakness, decreased libido, mild anemia, nephropathy (↓ glomerular filtration rate)	>70–80
Severe	Encephalopathy – obtundation, delirium, seizures, coma, headaches, papilledema, cerebral edema, focal motor signs; peripheral neuropathy (foot/wrist drop), abdominal colic; anemia, renal dysfunction, sterility, impotence, depression, blue-black discoloration of gingiva (Burton's lead lines)	>100–150

47-year-old man developed arthritis and gastrointestinal symptoms (constipation, abdominal pain, weight loss) 8 years after sustaining a gunshot to his knee.[554] The serum lead concentration in a blood sample drawn during hospitalization was 148 μg/dL.

Postmortem Limited postmortem data suggest little postmortem redistribution of lead. In a cross-sectional study of 66 adults dying without evidence of lead contamination, the geometric means of the lead concentration in femoral and cardiac blood were 1.78 μg/dL and 1.87 μg/dL, respectively.[555] The mean postmortem interval was 13.3 hours with a maximum of 24.5 hours. Case reports associate fatal lead intoxication with the following postmortem blood lead levels: 95 μg/dL in a 17-year-old girl chronically ingesting lead-contaminated flour;[556] 92 μg/dL in 4¾-year-old girl with pica and fatal lead encephalopathy (111 μg/dL 4 days prior to death and chelation);[557] and 530 μg/dL in a 54-year-old woman dying of lead encephalopathy from a retained bullet.[558] In the latter case, the antemortem blood collected 5 days before death contained 510 μg Pb/dL. These case reports did not list the source of postmortem blood.

Plasma/Serum

The concentration of plasma lead is ~0.5% of the whole blood lead concentration. In a study of 959 healthy Italians, the mean whole blood (BLL) was 15.8 ± 1 μg/dL compared with 0.03 ± 0.002 μg/dL in plasma (PLL) from 228 healthy Italians; the mean BLL/PLL ratio was ~500.[559] However, the ratio is variable because the association between BLL/PLL ratio is curvilinear depending on the lead concentration; this ratio decreases with increasing PLL as the lead-binding sites in the erythrocytes become saturated, particularly at BLL >40–70 μg/dL.[252,560] Additionally, the plasma lead concentration may vary 2–4-fold at a specific whole blood lead concentration.[561] In a group of 20 active lead smelter workers, the plasma lead concentration ranged 0.02–3.7 μg/dL, whereas the whole blood lead concentration ranged from 0.9–93 μg/dL.[562] As measured in these studies by inductively coupled plasma/mass spectrometry, a whole blood concentration of 40 μg/dL was correlated to plasma lead concentrations of ~0.2 μg/dL (BLL/PLL = ~200). In a study of healthy adults exposed to environmental lead, the whole blood/plasma/ ratio ranged ~140–370.[563] Plasma lead concentrations are somewhat less than serum lead concentrations.[564] The whole blood/serum lead ratio in samples from 49 active lead workers ranged from 40–125[565] compared with 30 in healthy adults[566] and 45 in healthy adolescents.[567]

At high lead concentrations, the relationship between plasma lead and exposure/effect is more rectilinear than whole blood because the latter reflects erythrocyte lead concentrations more than bioavailable lead in tissues.[568] Additionally, the lead exposure/whole blood lead relationship becomes curvilinear at high lead concentrations, whereas the lead exposure/plasma lead concentration probably does not.

Lead within the red cell does not diffuse readily into the plasma, whereas plasma lead equilibrates easily with soft tissue and bone lead stores. Consequently, plasma lead concentrations reflect very recent exposure (i.e., few hours).[569] Plasma lead concentrations must be interpreted cautiously because hemolysis elevates plasma lead concentrations. Hemolysis can cause a 15–30% elevation of plasma lead concentrations without any visible signs of hemolysis.[570] Consequently, plasma lead concentrations should not be used as biomarkers of lead exposure in the general population where lead concentrations are low.[532]

Erythrocyte Protoporphyrin (FEP, ZPP)

Several factors limit the usefulness of ZPP and FEP for lead screening including individual variability, poor specificity, low sensitivity at lower blood lead levels, and delayed response to changing blood lead levels.[571] Under steady-state conditions, whole blood lead levels >30–40 μg/dL correlate roughly to the ZPP and FEP concentrations; however, erythrocyte protoporphyrins are not sensitive screening tests below these levels. Neither the FEP nor ZPP offers a significant advantage over the BLL as a screening tool for lead toxicity; hence, whole blood lead levels remain the preferred screening test for excessive lead exposure. Predicting the whole blood lead concentration from the ZPP or FEP is difficult because of large individual variations and fluctuations in lead exposure.[572,573] Although the blood lead level is the most reliable measure of recent lead exposure, the FEP and the ZPP are better measures of soft tissue lead levels than whole blood lead because the FEP and ZPP depend on the lead concentration at the time of erythrocyte formation.[574] Consequently, these tests provide insight into the chronicity of current lead exposure and remain helpful to distinguish acute and chronic lead exposure, evaluate response to chelation therapy, diagnose lead re-exposure or false positive lead elevations, and aid in the diagnosis of lead poisoning in the absence of blood lead results. Both blood lead levels and either the FEP or ZPP are required to assess the body's lead burden because iron deficiency anemia causes an elevation of the FEP and ZPP. The ideal ratio of FEP to ZPP is 1:1.11 on a molecular formula weight basis, but this ideal ratio is altered by methodology, reagent purity, and extraction inefficiencies.

Following chronic lead exposure, the ZPP peaks after the whole blood lead levels; the ZPP concentration remains above reference values after whole blood lead levels decrease.[575] The ZPP and FEP help distinguish recent exposure (elevate whole blood lead, normal FEP and ZPP) from exposure more than several months in the past (normal whole blood lead, elevated ZPP and FEP). Elevations of the FEP and ZPP lag after an acute increase in the blood lead level by several weeks, up to 6–10 weeks, based on a study of lead workers returning to lead-contaminated environments after a strike.[576] Under conditions of continuing lead exposure, peak blood ZPP concentrations develop ~120 days after an acute increase in lead exposure; the ZPP returns to baseline levels ~3–4 months after an acute lead exposure ceased. Therefore, an elevation of blood lead with normal FEP or ZPP indicates recent lead exposure.

Free Erythrocyte Protoporphyrin (FEP) Lead inhibits the reduction of iron during the last step in the heme pathway by binding to sulfhydryl groups on heme synthetase (ferrochelatase), resulting in an accumulation of protoporphyrin in the erythrocyte. The FEP concentration correlates to lead exposure over the last 3–4 months based on an average erythrocyte survival time of 120 days. The FEP is not a sensitive test for acute lead intoxication; however, the presence of extremely high whole blood lead levels with normal FEP concentrations suggests acute lead poisoning. The FEP does not detect subjects with whole blood lead concentrations <25 μg/dL; an FEP concentration >35 μg Pb/dL demonstrated 73% sensitivity for detecting whole blood lead concentrations >25 μg/dL, but the sensitivity dropped to 8% for subjects with blood lead concentrations >15 μg/dL.[577] The Centers for Disease Control (CDC) recommends all children between 9 months and 6 years of age be tested for whole blood lead rather than FEP because of the insensitivity of FEP at whole blood lead concentrations <25 μg Pb/dL.[81] Therefore, the FEP is useful primarily to help determine the timing of acute lead exposure within the last 2–3 months and suggest false positive lead elevation.[578] However, a normal FEP does not exclude acute lead exposure and should be interpreted with other factors (e.g., time of exposure, source, clinical course). The FEP concentration rises exponentially at blood lead levels >40 μg/dL.[579]

Although iron deficiency and lead toxicity produce similar effects on the hematological system (microcytosis, anemia), lead intoxication can occur at high lead concentrations (>60 μg/dL) without the development of anemia.[580] At whole blood lead concentrations of 30 μg/dL, 60% of females, but only 10% of males, have an elevated FEP level. Following acute lead exposure, the peak elevation of the FEP in blood samples occurs several months after peak lead levels, despite the cessation of lead exposure.[581] A FEP concentration >35 μg/dL and a blood lead level >25 μg Pb/dL indicate excess lead exposure as well as the need for further medical evaluation and investigation of the lead source. Table 16.10 suggests the possible diagnoses associated with blood FEP >35 μg/dL and blood lead levels >25 μg/dL.

Zinc Protoporphyrin (ZPP) Zinc protoporphyrin is a metabolic product formed instead of heme under certain conditions (e.g., lead exposure, anemia). The final step in the heme pathway is the insertion of ferrous ion (Fe^{2+}) into the protoporphyrin XI molecule by ferrochelatase (heme synthetase). Lead inhibits ferrochelatase (acutely) and blocks the intracellular transfer of iron (chronically), resulting in the decreased

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 16.10. General interpretation of free erythrocyte protoporphyrin (FEP) and blood lead level (BLL). The clinical significance of these concentrations should be validated by symptoms, physical examination, and laboratory testing. (Adapted from Piomelli).[582]

BLL (μg/dL)	FEP <35 (μg/dL)	FEP 35–220 (μg/dL)	FEP >220 (μg/dL)
<25	Insensitive	Iron deficiency	Erythropoietic protoporphyria
25–59	Mild ↑ lead body burden	↑ Lead body burden	↑↑ Lead body burden
≥60	False +	↑↑ Lead body burden	Clinical lead toxicity

Abbreviation: BLL = blood lead level; FEP = free erythrocyte protoporphyrin.

transportation of ferrous ions into the mitochondria and the accumulation of protoporphyrin XI in the erythrocyte. Zinc chelates the free protoporphyrin to form zinc protoporphyrin *(*ZPP*)* in the red cell during the formation of the RBC in the marrow. Because the accumulation of ZPP occurs only in erythrocytes formed during the presence of lead in erythropoietic tissue, a lag occurs between excessive lead exposure and elevation of the ZPP, reflecting the maturation of erythrocytes.[583] Mean ZPP concentrations in whole blood are slightly higher (i.e., 10–15%) in women compared with men, and smoking does not affect the whole blood ZPP concentrations.[573]

During steady-state exposure to excessive amounts of lead, the ZPP does not reach steady-state values until the turnover of the entire population of erythrocytes (i.e., ~90–120 days). Consequently, this blood test measures the effects of lead on bone marrow averaged over the preceding 90–120 days.[584] Compared with whole blood lead levels, the ZPP requires more time to reach elevated concentrations after excessive lead exposure and longer to return to normal after cessation of lead exposure. Because chronic lead exposure causes higher bone lead stores and persistent increases in the blood lead level, the ZPP remains elevated longer compared with acute lead exposure. In a nonrandom clinical series of lead workers chelated with calcium disodium edetate for chronic lead intoxication (blood lead >60 μg/dL), the half-life of ZPP in whole blood was ~60–70 days following cessation of lead exposure.[585] The mean time for the ZPP to return to normal baseline concentrations was ~167 days.

Zinc protoporphyrin levels begin to increase at blood lead concentrations of 15–25 μg/dL in children, 20–25 μg/dL in women, and 30–40 μg/dL in men. In a study of 30 male lead-acid storage battery workers and 24 assembly workers during their initial year of occupational lead exposure, elevated ZPP concentrations (>40 μg/dL) were associated with steady-state BLL of ~30 μg/dL.[575] For blood lead concentrations <30 μg/dL, single ZPP concentrations do not predict the risk to an individual worker because of the presence of numerous confounding variables at blood lead concentrations <25–40 μg/dL.[586,587] An exponential increase in the ZPP concentration begins at blood lead levels of 40 μg/dL; almost all workers with blood lead levels >50 μg Pb/dL will have increased ZPP concentrations at steady state. The elevation of the blood ZPP begins later (i.e., several weeks >30–40 μg Pb/dL) than the increase in blood lead level following increased lead absorption; the ZPP is slower (e.g., several months) to return to normal after lead exposure ceases. Because the effect of lead on hemoglobin formation occurs before the classical symptoms of acute lead toxicity, the ZPP is a good biomarker for detecting elevated blood lead absorption before the effects of acute lead toxicity occur. Zinc protoporphyrin levels are more sensitive to the presence of high blood levels (>60 μg Pb/dL) in the presence of iron deficiency compared with the FEP.[580]

Delta-Aminolevulinic Acid Dehydratase Inhibition

Delta-aminolevulinic acid dehydratase (porphobilinogen synthase, ALAD) is the second enzyme in the heme biosynthetic pathway; this enzyme catalyzes the condensation of two aminolevulinic acid molecules to form porphobilinogen as displayed in Figure 16.2. The lead-induced reduction in ALAD activity and the activation of aminolevulinic acid synthetase by negative feedback cause an increase in δ-aminolevulinic acid in plasma, urine, and tissues. The inhibition of δ-aminolevulinic acid dehydratase is the most sensitive indicator of the lead effect with changes initially detected in plasma δ-aminolevulinic acid concentrations at blood lead levels near 5–10 μg/dL.[588]

The concentration of ALA in the plasma or whole blood is a more direct measure of the lead effects on the bone marrow than the urinary ALA. Plasma is a more practical sampling site for blood ALA compared with whole blood because ALA distributes primarily into plasma; additionally, plasma samples are more stable than whole blood in storage at 4°C (6 days vs. 3 days, respectively).[279,589] The plasma ALA concentration increases slowly at whole blood lead concentrations up to 40 μg/dL; then, plasma ALA concentrations increase

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

rapidly up to whole blood lead concentrations up to 100 μg/dL.[588] The instability of δ-aminolevulinic acid dehydratase requires analysis within 24 hours of blood sampling, depending on storage conditions and temperature. This instability and the inability to separate moderate and severe lead exposures at blood lead concentrations >40 μg/dL limit the usefulness of the ALA as a screening measure of lead exposure.[574]

Urine

Lead

Analysis of urine lead concentrations is a less reliable biomarker of lead exposure than whole blood lead levels because of the technical difficulties with 24-hour samples, substantial individual variability in urinary lead excretion rates, variation in urine volume, and potential lead contamination of the urine containers. Urine lead concentrations do not correlate well to blood lead concentrations on an individual basis.[590] None of the specific correction methods (specific gravity, creatinine) for adjusting urine volume completely normalize the urine lead concentration for volume differences between urine samples.[591] Although urine lead concentrations reflect recent lead exposure, urine lead concentrations are not routine measures of lead exposure or a substitute for whole blood lead levels.[279] The amount of lead excreted in the urine depends on the total body burden of lead, urine volume, and renal function, as well as the extent of lead exposure. Daily adult lead excretion can range up to 500 μg (average, 300 μg) Pb, but the lead excretion by children is substantially less (i.e., 30 μg Pb daily).[23] The lead in a 24-hour urine sample from an individual without occupational or excessive environmental lead exposure is usually <85 μg/24-hour total urine volume.[592]

Delta-Aminolevulinic Acid Dehydratase Inhibition

Lead poisoning mimics the clinical features of acute intermittent porphyria with abnormal urinary porphyrin concentrations. Screening for the latter disease involves measuring urinary porphobilinogen and total porphyrin concentrations normalized to urinary creatinine during an acute intermittent porphyria attack. ALA dehydratase-deficiency porphyria is an extremely rare disease.

Urine aminolevulinic acid concentrations in adults initially increase near whole blood lead concentrations of 30–40 μg/dL.[593] At that concentration, 20% of patients have 70% inhibition of δ-aminolevulinic acid dehydratase activity. The use of the ratio of ALA/log urine creatinine concentration improves the screening efficiency of the urinary ALA.[594] Smoking is a confounding variable for the interpretation of urinary ALA. The urinary δ-aminolevulinic acid level in smokers is higher than in nonsmokers with similar blood lead levels in the range that produces enzyme inhibition.[595] Impairment of heme synthesis also develops in this range; however, the whole blood lead concentration is a more practical screening method. Although the measurement of ALAD activity is a sensitive hematological marker of lead exposure, the extensive inhibition of the enzyme at blood lead levels >30 μg/dL significantly limits the ability of this test to distinguish between moderate and severe lead exposure. Thus, the need for 24-hour urine collections and the urinary excretion of excessive amounts of ALA restrict the usefulness of urine ALA as a screening measure at whole blood lead levels >40 μg/dL.

Coproporphyrin

Coproporphyrinogen I and III are intermediate metabolites of the heme pathway that easily oxidize to their respective coproporphyrins (CP). Increased excretion of CP III occurs at least 2 weeks after lead exposure begins. Urinary CP concentrations are relatively insensitive biomarkers of lead effects because significant changes in the urinary concentration of CP begin at whole blood lead concentrations of 70–80 μg/dL.[279] Increased urinary CP excretion occurs in certain disorders of porphyrin metabolism (e.g., hereditary coproporphyria (CP III), congenital erythropoietic porphyria (CP I)).

Urinary measurements of lead, aminolevulinic acid, and coproporphyrins are either too insensitive or too variable to use as a screening technique for excessive lead exposure in children or adults.[285] The use of erythrocyte or urinary aminolevulinic acid synthetase is also too sensitive to small changes in lead concentrations and ethanol. Urinary coproporphyrin III concentrations do not correlate to whole blood lead levels, whole blood ZPP, or urinary δ-aminolevulinic acid concentrations.

Bone

Bone lead is a reliable measure of lead accumulation in the body because the skeleton stores the vast majority of the absorbed lead; however, there is substantial variation in the lead content and turnover of different bones. Cortical bone accounts for 80% of the bone mass, but turnover rates of lead are lower in cortical bone (tibia) than trabecular (calcaneus, patellar) bone. The half-life of lead in cortical bone averages ~10–20 years, whereas the half-life of trabecular bone averages ~5–10 years. In a study of active lead smelter workers, the estimated mean biological half-lives of lead in the calcaneus and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tibia were 16 years (95% CI: 11–29 years) and 27 years (95% CI: 16–98 years), respectively, as measured by ^{109}Cd K X-ray fluorescence.[596] This study concluded that the precision of bone lead concentrations measured by X-ray fluorescence was greater in tibia than calcaneus bone. Lead has a stronger affinity for the organic portion of the bone matrix than the mineral component.[597] The lead concentration of active smelter workers was higher in the calcaneus (trabecular bone) than the tibia (cortical bone), suggesting more rapid lead absorption in trabecular bone.

Bone lead is a source of internal lead exposure during periods of increased bone activity (e.g., prolonged bed rest, pregnancy, lactation,[229] cisplatin chemotherapy, postmenopausal osteoporosis).[598] Some redistribution of lead from trabecular bone (patella, calcaneus) to cortical (tibia) bone may occur during chelation. Lead levels in trabecular bone tend to decrease more rapidly than in cortical bone following chelation probably as a result of greater turnover of lead in trabecular bone.[521] Case reports suggest that postmortem absorption of lead by skeletal bones may occur when the skeleton remains in contact with lead-containing coffins.[599] Analysis of bone lead in tibias from cadavers indicates higher bone lead concentrations in the mid-shaft than at the proximal and distal ends. In a series of nine cadavers (lead exposure history unknown), the tibial lead concentration ranged 3.1–27.9 μg/g bone *dry weight* with surface lead concentrations averaging ~5–8 μg/g higher than core lead concentration as measured by electrothermal atomization/atomic absorption spectrometry.[600]

The relationship between bone lead and blood lead varies depending on several factors including the analytic method, current employment status, and type of bone analyzed.[247,515] In general, models of lead transfer from bone to blood are limited by a lack of human data on transfer rates. A study of 776 participants in the US Normative Ageing Study indicated a significant but nonlinear association between bone lead and blood lead.[601] This nonlinear association was not modified by age or bone turnover as measured by urinary *N*-telopeptide. In a study of 81 lead smelter workers, bone lead was measured in the mid-tibia using K-X-ray fluorescence.[602] The slope of the blood lead compared with the tibial lead was 0.178 μg Pb/dL blood per μg Pb/g bone mineral. In a study of 77 male workers from a secondary lead smelter founded in 1942, linear regression analysis indicated that both trabecular lead concentrations (calcaneus, R^2 (proportion of variance explained) = 0.78) and cortical lead (tibia, R^2 = 0.80) measurements correlated to cumulative blood lead determinations.[603] Blood lead concentrations were available from 1968; the bone lead measurements were done in 1986 by *in vivo* K X-ray fluorescence.

Table 16.11 estimates the approximate correlation between bone and blood lead concentrations in adults based on K X-ray fluorescence and bone biopsies based on *wet weight*.

Hair

Hair lead concentrations are relatively poor predictors of blood lead concentrations, particularly at low hair lead concentrations (i.e., <12 μg/g). Case studies indicate that symptoms of lead toxicity do not correlate to the lead concentrations in hair;[604] additionally, hair lead concentrations are not sensitive screening tests for lead toxicity in children when compared with whole blood lead concentrations.[605] Properly washed and segmented hair samples give an approximate estimate of the history of lead absorption during the life of the hair shaft based on the average growth rate of 1 cm/month. However, interpretation of hair lead concentrations is difficult because of external lead contamination (e.g., hair dye/bleaches/permanents, lead water pipes), interindividual variability (hair type and texture), age,[606] washing and analytical technique,[607] source of the hair sample (e.g., proximal lead < distal lead), and residence.[72,608,609] In general, lead concentrations are higher in hair samples from urban residents than those from rural inhabitants unless a local source of lead exists.[610] Based on lead tracer studies, the appearance of lead in the hair shaft is delayed by ~35 days; however, the lead pattern in hair does not represent a simple

TABLE 16.11. Approximate correlation of blood and tibial lead levels in an adult. (Adapted from Wedeen).[510]

Exposure	Blood Lead Level (μg/dL)	Tibial Lead (μg/g wet weight)[a]	Tibial Lead/Calcium (μg/g wet weight)[b]
Low, continuous	<20	<20	<160
Moderate, occasional	20–50	20–60	260–480
High, persistent	>50	>60	>480
Massive, acute	>60	Time dependent	Time dependent

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

delay in the deposition of blood lead in hair.[611] Consequently, the lead pattern in the hair shaft is part of an intermediate pool in equilibrium with the blood.

Hair lead content varies substantially between various studies of the general population. The mean Pb concentration in hair samples from male and female patrons of a local barbershop in Port Arthur, Texas, was 26.7 μg/g (range, 10.6–191 μg/g) and 24.1 μg/g (range, 7.6–61 μg/g), respectively, as measured by flameless atomic absorption spectrophotometry.[612] In a study of hair samples from residents of New York City, the mean lead concentration was 12.2 μg/g (range, 2–155 μg/g).[613] Analysis of distal scalp hair from 126 male and 55 female customers of a Northeastern US barbershop demonstrated a mean lead concentration of 17.8 ± 2.17 μg/g and 19.0 ± 2.95 μg/g, respectively.[614] The samples were washed with carbon tetrachloride; bleached or dyed hair was excluded. The exact location of the residents (urban vs. rural) was not reported. The 90th percentile of lead concentrations in hair samples from a reference population of US residents without known lead exposure was 10.8 μg/g.[615] The median lead concentration in washed hair samples from 45 residents of Toronto was 16.9 μg/g with a range of 0.5–35 μg/g as measured by instrumental photon activation analysis.[616] In a study of distal hair samples from 250 subjects representing a cross-section of residents from a New Zealand city and surrounding rural areas, the geometric mean lead concentration was 128 μg/g hair (range, 2–360 μg/g hair).[617]

The precise relationship between blood lead and hair lead concentrations is not clearly defined. In a study of lead workers, a hair lead concentration of 70 μg/g (3 ng/cm) in the first 1-cm segment of hair samples corresponded to a whole blood lead concentration of ~60 μg/dL.[618] In another occupational study, 4 ng Pb/cm single hair corresponded to a blood lead concentration of ~60 μg/dL, whereas 3 ng Pb/cm single hair from a worker approximated a whole blood lead concentration of 40 μg/dL.[619] In a study of 21 children living with lead workers, the mean lead concentration in hair samples was 17 ± 14 μg/g with a range of 0.4–58.3 μg/g.[620] In a patient accidentally ingesting a lead-contaminated solution, the maximum blood lead concentration was 41.3 μg/dL 9.5 hours after ingestion.[621] Chelation with DMPS began 6 hours after ingestion. Hair samples analyzed for lead content on the day of admission and 3 months later were similar (2–5 ng/mg hair).

Teeth

Although the lead concentration in teeth is a potential biomarker for long-term lead exposure as a result of accumulation in the dentin and enamel,[622] the use of teeth as a biomarker requires validation of this biomarker against other biological and environmental matrices. Deciduous teeth are typically shed between 6–12 years of age; hence, this biomarker does not necessarily apply to ages outside this range. Determining the exact age is complicated, requiring sophisticated analytical methods and histological analysis.[623] Different sources of lead have unique isotopic signatures (e.g., relative short-lived ^{204}Pb and long-lived ^{206}Pb, ^{207}Pb, and ^{208}Pb); hence, isotopic lead concentrations vary with different populations. The application of stable isotope geochemical analysis to deciduous teeth allows the identification of lead sources during tooth formation.[25] Experimental studies in rodents indicate that the distribution of lead is not uniform as a result of the heterogenous distribution of lead between enamel and dentine depending in part on the time of lead exposure in relation to tooth formation.[624] In general, dentine contains 4–6-fold higher lead concentrations than enamel.[625,626] The circumpulpal dentine has particularly high lead concentrations compared with other areas of dentine. Some studies have not confirmed higher lead concentrations in the dentine of permanent teeth compared with enamel. In a study of 89 permanent teeth from rural Finnish subjects aged 8–67 years, lead concentration increased with age in the dentin (3.1 μg/g/10 years), but not in enamel; the mean Pb concentration in the enamel and dentine were similar in these subjects.[627] Table 16.12 displays the mean differences in lead concentrations between the 21 shed deciduous teeth of children living near heavy industries (i.e., oil refineries, fertilizer plants) and the 38 teeth of children living near light (i.e., hospital) industries in South Africa.[628]

Chemical concentrations in teeth are not necessarily stable over time; some exchange may occur between dentine lead and environmental exposures.[629] Lead concentrations are more stable in enamel than dentine; however, postmortem changes occur in enamel as a result of contact with lead in the burial site, particularly in the first 30 μm of enamel from ancient and modern teeth.[630] Isotopic lead patterns in teeth help identify the geographic origins of bones because of the incorporation of lead isotopes from ores specific to a geographic region; the isotopic lead patterns of teeth from US residents are unique in the world.[631]

EDTA Mobilization Test

In general, urine mobilization (challenge) tests are not reliable measures of metallic body burden or provide dependable data to determine appropriate therapy. These tests are rarely, if ever, clinically useful. Direct,

TABLE 16.12. Mean lead concentrations in shed deciduous teeth from children residing near heavy and light industrial sources in Cape Peninsula, South Africa. (Data from van Wyuk and Grobler).[628]

Sample	Heavy Industry (ppm)	Light Industry (ppm)	Statistical Significance
Whole teeth	20,419	16,556	$P > 0.01$
Enamel	10,952	2,919	$P > 0.01$
Dentine	22,733	19,926	$P > 0.05$

noninvasive procedures (K X-ray fluorescence) rather than calcium disodium EDTA mobilization (provocation) tests are preferable measures of bone lead stores. Reasons for lack of provocation test utility include difficulty collecting 24-hour urine samples after administering intravenous tests, poorly established post-chelation reference ranges, concern over possible redistribution of lead stores, concerns regarding patient safety, and questionable efficacy of chelating patients with blood lead levels <45 μg/dL.[632] Calcium disodium EDTA mobilization tests increase urine lead concentrations in healthy patients without symptoms or suspected lead poisoning.[633] This test is unnecessary for a patient with high blood lead concentrations (>70 μg/dL in adults, >45 μg/dL in children) or a symptomatic patient requiring chelation.[634] Mobilization tests probably reflect the lead in soft tissues and, to a lesser extent, in the trabecular bone pool. Most of the body burden of lead resides in cortical bone; this pool equilibrates very slowly with blood, and little transfer of lead to the blood occurs following the mobilization test.[635]

Little diuresis of lead occurs in children with blood lead levels <25–30 μg/dL.[636] In a study of 178 $CaNa_2EDTA$ mobilization tests, a positive test was rare in children <3 years of age with a blood lead <35 μg/dL and children >3 years of age with a blood lead <30 μg/dL.[637] The amount of lead removed by chelation with $CaNa_2$ EDTA from children with blood levels between 25–45 μg Pb/dL correlates positively with the initial blood lead level; there are inadequate clinical data to confirm the efficacy of administering $CaNa_2$ EDTA to these children.[638] Iron deficiency decreases the response to the lead mobilization test in the moderate toxicity range (25–40 μg Pb/dL).[639] Renal dysfunction alters the pharmacokinetics (e.g., ability to chelate lead, $CaNa_2$ EDTA-lead distribution or excretion, blood-lead distribution) of the $CaNa_2EDTA$-lead complex and lead.[640] The mobilization test may underestimate total body lead stores in patients with lead nephropathy.[641] Acute febrile reactions occur following $CaNa_2EDTA$ therapy, but complications following the single administration of $CaNa_2EDTA$ are very rare.[642]

$CaNa_2EDTA$, 1 g or 500 mg/m^2, is diluted in 5% dextrose in 0.45% NaCl, 250–500 mL, and administered intravenously over 1–2 hours. A painful but practical alternative is to deliver the undiluted dose intramuscularly with procaine. A 24-hour urine specimen is collected for lead concentration in lead-free containers. A 6-hour urine collection has better specificity but less sensitivity than the 24-hour collection.[643] A 3-hour urine test for lead is not an accurate predictor of the 24-hour urine lead level after the administration of $CaNa_2EDTA$.[644] The lead excretion ratio is the total urinary lead excreted in μg Pb/mg $CaNa_2EDTA$ administered. A ratio >1 *suggests* the possibility of chelatable lead. In a study of lead workers given $CaNa_2EDTA$, the plasma lead concentration at 2-hour postinjection correlated well ($r = 0.74$) with the amount of urinary lead excretion over 24 hours.[645] A lead excretion ratio (urine μg Pb/mg $CaNa_2EDTA$) exceeding 0.6[646] or a urinary lead concentration >1.0 μg Pb/mL[647] *suggest* chelatable lead in children. The difficulty of administering $CaNa_2EDTA$ and interpreting results (incomplete urine collection (i.e., creatinine clearance <90 mL/min/1.73 m^2 body surface area), efficacy) seriously limits the use of $CaNa_2EDTA$ mobilization test for the determination of chelatable lead in children.

Abnormalities

Blood

Lead toxicity produces hematological abnormalities primarily in erythrocytes as a result of the inhibition of hemoglobin synthesis and increased erythrocyte destruction. Common laboratory abnormalities during lead poisoning include normocytic or microcytic anemia, basophilic stippling, and renal/liver dysfunction. In adults, anemia is more common during acute lead toxicity than chronic inorganic lead intoxication. The microcytic, hypochromic anemia resembles iron-deficiency anemia; the anemia of lead toxicity is not usually severe, even during severe acute lead intoxication. Less often, normochromic, normocytic anemia occurs with reticulocytosis. The inhibition of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

δ-aminolevulinic acid dehydratase begins at blood lead levels of 10–20 μg Pb/dL; this inhibition is almost complete at 70–90 μg/dL.[648] In lead workers, the hemoglobin level does not correlate well to the blood lead level; most cases of lead-induced anemia occur at blood lead levels chronically exceeding 80 μg/dL.[649] Consequently, lead workers with anemia and blood lead levels <70–80 μg/dL should be carefully screened for causes of anemia unrelated to lead exposure. Basophilic stippling is an uncommon manifestation of chronic lead toxicity except during severe lead toxicity; however, the presence of basophilic stippling along with ringed sideroblasts and reticulocytosis is highly suggestive of lead intoxication. Other causes of basophilic stippling include sideroblastic anemia, arsenic or benzene poisoning, aniline toxicity, and various thalassemias.[650]

Changes in uric acid concentrations are usually subclinical. Hyperuricemia occurs primarily in patients with severe lead toxicity and lead-induced nephropathy. Although uric acid levels increase with increasing lead accumulation, there is no direct correlation between low-level lead exposure and gouty arthritis based on a retrospective cohort study of 777 middle-aged and elderly men with only environmental lead exposure.[651] There was a positive association ($P = 0.02$) between patellar bone lead and uric acid concentrations, but the association between blood lead and gouty arthritis was not statistically significant. The lead exposure of this male cohort was comparable to that of the general population as determined by a mean current blood lead concentration of 5.9 μg/dL.

Little data are available in humans on the effect of chronic low lead levels on the immune system. *In vitro* data suggest that exposure to lead exceeding 60 μg/dL may depress phagocytosis and chemotaxis of human neutrophils.[652,653] A study of lead-exposed workers revealed a statistically significant decrease in chemotaxis but not in phagocytosis.[654] The clinical significance of these changes remains unclear.

Imaging Studies

Conventional Radiography

Potential radiographic abnormalities associated with lead poisoning include metaphyseal densities at the ends of long bones, paint chips, and lead foreign bodies. The flat plate (plain film) of the abdomen is significant only if positive, reflecting recent lead ingestion (24–36 hours). Of 90 children in St. Louis, Missouri, with moderate to severe lead toxicity, 26% of the children with BLL >55 μg/dL had radiographic evidence of paint chips, whereas only 1% of children with BLL <55 μg/dL had positive abdominal X-rays for lead.[44] The width and density of lead lines on long-bone radiographs (wrist, knee) reflect a chronic exposure. These opacities represent dense zones of calcium rather than actual lead deposition, most commonly appearing in children aged 9 months to 5 years during the age of rapid bone growth. The development of long-bone opacities requires 4–8 weeks of heavy exposure (BLL >40–50 μg/dL).[646] Radiographs are insensitive screening tests for lead toxicity because the tests are helpful only in rare circumstances when they are positive. Radiographs demonstrate lead lines in metaphyseal ends of fast-growing bones of children (knees, wrists) with chronic plumbism typically at blood lead levels >70 μg/dL; however, these boney abnormalities may occur at BLL <50 μg/dL.[655] These bands represent failed remodeling of calcified cartilage in the zone of provisional calcification and primary trabeculae of bone rather than lead deposition. Radiographic findings in neonates exposed to lead *in utero* include dense cranial vault, delayed skeletal and deciduous dental development, and lead lines.[656]

Computerized Tomography

Classic findings of lead arthropathy include joint space narrowing, intact bone density, and intraarticular speckled lead deposits occasionally creating a lead arthrogram. Nonenhanced CT imaging and plain radiographs demonstrate intraarticular metallic material; however, CT is superior to plain radiographs for evaluating joint effusions, synovitis, and other soft tissue abnormalities.[657] Post-gadolinium MRI is an alternative to detect synovial inflammation and bone marrow edema. Several case reports[658,659] and case series[660] suggest an association between intracranial calcification and chronic lead poisoning, particularly in the cerebellum; however, many of these patients had multisystemic diseases and the etiology of the calcifications is unclear.

Magnetic Resonance Imaging

There are limited data on the MR scans in patients with lead encephalopathy with varying lesions in the deep gray matter, subcortical white matter, insula, pons, and cerebellum.[661] A 41-year-old man with short-term memory loss, poor balance, apathy, and a blood lead level of 161 μg/dL had bilateral symmetric hyperintensities on T2-weighted and fluid-attenuated inversion recovery (FLAIR) images in the occipital lobes; these lesions affected primarily the gray matter, gray-white matter junction, and the subcortical white matter.[662] Similar lesions occurred in the frontal, temporal, and parietal regions. T1-weighted images were hypointense. After chelation, these lesions mostly resolved with the exception of some focal subcortical white matter

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

lesions in the occipital lobe. Diffusion tensor imaging may be more sensitive than T2-weighted images for the detection of early changes in axonal integrity and myelination in the white matter of the cerebral cortex, hippocampus, occipital lobe, and cerebellum.[663]

Nerve Conduction

Lead toxicity produces a classical motor neuropathy characterized by reduction in the conduction velocity of the fast, large, myelinated fibers in the motor nerves of the upper (median, ulnar, radial) and lower extremities (peroneal). These effects are reversible following short-term lead exposure (several months), but continuous exposure for 6–23 months to high lead levels may produce irreversible changes.[664] In a case-control study of battery workers and referents, mild asymptomatic slowing of median motor/sensory nerve conduction, distal latency, and amplitude occurred in the group chronically exposed to 40–50 μg/dL; ulnar nerve conduction was minimally affected.[665] In contrast to sensory nerve changes, asymptomatic slowing of the maximal motor nerve conduction velocity (large myelinated fibers) occurred in lead storage battery workers with blood lead concentrations >60–70 μg/dL.[666,667] Motor conduction velocities and distal latency may be significantly prolonged or delayed without clinical evidence of lead toxicity at blood lead concentrations <70 μg/dL; sensory conduction velocities are usually normal or slightly reduced.[668,669] Some,[668,670,671] but not all,[672] studies of asymptomatic, lead-exposed workers suggest decreased nerve conduction in the small motor fibers (e.g., ulnar nerve, peroneal) is a sensitive measure of lead-induced peripheral neuropathy at blood lead concentrations ~50 μg/dL.[673] Lead exposure does not usually affect the amplitudes of the sensory compound nerve action potential (CNAP) or the motor compound muscle action potential (CMAP).[674]

The threshold for the lead-induced changes in peripheral nerve conduction occurs in the range of 30–50 μg/dL in some,[675,676] but not all,[666,677] studies of workers developing blood lead levels in this range following chronic lead exposure. In a group of asymptomatic lead smelting workers with a geometric mean blood lead concentration of ~40 μg/dL, no consistent abnormalities of nerve conduction were detected.[678] Although there were statistically significant differences between the control and the exposed groups for measures of motor and sensory nerve conduction as well as distal latency, the individual differences were within the normal range; the study detected no consistent correlation between blood lead concentrations and the neurophysiological measurements. A 2-year prospective study of lead battery workers suggested some reduction in median motor nerve velocity occurs in workers with blood lead concentrations >30 μg/dL, when compared with workers with blood lead concentrations <30 μg/dL.[679] However, there was a high dropout rate. The study contained an inadequate number of workers with a duration of employment >2 years and blood lead concentrations >30 μg/dL to determine the long-term effect of chronic lead exposure exceeding this value. A study of children exposed to lead near a smelter suggested the threshold for changes in the maximal motor nerve conduction velocity in children begins near blood lead concentrations ~30 μg Pb/dL.[680] For the detection of early changes in the peripheral nervous system, alternate electrophysiological tests to detect slowed nerve conduction include electromyography (neurogenic polyphasic waves, spontaneous activities) and prolonged distal motor latencies (e.g., median nerve).[681] However, there are few data to determine the clinical significance of changes in these electrophysiological tests.

Limited data suggest asymptomatic reduction in somatosensory evoked potentials, brainstem evoked potentials, visual evoked potentials, and event-related potential (i.e., P300) in workers with blood lead levels ~30–50 μg/dL;[682,683] however, the clinical significance of these changes remains unclear. A study of lead battery workers detected a threshold effect for vibration perception threshold ~30 μg Pb/dL based on 5-year cumulative measures of blood lead concentrations but not on current blood lead concentrations.[684] Case-control studies suggest that lead exposure may cause sensory-neural hearing loss[685] and asymptomatic reduction in neural transmission;[686] environmental noise probably contributes significantly to this loss.[687]

Neuropsychological Tests

Adults

Although exposure of workers to lead frequently is associated with abnormalities on neuropsychological testing, interpretation of the meaning of these changes is complicated by the complexity (confounding variables, selection and examiner bias, multiple tests, standardization of tests, large intersubject variability in test scores, pre-exposure test values, publication bias) created by comparing published test results between different groups. Most neuropsychological tests measure multiple, complex functions; furthermore, most studies use current blood lead (i.e., half-life ~1 month) rather than cumulative measures of chronic lead exposure (e.g., tibial lead, cumulative blood lead index). The Digit Symbol measures visuospatial processing, processing speed, working memory, and attention, whereas

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the Stroop test assesses selective attention. The most common domains potentially associated with blood lead concentrations are manual dexterity (e.g., Pursuit Aiming, Purdue Pegboard), visuomotor skills (e.g., Grooved Pegboard, Digit Symbol), psychomotor speed (e.g., simple reaction time), and verbal memory (e.g., Digit Span). To date, cross-sectional studies on lead workers suggest blood lead concentrations are better predictors of neurobehavioral performance than tibial lead concentrations.[688] The lack of correlation between cumulative exposure data and neurobehavioral test performance, the lack of preexposure data, and the inconsistencies between studies limit definitive conclusions regarding the effect of chronic lead exposure on specific neuropsychological functions.[689] A 22-year follow-up study of 83 lead-exposed and 51 nonexposed workers reported a 17% greater loss in total cognitive score than nonexposed workers during this period.[690] The most consistent association was between peak tibia lead levels and spatial ability, learning/memory, and total overall cognitive score. Multiple regression analysis detected a statistically significant difference ($P = <0.01$) for spatial abilities, executive function, and total cognitive score of the exposed workers based on peak tibial lead level after adjustment for age, education, and income; there were significant differences between spatial and general intelligence scores in lead-exposed workers compared with the nonexposed workers.

Reviews of cross-sectional testing of lead workers demonstrate few unequivocal differences in neuropsychological scores between lead workers with blood lead concentrations <70 μg/dL and control groups.[691,692] A meta-analysis of workers with chronic lead exposure resulting in blood lead concentrations 40–70 μg/dL demonstrated reduced scores on Block Design and Logical Memory of the exposed workers.[693,694] There was a tendency for reduced scores on other tests (Similarities, Trail Making A and B, Digit Symbol, simple reaction time) examined in this meta-analysis, but the effects were inconsistent across the studies and the size of the effects was generally small. This meta-analysis excluded 10 of 22 studies published between 1977 and 1997 because of inadequate exposure data or methodological flaws. The meta-analysis scores indicated impairment of central information processing, especially for visuospatial organization and short-term verbal memory. Although the size of these effects was relatively small compared with population norms, the decrement in test scores was relatively large compared with age-related changes in test scores. Not all studies using Block Design detected a significant difference between workers exposed to lead and controls.[695] Block Design is a performance subtest of the Wechsler Adult Intelligence Scale-Revised that uses perceptual organization, visuoconstructive abilities, and visuospatial organization to measure the speed of learning new responses. Studies on lead workers demonstrated an effect of lead exposure as measured by current blood lead concentration on reaction time and dexterity as well as on visuomotor functioning and verbal memory.[696,697] Cross-sectional studies of lead workers suggest reduction of test scores of visuomotor functions (Grooved Pegboard, Digit Symbol) occurs more commonly than deterioration of cognitive function. Measures of psychomotor speed and dexterity (Trail Making A and B) were inversely related to blood lead concentrations in some studies.[698] Overall, intelligence, long-term memory, common sense, and logical reasoning demonstrate minimal decline.[699,700]

Digit Span is a measure of auditory memory. The correlation between Digit Span Forward, a relatively pure measure of attention, and blood lead concentrations is inconsistent.[698] Digit Span Backward is a more complex skill of working memory; this test is usually unaffected by blood lead levels in adults. A cross-sectional study in Andean children suggested an inverse association between blood lead level and Digit Span scores.[701]

Cohort studies and case series associate subclinical effects in some scores on personality, memory, learning, choice reaction time,[702] verbal concept formation, psychomotor or visuomotor function, and motor coordination with chronic occupational exposure to lead defined by blood lead concentrations of 50–69[703,704] and 40–60 μg/dL.[705] The latter occurred in the absence of abnormalities in the peripheral nervous system. Impairment of neuropsychological tests is unusual below blood lead levels of 40 μg/dL;[693] reducing the blood lead below 40 μg/dL is associated with improvement in verbal memory scores in some studies of lead workers.[706] A study of workers with high exposure to lead (blood level 41–80 μg Pb/dL) indicated cognitive impairment primarily involved sensory motor speed and certain aspects of memory, whereas processing function and long-term memory were well preserved.[707] A study of 80 active lead smelter workers (mean BLL = 26 μg/dL; range 13–43 μg/dL; mean bone lead = 41 μg Pb/g bone mineral) measured the effect of lead on measures of verbal memory (Rey Auditory Verbal Learning Test, Verbal Paired Associates).[695] The fundamental processes of verbal memory involve acquisition (memory span, learning increment over time) and retention of information (storage, retrieval). All of the variance in verbal memory resulted from differences in measures of lead dose intensity (blood lead, TWA) rather than measures of cumulative lead dose (bone lead, working lifetime integrated blood lead). In a cross-sectional

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

study of 256 English-speaking lead smelter workers, the average age was 41 ± 9.4 years and the duration of employment was 17 ± 8.1 years.[708] The working lifetime weighted average blood lead was 39 ± 12.3 μg/dL; the working lifetime integrated blood lead index was 728 ± 434.4 μg-year/dL. As determined by the Rey Auditory Verbal Learning Test, measures of chronic lead exposure, but not current blood lead levels, were associated with impaired storage and retrieval of verbal information. There was no impairment of immediate memory span or verbal learning.

A small cross-sectional study of 17 gun-metal foundry workers detected a significant reduction only on the picture completion scale of the 5 performance scales of the Wechsler Adult Intelligence Scale at blood levels 40–64 μg/dL; these reductions resolved after chelation.[709] A cross-sectional study of 222 workers exposed to inorganic and organic lead revealed the most common abnormalities in neuropsychological testing occurred in manual dexterity and verbal memory and learning.[710] Although some studies attribute abnormalities on neuropsychological testing to peripheral sensorimotor deficits, no consistent relationship existed in this study between lead exposure and measures of peripheral nervous system function.

Little, if any, decrement in psychomotor performance (e.g., reaction time) occurs at blood lead levels <60 μg/dL.[699] Studies of personality and mood of lead-exposed workers suggest an increased prevalence of depression, fatigue, anxiety, irritability, and interpersonal problems.[704,705,711] Use of common neuropsychological tests (e.g., Profile of Mood States (POMS)) is complicated by the lack of normative data that correlates to groups of workers rather than psychiatric patients. Factor analysis did not support the use of the six separate POMS sub-scales (anger, confusion, depression, fatigue, tension, vigor) in a group of lead-exposed workers (mean current BLL, 28 μg/dL).[712] Although some studies suggest heavy, chronic lead exposure may cause personality changes and alterations of mood, neuropsychological studies of workers exposed to low lead concentrations are not well controlled for confounding variables (age, education, alcohol use, working conditions, motivation). Therefore, a causal relationship between these neuropsychological symptoms and exposure to low-level lead remains unconfirmed.

Children

There is no characteristic lead-induced neurodevelopmental pattern. In a study of 756 Indian children aged 3–7 years, comparisons of outcome Z-scores to assess the relationship between log-blood lead and the different behavioral domains suggested an association with anxiety, social problems, and ADHD, particularly with global executive function ($\beta = 0.42$; $P < 0.001$).[713] In the New Zealand observational and correlational 1972–1973 birth cohort study of 1,037 children, a population-representative sample of 565 children had BLL at age 11 years and were studied at age 38 years; the mean BLL at 11 years was 10.99 ± 4.63 μg/dL (range, 4–31 μg/dL) with 94% above the current lead standard of 5 μg/dL.[413] The mean IQ scores between these two samples were statistically different (tested, 101.01; not tested, 98.91). After adjustment for maternal IQ, childhood IQ, and childhood socioeconomic status, each 5 μg/dL-higher childhood BLL was associated with cognitive decline characterized by lower scores on overall adult IQ (mean = 1.61 IQ points), perceptual reasoning (mean = 2.07 points), and working memory (mean = 1.26 points); verbal comprehension and processing speed were not statistically different.

Renal Function

The serum BUN and creatinine increase only after the loss of ~2/3 of the kidney function. The lysosomal enzyme, *N*-acetyl-β-D-glucosaminidase (NAG), leaks from the brush borders of the proximal renal tubules early after injury to the renal tubules. Retinol-binding protein (a major α_1-microglobulin) is a low-molecular-weight protein that is also a sensitive indicator of early renal injury. This protein does not hydrolyze in the urine like β_2-microglobulins. A study of lead refinery workers indicated significant elevations of urinary NAG in workers with blood lead levels >80 μg/dL.[714] A cross-sectional study of 22 auto mechanics also associated elevated urinary NAG with blood levels of 30–69 μg/dL.[715] In this group, β_2-microglobulin concentrations were not correlated with blood lead levels; there was no significant decrement in creatinine clearance noted in the workers. Increased urinary NAG concentrations may be more closely related to the integrated blood lead level than BLL.[716]

HEALTH SURVEILLANCE

Risk Assessment

The estimated daily intake of lead corresponding to blood lead concentrations of 10 μg/dL in children and pregnant women and 30 μg/dL in adults includes the following: 60 μg for children ≤6 years old, 150 μg for children ≥7 years old, 250 μg for pregnant women, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

750 µg for adults.[717] In 2012, the CDC lowered the level of concern for lead in the blood of children ≤5 years old to 5 µg/dL. The CDC also introduced the population-based blood lead reference value (BLRV) to identify children with the highest blood lead levels; using the National Health and Nutrition Examination Survey (NHANES) data, this level was based on the 97.5% of the blood lead distribution in US children aged 1–5 years. The BLRV is a guide to prioritize primary prevention of lead exposure and determine the need for medical and/or environmental interventions rather than a toxicity threshold or health-based standard. In 2021, the BLRV was lowered from 5 to 3.5 µg/dL. There is a negligible risk of reproduction or teratogenic effects from the intake of lead at concentrations currently in the general environment.[51]

Children

Available models estimate blood lead concentrations in adults and children. These models are not interchangeable because adults and children differ in exposure pathways and pharmacokinetic parameters that determine the distribution of lead in the body.[718] The Integrated Exposure Uptake Biokinetic (IEUBK) Model was developed by the US EPA to predict the risk of blood lead concentrations >10 µg/dL in children <7 years old as a result of exposure to environmental lead sources.[719] This model was designed to estimate the average blood lead concentration for an entire population rather than a specific child based on assumptions regarding default media concentrations and media intake rates over an exposure period >3 months, as noted in Table 16.13. The recommended default values for lead in air and drinking water are 0.1 µg/m^3 and 4 µg/L, respectively, whereas site-specific data should be used for lead concentrations in soil and dust. This model is not designed to correlate environmental exposure to blood lead concentrations >30 µg/dL.

Adults

Estimation of blood lead concentrations in adults from environmental sources (air, water, soil/dust) involves calculating the biokinetic slope factor relating total uptake of lead in adults to blood lead. Equation 16.1 defines the estimated blood lead concentration (PbB) based on the baseline blood lead concentration ($PbB_{basline}$), the biokinetic slope factor (BSF), and the uptake of lead from sources in air (C_a), soil/dust ($C_s + C_d$), and water (C_w).

TABLE 16.13. Guidelines for the median lead intake when using the EPA integrated exposure uptake biokinetic model. (Based on The Technical Review Workgroup for Lead).[719]

Age	Daily Lead Intake
Soil/dust[a]	
0–1 year	0.085 g
1–4 years	0.135 g
4–5 years	0.100 g
5–6 years	0.090 g
6–7 years	0.085 g
Air[b]	
0–1 year	2 m^3
1–2 years	3 m^3
2–5 years	5 m^3
5–7 years	7 m^3
Drinking water[b]	
0–1 year	0.2 L
1–2 years	0.5 L
2–3 years	0.52 L
3–4 years	0.53 L
4–5 years	0.55 L
5–6 years	0.58 L
6–7 years	0.59 L
Diet[c]	
0–1 year	5.53 µg
1–2 years	5.78 µg
2–3 years	6.49 µg
3–4 years	6.24 µg
4–5 years	6.01 µg
5–6 years	6.34 µg
6–7 years	7.00 µg

[a] Default ratio for soil/dust ingestion is 45:55, default values recommended; [b] Default values recommended; [c] Site-specific data recommended to augment estimates of dietary intake.

$$PbB = PbB_{basline} + (BSF)(Uptake_{air} + Uptake_{water} + Uptake_{soil/dust}) \quad \text{(Equation 16.1)}$$

where:

$$Uptake_{air} = (A_a)\,(V_a)\,(C_a)$$
$$Uptake_{water} = (A_w)\,(I_w)\,(C_w)$$
$$Uptake_{soil/dust} = (A_{s/d})\,(I_{s/d})\,[(t_0)(C_s) + (t_i)(C_d)]$$

The parameters t_0 and t_i represent the relative amount of time spent in contact with soil (exterior) and dust (interior). The sum of t_0 and t_i is up to 1 depending on the fraction of time spent on the site where the soil and dust samples were taken. Table 16.14 defines the parameters used in Equation 16.1. The average absorption factor for lead in adults is ~8%,[720] whereas

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 16.14. Adult parameters for the calculation of blood lead concentrations from environmental exposure. (Based on The Technical Review Workgroup for Lead).[719]

Symbol	Description	Value
$A_{s/d}$	Soil/dust absorption	0.08
A_w	Water absorption	0.08
A_a	Pulmonary absorption	0.32
$I_{s/d}$	Soil/dust ingestion	0.02 g/day
I_w	Water ingestion	2.0 L/day
V_a	Ventilation rate during waking hours	20.0 m^3/day
BSF	Biokinetic slope factor	0.375 µg/dL per µg/day

the average daytime ventilation rate averaged over all activities except sleep is ~20 m^3 (0.83 m^3/hour) for men and 16 m^3 (0.67 m^3/hour) for women.[721]

Environmental Monitoring

Residential

House dust

House dust is a heterogeneous mixture of mineral and organic components with various sizes, densities, and shapes. In preschool children, lead-contaminated dust is a major determinate of lead exposure that originates primarily from lead-based paints, soil, and street dust. The US Centers for Disease Control and Prevention (CDC) reduced guidelines for blood lead in children from 10 to 5 µg/dL because of lack of evidence for a safe threshold of lead exposure in children.[722] Renovation of older houses with lead-based paint is a major source of residential lead dust.[723] The estimated percentage of older houses built before 1977 with lead hazards is as follows: before 1940, 68%; 1940–1959, 43%; and 1960–1977, 8%.[724] The relative contribution of each of these lead sources depends on local natural and anthropogenic sources, the age and condition of the housing, and the level of urbanization.[725] In 1995, the US EPA and the US Department of Housing and Urban Development issued interim guidelines regarding surface lead concentrations in public housing following remediation work based on lead loading of surface dust as measured by wipe samples.[726] Lead loading is the amount of lead in a given area (weight/surface area); Equation 16.2 calculates the absolute amount of lead available for absorption using the lead concentrations and amount in a specific area.

$$\text{Lead loading } (\mu g/m^2) = \text{lead concentration } (\mu g\ Pb/g\ dust) \times \text{amount of dust in defined area } (g\ dust/m^2) \quad \text{(Equation 16.2)}$$

High lead loading indicates a potential hazard, assuming the area sampled represents a relatively large portion of the living space of the inhabitants. High lead concentrations in dust are hazardous only if the total amount of dust is large. Dust wipe methods that measure lead loading (µg Pb/surface area) correlate more closely to blood lead concentrations of children than dust vacuum methods that measure dust lead concentration (µg Pb/g dust).[727] In general, the fine dust fractions (<10 µm) contain higher lead concentrations than more coarse fractions; there is some variation between wipe sample techniques based on differences in the collection of large lead particles.[728] Window wells are reservoirs for lead in the environment because the lead concentrations of dust are several orders of magnitude higher in window wells than in other accessible household areas.[729] Lead concentrations in dust from inaccessible surfaces (e.g., light fixtures, cabinets) may be significantly higher than in accessible areas in the living space; lead in these inaccessible areas does not correlate well to blood lead concentrations in children.[730]

In 2001, the US EPA issued a final regulation under Section 403 of the Toxic Substances Control Act (TSCA) that established standards for lead-based paint hazards in pre-1978 houses and child-occupied facilities.[731] As defined by US statutes, lead-based paint contains lead concentrations ≥1 mg/cm^2 or 0.5% (5,000 ppm) by weight. The current dust-lead hazard standards are 40 µg/ft^2 for floors (carpeted and uncarpeted), 250 µg/ft^2 for interior window sills, and 400 µg/ft^2 for window troughs based on a weighted average of all wipe samples. The US Consumer Protection Safety Commission's limit on lead in paint is 90 ppm. These standards were formulated to minimize the risk of children with blood lead concentrations >10 µg/dL; analysis of exposure pathways indicates that children's blood lead concentration directly correlates to floor lead concentrations, whereas the effect of sill lead concentrations is indirectly mediated by floor lead concentrations.[732] Carpets and rugs are large potential sources of lead-contaminated dust in the microenvironment of children.[733] The hazard standard for soil is 400 ppm by weight as an average in bare soil samples from play areas and an average of 1,200 ppm in bare soil samples from other areas. The endpoint for the risk analysis used to formulate these standards was a 1–5%

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. probability of a 1–2-year-old child having a blood lead concentration >10 μg/dL.

Water

The current WHO European standard for lead in drinking water is 10 μg/L. The Maximum Contaminant Level (MCL) for lead formulated by the US EPA is 15 μg/L. Assuming that contaminated drinking water contributes 7% of the lead burden of an adult and 15% of the lead burden of children, water concentrations of 100 μg Pb/L produce an average blood lead level of 24 μg Pb/dL, whereas the reduction of water lead concentrations to 10 μg/L decreases the population mean <15 μg/L blood.[734] Practical measures to reduce the absorption of lead from drinking water include increasing the pH of the water, using fully flushed water, and drinking from the cold faucet. Treatment technologies for diminishing lead in water distribution systems involve coagulation/filtration, ion exchange, reverse osmosis, and lime softening.

Soil

For each increase of 100 ppm lead in surface soil *above* 500–1,000 ppm lead, the mean whole blood lead level of a child exposed to that soil increases ~1–2 μg/dL.[735,736] The US EPA estimates that the blood lead level of a child increases 3–7 μg/dL for each 1,000 ppm lead increment in surrounding soil; however, the actual increase depends on a number of factors including the chemical form of lead, the particle size, access to soil, behavior patterns, the presence of vegetation (ground cover), personal and household hygiene (handwashing, wet mopping), and other factors.[81] For a soil lead concentration of 1,000 ppm lead, a child is unlikely to have a blood lead level exceeding 24 μg/dL unless the child plays outside and/or lives with a household smoker.[737] Although the abatement of soil containing 1,000 ppm lead or more results in a modest decline of blood lead levels in children with access to the soil, abatement is probably not a useful intervention for most urban children with low lead exposure.[738] The presence of soil concentrations exceeding 5,000 ppm lead indicates the need for abatement.

Occupational

The type of industry most commonly associated with high adult lead exposure depends on the type of industry in a particular region and work practices (e.g., housekeeping, personal hygiene, ventilation). In general, airborne lead levels are potentially high in the following industries: battery manufacturing, steel welding or cutting operations, printing, construction (painting, paper hanging), secondary smelting and refining of nonferrous metal, chemical plants, pigment manufacturing, telephone cable splicing/recycling,[739] and brass/bronze foundries.[740] The prevalence of blood lead levels ≥25 μg/dL declined from 14.0 per 100,000 employed adults in 1994 to 6.3 μg/dL in 2009.[110] Industries with the highest number of lead-exposed workers were battery manufacturing, secondary smelting and refining of nonferrous metals, and painting and paper hanging. Even though blood lead levels correlate to air lead concentrations, the range of blood lead levels is large and correlation between blood lead levels in workers and air lead levels is relatively weak.[741]

In California, workers in lead smelting, battery manufacturing, and brass foundries accounted for 80% of the elevated blood lead (>60 μg Pb/dL) reported in a statewide surveillance program, whereas construction, radiator repair, pottery ceramics manufacturing, and gun firing ranges accounted for the rest of the serious exposures to lead.[742] The demolition or repair of ships[743] and bridges[744] increases airborne lead levels as a result of the use of acetylene torches on leaded paint. The demolition of a steel bridge painted with lead paint (60% by weight) produced lead concentrations of 2–38 mg/m^3 in the breathing zone of the workers.[745] A cross-sectional study of 127 house painters in 5 North Carolina cities did not reveal any painters with whole blood lead levels >40 μg/dL.[746] The geometric mean BLL of this group was 6.8 μg/dL.

The mean air lead levels at indoor firing ranges may range up to 2 mg/m^3 during the firing of lead bullets.[747] In spite of natural ventilation, elevation of blood lead levels also occurs in instructors at uncovered, outdoor shooting ranges.[748] The exclusive use of completely copper-jacketed bullets substantially reduces the exposure of firing-range instructors to lead.[749] Lead naphthenate is a drying agent in paint and a high-pressure lubricant. The use of lead naphthenate as a spray without proper ventilation produced excessive concentrations (i.e., up to 430 $\mu g/m^3$) exceeding the current US occupational standard of 50 μg Pb/m^3 as a time-weighted average.[750]

In 1993, the US Occupational Safety and Health Administration (OSHA) reduced the PEL for lead in an 8-hour shift from 200 to 50 $\mu g/m^3$. In the US, OSHA requires medical surveillance of workers if the ambient air lead concentration exceeds 30 $\mu g/m^3$ air for more than 30 days as an 8-hour TWA or if the blood lead level of workers exceeds 40 μg/dL. The correlation between lead in air and blood lead levels in workers is not strong as a result of a number of confounding factors (e.g., nonoccupational sources of exposure, smoking, personal hygiene). A study of the relationship between

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ambient lead and whole blood lead levels in 219 battery workers exposed to a mean lead concentration in air of ~200 μg Pb/m^3 suggested improvement of personal hygiene practices was as important as lowering the ambient concentration of lead in air.[751] If a combination of changes in administrative, engineering, and work practices (e.g., personal hygiene, smoking and eating habits, laundry procedures, personal protective equipment) fails to reduce the lead concentration in ambient air to <50 μg/m^3, then improvement in these practices must be supplemented with the use of respirators. Table 16.15 lists the regulations and guidelines for exposure to lead.

Biological Monitoring

Children

The issue of mass screening for elevated blood lead levels in children remains controversial because of the

TABLE 16.15. Regulations and guidelines for inorganic lead exposure.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	50 μg/m^3 (toxic/hazardous substances)
	50 μg/m^3 (general/shipyard industry)[a]
Action level	30 μg/m^3[a]
NIOSH	
REL–TWA (10-hour)	50 μg/m^3 (0.006 ppm)
IDLH	100,000 μg/m^3
ACGIH	
TLV–TWA (8-hour)	50 μg/m^3 (0.006 ppm)
US FDA	
Bottled water allowable limit	5 μg/L
Action level (leaching solution)	
Flatware	3.0 mg/L
Small hollowware	2.0 mg/L
Large hollowware	1.0 mg/L
Cups/mugs/pitchers	0.5 mg/L
Silver-plated hollowware (adults)	7.0 mg/L
Silver-plated hollowware (infants)	0.5 mg/L
US EPA	
Ambient air (3-month average)	0.15 μg/m^3[b]
MCL (action level)[c]	15 μg/L
Residential	
Bare soil	1,200 ppm
Bare soil children's play area	400 ppm
Settled dust interior floors	40 μg/ft^2
Settled dust interior window sills	250 μg/ft^2
Settled dust interior window wells	400 μg/ft^2
WHO	
Drinking water	10 μg/L[d]
Air quality	0.5 μg/m^3

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time-weighted average; US EPA = United States Environmental Protection Agency; WHO = World Health Organization.

[a] Beginning 1/1/2025, Cal/OSHA lowered the eight-hour time-weighted average lead permissible exposure limit (PEL) in the construction and general industry from 50 μg/m^3 to 10 μg/m^3 and the action level from 30 μg/m^3 to 2 μg/m^3; [b] Not-to-exceed air lead concentration of 0.15 μg/m^3 in total suspended solids for a 3-month rolling average; [c] Treatment technique requires control of water corrosiveness and additional steps (replace lead distribution lines, reduce water sources with elevated lead levels) if >10% of water samples exceed action level. The MCL goal for lead in drinking water is zero; [d] Provisional guideline value on basis of treatment performance and analytical achievability.

TABLE 16.16. Recommended actions for pediatric screening of confirmed venous blood lead levels from CDC (https://www.cdc.gov/nceh/lead/advisory/acclpp/actions-blls.htm) and AAP. Environmental investigations in the BLL category 3.5–19 vary with jurisdictional requirements and resources. Some healthcare providers may repeat the BLL in this category within 1 month to determine if the BLL is increasing more than anticipated. (Adapted from Henretig).[755]

Blood Lead Level (μg/dL)	Recommend Action	Additional Actions
<3.5	Follow-up blood lead testing at recommended intervals depending on local risks	Routine assessment of developmental milestones and nutritional status (iron, calcium). Guidance regarding lead sources and preventing lead exposure. Correct iron deficiency.
3.5–9	Retest 3 months after BLL declining 6–9 months	Environmental exposure history plus environmental investigation when required. Nutritional counseling and correct deficiencies (iron, calcium) as needed. Assess development per AAP guidelines and refer as needed. Report BLL results to state or local health department.
10–19	Retest 1–3 months, after BLL declining 3–6 months	Actions similar to 3.5–9 category. Referral to supportive services as needed.
20–44	Clinical evaluation, retest 2 weeks–1 month, after BLL declining 1–3 months	Follow recommendations from above plus complete history and physical exam for lead toxicity, environmental investigation of home, and lead hazard reduction; consider abdominal X-ray for evidence of pica or lead foreign bodies, consult with poison control center or Pediatric Environmental Health Specialty Unit (PEHSU).
45–69	Clinical evaluation for symptomatic lead toxicity and need for hospitalization	Follow recommendations above plus case management within 48 hours, chelation, environmental investigation, lead hazard control, education, developmental monitoring. Follow-up BLL during and after documented decreasing BLL as soon as possible. Correct iron deficiency after chelation.
≥70	Hospitalization	Immediate chelation, environmental investigation, lead hazard control, education, developmental monitoring. Follow-up BLL during and after documented decreasing BLL. Correct iron deficiency after chelation.

large variation in the prevalence of elevated lead levels between children in different regions.[752,753,754] Most physicians now target specific populations of children at risk of lead poisoning including Medicaid-eligible, recent immigrants, refugees, international adoptees, and inner city children living in older housing. Many significant lead exposures occur in children living in older housing (pre-1950), where the ingestion of leaded paint and water from lead pipes substantially increases blood lead levels. Recommendations vary within state and local health departments. The American Academy of Pediatrics (AAP) and the CDC recommend screening all poverty assistance program-eligible children, including Medicaid, at ages 1 and 2, as well as children in these programs aged 3-6 years without prior screening and all children immigrating to the United States from foreign countries. Table 16.16 lists recommended guidelines for determining the actions for confirmed venous BLL screening results depending on state and local recommendations and requirements.

Occupational Exposure

The whole blood lead level (BLL) reflects lead exposure over the last few months; this value is the standard test for determining excessive lead exposure. Cross-sectional studies of lead battery workers suggest a number of factors affecting the BLL based on regression analysis of the blood lead concentrations including age, sex, alcohol consumption, personal hygiene practices, and the type of lead exposure.[751] US OSHA standards on initial biological monitoring (i.e., BLL, ZPP) of construction workers begin following any day when the ambient air lead concentration exceeds 30 μg/m^3 as an 8-hour TWA (action level). For all other employees, a biological monitoring program should begin whenever area samples indicate that the ambient air lead concentrations exceed the action level for 30 days or the BLL of a worker exceeds 40 μg/dL. Construction workers must be removed from their work environment if their BLL exceeds 50 μg/dL and the follow-up blood sample drawn within 2 weeks of the elevated BLL confirms a lead concentration >50 μg/dL. For general industry, the removal requirements are slightly different as displayed in Table 16.17.

Removal from airborne lead exposure above 30 μg/m^3 is also required if a medical examination detects the presence of a medical condition in the worker that increases the worker's risk of damage to a target organ of lead toxicity, particularly when the work has a documented blood lead level >50 μg/dL within the preceding 6 months.[756] Workers removed from lead exposure

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 16.17. Medical actions required by OSHA based on blood lead levels. The physician has the discretion to remove a worker from lead exposure if lead exposure may increase the risk of impairment from a detected medical condition.

Blood Lead Level, µg/dL	Medical Action	Repeat Testing
<40	Below BLL action level (AL).	None
	AL exceeded.	General industry (GI): repeat BLL and ZPP every 6 months.
		Construction industry (CI): repeat BLL and ZPP every 2 months for 6 months, then every 6 months thereafter.
40–49	Annual history/physical examination, BLL, ZPP, complete blood count (CBC) with red cell indices and peripheral smear, routine urinalysis, blood urea nitrogen (BUN), serum creatinine.	Repeat BLL and ZPP every 2 months until 2 consecutive BLL <40 µg/dL.
≥50 (CI)	Removal from lead exposure, complete lab and physical exam.	
≥50–60 (GI)	Removal from lead exposure if mean of three values ≥50 µg/dL or if single value ≥60 µg/dL; complete lab and physical exam.	Repeat BLL and ZPP monthly until 2 consecutive BLL <40 µg/dL.

Abbreviations: air = air concentration of lead; AL = action level (>30 µg Pb/m^3); BLL = blood lead level; CI = construction industry; GI = general industry; ZPP = zinc protoporphyrin.

may return to work when two consecutive blood samples demonstrate a BLL <40 µg/dL. Blood lead levels decline more rapidly in workers with more recent than long-term lead exposure.[757] Exposure to lower lead concentrations (i.e., <30 µg/dL) is recommended for male or female workers intending to have a child in the near future. Some,[751] but not all,[758] epidemiology studies associate elevated BLL with the use of alcohol by lead-exposed workers.

Medical Surveillance

Requirements for medical surveillance depend on the lead concentration in air, the blood lead level of the workers, and, in construction trades, work involving certain high-risk lead exposures (e.g., abrasive blasting, sanding, torch cutting, welding, or demolition where lead is present). The frequency of biological monitoring and medical surveillance of an individual worker also depends on the BLL, as outlined in Table 16.17.

Full medical surveillance (i.e., bimonthly blood lead levels) is required for workers with >30 days of lead exposure and BLL >40 µg/dL. Medical examinations should include the following: 1) detailed work and medical histories with particular attention to personal habits and past lead exposure, 2) a complete medical examination (gums, teeth, skin, gastrointestinal tract, kidney, heart, neurological system including mood, affect, cognitive function, and lung function, 3) blood samples to measure blood lead concentrations collected in lead-free containers, complete blood count, and renal function, and 4) urinalysis as outlined in Table 16.18. Additional air samples and biological monitoring of workers may be necessary in the following situations: 1) employees with symptoms of lead poisoning, 2) an employee requesting medical advice about the effects of lead exposure on plans to conceive children, and 3) an employee with difficulty using a respirator. More frequent (monthly) monitoring of blood lead concentrations of lead-exposed workers may be necessary when lead exposure is not well controlled.[759] The ACGIH-recommended biological exposure index (BEI) for lead is 30 µg/dL. This value represents the lead concentration in blood most likely to be present in samples from workers exposed to the threshold limit value (TLV) for lead. The TLV refers to the airborne lead concentration at which nearly all workers may be repeatedly exposed, day after day, without adverse effects.

Reliable clinical laboratory techniques are available for δ-aminolevulinic acid dehydratase, urinary coproporphyrin, and δ-aminolevulinic acid (plasma, urine);[760] however, these biochemical measures depend on physiological factors other than the blood lead level. Therefore, these indices are not specific to lead poisoning.

TREATMENT

Embedded solid lead objects do not usually produce significant lead toxicity because of the small surface area and the limited dissolution rate of lead objects in physiological pH.[761] Management of ingested lead

TABLE 16.18. Minimum components for medical evaluation of lead-exposed workers.

Category	Examples
Past lead exposure	
Environmental history	
Social history including hobbies	
Complete work and lead exposure history	
	History
	Review of systems
Constitutional	Anorexia, fatigue, weight loss
Cardiovascular	Dyspnea, cough, chest pain, palpitations, orthopnea, PND
Gastrointestinal	Nausea, vomiting, constipation, diarrhea, abdominal pain, melena
Hematological	Pallor, easy fatigability
Neurological	Weakness of hands/legs, irritability, insomnia, forgetfulness, confusion, hallucinations, gait disturbance, ataxia, seizures, headache.
Renal	Polyuria, polydipsia, frequency, renal disease
Reproductive	Infertility, loss of libido, pregnancy history, impotence
Musculoskeletal	Arthralgias, myalgias
	Complete Medical Examination
Gums/dentition	Lead lines, hyperpigmentation
Cardiovascular	Blood pressure
Gastrointestinal	Organomegaly, diffuse abdominal pain
Hematological	Anemia
Neurological	Mental status exam, behavioral/psychological abnormalities, memory loss, muscle weakness (extensors), gait, coordination, sensation
Renal	
Pulmonary (if symptomatic)	
	Laboratory
Blood lead level	
Complete blood count with smear	Serum iron, RBC indices, serum folate/B_{12} if indicated
Zinc protoporphyrin level	
Serum creatinine	
Urinalysis	Serum uric acid, if indicated.
	24-hour urine collection for creatinine clearance, protein, electrolytes, if indicated.
Pregnancy test or semen evaluation (if requested by employee)	

foreign bodies is similar to the management of an uncomplicated foreign body ingestion; however, the patient should be followed closely with abdominal X-rays to determine the progression of the lead foreign body and the blood lead levels (every 4 days) if the elimination from the gastrointestinal tract is slow (i.e., >1–2 weeks). Unrecognized retention of lead foreign bodies near acidic environments (stomach, joints) can produce severe lead toxicity.[362,762] Parenteral chelation should be considered following a large amount of liquid lead (e.g., lead glaze) ingestion when the material is not removed by whole bowel irrigation and the BLL exceeds 45 μg/dL.[173,763] Although there are inadequate human data, primate studies suggest the initiation of oral succimer does not increase the gastrointestinal absorption of lead.[764]

Gut Decontamination

Activated charcoal does not adsorb lead well, while the presence of activated charcoal obscures endoscopic visualization of the foreign body. The decision to use whole bowel irrigation, endoscopic removal, or surgery to remove lead material depends on clinical judgment regarding the severity of the poisoning (e.g., BLL) and the location of the foreign body. The latter should be removed prior to initiation of chelation if amenable to removal. Elemental lead is relatively insoluble at alkaline pH and more soluble in acidic environments with most lead absorption occurring in the duodenum after passage through the acidic environment of the stomach. The reduction in absorption following alkalinization is time-sensitive. An *in vitro* controlled

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

study comparing simulated gastric fluid at pH 1 with gastric fluid alkalinized with calcium carbonate at pH 6 suggested the administration of calcium carbonate (TUMS®) reduced elemental lead absorption.[765] At 4 hours, total lead liberated from the soluble fraction at pH 1 and pH 6 was 850 µg and 12.4 µg, respectively, resulting in a 60-fold difference. Inadequate human data are available to confirm efficacy of alkalinization following lead overdoses.

Remediation

The primary goal of lead screening programs is the identification and elimination of lead from the environment of children, particularly the stabilization or removal of peeling lead paint and cleaning of lead-contaminated house dust.[81] Table 16.19 lists potential sources of excessive lead exposure. Without remediation of lead sources in the environment at an individual level, chelation will have little impact on the total body burden of lead. Community-wide environmental interventions (e.g., widespread removal, replacement of lead-contaminated soil) are less effective than abatement of individual houses for the reduction of BLL among residents;[766] currently, there is inadequate evidence at the *population level* that education or dust control measures reduce blood lead levels in children. Education and dust control do not improve the effectiveness of abatement and cleaning lead-contaminated houses as a *population* health strategy based on a meta-analysis of BLL from 12 studies (n = 2,239 children).[767]

Table 16.20 lists procedures for the reduction of lead absorption by children from environmental sources. A study of 113 urban children with ages ranging from 6–36 months revealed maternal education and biweekly assistance with household cleaning reduced the mean BLL by an average of 17% over ~1 year compared with baseline lead concentrations.[768] The primary methods of cleaning included wet mopping, damp-sponging of walls and horizontal surfaces, and vacuuming with a high-efficiency particle accumulating vacuum. During a pilot study of the cleaning of buildings with highly deteriorated lead-based paint, the wet scrape/high-efficiency particulate air (HEPA) vacuum method produced substantially less lead exposure to workers than the dry scrape/sweep method.[769] However, the addition of portable HEPA-filtered exhaust fans did not reduce the lead exposure of workers using the wet method.

The three methods of lead abatement include replacement, encapsulation, and removal. Replacement is the process whereby lead-painted structures (e.g., windows, doors, frames) are exchanged for non-leaded structures. Encapsulation involves the covering or resurfacing of lead-painted surfaces with durable materials (e.g., Formica®, paneling, tile, gypsum board, canvas-backed vinyl, vinyl flooring, wood stone, plastic, metal). Removal of lead paint from a structure is the most hazardous alternative; this action should be considered only when replacement and encapsulation are not feasible. Safe work practices include 1) relocating families as indicated, 2) minimizing dust creation, 3) containing dust in the work area, 4) completing cleanup, 5) safe waste disposal, and 6) clearance testing to confirm residences comply with EPA lead standards.[395]

X-ray fluorescence is the most accurate method available to detect lead in paint. Lead abatement performed by legal standards reduces the blood lead level of children by ~30% over 6 months.[122] Deleading should be performed by trained and certified crews with experience in lead removal. Cleanup of the contaminated house dust (>1,000 µg Pb/ft^2) involves vacuuming with a high-efficiency particulate accumulator (HEPA vacuum) and wet mopping with a high-phosphate detergent. Household members should leave the house

TABLE 16.19. Potential sources of lead exposure. (Based on Roper).[81]

Category	Source
Para-occupational exposure	Home production of belt buckles, awards, and type printing, pottery manufacturing, battery repair shops, lead or copper smelters, radiator mechanics, capacitor and resister plants, electric cable manufacturing
Lead-containing materials	Folk medicines, costume jewelry, herbal supplements, cosmetics
Hobbies	Pottery glazing, toy soldiers, stained glass construction or repair, lead soldering, car or boat repainting, fishing or hunting with lead sinkers or shot, target shooting, gold/silver extraction
Residences	Dilapidated condition, pre-1960 buildings, inner-city location, older day care facilities/caretaker residence, preschool
Home remodeling	Pre-1960 construction
Proximity to point sources	Industrial facilities, hazardous waste sites
Diet	Food utensils (imported or glazed ceramics), herbal products
Drinking water	Lead pipes
Drugs	Moonshine whiskey, lead-contaminated illicit drugs

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 16.20. Simple methods to reduce lead exposure.

Actions	Examples
Keep home as clean and dust-free as possible. Remove or clean shoes before entering house.	Wet mop floors, wipe window ledges, wash surfaces with water and detergent.
Leave lead contamination at work.	Leave work clothes at work; shower at work if lead-exposed.
Lead-contaminated paint.	Never sand, burn or scrape paint with high lead content (pre-1960); X-ray fluorescence is the best method to detect leaded paint; keep furniture away from old, damaged paint.
Encourage good nutrition. Wash children's hands often.	Calcium and iron-rich foods, low-fat diet.
Avoid lead-contaminated objects.	Lead-glazed utensils, toys, hobbies, home remedies, cosmetics. Restrict play in lead-contaminated areas.
Reduce lead consumption from drinking water.	Use only cold water that was flushed prior to consumption until it is as cold as possible. Use only cold water for cooking, and preparing baby formula.

during the deleading and return after inspection of the house confirms that dust-wipe samples meet US EPA clearance standards as defined in the section on Environmental Monitoring.

Nutrition

A review of the nutritional status with emphasis on adequate dietary intake of iron, calcium, and zinc is necessary to ensure the maximum therapeutic benefit from efforts to reduce blood lead levels. Experimental evidence indicates that iron deficiency facilitates the absorption of lead and adequate iron stores improve the efficiency of EDTA chelation.[770] Iron supplements (6 mg elemental iron/kg/day) for 2–4 weeks are recommended in order to reduce lead absorption. Iron therapy during chelation is not recommended. Concomitant administration of iron and BAL is contraindicated because of the formation of a toxic complex that produces protracted vomiting. Observational studies also suggest that a low-fat diet may be beneficial for children at high risk of developing lead toxicity.[771]

Chelation

Chelation is a relatively inefficient form of therapy because a course of treatment removes only ~1–2% of the total body burden of lead depending on the length of exposure, primarily from soft tissue stores.[772] Although chelation therapy produces definite short-term benefits, successful long-term therapy requires a drastic reduction in lead exposure as the first priority. Discharge planning should include 1) identification and remediation of lead exposure hazards, 2) education of parents or guardians regarding compliance and dosing of chelator, and 3) adequate reduction in BLL during inpatient therapy.[773]

Dimercaprol (British Anti-Lewisite Compound, BAL)

Mechanism of Action

The sulfhydryl ligands of BAL attract heavy metals (e.g., lead) to form a stable heterocyclic metal-chelate complex. BAL enhances fecal and urinary lead excretion; this chelating agent diffuses well into erythrocytes and brain cells. The high affinity of BAL for heavy metals reduces the binding of these metals to essential sulfhydryl groups in enzyme systems in the body, thus decreasing toxicity. Disassociation of the complex and oxidation of BAL can occur *in vivo* when the plasma BAL concentrations decrease.

Pharmacokinetics

The onset of action of BAL is ~30 minutes; excretion of the majority of the chelated metal complex occurs within 4–6 hours, primarily in the bile.[774] BAL promotes the renal excretion of lead from the RBC pool within several hours.

Uses

Indications for lead chelation are acute encephalopathy, classic plumbism, and some asymptomatic cases with high BLL.

Adverse Effects

Adverse effects associated with BAL are common and dose-related with ~50% of patients treated with 5 mg/kg developing BAL-related symptoms. Transient hypertension and tachycardia can occur within 30 minutes of administration and last several hours. Reported adverse effects include irritability, anxiety, nausea, vomiting, paresthesias, headache, lacrimation, rhinorrhea, conjunctivitis, salivation, diaphoresis, burning of the throat, lips, and eyes, muscle cramps, abdominal pain, and fever (more common in children). Transient elevation of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

serum hepatic transaminases occurs commonly. Excessive doses may result in coma, stupor, convulsions, and hypotension because of direct capillary damage and relative hypovolemia. Patients should be well-hydrated with intravenous fluids to reduce gastrointestinal distress. Fever occurs in ~30% of children receiving BAL; hemolytic anemia may develop in patients with G-6-PDase deficiency.[770] Because BAL is formulated in peanut oil, an allergic reaction may occur in patients allergic to peanuts.

Contraindications

BAL is contraindicated in the presence of liver failure and glucose-6-phosphate dehydrogenase deficiency (which induces hemolysis). Renal impairment is not an absolute contraindication because BAL excretion occurs primarily in the bile. The concurrent administration of medicinal iron is contraindicated because the BAL–iron complex is toxic. BAL may potentiate the renal toxicity of cadmium and selenium; therefore, BAL is not recommended in patients with cadmium or selenium toxicity.

Dosage

For maximum effect, BAL should be given as soon as possible to prevent irreversible cell damage by metallic cations. The severity of the lead poisoning and the response of the patient determine the amount administered as displayed in Tables 16.21 and 16.22. BAL is available only as a 10% solution in oil for intramuscular injection. The initial daily BAL dose ranges from 18–24 mg/kg (300–450 mg/m^2) in 2–6 divided doses by deep intramuscular injection. Dosage is often reduced on the second day; a full course continues for 5–7 days, followed by a rest period. A repeat course may be necessary. Pre-administration of diphenhydramine may alleviate some of the adverse effects of BAL. The presence of lead encephalopathy indicates the need

TABLE 16.21. Recommendations for chelation of symptomatic and asymptomatic children.

Clinical Presentation (BLL, µg/dL)	Chelating Agent	Dose	Comments
		Symptomatic Children	
Acute encephalopathy	BAL	450 mg/m^2/day	Initially start BAL, 75 mg/m^2 IM every 4 hours for 5 days.[a] Maximum *daily* dose ~24 mg/kg.
	$CaNa_2EDTA$	1,500 mg/m^2/day	Start 4 hours *after* BAL with continuous or 2–4 divided doses/24 hours for 5 days. Repeat 5-day cycles after a 2-day rest may be necessary if BLL remains high or lead rebound occurs. The maximum *daily* dose is ~2–3 g.
Symptomatic without encephalopathy or BLL >69	BAL	300–450 mg/m^2/day	Initially start BAL, 50–75 mg/m^2 IM every 4 hours for 5 days.[a]
	$CaNa_2EDTA$	1,000–1,500 mg/m^2/day	Start 4 hours *after* BAL with continuous or 2–4 divided doses/24 hours for 5 days. Repeat 5-day BAL/$CaNa_2EDTA$ cycles after a 2-day rest may be necessary if BLL remains high or lead rebound occurs depending on duration/severity of symptoms and BLL.
		Asymptomatic Children	
45–69	DMSA[b] (Succimer)	700–1,050 mg/m^2/day	350 mg/m^2/day tid PO for 5 days, then bid PO for 14 days.[c] Remove from lead exposure. $CaNa_2EDTA$ provocation test not recommended. Maximum *single* dose is ~10 mg/kg.
45–69 (option to use DMSA)	$CaNa_2EDTA$[b]	1,000 mg/m^2/day	Continuous or 2–4 divided doses/24 hours for 5 days. Repeat 5-day cycle after rest period depends on BLL, rebound, and duration of lead exposure.[a]
20–44	DMSA (Succimer)	700–1,000 mg/m^2/day	Routine chelation is *not* recommended; however, if clinically indicated 350 mg/m^2/day tid PO for 5 days, then bid PO for 14 days.[c] Emphasis on reduction of lead exposure.
<20	No chelation		Emphasis on reduction of lead exposure.

Abbreviation: BLL = blood lead level.

[a] Baseline labs include CBC, BLL, Ca, Cr/BUN, LFTs, UA with repeat BLL on days 3 and 5; [b] D-Penicillamine is a rare option to DMSA or $CaNa_2EDTA$; [c] Baseline labs include CBC, BLL, LFTs with a repeat on days 7 and 21.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 16.22. Recommendations for chelation in lead-exposed adults.

Clinical Presentation (BLL, µg/dL)	Chelating Agent	Dose	Comments
Acute encephalopathy	BAL	450 mg/m^2/day	Initially start BAL, 75 mg/m^2 IM every 4 hours for 5 days.
	$CaNa_2EDTA$	1,500 mg/m^2/day	Start 4 hours *after* BAL with continuous or 2–4 divided doses/24 hours for 5 days. Repeat 5-day cycles after a 2-day rest may be necessary if BLL remains high or lead rebound occurs.[a] Maximum dose ~2–3 g/day.
Encephalopathic symptoms or BLL >100	BAL	300–450 mg/m^2/day	Initially start BAL, 50–75 mg/m^2 IM every 4 hours for 5 days.
	$CaNa_2EDTA$	1,000–1,500 mg/m^2/day	Start 4 hours *after* BAL with continuous or 2–4 divided doses/24 hours for 5 days. Repeat 5-day BAL/$CaNa_2EDTA$ cycles after a 2-day rest may be necessary if BLL remains high or lead rebound occurs depending on duration/severity of symptoms and BLL.[a] Maximum dose ~2–3 g/day.
Mildly symptomatic without evidence of encephalopathy or 70–100	DMSA	700–1,050 mg/m^2/day	350 mg/m^2/day tid PO for 5 days, then bid PO for 14 days.[b] Remove from lead exposure. Maximum dose ~10 mg/kg.
Asymptomatic or <70	—	—	No chelation routinely recommended. $CaNa_2EDTA$ provocation test not recommended.

Abbreviation: BLL = blood lead level.
[a] Baseline labs include CBC, BLL, Ca, Cr/BUN, LFTs, UA with repeat BLL on days 3 and 5; [b] Baseline labs include CBC, BLL, LFTs with a repeat on days 7 and 21.

for coadministration of BAL and the administration of $CaNa_2EDTA$ beginning 4 hours after BAL. The urine specific gravity typically is kept below 1.020 with IV fluids; however, fluid balance and electrolytes should be monitored closely as SIADH and hyponatremia may develop after several days of BAL, particularly in patients with very high BLL and inadequate fluids. Keeping the urine specific gravity below 1.020 decrease the risk of SIADH. Oral iron therapy and parenteral BAL are not recommended concurrently.

$CaNa_2EDTA$

Mechanism of Action

This compound forms a stable, soluble complex with lead drawn from extracellular stores. $CaNa_2EDTA$ does not penetrate cells and removes only extracellular lead; the reduction of lead stores in erythrocytes, soft tissue, and the central nervous system results from equilibration of intracellular lead with lead in the extracellular compartment. The kidneys excrete the complex. At lead levels <40 µg/dL, rodent studies suggest some redistribution of lead following a single dose of CaNa2EDTA.[775] This model demonstrates increased hepatic and central nervous system lead, whereas bone and renal lead concentrations decrease. These effects are probably transient. In a subsequent study in albino rats ingesting drinking water containing 100 µg Pb/L, stable Pb isotope tracer methodology confirmed the reduction of soft tissue lead stores following $CaNa_2EDTA$ chelation.[776] There was no evidence of redistribution of lead to the brain. When used alone, $CaNa_2EDTA$ may worsen an acute encephalopathy in children; however, all symptoms related to acute lead toxicity resolved in adults after the use of intravenous $CaNa_2EDTA$.[744]

Pharmacokinetics

The gastrointestinal tract absorbs small amounts (<5%) of $CaNa_2EDTA$; the plasma half-life is <1 hour. In patients with normal renal function, most excretion of the lead-EDTA complex occurs within 8 hours; elimination results from renal tubular secretion of unchanged lead-$CaNa_2EDTA$ with ~95% excreted within 24 hours.[777] The presence of renal failure may delay the excretion of the lead–EDTA complex for up to several days. The drug appears primarily in extracellular fluid; little of the drug diffuses into erythrocytes or crosses the blood–brain barrier. $CaNa_2EDTA$ does cross the placenta with similar distribution in the fetus and mother.[770]

Adverse Effects

The kidney is the target organ of toxicity for $CaNa_2EDTA$. Proximal tubular damage (hydropic vacuolization, loss of brush borders, degeneration) is unusual in doses below 1,500 mg $CaNa_2EDTA$/m^2; the effects are usually reversible. Maintenance of adequate urinary output before administration of $CaNa_2EDTA$ reduces renal complications. Side effects reported after the administration of $CaNa_2EDTA$ include headache,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

anorexia, nausea, vomiting, chills, fever, myalgias, excessive thirst, malaise, fatigue, and a mucocutaneous reaction similar to vitamin B_6 deficiency.[770] Although urticaria and other rashes may occur, allergic reactions to $CaNa_2EDTA$ are rare.

This compound should not be administered orally because it probably enhances lead absorption by this route. $CaNa_2EDTA$ depletes iron and trace metals (copper, zinc, manganese) stores; therefore, this chelating agent should be used cautiously in any patient with decreased zinc stores. Rest periods of 2–14 days between $CaNa_2EDTA$ doses are necessary to allow equilibration of blood lead and the recovery from zinc depletion.

Dosage

The combination of $CaNa_2EDTA$ (ASD Healthcare, https://www.asdhealthcare.com/, 800-746-6273) and BAL effectively prevents rapid mobilization of lead into the blood for patients requiring chelation with BLL >60–70 μg/dL. When used in combination with BAL, $CaNa_2EDTA$ therapy should begin after the second dose of BAL to prevent elevated blood lead levels from soft tissue stores. $CaNa_2EDTA$ should not be administered alone to treat lead encephalopathy. The precise dose depends on the clinical situation. In children, the standard dose is 50 mg $CaNa_2EDTA$/kg/day (1,500 mg/m^2/day) intravenously as a dilute, continuous infusion (maximum concentration, 0.2–0.5% solution or 2–5 mg $CaNa_2EDTA$/mL in dextrose and water); an alternative is the administration of the daily dose as 2–4 divided doses intravenously over several hours.[778] In severe cases, the daily dose may be increased to 75 mg $CaNa_2EDTA$/kg/day. The maximum daily dose of $CaNa_2EDTA$ in adults is 2–4 g, depending on the severity of the poisoning. Intramuscular injections are painful; the addition of 0.5 mL of 2% procaine or lidocaine reduces the pain of deep intramuscular injection. Adequate renal function must be documented daily. The full course of chelation is 5 days with at least a 2–5 day rest period between courses for equilibration of lead stores and replenishment of zinc stores. Case studies suggest equilibration of lead between blood and bone stores requires at least 2 weeks.[779] The number of courses depends on the clinical response and the severity of symptoms. Initially, lead levels should be monitored weekly after chelation until the blood level no longer rebounds.

The use of disodium edetate (Endrate, sodium versenate, disodium EDTA, Na_2EDTA) for lead chelation is contraindicated because of the potential for fatal hypocalcemia.[780] Iron and zinc supplements should not be administered during chelation because the use of these metals with $CaNa_2EDTA$ decreases the effectiveness of lead chelation. $CaNa_2EDTA$ should be used cautiously in oliguric patients. The addition of $CaNa_2EDTA$ to the peritoneal dialysate of an anuric patient with lead toxicity chelated lead with ~70% of the efficiency of intravenous $CaNa_2EDTA$.[781] During chelation therapy, the blood should be monitored closely for urine output, renal function, complete blood count, and serum hepatic transaminases.

Meso-2,3-dimercaptosuccinic acid (DMSA)

Dimercaptosuccinic acid (DMSA) and 2,3-dimercapto-1-propanesulfonic acid (DMPS) are water-soluble, highly polar chemical analogs of dimercaprol (BAL). In animal models, DMSA and DMPS are less toxic and more effective orally than BAL.[782] Both DMSA and DMPS have much higher LD_{50} values in rats and wider therapeutic indexes than BAL; DMSA appears to be the least toxic of the two analogs.[783] DMPS is used extensively in Europe for mercury poisoning, but practical concerns (smell) and complications with Steven–Johnson syndrome limit the use of DMPS in the United States. Both DMSA and DMPS also chelate arsenic, organic/inorganic mercury, and other heavy metals, whereas these drugs cause minimal effects on iron, calcium, and magnesium. Small increases in urinary zinc and copper excretion may occur.[784]

Indication

DMSA is the preferred chelating agent for mild or asymptomatic cases of lead toxicity with BLL >45 μg/dL; the use of this drug in children with BLL <45 μg/dL remains controversial despite two negative clinical studies.[785] Although short-term courses of DMSA increase the urinary excretion of lead and reduce the blood lead level in children with moderate lead toxicity,[786] insufficient data are available to recommend DMSA chelation of children with lead-related neurotoxicity and BLL <45 μg/dL. Experimental studies suggest that both oral DMSA and parenteral calcium disodium EDTA are effective chelating agents; DMSA is the preferred alternative to calcium disodium EDTA in the United States and the United Kingdom for moderate lead poisoning, particularly when the oral route is preferable for the treatment.[787] Adults are not typically administered chelating agents with BLL <45 μg/dL. The US FDA approved DMSA for the oral chelation of children with blood lead levels >45 μg/dL. A case report of a 66-year-old woman with lead encephalopathy (headache, altered mental status, irritability, BLL = 148.2 μg/dL on hospital day 14) associated rapidly reduced BLL and marked improvement

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in her mental status with the administration of the usual course of DMSA.[788] She received one dose of BAL (BAL was discontinued when DMSA administration began) and no $CaNa_2EDTA$ because of a national shortage.

Mechanism of Action

DMSA efficiently mobilizes lead from soft tissue stores including the brain.[789] The lack of serious side effects allows prolonged therapy; however, blood lead levels rebound (~70% pre-chelation levels) rapidly after chelation ceases.[790] In a study of 10 workers with a mean blood lead concentration of 67.9 µg/dL, the mean blood lead concentration 12 and 72 hours after the last DMSA dose was 38.92 µg/dL (i.e., 53% baseline) and 49.38 µg/dL (i.e., 73% baseline), respectively.[791] A study of Korean lead workers suggests that tibial lead stores are less bioavailable (and contribute less to blood lead concentrations) in older subjects than in younger subjects.[792] Lead chelatable by DMSA represents the currently bioavailable lead burden, whereas tibial lead represents cumulative lead exposure.

DMSA chelates lead and cadmium with a sulfur-oxygen ligand, whereas mercury and nickel attach to two sulfur atoms. At 1,050 mg DMSA/m^2/day (equivalent to 30 mg/kg) in three divided doses, DMSA was more effective at lowering the blood lead levels and restoring erythrocyte delta-aminolevulinic acid dehydratase activity than intravenous $CaNa_2EDTA$. The excretion of urinary lead with these two chelating agents was comparable.[793] DMSA does not enhance the excretion of zinc, copper, iron, or calcium to the same extent as $CaNa_2EDTA$.[794] Furthermore, DMSA does not interfere with the parenteral administration of iron during long-term chelation therapy.[795]

Pharmacokinetics

Absorption of DMSA from the gastrointestinal tract is rapid, but variable with peak plasma DMSA concentrations occurring ~3 hours after ingestion.[796] DMSA probably does not increase the absorption of lead from the gut. The volume of distribution (V_d) is limited mostly to the extracellular space with V_d in the range of ~0.35 L/kg; most (92–95%) of the DMSA is protein-bound, primarily by albumin via a disulfide bond. Minor amounts of free DMSA appear in the plasma.[797] DMSA probably does not cross the blood–brain barrier. The urinary excretion of DMSA is rapid. Maximal renal excretion of DMSA/metabolites occurs on the first day after ingestion with about ¾ of the DMSA appearing in the urine within 24 hours. After the administration of a single 10 mg/kg dose of DMSA to lead workers, the maximum urinary excretion of lead occurred ~2 hours after ingestion.[798] During this study, the administration of intravenous $CaNa_2EDTA$ 2 weeks before DMSA increased DMSA-induced lead excretion. Biotransformation of DMSA primarily involves the formation of mixed disulfides of L-cysteine, probably in the kidney.[799] Elimination of DMSA occurs almost exclusively (90–95%) by the renal excretion of these mixed succimer-cysteine disulfides. Compared with healthy subjects, lead toxicity may slightly reduce DMSA clearance[800] There are few data on the excretion of DMSA in breast milk. Most lead excretion occurs in the first week with excretion rates declining after the first week of therapy. Although the administration of DMSA initially reduces the blood lead concentrations, redistribution of lead from bone stores causes a rebound in the blood lead concentrations beginning within several weeks of the cessation of chelation.[801] The rebound in blood lead concentrations depends on the extent of bone lead stores; however, chelation in some patients with acute and subacute lead toxicity may not produce a rebound in blood lead concentrations.[802]

Dosage

The preferred oral dose of DMSA is ~30 mg/kg/day. A dose of 30 mg DMSA/kg divided into 3 doses daily and administered over 5 days reduced pretreatment blood lead levels in 18 patients by an average of 72.5%; a mild, asymptomatic elevation of serum alanine aminotransferase occurred in two subjects.[803] Data on the bioavailability of DMSA in food and fruit drinks are limited; therefore, DMSA should not be mixed with these agents immediately before administration. The 5-day dose is followed by 20 mg DMSA/kg body weight/day for 14–21 days in two divided doses as a means to blunt the rebound in blood lead concentrations; rebound up to 70% of the pre-chelation level often occurs within weeks to months. Limited clinical data suggest the repeat 5-day 30 mg/kg/day courses may be as effective as the prolonged course as long as a week separates the repeat courses to allow lead redistribution; some benefit may result from extending the 5-day course in severely lead-poisoned patients.[799] $CaNa_2EDTA$ is an alternative to DMSA in the pregnant patient because rodent studies suggest high daily DMSA doses (100, 300, and 1,000 mg/kg) produce maternal toxicity manifested by decreased weight gain without teratogenicity;[804,805] however, there are inadequate clinical data to determine the risk/benefit of DMSA and $CaNa_2EDTA$ chelation in the pregnant female.

Monitoring of blood lead and serum hepatic aminotransferases during chelation therapy involves the analysis of samples at baseline (i.e., pretreatment), 14 and 21 days after initiation of therapy, and 2 weeks after

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. chelation ceases (i.e., rebound). A 2-week rest period is recommended between the 19th and 26th days of chelation in order to allow equilibration of lead in blood and bone. In the Treatment of Lead-Exposed Children Trial (1994–2004), DMSA reduced short-term BLL; however, 36-month follow-up cognitive, neuropsychological, and behavioral scores did not improve compared with controls. In the Treatment of Lead-Exposed Children Trial of 12–33-month-old children with blood lead concentrations 20–44 μg/dL, DMSA reduced the blood lead concentration in the short term, but the blood lead concentrations of controls and treated children were statistically similar 1 year after cessation of treatment.[806] There were no detectable improvements in a variety of measurements of cognitive and behavioral functions. DMSA is not indicated for prophylaxis of lead poisoning in a lead-contaminated environment.

Adverse Effects

DMSA lowers blood lead concentrations in children with relatively few side effects, although a rebound occurs following cessation of therapy.[801] Common adverse reactions to DMSA include gastrointestinal symptoms (nausea, vomiting, diarrhea, anorexia), mucocutaneous lesions, and erythematous rash. DMSA administration produces an unpleasant odor to urine, feces, and sweat resulting in compliance issues in some patients. Although DMSA increases copper and zinc elimination, the changes are not usually clinically significant compared with $CaNa_2EDTA$.[807] Transient elevations of serum hepatic transaminases tests may occur at the beginning of therapy, but the continued elevation of these tests is uncommon; the clinical significance of these changes is unclear. Children with both G-6-PD deficiency and sickle cell anemia have been treated with DMSA without complications.[808] The US FDA classifies DMSA as a category C agent based on teratogenicity and fetotoxicity in rodents.[809] There are few data on the human teratogenicity of DMSA.

D-Penicillamine

This compound is a weak oral chelator; prior to the approval of DMSA in the United States, D-penicillamine was the only oral agent available experimentally for the reduction of BLL 25–40 μg/dL. This drug produces less effective enhancement of urinary lead excretion than $CaNa_2EDTA$;[810] the mechanism of its action is unclear. Although D-penicillamine effectively reduces BLL in children in the short term, the high incidence of adverse effects limits the use of this chelating agent.[810] DMSA is generally preferred to D-penicillamine as an oral chelating agent for lead toxicity.

General Chelation Guidelines

Tables 16.21 and 16.22 provide general guidelines for chelation therapy for children and adults, respectively; however, certain areas remain controversial including what is the lowest blood lead concentration to initiate chelation therapy in asymptomatic patients. The EDTA lead mobilization test is rarely used to determine the need for chelation.

Symptomatic Children (Acute Symptomatic Plumbism)

The presence of an acute encephalopathy requires the administration of high-dose combination chelation (BAL, 4 mg/kg every 4 hours for 5–7 days, together with $CaNa_2EDTA$, 12–24 mg/kg every 4 hours beginning with the second dose of BAL). In mildly symptomatic cases without acute encephalopathy, BAL may be discontinued after 3 days when the BLL declines <50 μg/dL. Repeat chelation courses may be necessary after a 2–4-day interval depending on the resolution of symptoms and repeat blood lead levels. An additional course with 7–10 days of treatment is necessary when the BLL rebounds >50 μg/dL.[640]

Asymptomatic Children (Subclinical Plumbism)

Table 16.21 outlines the treatment of symptomatic and asymptomatic children. In asymptomatic children with blood levels <70 μg Pb/dL, the decision to perform chelation should be based on factors in addition to the BLL including the following: 1) age (the brain of children <2–3 years is more susceptible to neurotoxicity), 2) source of poisoning and likelihood of reduction in exposure to lead, 3) duration of poisoning (short-term exposure responds better to chelation), and 4) iron status. Chelation is commonly recommended for children with BLL of 45–69 μg/dL including asymptomatic children.[811] All patients with elevated BLL should have repeat blood samples drawn to exclude the possibility of contamination or laboratory error; the FEP may be helpful if the BLL is >30 μg/dL. Check blood iron levels before chelating because iron deficiency alone causes elevated FEP levels. FEP concentrations <35 μg/dL are normal, whereas concentrations >250 μg/dL are grossly abnormal. Following chelation, the FEP concentration helps distinguish a continuing lead exposure; a rising FEP level indicates reexposure, whereas a steady or declining FEP concentration suggests rebound from bone stores.

BLL >70 μg/dL

Children with blood levels over 70 μg/dL require hospitalization for chelation therapy and immediate confirmation of the blood lead level to reduce the risk of cerebral edema, coma, and severe neurological damage. They usually receive the combination of BAL and $CaNa_2EDTA$ to prevent a transient rise in lead levels and the precipitation of acute encephalopathy. Children with BLL >70 μg/dL require careful observation during chelation. Fluid administration should be generous (10 cc/kg bolus, 1½ times maintenance therapy). The presence of lead on the KUB indicates the need for decontamination (i.e., whole bowel lavage). There are limited data on DMSA use in developed countries for BLLs in this range. In a retrospective study of severe lead poisoning in rural Zamfara, Northern Nigeria, 1,156 children ≤5 years of age underwent 1–15 courses of DMSA chelation.[812] The study reported no clinically severe adverse drug effects or laboratory findings that required discontinuation of treatment. The authors considered oral DMSA pharmacodynamically effective in a resource-limited setting.

BLL 45–70 μg/dL

Initial blood lead levels in this range should be repeated within 2 days. Asymptomatic children with repeat blood levels between 45–70 μg/dL usually require chelation depending on clinical judgment. Outpatient oral therapy (DMSA) is an adequate treatment regimen *if* the child is discharged to a lead-safe environment. Positive long-bone X-rays for lead lines also indicate the need for chelation. Although D-penicillamine previously was used for mild to moderate lead poisoning, adverse effects of this drug limit its current use to patients unable to tolerate DMSA or $CaNa_2EDTA$ in a clinical situation requiring chelation.

BLL 20–45 μg/dL

Confirmed venous blood lead concentrations in this range should be repeated within 2 weeks to 1 month. Although somewhat controversial, routine chelation is not recommended in this range. The decision to use chelation therapy following confirmation of blood lead concentrations in this range depends on clinical judgment of various factors including the presence of biochemical evidence of toxicity, the persistence of elevated blood lead levels for several months despite the removal of lead from the child's environment, and susceptibility to lead toxicity (<2 years of age). Remediation of the home environment is the most important aspect of clinical management for reducing blood lead exposure in children. A small-scale study of children with blood lead concentrations 30–45 μg/dL randomized to DMSA treatment and placebo did not detect a statistically significant difference in the blood lead concentration between the two groups at 1-month (end of treatment) and 6-month follow-up.[813] Although the blood lead concentrations following treatment were lower than baseline, remediation of the home environment in both groups accounted for the difference in the mean blood lead concentrations.

$CaNa_2EDTA$ provocation test previously was used to decide the necessity of chelation in children with BLL 35–45 μg/dL, particularly when the FEP concentration was elevated. The increasing use of oral chelation with the technical and practical limitations of the lead mobilization test significantly restricts the current use of the $CaNa_2EDTA$ provocation test.[814] Lack of adequate hydration, difficulty obtaining complete urine collection, and iron deficiency can produce false-negative lead mobilization tests, commonly when blood lead levels remain elevated after remediation.

The lack of data to support the effectiveness of chelation in the reversal of neurotoxicity restricts the use of chelation for BLL 20–45 μg/dL. A modest cognitive improvement following $CaNa_2EDTA$ chelation occurred in children treated with $CaNa_2EDTA$, but the nonrandom design of the study prevented adequate evaluation of confounding environmental and genetic variables.[815] In a randomized, placebo-controlled, double-blind (treatment of lead-exposed children) study of 780 children with BLL of 20–44 μg/dL at ages 12–33 months, the use of up to three 26-day courses of DMSA did not improve scores on cognitive, neuropsychological, or behavioral tests when compared with placebo.[806,816] At 7 years of age, 647 subjects remained in the study. Although the use of DMSA did lower the mean blood lead concentration ~4.5 μg/dL (95% CI: 3.7–5.3 μg/dL) during the first 6 months of treatment, the mean scores on cognitive, behavioral, and neuropsychological function at the 36-month follow-up period were similar to placebo. Reanalysis of the control data indicated that improvement in scores in the placebo group (i.e., no chelation) resulted from factors other than declining blood lead levels.[817] The mean blood lead concentration in the study group was 26 μg/mL; the mean maternal IQ was 80.

BLL <20 μg/dL

Confirmed venous blood lead levels <10 μg Pb/dL usually require follow-up BLL within 3 months and then 6–9 months after the BLL declines. Blood lead levels in the range of 10–20 μg Pb/dL should be repeated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

within 1–3 months as displayed in Table 16.16 followed by retesting 3–6 months after the BLL declines. If the blood lead level remains within 10–14 μg/dL, the patient's family should receive additional advice on methods to reduce blood lead exposure (see Table 16.20) and the blood lead test repeated within 1–3 months along with a careful environmental history, advice on nutrition (e.g., iron, calcium), and education to decrease blood lead exposure.[818] There is no clear evidence that chelation alone improves IQ in children with lead levels elevated above population norms.[816]

Adults

The treatment of adults is based primarily on the presence of symptoms of lead intoxication that usually occur at somewhat higher blood lead levels compared with children. Symptomatic patients (usually >70 μg/dL) should be chelated. Chelation based on specific BLL for adults is controversial (see Table 16.22) because of the lack of data documenting the improvement in neurological function in asymptomatic patients.[632] Furthermore, a 5-day course of $CaNa_2EDTA$ does not reduce brain lead concentrations.[819] A prospective, observational study of Taiwan residents with high-normal body lead burdens (EDTA-mobilization test results ≥80 μg to <600 μg over 72 hours) suggested that chelation may slow the progression of chronic renal disease in these patients, but the study did not separate the effects of EDTA chelation from the effects of a reduction of the body lead burden.[820]

There are limited clinical data on the efficacy of DMSA to reduce symptoms during lead intoxication in adults. A case report on a 54-year-old man with chronic lead toxicity associated a dramatic drop in the blood lead concentration following administration of a daily dose of 30 mg DMSA/kg bodyweight for 3 days and 20 mg DMSA/kg for 4 days.[821] Although substantial rebound in the lead concentration occurred within 89% of baseline, he reported improved memory and fewer headaches. Treatment was terminated because of mucocutaneous lesions; the BLL rebounded to 52 μg/dL.

Pregnant Patients

Scientific evidence regarding chelation in pregnant patients is very limited consisting primarily of animal studies and a few case reports mostly on $CaNa_2EDTA$ administration during the second and third trimesters. Calcium disodium edetate is usually the preferred lead chelator during pregnancy.[787] Edetate disodium (Na_2EDTA) should never be administered because of the potential for life-threatening hypocalcemia. Most experts recommend inpatient chelation for pregnant women with BLL >70 μg/dL and particularly with evidence of encephalopathy to reduce maternal and fetal toxicity regardless of the trimester. Rodent studies with calcium edetate suggest chelation therapy during organogenesis potentially increases the risk of congenital abnormalities from the excretion of essential metals.[822] Thus, the CDC recommends considering chelation for maternal BLL >45 and <70 μg/dL after completion of organogenesis in consultation with lead poisoning and high-risk pregnancy experts consistent with the general concern about administering unusual drugs during organogenesis.[823] Rodent studies indicate that DMSA is not teratogenic, but high daily doses (100–1,000 mg/kg) produce maternal toxicity (decreased weight gain) and fetotoxicity. A single case report described the outpatient administration of DMSA to a 38-year-old woman with chronic lead poisoning (BLL = 57 μg/dL in the late third trimester).[824] The maternal blood level did not decline (questionable compliance), and the cord blood lead was 126 μg/dL. The lead source was never identified. The maternal BLL should be confirmed in a second blood sample drawn within 24 hours of the first draw. The CDC recommends pumping and discarding breast milk when the maternal BLL is ≥40 μg/dL and the initiation of breastfeeding when the maternal BLL declines below 40 μg/dL.[823]

Pregnant women with BLL <5 μg/dL do not require follow-up during pregnancy; BLL above this value should be repeated to confirm excessive lead exposure. Repeat BLL should be drawn depending on the extent of BLL elevation and risk factors. Pregnant patients with BLL 15–24 μg/dL may retest every 2–3 months along with evaluation of lead sources, whereas patients with BLL 25–44 μg/dL require monthly blood lead concentrations and examination of their environment for lead sources.[825]

Enhancement of Elimination

Methods to enhance elimination typically do not alter blood lead concentrations. Hemodialysis of a patient following the ingestion of lead oxide reduced the blood lead half-life to 9 hours in combination with EDTA chelation; the blood lead half-life during EDTA infusion alone was 96 hours.[826] The case report provided no assessment of the efficacy of hemodialysis including no data on the amount of lead removed in the dialysate.

Supplemental Care

Acute Encephalopathy

Laboratory studies during treatment of lead-induced encephalopathy include serum creatinine BUN, and calcium, serum hepatic aminotransferases, urinalysis, 24-hour urine creatinine and protein, peripheral motor nerve conduction velocity, intelligence/personality tests, and sperm counts.

1. Maintain generous daily urine flow (350–500 mL/m^2) to keep the urine specific gravity <1.020.
2. Treat acute encephalopathy promptly.
3. Monitor blood lead levels daily. Stop BAL if BLL decreases <50–60 µg/dL. Stop $CaNa_2EDTA$ if BLL decreases <40 µg/dL or urinary lead decreases <2 mg Pb/24 hours.
4. Usually, three or four 5-day courses are necessary for acute encephalopathy. Obtain a CT head to evaluate cerebral edema if acute changes in neurological status develop.
5. Maintain hydration and watch for deteriorating renal function with daily urinary protein and serum creatinine measurements.
6. After treatment courses, measure blood lead in 10–12 days for rebound from bone stores. The post-chelation lead value is highly variable depending on dose and chelating agent, body burden of lead, continuing lead exposure (e.g., retained lead foreign body near acidic environment), and time since chelation ended. The post-chelation rebound usually does not exceed pre-chelation values.
7. *Always* identify the lead source in the environment to prevent reexposure. Children should be hospitalized until they can be discharged into a lead-safe environment. Focused dust-control programs in contaminated homes can significantly reduce BLL in children.[827]
8. Cerebral edema usually responds to chelation therapy. IV or IM midazolam is the preferred drug of choice for rapid control of seizures. The use of surgical decompression and mannitol to relieve intracranial pressure should be used cautiously.[646]

Retained Lead Bullets

Most retained bullets require no surgical intervention as the *initial* therapy. Surveillance of blood lead levels depends on the assessment of risk. High risk of lead toxicity involves bullets near joints (shoulder, hip, knee), large load of multiple lead fragments (e.g., multiple shotgun pellets), direct contact with bone, and possibly intraabdominal fragments. These patients should have a baseline blood lead level, then repeat BLL within 2 weeks. Depending on the risk, these patients should be followed monthly for several months, then yearly. Lead toxicity may develop long after the initial injury; hence, these patients should be followed long-term. Removal of bullets is usually necessary for patients with high BLL and/or symptoms of lead toxicity. Chelation should be started before surgery to reduce the postoperative elevation of the BLL. Intraarticular lead bullets may produce opacification of the synovium with fine lead particles (lead arthrogram), thinning of the cartilage, proliferative synovitis, and arthritic changes.

ORGANIC LEAD

HISTORY

The research lab of General Motors Corporation in Dayton, Ohio discovered the value of tetraethyl lead as a gasoline additive in 1921; the use of leaded gasoline allowed the development of powerful, high-compression engines. The US Surgeon General temporarily suspended the production and sale of leaded gasoline in 1925 as a result of the occurrence of behavioral abnormalities and fatalities in workers manufacturing tetramethyl lead. Production continued in 1926 after an investigatory committee formed by the US Surgeon General recommended continued use of leaded gasoline as a motor fuel as long as distribution and use were controlled by proper regulation. The Committee warned that widespread use may create more hazardous conditions than their investigation uncovered. Production of tetraethyl lead increased dramatically during World War II with most gasoline containing lead by the 1950s.[828] US peak consumption of tetraethyl lead occurred in 1969.[829] Other organolead compounds used to improve octane in gasoline include tetramethyl lead, ethyltrimethyl lead, triethylmethyl lead, and dimethyldiethyl lead; however, tetraethyl lead was by far the most common gasoline additive. In 1973, the US EPA issued regulations requiring the gradual reduction of lead in all gasoline. US automakers introduced catalytic converters in 1975 in response to the timetable for the reduction of lead in gasoline. Although farm equipment and aviation fuel can still contain alkyl lead additives, the use of lead >0.05 g Pb/gallon was banned in automobile fuel by 1996.

PHYSIOCHEMICAL PROPERTIES

Tetramethyl lead is highly flammable with a tendency to collect in low areas as a result of a vapor density of 6.5. Table 16.23 lists the identifying information and physical properties of organic lead compounds.

EXPOSURE

Exposure to organic lead occurs almost exclusively as a result of direct contact (e.g., service station, refinery) with leaded fuel because combustion of gasoline oxidizes organic lead to inorganic lead salts. Organolead compounds are fuel additives and antiknock agents in aviation and motor vehicle fuels including tetraethyl lead, tetramethyl lead, diethyldimethyl lead, triethylmethyl lead, and ethyltrimethyl lead.

ENVIRONMENTAL FATE

Air

More than 90% of the lead emitted from automobile exhaust appears in the form of inorganic particulate matter (e.g., lead bromochloride, double salts with ammonia halides), whereas the remainder occurs as organic lead vapors.[37] About 1% of the organolead content of gasoline releases unchanged to the atmosphere from car exhaust.[830] In the atmosphere, tetraethyl and tetramethyl lead compounds exist primarily in the vapor phase.[831] The atmospheric half-life of organic (i.e., tetraethyl, tetramethyl) lead ranges up to ~2 days with the trialkyl and dialkyl lead compounds being more persistent than tetraalkyl compounds.[832] The organic lead vapors are photoreactive; consequently, the residence time of these vapors is limited. Tetraethyl and tetramethyl lead compounds decompose rapidly to trialkyl and dialkyl lead compounds after exposure to sunlight within 12 hours during summer and 36 hours in winter;[829] subsequently, these compounds degrade to inorganic lead oxides as a result of direct photolysis or reactions with hydroxyl radicals and/or ozone. The reaction of tetraethyl lead and hydroxyl radicals during summer has a half-life of ~6 hours, whereas the estimated overall half-life of tetraethyl lead is <2–3 days.[833] Halogenated lead compounds form during combustion by the reaction of halogenated lead scavenger compounds with tetraalkyl lead compounds. Within 1 day, ~75% of the brominated lead compounds and ~30–40% of chlorinated lead compounds undergo conversion to lead carbonates, oxycarbonates, and oxides.[834]

Water

In water, tetraethyl lead and tetramethyl lead rapidly undergo photolysis and volatilization with <1% tetraethyl lead remaining after 2 weeks.[829] In experimental studies, tetraethyl lead compounds decompose within 48 hours to trialkyl lead in rainwater samples exposed to sunlight; trialkyl and dialkyl compounds are stable in rainwater without light.[835] Tetraalkyl lead compounds (e.g., tetraethyl lead) are insoluble in water; consequently, leaching from the soil is unlikely. Trialkyl and tetraalkyl lead compounds can bioconcentrate in aquatic organisms; however, biomagnification of organolead compounds does not occur.[37]

TABLE 16.23. Identifying information and physical properties of some organic lead compounds.

Physical Characteristic	Tetraethyl Lead	Tetramethyl Lead	Diethyldimethyl Lead	Triethylmethyl Lead
Synonym	TEL, tetraethyl-plumbane	Tetramethyl-plumbane	Diethyldimethyl-plumbane	Methyltriethyl-plumbane
CAS RN	78-00-2	75-74-1	1762-27-2	172-28-3
Molecular formula	PbC_8H_{20}	PbC_4H_{12}	PbC_6H_{16}	PbC_7H_{18}
Molecular weight (g/mol)	323.45	267.3	295.4	309.4
Valence	+4	+4	+4	+4

Soil

Although dry deposition is an important process for the removal of lead from the air, the majority (40–70%) of lead partitions from air to soil via wet deposition. Most lead remains in the area of deposition as a result of poor solubility and binding to organic matter. At a pH of 4–6, organic lead complexes become soluble; these compounds leach from the soil, resulting in uptake by plants.

DOSE EFFECT

Organolead compounds are potent neurotoxins. A 13-year-old boy accidentally ingested a mouthful of fuel stabilizer containing 80–90% tetraethyllead along with dibromoethane and dichloroethane.[836] He developed severe neurological symptoms including agitation, visual hallucinations, tremor, muscle weakness, and respiratory insufficiency that required hospitalization for 2 months. Three months after ingestion, he was able to ride his bike; his parents reported some difficulty concentrating. Two adolescents ingested ~15 mL tetraethyllead; within 12 hours, they developed altered consciousness, convulsions, hyperreflexia, and respiratory insufficiency.[837] They ultimately sustained a fatal cardiac arrest (19 hours and 26 days after ingestion) after developing hypotension.

TOXICOKINETICS

The absorption of inhaled aerosols of tetraethyl lead is relatively rapid and almost complete based on experimental radiotracer studies. Dermal absorption of tetraethyl lead is also greater than inorganic lead based primarily on *in vitro* studies.[37] In contrast to inorganic lead, organic alkyl lead (tetraethyl lead, lead naphthenate) may diffuse across the epidermal layer in sufficient quantities to produce toxicity after prolonged, heavy dermal exposure.

Organic lead is distributed primarily to liver, brain, and kidney.[838] The liver metabolizes organic lead compounds by oxidative dealkylation via CYP450 isoenzymes; metabolites appear primarily in the urine and feces. After absorption, tetraethyl lead undergoes biotransformation to triethyl lead (central nervous system toxin), followed by dealkylation to diethyl lead and inorganic lead based on the analysis of urine from patients poisoned with tetraethyl lead. A worker was hospitalized for 2 months for tetraethyl lead poisoning after cleaning an aviation fuel tank; 3 weeks after exposure to tetraethyl lead, his urine contained the following lead species: triethyl lead, 2%; diethyl lead, 50%; and inorganic lead, 48%.[839]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Inhibition of dopamine, γ-aminobutyric acid (GABA), and glutamate uptake and/or metabolism is a suspected cause of the neuromuscular and behavioral abnormalities associated with organic lead toxicity; however, the exact role of these neurotransmitters in the development of triethyl lead neurotoxicity remains unclear.[287] The inhibition of intracellular ATP synthesis and transduction and/or binding of lead to intracellular Ca^{2+}-cytoplasmic proteins (e.g., calmodulin) causes mitochondrial swelling, dysfunction, and cell death. *In vitro*, triethyl lead interacts with two thiol groups of the tubulin dimer, inhibiting microtubule assembly and direct cellular movement (chemotaxis); *in vivo*, interactions with the tubulin/microtubule system cause aneuploidy and subsequently cytotoxicity.[840]

Nonpolar organic lead compounds penetrate the blood–brain barrier more easily than inorganic lead. Animal data and a case report suggest that the toxicity of tetramethyl lead is substantially less than that of tetraethyl lead, consistent with the lack of formation of the toxic metabolite, triethyl lead.

Pathological Changes

Exposure of animals to organic lead produces a limited pattern of neuropathological changes, primarily involving the frontal cortex and the limbic forebrain, particularly the hippocampus and anterior pyriform cortex.[841] The limbic system modulates learning, memory, motivation, and behavioral reactivity; organolead toxicity resembles the neurobehavioral deficits associated with limbic system damage. In rodents exposed to tetraethyl lead and the neurotoxic metabolite (triethyl lead), neurotoxic effects include lethargy followed by hyperexcitability, hypermotility, tremors, aggression, and convulsions consistent with damage to this region of the brain.[842]

Postmortem

The most severe damage following death from tetraethyl lead exposure involves the central nervous system; pathological changes also occur in the kidneys, bone

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

marrow, and peripheral nervous systems. The most dramatic histological change in the brain of a 25-year-old male with a 5-year history of sniffing leaded gasoline was cerebellar atrophy manifested by severe loss of Purkinje cells and thinning of the granule cell layer of the superior vermis.[843] Neuropathological abnormalities included chromatolysis of neurons in the reticular formation and cerebral cortex as well as loss of neurons in both the hippocampus (Ammon's horn) and cerebellum. The lead concentration in his brain tissue was 2.1 μg/g compared with 0.1 μg/g in tissue from a man with similar age and no unusual lead exposure.

CLINICAL RESPONSE

Acute Toxicity

A 22-year-old man sustained blast injuries when an angle-valve on an autoclave containing tetramethyl lead blew off; he was doused with material containing ~30% tetramethyl lead and ~70% inorganic lead that also partially blocked his mouth and nose.[844] He remained in the hospital for 58 days recuperating from traumatic injuries; at no time did he develop neurotoxic symptoms suggestive of lead poisoning, despite a blood lead level of 81 μg/dL the day after admission.

Inhalation

Tetraethyl lead is a central nervous system toxin characteristically causing an acute toxic psychosis with early subtle, nonspecific symptoms.[845] This toxic psychosis differs from the motor neuropathy, anemia, and coproporphyrinuria commonly seen with inorganic lead toxicity. Clinical features of acute tetraethyl lead encephalopathy include headache, anxiety, diaphoresis, sialorrhea, weakness, lethargy, tremor, insomnia, euphoria, hallucination, memory disturbances, and ataxia;[846] these symptoms may be delayed 12–24 hours after acute ingestion.[837] Abnormal myoclonic (chorea, facial grimacing) movements, confusion, disorientation, and decreased concentration often develop.[847] In more severe cases, the clinical effects progress to hyperexcitability, hypermotility, aggression, toxic delirium, hallucinations, convulsions, coma, hypotension, and cardiac arrest.

Ingestion

A 13-year-old adolescent developed severe neurological symptoms after the accidental ingestion of a fuel stabilizer containing 80–90% tetraethyl lead.[836] He had vomiting and abdominal pain immediately after ingestion; then, he developed progressive tremors, generalized weakness, hallucinations, and tremors over the next 48 hours. By the third day post-ingestion, he had slurred speech and was unable to stand; he ultimately required high doses of benzodiazepines, prolonged propofol infusion, and several days of intubation to control his severe neuromuscular symptoms. His cardiovascular system remained stable throughout his hospitalization. By 2 months after ingestion, he was able to perform all activities of daily living with mild slurred speech and a slight limp.

Environmental Exposure

Available data on organic (e.g., alkyl) lead compounds suggest these chemicals produce toxicity primarily through metabolism to inorganic lead including the release of inorganic lead from the combustion of gasoline containing alkyl lead.[37] The rapid oxidation of lead alkyl halides in automobile exhausts by sunlight and air significantly limits exposure to these compounds. In cases of chronic gasoline sniffing with tetraethyl lead, most cases of encephalopathy have substantially elevated inorganic blood lead concentrations.[848] Aspiration pneumonia and sepsis are the main causes of death in patients with lead encephalopathy from sniffing organic lead in gasoline.[849] Case reports associate gasoline sniffing with the development of an acute myopathy with myoglobinuria and markedly elevated creatine kinase activity.[850]

Occupational Exposure

The most common symptoms reported by 58 organic lead workers who self-referred to an occupational medicine clinic relate to the central and peripheral nervous systems. Forty-two of these workers participated in an epidemiological study of neurobehavioral performance involving mixed exposure to inorganic and organic lead.[851] The most common reported symptoms were memory loss (74%), joint pain (56%), trouble sleeping (54%), paresthesias (49%), fatigue (49%), nightmares (35%), and moodiness (28%). The co-exposure to inorganic lead complicates the determination of the cause of these symptoms. All workers had current BLL <40 μg/dL (mean = 19.4 ± 6.5 μg/dL).

Carcinogenesis

The IARC lists organic lead as a group 3 (not classifiable to carcinogenicity to humans) compound. The US

National Toxicology Program lists lead and lead compounds as reasonably anticipated to be carcinogenic; however, the monograph does not specifically comment on cancer risk following exposure to organic lead other than mentioning positive animal studies. A case-control study of occupational exposure to lead compounds suggests an increased risk of stomach cancer (odds ratio = 2.0, 95% CI: 1.1–3.8) for exposure to organic lead compared with cancer controls.[852] Determination of organic lead exposure was based on job history and interpretation by expert chemists. This study did not detect an association between organic lead and other types of cancer or between inorganic lead and cancer. A Canadian case-control study of histologically confirmed cases of lung cancer did not find an excess lung cancer risk associated with occupational exposure to organic lead based on blinded expert-based assessment of lifetime occupational exposure and adjustment for smoking and sociodemographic characteristics.[491] Comparing ever- to never-exposed subjects, the odds ratio for lung cancer and organic lead exposure was 1.39 (95% CI: 0.77–2.52). A case-control study of cancer incidence and tetraethyl lead manufacturing workers exposed to both organic and inorganic lead detected a statistically significant increased incidence of rectal cancer (OR, 3.7, 90% CI: 1.3–10.2).[853] The incidence of rectal and sigmoid cancers increased with increasing exposure to the organolead manufacturing process, particularly with a 10-year latency. The incidence of cancer in exposed workers did not increase at other sites (i.e., bone, brain, kidney, lung, spleen, stomach). There are few data on the carcinogenic effect of tetra-alkyl lead compounds in animals, in part because of the difficulty of administering these relatively less soluble lead compounds compared with lead acetate.

DIAGNOSTIC TESTING

Three days after the ingestion of tetraethyl lead-containing fuel additive, the whole blood of a 13-year-old adolescent contained 62 μg Pb/dL; he was severely symptomatic with agitation, confusion, hallucination, hyperreflexia, severe rhythmic myoclonus, and generalized muscle weakness. The whole blood lead remained at 62 μg/dL 1 month later, despite clinical improvement. By 2 months, his whole blood lead was 51 μg/dL; he recovered with the exception of mild slurred speech and a slight limp. A cross-sectional cohort study of 543 of 2,798 former organic lead workers used X-ray fluorescence of tibial lead as the measure of long-term cumulative exposure to lead.[854] The study detected statistically significant negative correlations between tibial lead concentrations and the following domains during neuropsychological testing: manual dexterity (finger tapping), executive ability (Trail Making Test B), verbal intelligence (Wechsler Adult Intelligence Scale-Revised Vocabulary Subtest), and verbal memory (Rey Auditory-Verbal Learning Test). There were multiple comparisons; pre-lead exposure estimates of premorbid function of these workers were not available. Furthermore, verbal intelligence is usually relatively resistant to neurotoxic effects.

HEALTH SURVEILLANCE

The US OSHA PEL (8-hour TWA) for tetraethyl lead and tetramethyl lead in general industry is 75 $\mu g/m^3$ compared with 100 $\mu g/m^3$ for tetraethyl lead and 150 $\mu g/m^3$ for tetramethyl lead in the construction and shipyards industries. The NIOSH REL (10-hour TWA) and IDLH for tetraethyl lead and tetramethyl lead are 75 $\mu g/m^3$ and 40,000 $\mu g/m^3$, respectively, as lead. Studies of occupational cohorts indicate diethyl lead is the most sensitive and specific biomarker of tetraethyl lead exposure. Urinary concentrations of triethyl lead are relatively low compared with diethyl lead; total urinary lead and the BLL do not correlate to the ambient air concentration of tetraethyl lead.[855] In a study of 26 workers at a petrol plant exposed to tetraethyllead, the BLL (mean = 25.6 μg/dL; range, 19.0–53.5 μg/dL) did not correlate to ambient air concentrations of tetraethyllead;[856] however, the urinary diethyl lead ranged from 0.25–2.7 μg/dL and correlated (r = 0.70) to airborne tetraethyllead concentrations (range up to 810 $\mu g/m^3$).

TREATMENT

Treatment of acute tetraethyl lead toxicity is primarily supportive. The efficacy of chelation for tetraethyl lead toxicity is unproven. Theoretically, chelation provides some utility by chelating the tetraethyl lead converted to inorganic lead; however, rodent studies indicate that none of the alkyl lead forms bind well to traditional chelating agents.[842] Chelation of two patients with severe tetraethyl lead poisoning did not alter their fatal course.[837] In a case series of neurotoxic leaded gasoline sniffers, the use of BAL and $CaNa_2EDTA$ substantially reduced blood lead levels; however, the long-term efficacy remained equivocal. In a case series of 20 males admitted for lead encephalopathy from petrol sniffing and chelated with intramuscular $CaNa_2EDTA$ and BAL, the median blood lead level decreased from 99.5 μg/dL pre-chelation to 39.3 μg/dL post-chelation.[849]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. This study indicates that these patients have a significant pool of inorganic lead similar to heavily lead-exposed workers; however, the study did not evaluate the effect of chelation on the neurotoxicity associated with lead toxicity. Chelation remains an option for severely symptomatic patients with very elevated BLL.

Chapter 17

LITHIUM

HISTORY

In 1817, Johan August Arfedsson discovered lithium; medical use of lithium began in 1844 when Alexander Ure introduced the use of lithium carbonate for the dissolution of rheumatic nodes and bladder stones.[1] The widespread use of daily doses of 3–26 mmol Li for anti-rheumatic treatment was not commonly associated with reports of toxicity. In 1871, William Hammond recommended the use of relatively high lithium carbonate doses (45 mmol Li every 2–4 hours during the first day or until sleep occurred followed by 3–4 times daily maintenance doses) for the treatment of acute mania and melancholia; however, acute toxicity associated with these large doses limited the widespread use of these recommendations.[2] Kopilinski reported symptoms of lithium toxicity associated with the use of lithium citrate in 1898.[3] During the 19th century, lithium was administered for gout based on the *in vitro* solubility of urate in lithium solutions; however, toxicity occurred with the required lithium dose.[4] Commercial production of lithium began in 1925, but significant production occurred during World War II with the use of lithium to absorb CO_2 in submarines, inflate emergency signal balloons (lithium hydride), and lubricate high-temperature parts.

The use of 25% lithium chloride as a salt substitute in the 1930s and 1940s for patients with hypertension and heart failure caused serious lithium toxicity; in early 1949, the US Food and Drug Administration (US FDA) banned the use of lithium salts as drugs and food supplements including the use of lithium as a flavoring agent in beverages.[5,6] In the same year, John Cade initiated the beginning of the "second lithium era" by recommending the use of lithium carbonate for acute mania;[7] however, high lithium doses (50 mmol Li daily) frequently produce adverse neurological effects. The Danish psychiatrist, Mogens Schou, in collaboration with Paul Christian Baastrup, conducted the first clinical trial on the mood-stabilizing effects of lithium. In 1970, the US FDA approved the administration of lithium carbonate in the treatment of bipolar mental illness. Currently, lithium is an important drug for the treatment of manic–depressive affective disorders. Lithium has a narrow toxic therapeutic index with most accidental poisoning resulting from altered drug kinetics during chronic therapeutic use. During 1995, the database for the American Association of Poison Control Centers recorded ~5,300 cases of potential lithium toxicity.[8] Of these cases, ~3% were considered serious and five deaths were ascribed to lithium intoxication. Twenty years later, lithium exposures reported to AAPCC were ~6,700 with ~2% listed as serious and 3 deaths attributed to lithium toxicity.[9]

PHYSIOCHEMICAL PROPERTIES

Lithium (CAS RN: 7440-73-5) is a soft, silvery-white Group 1 (Group IA) alkali metal with physical properties similar to sodium. This metal is the lightest solid metallic element with a atomic weight of 6.94 g/mol and density of 0.534 g/cm^3; its water solubility is 12.8 g/L. Lithium exists almost exclusively as the ^{6}Li and ^{7}Li isotopes. The melting point of lithium is relatively low (180.5°C). Lithium is a univalent cation that requires administration with an anion (carbonate, citrate).

Lithium exists naturally in minerals (pegmatite, brines) as stable salts rather than a pure element because of its reactivity. Lithium orotate is an organic lithium compound that provides 3.83 mg elemental lithium/100 mg compared with 18.8 mg/100 mg inorganic lithium carbonate.

Lithium hydride (CAS RN: 7580-67-8; MW: 7.95 g/mol) is an odorless, combustible white-to-gray solid that forms when lithium reacts with hydrogen at ~500°C; the compound darkens after exposure to light. This compound has a melting point of 680°C, specific gravity of ~0.77, and vapor pressure of 0 at 20°C. This compound forms flammable dust clouds and decomposes in water to form lithium hydroxide and explosive hydrogen gas.

EXPOSURE

Uses

Lithium carbonate possesses a wide variety of useful industrial applications including a fluxing agent to reduce the thermal expansion in enamel coatings, the consumption of electricity, and the emissions of fluorine in aluminum pot lines. Lithium carbonate is a constituent of ceramic/glass production and primary aluminum production. Lithium hydroxide is an important compound for the production of lithium grease, which has numerous high-temperature applications. Lithium is a strong fluxing agent in the ceramics and glass industry, particularly in heat-resistant cookware as well as a component of alkaline cells and rechargeable batteries. The uses of lithium hydride include nuclear shielding material, a desiccant, a source of hydrogen, and a condensing agent for chemical synthesis. Although lithium is used in a variety of occupational settings, lithium intoxication in the work environment is rare. Toxicity from lithium compounds in the work environment results primarily from the corrosive actions of lithium hydride.

Sources

Soil

Lithium exists in most soils in trace concentrations. In a study of 180 soil samples from the Jordan Valley, the mean water-soluble lithium concentration from different locations ranged from 950–1,040 ng/mL in top soil (0–20 cm) and from 1,060–2,680 ng/mL in subsoil (20–40 cm).[10] In a study of soil samples from the Piedmont and Coastal Plain regions of Georgia and South Carolina, the total lithium content correlated with clay content ranged from 3.74–59.93 mg/kg.[11] Total exchangeable lithium was insignificant (<0.1%).

Water

Lithium typically occurs in low concentrations (<40 ng/mL) in surface waters with lithium concentrations in major US rivers of <2 ng/mL.[12] Surface waters in the Atacama Desert of northern Chile may contain lithium concentrations up to a few thousand ng/mL as a result of natural sources of lithium.[13] This desert is one of the driest in the world. In a study of maternal and neonatal lithium concentrations in the Atacama Desert and Argentina, water samples contained the following geometric mean of the lithium concentrations (ng/mL): San Antonio del los Cobres (n = 4), 705 (range, 650–740); Arica (n = 9), 60 (range, 25–80); and Santiago (n = 6), 21 (range, 16–34).[14]

Volcanism is a major source of lithium, resulting in relatively high lithium concentrations in thermal sources including natural spas. In a study of soil samples from the Piedmont and Coastal Plain regions of Georgia and South Carolina, the mean dissolved lithium concentrations in surface water from these two regions were 1.16 ng/mL and 0.70 ng/mL, respectively, with an overall range of 0.08–4.62 ng/mL.[11]

Lithium usually exists in drinking water at concentration of <10 ng/mL except in areas of naturally high soil content (northern Chile, northern Argentina, Austria) or anthropogenic sources (e.g., nuclear waste-disposal areas). In a study of 37 imported and US bottled mineral waters purchased in Chicago and Pittsburgh, the lithium concentration ranged from 2–5,240 ng/mL with the majority of bottle water containing <100 ng/mL.[15]

Diet

Lithium occurs in highly variable amounts in foods and drinking water. Limited data on US residents suggest the daily dietary lithium intake ranges from 650–3,100 µg.[16] Although no human diseases are clearly linked to lithium deficiency, animal studies suggest some reproductive and behavioral abnormalities in lithium-deficient animals with resulting recommendations for daily lithium intake of 1 mg.[16,17] The primary sources of lithium in the diet are grains and vegetables, particularly spinach; typically lithium concentrations in these foods range from 0.5–4.6 µg/g (ppm). Preliminary Chilean studies in areas of very high lithium concentrations in drinking water (>1,000 ng/mL) suggest that the diet may contribute substantial amounts of lithium (i.e., up to ~100 mg/day) to daily lithium intake; green vegetables (chard, parsley, lettuce), alfalfa, and milk contained the highest lithium concentrations.[18]

Pharmaceuticals

Pharmaceutical preparations of lithium include lithium carbonate as a 300-mg tablet (8.12 mEq Li) and lithium citrate as a syrup (8 mEq Li/5 mL). The lithium carbonate capsules are also available as slow-release preparations. Lithium orotate is an organic lithium compound that is available over the Internet as a "dietary supplement." Lithium carbonate contains ~5 times the elemental lithium content as an equivalent amount of lithium orotate.

ENVIRONMENT FATE

Lithium occurs naturally in water and soil, primarily at low concentrations.[19] Representative background concentrations based on limited data include the following values: fresh water, 0.07–40 μg/L; seawater, 170–190 μg/L; sediment, 56 mg/kg; soil, 3–350 mg/kg (ppm); and atmosphere, 2 ng/m^3.[20] Li concentrations in major US rivers are <2 μg/L with some surface waters reaching 40 μg/L.[12] Metallic lithium reacts with water to form hydrogen and lithium hydroxide. High lithium concentrations exist in natural brines including Searle's Lake (Mojave Desert, California), Clayton Valley (Nevada), Salar de Rincon (Argentina), and Salar de Atacama (Chile) as well as certain lakes (Dead Sea, Israel; Great Salt Lake, Utah).

A variety of environmental chemicals have been associated with an increased incidence of autism spectrum disease including lithium in drinking water; however, current epidemiological evidence is insufficient to distinguish spurious from causal associations. Trace amounts of lithium occur in most soils, primarily in the clay fraction from sedimentary rocks. The earth's crust contains an average of 0.006 ppm (27th most abundant element). Although lithium is not an essential element for plant development, low Li concentrations stimulate growth, whereas high concentrations produce chlorosis-like effects.[21] The estimated average daily lithium intake for a 70-kg US adult ranges from 0.65–3.1 mg with grains (e.g., oats) and vegetables being the major sources.[16] Although the data on lithium bioaccumulation are limited, low Li affinity for particles suggests bioaccumulation is not clinically significant. Acidity increases lithium uptake by plants.

DOSE EFFECT

The therapeutic daily dose of lithium carbonate varies widely between individuals. The average daily dose of lithium is 900–1200 mg (62–83 mmol) Li. Before the era of therapeutic drug monitoring, neurological symptoms associated with daily doses of 24–80 mmol Li included asthenia, ataxia, depression, giddiness, myoclonus, and slurred speech.[22] Renal dysfunction reduces lithium clearance; therefore, dose reductions are necessary for patients with renal insufficiency in order to prevent lithium intoxication. Recommendations for patients with renal dysfunction include 50–75% of the maintenance dose for glomerular filtration rates between 10–50 mL/minute and 25–50% of the maintenance dose for glomerular filtration rates of <10 mL/minute.[23] A single ingestion of 40 mg Li/kg by a patient with a history of prior lithium use may produce toxic lithium blood concentrations. Lithium orotate is an organic lithium compound that provides ~1/5 of the elemental lithium present in an equivalent amount of inorganic lithium carbonate. The estimated ingestion of 2.7 g lithium orotate by an 18-year-old woman was associated with the development of mild tremor, nausea, and vomiting; symptoms resolved within 4.5 hours post-ingestion.[24] The serum lithium concentration 2.5 hours after ingestion was 0.41 mEq/L.

TOXICOKINETICS

Absorption

Nearly complete lithium absorption of therapeutic lithium carbonate doses occurs from the gastrointestinal tract with peak therapeutic concentrations developing within ~1–3 hours after the ingestion of standard-release lithium preparations. Average peak plasma lithium concentration of 1.66 mEq/L occurred ~1 hour after the ingestion of 1,500 mg lithium carbonate, standard-release preparation by 3 healthy adult volunteers.[25] Sustained-release preparations produce peak levels ~2–6 hours after ingestion with peak serum concentrations reaching ~50% of the peak concentration after standard formulations.[26] The water solubility of lithium carbonate is low; case reports suggest clinically significant delayed absorption may occur up to 48–72 hours after large ingestions of sustained-release preparations.[27,28]

Distribution

Lithium initially distributes into the extracellular space with an apparent volume of distribution of ~0.7–1.0 L/kg, similar to total body water; lithium does not bind to serum proteins.[29] The distribution of lithium after ingestion is complex with preferential uptake in certain compartments (bone, kidney, thyroid, pituitary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

glands). Lithium concentrations in plasma, lung, heart, and umbilical cord are similar, whereas lithium concentrations in erythrocytes are approximately half of the serum lithium concentration. Although equilibrium between the cerebrospinal fluid and serum is rapid, lithium concentrations in cerebrospinal fluid at equilibrium are ~25–65% of the serum lithium concentrations as a result of the active efflux of lithium from cerebrospinal fluid by arachidonic membranes and capillary endothelium.[30] However, lithium concentrations in cerebrospinal fluid do not accurately reflect brain lithium concentrations.[31] The distribution of lithium into the liver and kidneys is relatively rapid compared with lithium distribution into bone, muscle, and brain. Equilibration of lithium between serum and brain tissue requires ~1 day.[32,33] Complete equilibrium between the serum and deep compartments in the brain, bone, and muscle may require up to ~1 week.[34]

Lithium crosses cellular membranes slowly; this slow re-distribution accounts for the delayed onset of action and the slow clinical response of serum lithium concentrations to hemodialysis. Severe toxicity does not usually develop until the distribution phase is sufficiently complete to allow significant penetration of lithium into the central nervous system. Consequently, a patient with an acute overdose and high initial serum concentrations of lithium may not develop neurological symptoms, if hemodialysis removes the lithium before penetration into the central nervous system. Conversely, symptoms may persist in a chronically intoxicated patient despite the reduction of serum lithium concentrations to the normal therapeutic range.

Persistently high concentrations of lithium in the brain of chronically intoxicated patients may account for slow neurological improvement despite relatively low serum lithium concentrations.

Elimination

There is no significant biotransformation of lithium in the body; lithium clearance occurs almost exclusively through the kidneys with negligible amounts of lithium (i.e., <5%) excreted in the bile, saliva, and feces. The kidneys process lithium similar to potassium, magnesium, and sodium through glomerular filtration.[26] The proximal renal tubules absorb 60–80% of the filtered lithium load, whereas minimal lithium absorption occurs in the distal tubule.[35] Lithium clearance is proportional to the glomerular filtration rate; during impaired renal function, a proportional decrease in the effective renal plasma flow results in a reduction in the clearance of lithium.[36] In patients with chronic nephropathy and reduced glomerular filtration rates, the fraction of lithium excreted into the urine remains normal until the glomerular filtration rate decreases below 25–35 mL/minute.[37] Events that increase the absorption of sodium and water in the proximal tubule will increase serum lithium concentrations including hyponatremia, low-salt diet, volume depletion, cardiac failure, diuretics, and nonsteroidal anti-inflammatory medication. The development of polyuria and diarrhea during long-term lithium therapy enhances the accumulation of lithium in the blood by causing sodium and water depletion.[38] Lithium clearance increases in alkaline urine.

The wide variation in the reported serum lithium elimination half-lives in randomly selected subjects results from differences in renal function and duration of lithium use. In volunteers receiving a single dose of lithium, the serum lithium half-life was ~9–13 hours during the initial elimination phase.[25] A two-compartment model best describes the elimination kinetics of lithium. The terminal β-serum lithium half-life ranges from ~18–36 hours during the beginning of lithium therapy; however, the terminal serum half-life increases up to ~60 hours following chronic therapy. In a study of 30 patients hospitalized for primary affective disorders, the approximate mean serum elimination half-life of lithium in patients receiving chronic lithium therapy recently, <1 year, and >1 year was 31 hours, 40 hours, and 58 hours, respectively.[39] Similarly, the lithium elimination half-life is longer during chronic lithium intoxication than acute or acute-on-chronic lithium intoxication. In a series of lithium intoxications reported to a regional poison control center, the mean elimination half-lives of lithium during acute, acute-on-chronic, and chronic lithium intoxications were ~12 ± 10 hours (range, 6–24 hours), 13 ± 8 hours (range, 3.5–45 hours), and 36 ± 23 hours (range, 11–100 hours), respectively.[40] In a study of 68 patients admitted for lithium intoxication, the approximate mean serum lithium half-lives for acute, acute-on-chronic, and chronic lithium intoxication were 12 hours, 21 ± 1 hours, and 32 ± 3.5 hours, respectively.[41] The mean serum lithium half-life in a cohort of 14 patients admitted to an intensive care unit with lithium toxicity was ~23 ± 9 hours.[42] The cohort contained a mixture of acute, acute-on-chronic, and chronic lithium poisoning with the serum lithium concentrations ranging from 1.4–9.6 mEq/L.

Maternal-Fetal Kinetics

Breast milk contains variable amounts of lithium in mothers receiving therapeutic lithium doses. Serum lithium concentrations in infants breast-fed by mothers on lithium are somewhat lower than maternal serum lithium concentrations. An analysis of case reports of mothers on lithium during breastfeeding suggested

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

that lithium concentrations in breast milk are ~40% of the maternal lithium concentrations with a range of ~25–70%.[43,44] Similarly, in a study of lactating mothers from areas in Chile and Argentina, the geometric mean of the breast milk/blood ratios from three cohorts residing in different areas was ~40% despite widely varying blood lithium concentrations.[14] In a study of 11 lactating women receiving lithium doses of 600–1,500 mg/day, the mean neonatal lithium dose ranged from 0–30% (mean = 12.2% ± 8.5%, 95% CI: 6.3–18.0%) of the maternal dose.[45] Although the authors observed no adverse effects in the neonates, they recommended close monitoring of neonatal serum lithium concentrations and adverse effects. There are few data on the clinical consequences of lithium concentrations in these infants; most physicians do not encourage breastfeeding during lithium therapy without close monitoring.

Drug Interactions

Table 17.1 lists numerous drug interactions associated with lithium use. Drug–drug interactions are classified into pharmacokinetic and pharmacodynamic interactions based on pharmacological mechanisms. Pharmacokinetic drug interactions result from alterations in absorption, distribution, or elimination of a drug and/or the metabolites. Lithium is not metabolized; therefore, lithium toxicity from these interactions usually develops from the interaction of drugs on the renal clearance of lithium ions, particularly thiazide diuretics and angiotensin-converting enzyme inhibitors in the elderly.[46,47,48] Pharmacodynamic drug interactions occur directly at the site of action or indirectly from interference by another physiological mechanism.[49] These interactions are subclassified as the following: 1) additive (the sum of individual drug effects); 2) synergistic (greater than additive); and 3) antagonistic (less than additive). The pharmacodynamic interactions of lithium are complex, affecting many biological processes, but not serum lithium concentrations.[50,51] Pharmacodynamic interactions with lithium most commonly involve antipsychotic agents, calcium antagonists, and antiepileptic drugs (e.g., carbamazepine, lamotrigine, valproate).[49,52] The simultaneous ingestion of ethanol and lithium does not significantly alter the pharmacokinetics of therapeutic lithium doses except for a minor increase in peak lithium concentrations.[53] Case reports associate elevated lithium concentrations with the administration of some COX-1 (e.g., ibuprofen) and selective COX-2 (e.g., celecoxib) nonsteroidal anti-inflammatory drugs,[54] particularly in the setting of renal dysfunction.[55]

TABLE 17.1. Drug interactions with lithium. (Adapted from Timmer and Sands).[56]

Drug Classification	Effect on Plasma Lithium Concentration
Diuretics	
Thiazide	Increase
Loop diuretics	Variable (increase/decrease)
Osmotic diuretics	Decrease
Potassium sparing	Variable (increase/decrease)
Acetazolamide	Decrease
Mannitol	Decrease
Angiotensin-converting enzyme inhibitors	Increase
Angiotensin receptor blockers	Increase
Nonsteroidal anti-inflammatory drugs[a]	
Indomethacin	Increase
Ibuprofen	Increase
Mefenamic acid	Increase
Naproxen	Increase
Sulindac	No effect
Aspirin	No effect
Theophylline, caffeine	Decrease
Verapamil	Decrease
Topiramate	Slight decrease
Carbamazepine	Increase

[a] Effects vary between nonsteroidal anti-inflammatory drugs. Sulindac and aspirin do not usually alter the lithium concentration.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

At the neuronal level, lithium inhibits gamma-aminobutyric acid (GABA) neurotransmission, while reducing excitatory dopamine and glutamate neurotransmission. Although the mechanism of action is not well defined, lithium probably acts through multiple pathways as a substitute for body cations (sodium, potassium) on several transport proteins (e.g., sodium channel, sodium-proton exchanger) and as an inhibitor of glycogen synthetase kinase-3β. The latter action reduces phosphorylation of nuclear factors that promote cell growth and protective mechanisms (nuclear factor of activated T cells, Wnt/β-catenin signaling pathway).[57] Lithium also upregulates neurotrophins including nerve growth factor, neurotrophin-3, and brain-derived neurotrophic factor; additionally, lithium alters transduction pathways related to glutamate, decreases noradrenaline and dopamine release, and transiently increases serotonin release.[58] Potential mechanisms for the effectiveness of lithium in bipolar disease include the following: 1) decrease in excitatory glutamatergic activity by modulation of neurotransmitters, and 2) modulation of messenger systems

including protein kinase C, cAMP-dependent kinase, and glycogen synthetase kinase 3β.[59]

A partial substitution for normal cations causes changes in ion exchange and transfer in cellular processes. The sodium channel is the key transporter for sodium homeostasis in the renal collecting ducts; this channel is equally permeable to lithium and sodium. Under normal physiological conditions, the sodium-proton exchanger is the transport system that is responsible for sodium reabsorption across the proximal tubule. This protein also transports lithium, although the maximal transport rate for lithium is half the rate of sodium transport.[60] Amiloride inhibits both the sodium channel and sodium-proton exchanger transporters. The transport of lithium by Na^+/K^+ ATPase pump is probably small under normal physiological conditions because the affinity of lithium for this protein is at least an order of magnitude less than the affinity of this protein for sodium and potassium. Lithium does not equilibrate passively between intracellular and extracellular compartments; this ion must be actively transported out of most cells by proteins (e.g., the sodium–sodium exchange protein).[56] The exact molecular basis for lithium transport currently is unknown. Incorporation of lithium into membrane structures may alter responses to hormones and the uncoupling of energy processes.

Mechanism of Toxicity

Central Nervous System

The major target organ for lithium toxicity is the central nervous system.[61] Damage to the basal ganglia may produce cerebellar signs;[62] rarely, horizontal down-beating nystagmus occurs following an acute lithium overdose as a result of cytotoxic damage to the nuclear structures in the cervicomedullary region.[63] Other reported ocular disturbances include horizontal gaze-evoked nystagmus, saccadic pursuit, saccadic dysmetria, unilateral gaze palsy, and oculogyric crisis. Electrolyte abnormalities (hypernatremia, hypomagnesemia) may contribute to the development of neurological symptoms; the rapid increase of serum sodium concentrations may cause central pontine myelinolysis. This demyelinating condition occurs in patients with chronic systemic illness (e.g., alcoholism, cancer, liver disease, malnutrition, sepsis) as well as hyperosmotic stress and disruption of the blood–brain barrier from rapidly correcting hyponatremia.[64] Common features of central pontine myelinolysis include dysarthria, dysphagia, mutism, and quadriplegia. Loss of myelin and oligodendrocytes may also occur at extra-pontine locations (e.g., basal ganglia, cerebral gray–white junction, cerebellar cortices, lateral geniculate);[65] furthermore, elevation of the serum sodium concentration above 160 mEq/L can cause parenchymal or subdural hemorrhages as a result of the rapid shrinkage of the brain matter.

Kidney

Acquired Nephrogenic Diabetes Insipidus

Arginine vasopressin-resistant, nephrogenic diabetes insipidus resulting in polyuria is the most common renal side effect of lithium therapy occurring in up to 55% of patients on long-term lithium therapy. Mechanisms of toxicity are multifactorial including the following: 1) inhibition of adenylyl cyclase in the principal cells within the collecting duct, and 2) reduction of medullary interstitial osmolality by decreasing the abundance of AQP2, UT-A1, and UT-B proteins.[66] Downregulation of AQP2 protein decreases vasopressin-induced water reabsorption across the apical membrane in the collecting duct. Reducing UT-A1 protein abundance interferes with vasopressin-induced phosphorylation of UT-A1, whereas a reduction in UT-B abundance in the inner medulla reduces the urinary concentrating ability by decreasing urea recycling and countercurrent exchange efficiency. The slow recovery from lithium-induced renal dysfunction relates to the partial reversal of AQP2 abundance following discontinuation of lithium therapy, desmopressin treatment, and water restriction.[67]

In nephrogenic diabetes insipidus, the renal tubules fail to respond to the antidiuretic action of arginine vasopressin (antidiuretic hormone, ADH), whereas central (neurogenic) diabetes insipidus results from inadequate secretion of ADH from the posterior pituitary. Cellular remodeling of the collecting duct and downregulation of the vasopressin-regulated water channel aquaporin-2 on the apical plasma membrane of the renal collecting ducts produce nephrogenic diabetes insipidus in patients on chronic lithium therapy.[67] Lithium enters the cells of the collecting duct via the luminal apical epithelial sodium channel;[68] the proximal tubule and thick ascending limb proteins are not affected by lithium. In volunteer studies, the epithelial sodium channel inhibitor, amiloride, reduces lithium uptake in the principal cells of the collecting duct and improves responsiveness to vasopressin-stimulated translocation of urinary aquaporin-2 to the apical membrane of the principal cells.[69]

Arginine vasopressin produces fluid retention by increasing the water permeability of the renal collecting ducts. The binding of vasopressin to the V_2 receptor on the basolateral membrane of the collecting duct causes activation of adenyl cyclase via magnesium-dependent

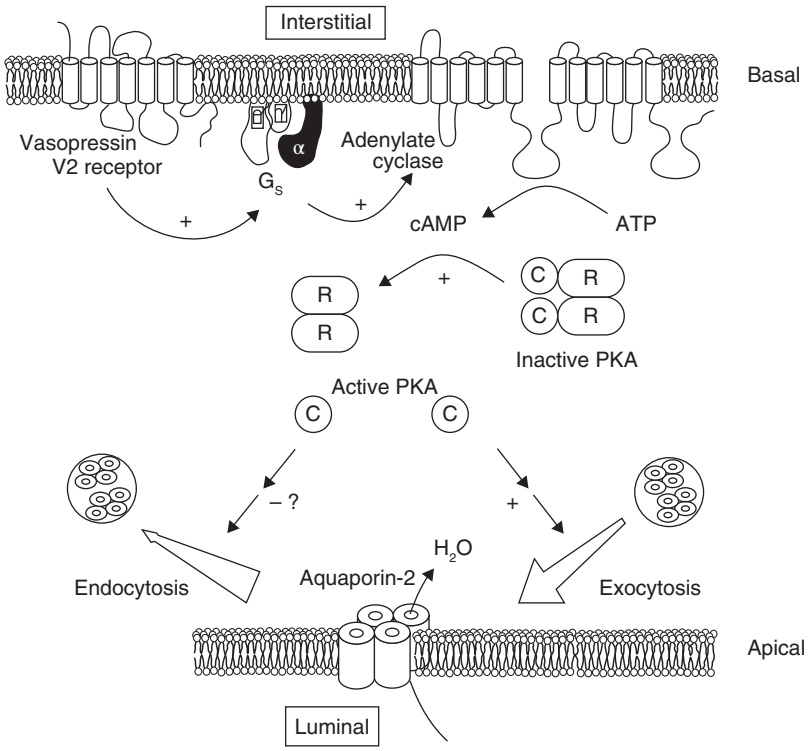

FIGURE 17.1. Schematic representation of the antidiuretic effect of vasopressin on the collecting duct. Catalytic (C) and Regulatory (R) are subunits of Protein Kinase A (PKA). (Modified from Oksche et al.).[70]

protein G_s. Aquaporine-2 channels in the luminal membrane markedly increase water permeability. Under normal circumstances, the increased cAMP and stimulation of protein kinase A fuse vesicles carrying aquaporine-2 leading to reduced water excretion into the collecting ducts as demonstrated by Figure 17.1. Patients with nephrogenic diabetes insipidus are unable to concentrate urine on fluid restriction as reflected by high **serum** osmolalities (>300 mOsmol/kg) compared with relatively low **urine** osmolality (<280 mOsmol/kg, specific gravity <1.010) associated with a normal response to dehydration. Their kidneys do not respond to pharmacological doses of vasopressin. Normal patients and patients with psychogenic polydipsia respond to dehydration by concentrating their urine (>450 mOsmol/kg, specific gravity >1.020).

Lithium accumulates in collecting tubule cells after passage through the sodium channels in the luminal membrane; lithium directly impairs arginine vasopressin-mediated activation of adenylate cyclase in the collecting ducts.[71] This action decreases intracellular cyclic AMP formation and protein kinase A stimulation of the aquaporine-2 channels.[72] The effect of these changes is a reduction of aquaporin-2, the vasopressin-regulated water channels in the collecting ducts, resulting in loss of renal concentrating ability. Lithium also modulates the phosphoinositol pathway by decreasing the metabolism of inositol-1,4,5-trisphosphate (IP_3) and increasing the concentration of inositol-1,4-bisphosphate (IP_2) and IP_3. IP_3 is a common second messenger that mediates the increased concentrations of cytosolic calcium by various cell types. Other potential lithium-induced causes of vasopressin resistance include inhibition of glycogen synthase kinase-3, β-isoform, dysregulation of renal prostaglandins, and altered purinergic signaling.[73]

Chronic Renal Disease

Impairment of renal concentrating capacity is the most consistent renal abnormality detected by cross-sectional and longitudinal studies of patients on long-term lithium therapy. Both retrospective and prospective studies of patients treated chronically with lithium demonstrate that long-term lithium therapy produces urinary concentrating defects, but the effect on glomerular function is relatively small.[74,75] Progression to end-stage renal disease is rare. The histological changes present in renal biopsies from patients on chronic lithium therapy include interstitial fibrosis (increased myofibroblasts, collagen deposition, enhanced transforming growth

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

factor-β1 expression), tubular atrophy, and minor glomerulosclerosis.[76] Although studies of patients on long-term lithium therapy suggest that maximum renal concentrating capacity correlates to the degree of tubular atrophy, there is no simple relationship between renal function and structure.[77] These renal changes are nonspecific, and the exact contribution of lithium to these changes remains unclear. Minimal change disease and nephrotic syndrome occur rarely during lithium therapy.[78] Chronic lithium toxicity produces abnormalities in the distal renal tubule, whereas a large, single ingestion of lithium causes proximal tubular damage along with prerenal azotemia.

Cardiovascular System

Bradycardia associated with lithium toxicity probably results from suppression of cardiac muscle automaticity. Lithium alters phase 4 of the pacemaker action potential by attenuating inward Na^+ current by competing with Na^+ for passage through the slow voltage-dependent (f-Na^+) channels and reducing resting membrane voltage/f-Na^+ channel opening during the end of phase 3 repolarization.[79] Similarly, lithium intoxication may produce PR and QRS prolongation by inactivating fast voltage-dependent channels. Other adverse cardiac effects following the treatment of patients with lithium involve T wave changes, QT prolongation, and the appearance of U waves on the ECG, similar to hypokalemia. These changes probably result from cation shifts that produce intracellular lithium accumulation and intracellular potassium depletion; however, human data correlating intracellular potassium concentrations to lithium-induced changes in cardiac conduction or excitability are limited.[80] Conduction and rhythm disturbances are rare during lithium intoxication except for cases of severe overdose, particularly in patients with preexisting cardiovascular disease. In a study of 83 patients on lithium, there was no increased risk (unadjusted odds ratio = 1.0, 95% CI = 0.43–2.4) of prolongation of the QTc interval (i.e., >456 msec) when compared with healthy controls.[81] There was an increased risk of QTc dispersion in the lithium group, but this measurement is not directly correlated to an increased risk of dysrhythmias in patients *without* cardiovascular disease. Animal studies suggest that lithium has some anti-arrhythmic properties in treating digitalis-induced ventricular tachycardia, but the clinical relevance of these effects in humans is unclear.[82] The effect of lithium on cardiac contractile function is less pronounced than cardiac conduction, probably resulting from inhibitory effects on the Na^+/Ca^{2+} exchanger; hypotension usually develops after serious neurological dysfunction (i.e., coma).[83]

Thyroid

Lithium concentrates in the thyroid gland where Li inhibits the uptake of iodine.[84] In addition, lithium inhibits iodotyrosine coupling, alters thyroglobulin structure, and decreases the secretion of thyroid hormones. As a result of increased thyrotropin release secondary to the inhibition of T_4 release from the thyroid gland, a smooth, non-tender goiter develops in ~5% of the patients chronically treated with lithium.[85] Chronic toxicity may present as euthyroid goiter, hypothyroid goiter, subclinical hypothyroidism, and exophthalmos with classical hypothyroidism.[86] Hypothyroidism may contribute to the occurrence of sinus node dysfunction associated with lithium therapy.[87]

Pathological Changes

A small minority of patients on chronic lithium therapy develop a chronic tubulointerstitial nephropathy. Typically, renal biopsies demonstrate interstitial fibrosis, distal renal tubular and collecting duct microcysts, and tubular atrophy out of proportion to the degree of glomerulosclerosis or vascular disease.

CLINICAL RESPONSE

Adverse Medicinal Effects

Adverse effects associated with lithium therapy include gastrointestinal irritation, weight gain, drowsiness, mild essential or postural tremor (i.e., rhythmic with frequency 8–12 Hz), muscle weakness, polyuria, and polydipsia. The tremor associated with lithium is usually regular and rhythmic (i.e., different than the pin-rolling tremor associated with Parkinson's disease). Typically, the prevalence and intensity of these side effects increase when serum lithium concentrations exceed 1.5–2.0 mEq/L, but these adverse effects also develop in the upper therapeutic ranges of lithium. Worsening tremor may occur as the first sign of lithium toxicity.[88] Dermatological side effects following chronic lithium therapy are uncommon. Hair loss and dry skin may occur during lithium therapy, but the presence of these dermatological effects also suggests the presence of hypothyroidism.

Complications of chronic lithium therapy primarily involve the kidney (reduced urinary concentrating ability), thyroid/parathyroid glands (hypothyroidism,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

hyperparathyroidism), central nervous system, and rarely, the cardiovascular system.[89] The risk of end-stage renal failure from chronic lithium therapy is low.[90] Patient factors contributing to the development of lithium toxicity include age of >50 years, renal impairment, nephrogenic diabetes insipidus, thyroid dysfunction, and hyperparathyroidism.[58] Physiological factors (e.g., dehydration, renal insufficiency, heart failure) or drug interactions (thiazide diuretics, angiotensin-converting enzyme inhibitors)[46] increase proximal renal tubule lithium absorption and/or reduced glomerular filtration, resulting in decreased lithium excretion and increased serum lithium concentrations along with the development of toxicity. Although the neurological features of chronic lithium intoxication typically occur in patients with elevated serum lithium concentrations, neurological symptoms may develop in patients with therapeutic concentrations of lithium.[91]

Central Nervous System

Cerebellar dysfunction is the most common chronic neurological complication following acute and chronic lithium intoxication including ataxia, dysarthria, and dysmetria with neuronal loss and gliosis of cerebellar gray matter. In a review of 90 cases of neurological symptoms persisting at least 2 months after lithium cessation described as SILENT (Syndrome of Irreversible Lithium-Effectuated Neurotoxicity), cerebellar dysfunction (e.g., dysarthria, ataxia) was the most common presentation. Atypical presentations of SILENT included extrapyramidal syndrome, brainstem dysfunction, retrobulbar optic neuritis, central pontine myelinolysis, and dementia.[92] A 44-year-old woman developed SILENT after a lithium overdose; eight weeks after the overdose, she had coarse axial tremor, ataxic gait, nystagmus, severe scanning dysarthria, and limb incoordination that was severely disabling.[93] At 1-year follow-up, the severe gait difficulties, ataxia, and tremor continued. The prognosis of patients with SILENT is not well defined.

In a series of 28 patients hospitalized for lithium toxicity primarily after chronic therapeutic use, the most frequent clinical abnormalities in decreasing order of occurrence were hyperreflexia, confusion, tremor, agitation, muscle rigidity (usually cogwheel type), drowsiness, and ataxia.[41] Alterations in mental status may develop despite declining serum lithium concentrations as a result of lithium neurotoxicity or electrolyte imbalance following the development of diabetes insipidus. These mental status changes range from drowsiness, lethargy, and disorientation to paralysis, stupor, seizures, and coma.[94] Although chronic lithium intoxication is usually associated with central nervous system depression, occasionally agitation, disorientation, and confusion similar to a manic episode complicate lithium intoxication.[95] Most neurological effects of lithium toxicity resolve when lithium concentrations return to the normal therapeutic range. Persistent neurological abnormalities following lithium intoxication are unusual;[88] however, some neurological signs of lithium toxicity may persist, particularly cerebellar signs (i.e., truncal ataxia, hyperreflexia, dysarthria, intention tremors).[96] Improvement in these cerebellar effects occurs over 6–12 months; residual effects are usually relatively minor.[97] Case reports also associate chronic lithium intoxication with movement disorders (myoclonus, choreoathetosis), proximal muscle weakness, fasciculations, bilateral horizontal nystagmus, incontinence, and corticospinal tract signs.[88,98]

Cardiovascular System

Serious cardiac complications do not usually occur in patients with chronic lithium intoxication unless severe neurological abnormalities (e.g., coma) are also present. Hypotension typically results from volume depletion rather than cardiotoxicity. A case report associated sinus arrest and asystole requiring a temporary pacemaker with chronic lithium toxicity (serum lithium concentration = 3.49 mEq/L) in a 72-year-old man with preexisting right bundle branch block and left axis deviation.[99] Lethargy, coarse hand tremor, and multiple syncopal episodes developed after he began a starvation diet to lose weight. Case reports suggest that delayed effects of chronic lithium toxicity may occur up to 48 hours after admission. A 72-year-old woman developed severe bradycardia, hypotension, and confusion about 48 hours after admission for chronic lithium toxicity secondary to dehydration.[100] A 54-year-old man with a history of bipolar disorder treated with lithium carbonate developed a sinus arrest with a slow junctional escape rhythm and lightheadedness; he also had renal dysfunction (serum creatinine, 4.15 mg/dL; potassium not reported).[101] He recovered without sequelae after hemodialysis with recovery of a normal sinus rhythm.

Kidney

Partial nephrogenic diabetes insipidus is the most common renal complication of lithium therapy with polyuria (>3 L urine/day) and secondary polydipsia occurring in a substantial portion of patients on chronic lithium therapy.[102] Mild symptoms typically occur following the development of partial nephrogenic diabetes insipidus in patients on lithium therapy that include

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

polyuria (3–6 L/day), normal serum sodium and osmolality, and low urine osmolality (<300 mOsmol/kg). Partial nephrogenic diabetes insipidus may develop in patients on chronic lithium therapy, despite the absence of a history of excessive serum lithium concentrations.[103] Rarely lithium-associated nephrogenic diabetes insipidus may persist for several years after cessation of lithium use, despite desmopressin acetate and triamterene-hydrochlorothiazide therapy.[104] Although chronic lithium therapy may contribute to a reduction in glomerular filtration rate, the development of chronic renal failure requiring hemodialysis and the cessation of lithium therapy are rare.[105] Similarly, minimal change disease with nephrotic syndrome and heavy proteinuria is a rare, idiosyncratic effect associated with chronic lithium therapy.[106] Potential complications of the reduction of maximum concentration capacity include increased urinary water loss (i.e., polyuria), polydipsia, nocturia, hypernatremia, hypotension, mental status changes, and hyperosmolar coma. The physiological changes associated with nephrogenic diabetes insipidus and chronic lithium therapy usually resolve after cessation of lithium therapy.[107] The differential diagnosis of lithium-associated nephrogenic diabetes includes hypercalcemia, hypokalemia, excessive water ingestion, and osmotic diuresis (e.g., hyperglycemia).

Case reports indicate that a small group of patients on long-term lithium therapy may develop renal insufficiency without obvious episodes of lithium intoxication. Renal function of 82 patients attending an affective disorders clinic was monitored (mean duration, 4.3 years).[108] Three patients (i.e., 3.7%) initially with normal renal function developed serum creatinine concentrations above 2 mg/dL. One patient developed chronic renal failure requiring dialysis after deciding to continue lithium therapy despite the presence of deteriorating renal function. His renal biopsy demonstrated interstitial fibrosis, focal sclerosis, and renal cysts. A meta-analysis of six case-control studies (cases = 372, controls = 307) demonstrated a small difference in the weighted mean (−6.22 mL/minute, 95% CI: −14.65 to 2.20 mL/minute) in patients on lithium followed a mean of 1 year; however, the difference was not statistically significant ($P = 0.148$).[90] The mean maximum urinary concentrating ability was reduced by ~15% (weighted mean difference = −158.43 mOsm/kg, 95% CI: −229·78 to −87.07 mOsm/kg, $P < 0.0001$) in the treated patients from four of these studies.

The predominant form of chronic renal disease in the small minority of patients with renal insufficiency on long-term lithium therapy is a chronic tubulointerstitial nephropathy. Clinical features of these patients involve the insidious onset of mild renal insufficiency and minimal proteinuria.[109] End-stage renal failure is a rare complication in patients with lithium-associated renal insufficiency that requires about 20 years to develop.[110,111] Although the primary targets of lithium nephrotoxicity are the collecting ducts, proteinuria and hematuria may occur in patients on long-term lithium therapy with moderately severe renal dysfunction.[112] Rare case reports associated the development of nephrotic syndrome with chronic lithium therapy, primarily as a result of minimal change disease.[113] The proteinuria usually resolves within 4 weeks, sometimes without steroid therapy. Even rarer case reports associate proteinuria and hematuria with membranous nephropathy or focal glomerulosclerosis.[114]

Thyroid/Parathyroid

Hypothyroidism most commonly occurs 6–18 months after initiation of lithium therapy. The incidence of clinically significant hypothyroidism is ~5% with rapidly cycling, bipolar women particularly susceptible.[115] In a meta-analysis of case-control studies (cases = 654, controls = 377), the weighted mean difference in TSH concentrations between cases and controls was 4.00 IU (95% CI: 3.90–4.10 IU, $P \leq 0.001$) higher in treated patients.[90] Rarely, hyperthyroidism occurs during the chronic administration of lithium. Hyperparathyroidism may also develop during lithium therapy. The risk of hyperparathyroidism is small (<3%), but hypercalcemia secondary to hyperparathyroidism may increase the risk of lithium toxicity as a result of an osmotic diuresis and volume depletion producing decreased lithium clearance and increased serum lithium concentrations. In a meta-analysis of 13 case-control studies comparing patients receiving lithium with unexposed controls using random effects models, serum calcium concentrations were ~10% higher in treated patients (weighted mean difference = 0.09 mEq/L, 95% CI: 0.02–0.17 mEq/L, $P = 0.009$).[90] The weighted mean difference in serum parathyroid hormone was also higher in patients on lithium (i.e., mean = 7.32 pg/mL, 95% CI: 3.42–11.32 pg/mL, $n = 10$ studies). Both meta-analyses displayed serious heterogeneity ($I^2 = 99.5\%$, $P_{\text{heterogeneity}} \leq 0.0001$ and $I^2 = 89.2\%$, $P_{\text{heterogeneity}} \leq 0.0001$, respectively).

Acute Overdose

Categorization of lithium intoxication involves separation of patients into acute overdose (i.e., no recent lithium use), acute-on-chronic toxicity (i.e., acute overdose in patient currently using lithium), and chronic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

toxicity (i.e., therapeutic use of lithium without history of excessive lithium ingestion).[40] The latter has the highest risk of neurotoxicity secondary to accumulation of lithium in neural tissue and the prolonged elimination half-life of lithium. The basis for this classification is the multicompartmental pharmacokinetic lithium profile and the resulting difference in the course of toxicity; the profile reflects the slow intracellular distribution of lithium to the brain. Factors potentially contributing to lithium toxicity include the following: 1) the amount ingested; 2) time course of treatment (acute, acute-on-chronic, chronic); 3) clinical presentation; and 4) plasma/serum lithium concentrations, lithium formulation (immediate-, controlled-release), and patient profile (age >50 years, concurrent illness, renal function, thyroid dysfunction, volume status/hypercalcemia). Mortality from the three forms of lithium toxicity currently is relatively low (≤1%).[58] Acute exploratory lithium ingestions in children of <6 years of age are usually not associated with serious symptoms. In a retrospective observational study of 1,863 single-substance exploratory lithium ingestions in children of <6 years of age reported to US poison centers, symptoms were described in 184 children.[116] The most common symptoms were vomiting ($n = 76$), drowsiness/lethargy ($n = 58$), and ataxia ($n = 20$). Most of the children remained asymptomatic.

Absent Recent Lithium Use

In general, acute lithium poisoning in patients without recent lithium use produces relatively mild effects. The central nervous system is the primary target organ for acute lithium intoxication. Neurological symptoms (e.g., slurred speech, coarse tremor, ataxia, lethargy, confusion) usually predominate in symptomatic acute lithium ingestions;[117,118] severe neurological complications are unusual during acute lithium poisoning.[119] Gastrointestinal symptoms (nausea, vomiting, diarrhea) occur more commonly during acute rather than chronic lithium intoxication.[61] The ingestion of a single, large dose of lithium frequently produces vomiting within 1 hour of ingestion.[120]

Chronic Lithium Therapy

Potentially, acute-on-therapeutic lithium intoxication produces more serious toxicity compared with the acute ingestion of lithium in drug naïve individuals, primarily from saturation of lithium binding sites following chronic lithium therapy.[121] Serious complications of acute-on-chronic lithium toxicity primarily involve the central nervous and cardiovascular systems; renal dysfunction following acute lithium intoxication is uncommon. Rare case reports associate the acute coingestion of lithium with neuroleptic agents and the neuroleptic malignant syndrome.[122]

Central Nervous System

The presentation of acute-on-chronic lithium toxicity is variable with neurological effects primarily involving ataxia, extrapyramidal symptoms, neuromuscular signs, and behavioral abnormalities (poor memory, disorientation, apathy, incoherent speech).[123] Tremor, extrapyramidal symptoms, drowsiness, and stupor occur more often in acute-on-therapeutic poisonings than chronic lithium poisoning, whereas neurological impairments are more common following ICU discharge than acute-on-therapeutic poisonings.[124] Deterioration in the neurological status may occur 1–2 days after presentation to the emergency department in patients, particularly following the ingestion of large doses of sustained-release preparations by patients on lithium therapy. The presence of seizures, coma, and cardiovascular instability indicates serious lithium toxicity. Status epilepticus is a rare complication of lithium toxicity. Signs of lithium intoxication typically resolve within 2 days of the return of the serum lithium concentrations to the normal therapeutic range (<1.2 mEq/L).

Cardiovascular System

Cardiac abnormalities including rhythm disturbances (sinus node arrest) and conduction delay (reversible 1° A-V block, intraventricular conduction delay, prolonged Q-T interval) typically develop after the appearance of serious neurological symptoms (seizures, mental status alterations).[125] Electrocardiographic abnormalities are relatively uncommon during lithium intoxication. Rarely, monomorphic ventricular tachycardia,[126] hypotension, cardiovascular collapse, and acute myocardial infarction occur during severe, acute-on-chronic lithium intoxication (e.g., admission serum lithium concentration = 14.6 mEq/L).[127] The occurrence of fatal cardiac dysrhythmias is unlikely without the presence of severe CNS manifestations (e.g., coma).[125]

Kidney

Mild renal dysfunction often occurs in association with lithium intoxication, but acute renal failure is a rare complication of lithium poisoning including acute-on-therapeutic lithium intoxication.[128] The acute kidney injury associated with acute lithium toxicity is usually reversible; however, data are insufficient to determine the long-term impact of acute lithium poisoning on kidney function. Fatalities are unusual

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

complications of lithium intoxication, occurring primarily following large acute-on-therapeutic ingestions. A 65-year-old woman on lithium therapy for chronic depression developed acute renal failure, hypotension, high-degree atrioventricular block, and confusion 48 hours after a large lithium carbonate overdose (peak serum lithium concentration = 8.5 mEq/L).[129] She died after developing refractory hypotension and ventricular fibrillation.

Occupational Exposure

Lithium hydride is a highly corrosive material. Skin contact with lithium hydride produces a severe chemical burn; exposure to dust from lithium hydride causes inflammation of the eyes and respiratory tract. Corneal scarring and strictures of the lower respiratory tract and of the esophagus developed in a technician following exposure of his eyes and ingestion of a small amount of lithium hydride during an explosion of a lithium hydride cylinder.[130]

Carcinogenesis

Neither the IARC nor the US Toxicology Program lists lithium as a suspected human carcinogen; however, data are limited. Population studies support the lack of increased cancer risk in lithium-treated patients including the absence of an increased incidence of acute or chronic myelogenous leukemia following exposure to elevated lithium concentrations in drinking water.[131]

Reproductive Abnormalities

Lithium is a pregnancy class D drug (i.e., positive evidence of risk) based on the US FDA classification that grades the increasing risk of abnormalities from A–D with class X being contraindicated and class D being the highest intermediate risk of reproductive abnormalities. Lithium crosses the placental barrier; evidence in animals suggests that lithium may cause teratogenesis. Both therapeutic and toxic doses of lithium carbonate produce craniofacial defects in rodents,[132] but studies in primates have not duplicated these abnormalities.[133] Since 1968, the Danish Register of Lithium Babies has collected cases of congenital abnormalities in infants born to mothers on lithium therapy during the first trimester of pregnancy. By 1983, this voluntary, retrospective cohort collected 225 cases with most of the serious cardiac abnormalities consisting of the rare Ebstein's anomaly (severe tricuspid valve insufficiency, right ventricular hypoplasia, varying degrees of septal defects). The relative risk for Ebstein's anomaly in this early study was high (i.e., 400). In a cohort study of 1,325,563 pregnancies in women receiving Medicaid and delivering a live-born infant during 2000–2010, cardiac malformations accounted for 2.41% of the lithium-exposed infants compared with 1.15% for nonexposed infants and 1.39% for lamotrigine-exposed infants.[134] The adjusted risk ratio for cardiac malformation in lithium-exposed compared with nonexposed infants was 1.65 (95% CI: 1.02–2.68) with the risk ratio for right ventricular outflow tract obstruction defects marginally significant (RR = 2.66, 95% CI: 1.00–7.06). The risk ratio was statistically different for these two groups only for daily lithium doses exceeding 900 mg.

Case reports of other congenital heart defects in newborns from mothers treated with lithium during pregnancy included coarctation of the aorta, dextrocardia, mitral and tricuspid valve atresia, tricuspid regurgitation, intraventricular septal defect, patent ductus arteriosus, atrial fluter, and congestive heart failure. A subsequent retrospective cohort study of 59 women with manic-depressive illness in the Swedish birth registry demonstrated a statistically significant increase in the risk for all congenital anomalies (RR = 3.0, 95% CI: 1.2–7.7) and cardiac malformations (RR = 7.7, 95% CI: 1.5–41.2).[135] A later review of the teratogenic risk of lithium treatment during the first trimester indicated that the risk of teratogenesis was less than previously suggested because of the biases associated with retrospective studies.[136] A prospective study of 148 women on lithium therapy during the first trimester of pregnancy revealed a major malformation rate of 2.8% that was not statistically different than the control rate of 2.4%.[137]

Case reports associate a variety of neonatal abnormalities with lithium therapy during pregnancy including poor respiratory effort and cyanosis, rhythm disturbances, thyroid dysfunction, hypoglycemia, hypotonia, and lethargy; however, the role of lithium in the development of these abnormalities remains unclear. The use of lithium in manic-depressive mothers during the first trimester requires careful evaluation of the risks and benefits as well as fetal screening tests (ultrasound, echocardiography) and monitoring of maternal lithium concentrations. In general, lithium remains the safest mood stabilizer for use during pregnancy.[138] Transient neurodevelopmental deficits (e.g., lethargy, poor oral feeding, hypotonia) can occur in neonates born to mothers receiving lithium during pregnancy.[139] Given the high rate of maternal relapse following discontinuation of lithium therapy and the low rate of malformations following fetal exposure to lithium, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. continuation of lithium therapy during pregnancy is currently recommended with close monitoring. Limited data from cohort studies of children exposed to lithium during the second and third trimesters of pregnancy do not indicate significant behavioral problems during the first 5 years of life.[140] Population-based cohort studies indicate that bipolar disorders are associated with increased risks of adverse pregnancy outcomes, whether or not the mother is treated with lithium during pregnancy.[141]

DIAGNOSTIC TESTING

SI Conversion Units

1 mEq = 1 mmol
1 mg = 0.1441 mmol

Analytical Methods

Blood samples for serum lithium concentrations should be collected in red top vacuum tubes. The collection of blood in green top tubes for lithium analysis may result in the factitious elevation of serum lithium concentrations as a result of the presence of the anticoagulant, lithium heparin.[142] Collection of blood samples in these speckled green top tubes caused the false elevation of serum lithium concentrations, particularly when the tube is partially filled with blood.[143] Experimental studies of healthy volunteers and case reports suggest the collection of blood samples in lithium heparin-containing green top tubes may result in factitiously elevated serum lithium concentrations in partially filled vacuum blood tubes up to 4.3 mEq/L.[144,145]

Biomarkers

Blood

The red blood cell actively transports lithium into the cell via the sodium–potassium pump; erythrocyte lithium concentrations are approximately half of the serum lithium concentrations with a mean range of 0.35–0.55.[146] Therefore, whole blood lithium levels average about 20–30% less than serum lithium concentrations. Erythrocyte lithium concentrations do not clearly correlate to clinical effects better than serum or plasma lithium concentration.[147] Lithium is not bound to plasma proteins; therefore, serum and plasma lithium concentrations do not vary significantly. However, serum lithium typically is the preferred medium to avoid contamination of the sample by lithium heparin.

General Population

In a convenience sample of 186 healthy adult Norwegians without known exposure to lithium, the median serum lithium concentration was 0.42 ng/mL as measured by inductively coupled plasma/atomic emission spectrometry.[148] The median plasma lithium concentration in blood samples from 106 healthy French hospital staff volunteers was 0.64 ng/mL (95% CI: <0.06–1.88 ng/mL) as measured by inductively coupled plasma/mass spectrometry.[149] Increased lithium exposure occurs in a few areas (e.g., northern Chile, northern Argentina), where high lithium concentrations in drinking water produce detectable plasma lithium concentrations (e.g., 2–83 ng/mL).[150]

Therapeutic

Peak serum lithium concentrations occur within 3 hours after ingestion of standard-release preparations and within ~6 hours after ingestion of sustained-release preparations. Steady-state lithium concentrations develop within ~5–6 days after the initiation of treatment. On average, the ingestion of an additional 300 mg lithium carbonate (8.1 mEq Li) in a healthy adult raises the serum lithium concentration by 0.2–0.4 mEq/L after equilibration. The daily dose of lithium varies substantially between patients; lithium concentrations in blood samples also vary significantly in relation to time of lithium ingestion during the preceding 24-hour period. Lithium concentrations in plasma or serum typically are <0.2 mEq/L in drug-naïve individuals. The therapeutic concentration of lithium ranges from 0.6–1.2 mEq/L in serum or plasma samples drawn during the morning before the first daily dose of lithium. Recent recommendations suggest that serum lithium concentrations should be maintained in the lower therapeutic range (i.e., 0.6–0.8 mEq/L) to reduce adverse effects.[151] Serum lithium concentrations in the upper therapeutic range may be necessary during the treatment of acute mania.

Toxic

Serum and plasma lithium concentrations should be interpreted as part of the overall clinical evaluation of patients with suspected lithium intoxication because lithium toxicity correlates best to target organ symptoms (i.e., primarily central nervous system and renal effects) and tissue lithium concentrations rather than plasma, erythrocyte, or whole blood lithium concentrations.[58] Factors affecting the correlation of serum lithium concentrations to clinical effects include the following: 1) time since ingestion; 2) drug interactions; 3) coexisting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

disease processes including kidney function; 4) duration of lithium therapy; 5) ingestion of sustained-release lithium preparations; and 6) the delayed transfer of blood lithium to intracellular receptors. Interindividual variability of the brain/serum ratio also complicates the interpretation of the serum lithium concentration.[152] Animal studies suggest neurotoxicity correlates primarily to brain lithium content, which depends more on the pattern of lithium poisoning than serum or RBC lithium concentrations.[153] Although interpretation of serum lithium concentration typically requires analysis of specimens drawn at least 6–12 hours after acute or acute-on-chronic ingestions, earlier determination may aid the toxicologist's determination of the causal effect of lithium or anticipate serious lithium toxicity.

Table 17.2 correlates serum lithium concentrations with toxicity in patients currently on lithium therapy. Fine tremor of the hands and mild nausea may occur at therapeutic concentrations of lithium; the presence of myoclonic or choreoathetosis movements suggests moderate lithium intoxication.[80] In general, mild lithium toxicity is associated with serum concentrations between 1.5 and 2.5 mEq/L, whereas lithium concentrations between 2.5 and 3.5 mEq/L produce moderate lithium intoxication. Serum lithium concentrations above 3.5–4.0 mEq/L are associated with life-threatening toxicity. However, these ranges do not define toxic responses at a given serum lithium concentration in all patients because of the factors listed above. Consequently, interpretation of serum lithium concentrations requires careful correlation to clinical effects.

Case reports suggest that single acute ingestions of lithium by patients without recent use of lithium usually produce less severe toxicity compared with chronic intoxication producing the same serum lithium concentration, primarily because of the slow distribution of lithium and the lack of intracellular lithium stores.[154] Thus, lithium toxicity may occur at lower serum lithium concentrations in patients on chronic lithium therapy than patients without recent lithium use. Typically, the acute ingestion of lithium without recent lithium use produces only mild symptoms independent of the serum lithium concentration.[155,156] Conversely, some features of lithium intoxication may develop in patients concurrently receiving lithium, despite serum lithium concentrations below 1.5 mEq/L. Following the ingestion of sustained-release lithium preparations, delayed peak lithium concentrations may occur up to ~2 days after ingestion.[27]

Urine

In a convenience sample of 87 urban German residents, the mean urine lithium concentration was 35 ng/mL with a range of 4–237 ng/mL (95% CI: 115 ng/mL) as measured by ICP/MS.[157] The mean urine lithium concentration for 72 children from the same region was somewhat higher (mean = 77 ng/mL with range of 7–580 and 95 percentile of 306 ng/mL). Lithium concentrations in the environment and diet were not reported. The median urine lithium concentration in 100 healthy French volunteers was 12 ng/mL (95% CI: 4.6–219 ng/mL).[158] Urine lithium concentrations in residents of areas with very high lithium concentrations (e.g., the Atacama Desert of northern Chile) may range up to 7,000 ng/mL.[14]

Abnormalities

Blood

Leukocytosis commonly occurs following the initiation of lithium therapy, but lithium does not interfere with neutrophil function. Lithium also suppresses T cell production without reducing lymphocyte activity.[57] The leukocytosis and lymphopenia in patients ingesting

TABLE 17.2. Clinical manifestations associated with serum lithium concentrations in patients on lithium therapy. However, the multiple factors that affect serum lithium concentrations should be interpreted cautiously as adjunctive data to the clinical presentation because of the multiple factors that affect them. Toxic effects may occur at serum lithium concentrations lower than indicated in this chart, particularly in acute-on-chronic intoxication, as a result of delayed absorption and distribution of lithium. Patients ingesting lithium without prior recent exposure may exhibit relatively few symptoms despite high serum lithium concentrations. Consequently, interpretation of serum lithium concentrations requires correlation to dosing history and clinical effects. (Adapted from Hansen and Amdisen).[61]

Serum Lithium (mEq/L)	Severity of Intoxication	Clinical Effects
1.5–2.5	Mild	Lethargy, drowsiness, increased hand tremor, nausea, vomiting, diarrhea, polyuria, polydipsia, blurred vision, dizziness
2.5–3.5	Moderate	Confusion, disorientation, ataxia, muscle weakness, fasciculations, nystagmus, dysarthria
>3.5	Severe	Serious alteration of consciousness, syncope, coma, renal insufficiency, seizures, hypotension, dysrhythmias

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

lithium do not correlate to lithium dose or serum lithium concentration.[159] Lithium is a cation; the presence of lithium lowers the serum anion gap depending on the lithium concentration. Although therapeutic lithium concentrations may slightly reduce the serum anion gap, substantial reductions in the serum anion gap usually occur only in the presence of high lithium concentrations (>4 mEq/L).[160,161]

Urine

Nephrogenic diabetes insipidus results from the interference of lithium with the ability of the renal tubules to respond to antidiuretic hormone (arginine vasopressin). This defect results in polydipsia, hypotonic polyuria (urine volume >3 L/day, urine hypoosmolality), and the inability to concentrate urine on fluid restriction. Other conditions associated with decreased ability to concentrate urine include hypokalemia (e.g., hyperaldosteronism), hypercalcemia (e.g., hypervitaminosis D, bone cancer), and renal tubular abnormalities (e.g., Fanconi's syndrome). Laboratory abnormalities associated with nephrogenic diabetes insipidus include plasma hyperosmolality (>300 mOsm/kg water), urine hypoosmolality (<280 mOsm/kg water), and low urine specific gravity (<1.010). Restriction of access to water during the polyuria associated with diabetes insipidus causes serum hypernatremia. Polyuria develops from water diuresis (hypotonic polyuria), osmotic or solute diuresis (hypertonic polyuria), or renal tubular dysfunction. The presence of normal or low urine osmolality excludes the diagnosis of osmotic diuresis from the excessive excretion of solutes (e.g., glucose). Typically, patients with water diuresis have urine osmolalities below 250 mOsm/kg, whereas patients with osmotic diuresis have either isoosmotic or hyperosmotic (>300 mOsm/kg) urine. Other causes of the water diuresis in addition to lithium-induced nephrogenic diabetes insipidus include central diabetes insipidus (inadequate ADH secretion), mobilization of "third-space" fluids, and excessive water ingestion (psychogenic polydipsia). In a patient presenting with polyuria/polydipsia and a urine osmolality of <300 mOsm/L, the occurrence of urine osmolality of >300 mOsm/L after a 6-hour water deprivation test indicates psychogenic polydipsia. The normal response to the water-deprivation test is the maintenance of a urine osmolality below 300 mOsm/kg after dehydration with no or minimal (<9%) rise in urine osmolality after the administration of desmopressin. In partial diabetes insipidus, the urine osmolality rises to 300–750 mOsm/kg after dehydration and urine osmolality remains below 750 mOsm/kg after the administration of desmopressin.

Electrophysiological Testing

Electroencephalogram

The most common changes associated with lithium toxicity involve continuous or paroxysmal polymorphic and rhythmic slowing in the theta and delta range along with disorganization of the background and increased response to hyperventilation; the EEG changes may mimic the changes associated with status epilepticus.[162] Diffuse, nonsynchronous slowing (<8/second) of the EEG occurs during lithium intoxication along with increased amplitude and bilateral synchronous bursts of delta activity.[163] Lithium produces a persistent or intermittent generalized slowing of the electroencephalogram, involving the dominant rhythms (e.g., theta (5–7 cps), delta (2–3 cps) activities.)[164] Grouped delta–theta waves may dominate the EEG in severe Li intoxication.[165]

Electrocardiogram

Cardiac complications from lithium toxicity are relatively uncommon compared with adverse neurological effects. In a study of 629 hospitalized lithium overdoses reported to the California Poison Control System, there were 29 cases with adverse cardiovascular effects; the majority of these patients developed isolated bradycardia in the absence of hypotension.[166] Only seven patients (i.e., all with chronic lithium toxicity) required cardiovascular support including two cases of bradycardic arrest. Minor electrocardiographic abnormalities in lithium intoxication included intraventricular conduction defects (first-degree atrioventricular block, intraventricular conduction delay),[125] prolongation of the QT_c interval, T-wave flattening or inversion, the appearance of U waves, and nonspecific ST-T wave changes.[167] Sinus node dysfunction is the most commonly reported, clinically significant conduction defect in patients on lithium, primarily in patients with underlying structural disease.[80] Case reports of lithium toxicity occasionally associate impaired conduction with serious lithium intoxication including sinoatrial block,[168,169] sinus bradycardia,[101,170] and junctional bradycardia.[128]

Lithium therapy may unmask underlying cardiac diseases including sick sinus syndrome,[171] Brugada syndrome (RBBB, ST elevation V_1–V_3),[172,173] and sinoatrial block with slow idioventricular escape rhythm.[174] Type I Brugada Syndrome may occur in patients with therapeutic or toxic lithium concentrations. Lithium-induced, dose-dependent sodium blockade begins at lithium concentrations below therapeutic concentrations.[175] Predisposing factors to the development of type I Bragada in patients receiving lithium include hyponatremia

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. and the administration of ACE inhibitors (↓ glomerular filtrations rates from vasoconstriction)[176] or sodium channel blockers (e.g., lamotrigine).[177] Serious ventricular dysrhythmias are uncommon during lithium intoxication in the absence of electrolyte abnormalities (e.g., hypokalemia, hypomagnesemia) or preexisting cardiovascular disease. Rare case reports associate lithium toxicity (Li = 3.0 mEq/L) and hypothyroidism with the development of ventricular fibrillation in a patient with normal serum electrolytes including normal serum magnesium concentrations.[178]

Imaging

Lithium is not radiopaque. The presence of mild, increased echogenicity on renal ultrasound with or without the presence of punctate, hyperechogenic foci suggests the possibility of underlying renal parenchymal injury; MRI is more sensitive and specific for the detection of the parenchymal renal cysts associated with chronic lithium therapy.[179] MR imaging of the kidney may demonstrate fluid-filled microcysts (i.e., 1–2 mm) in the cortex and medulla of patients with moderate-to-severe chronic renal insufficiency and a history of chronic lithium therapy.[180]

Neuropsychological Testing

Neuropsychological testing of patients after chronic lithium intoxication suggests that visuoperceptive, verbal recognition, and constructive abilities are the most sensitive measures of lithium toxicity, whereas orientation, language comprehension, and memory are not significantly impaired.[181] However, the lack of premorbid data and the limited amount of neuropsychological testing after lithium intoxication limit conclusions regarding the permanent cognitive effects of lithium toxicity.

HEALTH SURVEILLANCE

The US OSHA PEL–TWA and the ACGIH TLV–TWA is 0.025 mg lithium hydride/m^3 based on the prevention of nasal, ocular, and skin irritation. Permissible exposure limits for lithium hydride are similar in Australia and the United Kingdom.

TREATMENT

After assessment and stabilization of the airway, breathing, and circulation, the treatment of lithium intoxication primarily involves fluid resuscitation to optimize renal perfusion, routine poisoning treatment (gastrointestinal decontamination, electrocardiogram/cardiac monitoring, pulse oximetry, serum acetaminophen/salicylate concentrations), cessation of drugs contributing to increased serum lithium concentrations (NSAIDS, renin-angiotensin system inhibitors, thiazide diuretics, spirolactones, calcium channel blockers), evaluation of the need for enhanced elimination, and serial lithium concentrations every 4 hours until steady state. Serum lithium concentrations may not reach steady state until 12–24 hours after ingestion depending on the amount, formulation, and renal function. Collection of blood for lithium in a tube containing lithium heparin (light green top) must be avoided.

Decontamination

In vitro studies indicated that activated charcoal does not effectively adsorb lithium.[182] Syrup of ipecac should not be administered to patients following the ingestion of drugs that potentially produce obtundation and seizures. Because of the lack of adsorption of lithium to activated charcoal, other decontamination measures (e.g., lavage) are therapeutic options in patients ingesting >40 mg immediate-release lithium/kg, when the patients present within 1–2 hours of an acute ingestion. Limited data suggest that the use of gastric lavage does not improve clinical outcome.[183] Furthermore, the use of gastric lavage for sustained-release preparations is probably not efficacious because these large capsules usually do not dissolve in the stomach.

Although the absorption of therapeutic lithium doses is rapid, ingestion of sustained-release tablets may delay absorption following an overdose. Whole bowel irrigation is an option to other decontamination measures within the first few hours following the large ingestion of sustained-release preparations (e.g., >80 mg/kg lithium carbonate) based on a volunteer study demonstrating a two-third reduction in area under the lithium serum concentration-versus-time curve.[184,185] However, there are no data to confirm that reduced absorption demonstrated in volunteer studies improves clinical outcome without significant adverse effects (e.g., hypokalemia, fluid depletion). The administration of cathartics is discouraged because of potential exacerbation of lithium toxicity following fluid imbalance caused by cathartic administration.

Elimination Enhancement

Peritoneal dialysis is a relatively inefficient method for removing lithium with case studies suggesting peritoneal dialysis and endogenous clearance are similar.[186] Lithium does not adhere well to charcoal; hence,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. charcoal hemoperfusion does not increase lithium clearance. There is little evidence that the administration of amiloride or furosemide significantly increases lithium elimination.

Sodium Polystyrene Sulfonate

The role of sodium polystyrene sulfonate in reducing the lithium load is not well defined and probably limited because of the limited capacity to bind lithium and the risk of hypokalemia. A study in human volunteers demonstrated that 30 g sodium polystyrene sulfonate administered 1 hour after a dose of 18.5 mg lithium carbonate/kg reduced the absorption of lithium by ~30%.[187] An *in vitro* study indicated that lithium binds more readily to polystyrene sulfonate than activated charcoal; however, potassium also binds to polystyrene sulfonate and hypokalemia potentially may complicate the use of polystyrene sulfonate.[188,189] The use of multiple doses of sodium polystyrene sulfonate (150 g over 24 hours) was associated with a reduction in the serum lithium half-life to 12 hours in a patient with an acute-on-chronic overdose of lithium.[190] A retrospective cohort study of 48 patients with chronic lithium intoxication compared the median serum lithium half-life in 12 patients treated with sodium polystyrene sulfonate with controls (no treatment).[191] The median serum half-lives were 20.5 hours and 43.5 hours, respectively. Adverse effects in the treatment group included mild hypokalemia and constipation. The study did not standardize the group dose, interval between ingestion and presentation, or treatment. The use of multiple doses of sodium polystyrene sulfonate also reduces lithium concentrations in mice, but the clinical significance of these reductions in mice given low doses of lithium is unclear.[192] Although these data suggest a role for polystyrene sulfonate in the decontamination of patients with an overdose of lithium, more clinical data are necessary before the routine use of polystyrene sulfonate can be recommended. The limited binding of sodium polystyrene sulfonate to lithium and the need to use large volumes to significantly increase lithium clearance complicate the use of this modality. The use of forced diuresis during lithium intoxication is not recommended.[61] Correction of fluid and electrolyte imbalances is important to prevent reduced lithium clearance from decreased glomerular filtration rates.

Hemodialysis

Hemodialysis effectively removes lithium from the blood and substantially reduces the elimination half-life of lithium based on case reports.[193] The significant variability in recommendation for extracorporal treatments following lithium intoxication reflects the absence of randomized controlled clinical trials and the heterogeneity of patients with lithium poisoning (e.g., acute, acute-on-chronic, chronic). Intermittent hemodialysis is the usually recommended extracorporeal modality for lithium removal unless the patient is clinically unstable (e.g., hypotensive) or hemodialysis is unavailable. The low molecular weight, small volume of distribution, and the negligible protein binding of lithium favors removal by extracorporal measures. Hemodialysis decreases the serum lithium half-life during acute lithium intoxication to ~3–6 hours with lithium clearance up to 170 mL/minute (i.e., >8 times endogenous clearance);[194] a 6-hour hemodialysis reduces the serum lithium concentration by ~50–60% during the elimination phase.[42,195] In spite of the reduction of serum lithium concentrations following hemodialysis, immediate improvement in clinical status often does not occur as a result of the slow lithium redistribution from intracellular stores. In a case of chronic lithium intoxication, hemodialysis decreased the serum lithium half-life from 54 hours to 25 hours.[34] In these cases, tissue stores of lithium act as a reservoir for the extracellular compartment. About 6–12 hours after hemodialysis, the serum lithium concentration rebounds to 20–100% of pretreatment lithium concentrations from the slow shift of lithium from the intracellular to extracellular compartment. The hemodialysis catheter should remain in place until the serum lithium concentration remains consistently below 1 mEq/L. Newer extracorporeal measures other than standard hemodialysis include sustained low-efficiency dialysis (e.g., blood flow of 200 mL/minute and countercurrent dialysate flow of 300 mL/minute over 8 hours);[196] however, clearance data on these new techniques are limited.

Clearance

Lithium freely diffuses across the glomerulus and reabsorbs into the proximal convoluted tubule with a clearance of 20–30 mL/minute. Consequently, lithium clearance is proportional to the glomerular filtration rate with a fractional excretion rate of ~25%. Hemodialysis significantly increases lithium clearance with lithium plasma dialyzer clearance (dialysance) of ~60–170 mL/minute compared with normal renal clearance of ~20–30 mL/minute.[186,194] A case report documented a lithium clearance of 272 mL/minute with the use of high blood pump speed (300 mL/minute) during severe lithium intoxication.[160] Hemodialysis does not reduce the normal lithium renal excretion.[42] Although the serum lithium concentrations typically

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. rebound after cessation of intermittent hemodialysis, case reports suggest cerebral spinal fluid lithium concentration continues to decline despite the rebound in serum lithium concentration.[197]

Indications

In addition to the serum lithium concentration, the decision to institute dialysis depends on clinical judgment regarding the duration of the poisoning, the estimated time to peak serum lithium concentrations, type of poisoning (acute vs. chronic), severity of neurological impairment, renal function, age, and the clinical course of the patient during the first 8–12 hours following admission. A deterioration of the clinical condition (i.e., altered consciousness, seizure, hypotension) during this period indicates the need for hemodialysis. Intermittent hemodialysis is an effective method to increase serum lithium clearance.[198] Increasing muscle rigidity and tremulousness often precedes the development of life-threatening deterioration of the condition of the patient by several hours. Recommended indications for hemodialysis during lithium intoxication based on expert opinions include the following: 1) the presence of serum lithium concentrations exceeding 4 mEq/L with impaired kidney glomerular filtration rate below 45 mL/minute/1.73 m^2 (EXTRIP workgroup criteria, https://www.extrip-workgroup.org/lithium) or ≥5.2 or serum creatinine >2.25 mg/dL (Paris criteria); 2) the appearance of serious central nervous system (↓consciousness, seizure) or cardiovascular symptoms (life-threatening dysrhythmia); and 3) chronic lithium intoxication and signs of neurotoxicity or nephrotoxicity. The use of hemodialysis may be considered in patients with serum lithium concentrations between 2.5 and 4.0 mEq/L, particularly older patients on lithium with renal dysfunction and neurological impairment (e.g., confusion). The lack of randomized clinical trials and the complex pharmacology of lithium limit the development of definitive guidelines.

Patients with normal renal function and no prior use of lithium may tolerate lithium concentrations substantially exceeding 4 mEq/L with supportive care only (i.e., no dialysis), following an acute overdose without developing neurological symptoms.[199] Dialysis is usually unnecessary for patients with lithium concentrations below 2.5 mEq/L unless associated with clinically significant neurological abnormalities or serious renal impairment. A 60-year-old bipolar woman on chronic lithium therapy developed ataxia, myoclonic jerks, irritability, dysphoria, and dementia; her serum lithium concentration was 2.45 mEq/L.[200] Her neurological examination became normal with resolution of the ataxia and dementia after her serum lithium concentrations returned to baseline.

Endpoint

Intermittent hemodialysis can be stopped when clinical improvement occurs or the serum lithium concentration is <1 mEq/L.[201] In the absence of serum or plasma lithium concentrations, hemodialysis should continue for at least 6 or 18 hours for less efficient methods (e.g., CAVH). Because of a slow redistribution phase (6–12 hours) and distant receptor sites, repeat dialysis may be necessary to reduce the tissue stores of lithium manifested by a rebound in serum lithium concentrations following intermittent hemodialysis.[202] For similar reasons, clinical recovery may not closely follow declining serum lithium concentrations. Hence, repeat dialysis should be based both on the clinical response and the serum lithium concentrations with the options of repeat intermittent hemodialysis or the initiation of continuous renal replacement therapy. The latter is associated with a reduced risk of rebound plasma or serum lithium concentrations; however, lithium clearance is lower and few patients exhibit clinical deterioration because of rebound elevations in the serum lithium concentration. Serial serum lithium concentrations should be followed closely after dialysis (e.g., 2, 6, 12 hours post-treatment). Continuing lithium absorption from sustained-release preparations may require the extension of lithium monitoring up to 72 hours after ingestion. The hemodialysis endpoint of <1 mEq Li/L 6–8 hours after the end of hemodialysis is based on a research protocol rather than a study of clinical outcome.[120]

Continuous Arteriovenous Hemofiltration (CAVH)

The main advantages of continuous renal replacement therapies (e.g., CAVH) include the suitability of this technique in unstable, hypotensive patients, ease of operation, and reduction of lithium rebound after cessation of use; however, limited data on the efficacy of these techniques limit conclusions about the role of these therapies in lithium intoxication. The clearance of lithium by CAVH is similar to the lithium clearance by the normal kidney and lower than that of intermittent dialysis.[203] Generally, 24 hours of CAVH and 4 hours of intermittent hemodialysis eliminate similar amounts of lithium. The lithium clearance during 14 hours of continuous venovenous hemodiafiltration in a 45-year-old woman with oliguria and mild hypotension ranged from ~30–35 mL/minute.[204] Although the clearance of lithium by CAVH (i.e., 20–40 mL/minute)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. is slower than the lithium clearance during hemodialysis (60–170 mL/minute),[42,186,205] the continuous use of CAVH allows the clearance of lithium over many hours as long as the patient is hemodynamically stable. The use of CAVH after dialysis substantially reduces the rebound in serum lithium concentrations.[206] Although repeat hemodialysis is often unnecessary following the use of CAVH,[207] repeat sessions may be necessary depending on the duration of the initial session of CAVH. In a 58-year-old woman, 14 hours of CAVH removed an amount of lithium equivalent to the quantity eliminated by 3–5 hours of hemodialysis.[208] Repeat hemofiltration was necessary 17 hours after cessation of the first session when the serum lithium concentration increased to 1.1–2 mEq/L.

Antidotes

There are no antidotes for lithium intoxication.

Supplemental Care

Medications associated with potentiation of lithium toxicity should be discontinued including nonsteroidal anti-inflammatory drugs, rennin–angiotensin system inhibitors, thiazide diuretics, spironolactone, and calcium channel blockers (diltiazem, nifedipine, verapamil) unless their use is expected to improve fluid and/or electrolyte balance. For patients with nephrogenic diabetes insipidus and lithium intoxication, correction of fluid and electrolyte balance along with withdrawal of lithium is the important method of supportive care. Large amounts of fluid may be necessary to prevent hypotension and underperfusion of vital organs. The use of normal saline (0.9% NaCl) has theoretical benefits by reducing lithium tubular reabsorption by providing an additional sodium load; however, the patient should be closely monitored for nephrogenic diabetes insipidus and hypernatremia.[41] Assessment of electrolytes loss during polyuria (e.g., potassium, magnesium) is essential to prevent serious dysrhythmias.

Adjunctive therapy to reduce urine volume for patients with nephrogenic diabetes insipidus *without* lithium toxicity includes indomethacin (50 mg t.i.d.), thiazides (with sodium restriction to enhance sodium depletion), and amiloride (10–20 mg/day) as well as protein- and sodium-restricted diet. Therapy with indomethacin is most useful when immediate reduction in urine volume is necessary, but the chronic use of indomethacin therapy for maintenance of patients with polyuria is not recommended. Thiazide diuretics decrease extracellular fluid volume and increase the resorption of fluid and lithium. Consequently, lithium, magnesium, and potassium concentrations should be monitored closely. The medications of the patient should be reviewed to determine any adverse drug reactions while the lithium dose is reevaluated. Anecdotal reports suggest acetazolamide may reduce daily urine output in patients with nephrogenic diabetes insipidus resistant to treatment with desmopressin, hydrochlorothiazide, amiloride, and sodium restriction.[209]

Evaluation of electrolyte status including serum magnesium concentrations is particularly important during serious lithium intoxication.[178] Severe chronic hyponatremia should be corrected relatively slowly (<0.55 mEq/L/hour) to prevent the development of central pontine myelinolysis. Depending on the initial serum sodium concentration, the serum sodium should not exceed 135 mEq/L with in the first 48 hours of treatment; hypernatremia should be avoided. Diuretics (e.g., furosemide, amiloride) are not typically recommended during acute lithium poisoning.[58]

Admission Criteria

The decision to admit patients with suspected lithium intoxication requires careful evaluation of initial and serial lithium concentrations, estimated lithium dose, concurrent use of lithium, renal function, and the presence of clinical features of lithium intoxication. Because of the delayed equilibration of serum and tissue lithium concentrations, the serum lithium concentration does not always reflect the severity of lithium intoxication, particularly during the first 6 hours after ingestion. Most symptomatic patients should be admitted to a monitored bed for observation and serial lithium concentrations collected in tubes without lithium heparin (q4h or sooner for large recent ingestions), especially following the ingestion of sustained-release preparations until peak lithium concentrations occur (i.e., typically 12–24 hours). Subsequently, serial lithium concentrations every 6–12 hours should be sufficient.

Asymptomatic patients with serum lithium concentrations exceeding 2.0 mEq/L and all patients with substantial ingestion of sustained-release preparations should be considered for admission and monitoring. Asymptomatic or minimally symptomatic patients may be considered for discharge if the serial lithium concentrations obtained at least 4–6 hours apart remain below 1.5–2.0 mEq/L with no evidence of continued lithium absorption. These patients should be evaluated for factors (e.g., dehydration, loop diuretics, drug interactions) contributing to toxicity as well as for psychiatric stability prior to discharge.

Chapter 18

MAGNESIUM

PHYSIOCHEMICAL PROPERTIES

Magnesium (CAS RN: 7439-95-4, atomic weight 24.31 g/mol) is an abundant silvery-white metal that is part of the Group 1 (Group IIa) alkaline earth metals along with barium, beryllium, calcium, radium, and strontium. Naturally occurring isotopes include ^{24}Mg (78.7%), ^{25}Mg (10.13%), and ^{26}Mg (11.17%).[1] This metal does not occur naturally in its elemental form. In nature, magnesium exists in >50 salts and several minerals including carnallite ($KMgCl_3$), dolomite [$CaMg(CO_3)_2$], epsomite ($MgSO_4$), kieserite ($MgSO_4$), olivine [$(Mg^{2+}, Fe^{2+})_2SiO_4$], and magnesite ($MgCO_3$). This extremely flammable metal is water-insoluble but reacts with water to produce hydrogen gas. Magnesium is the lightest structural metal, displaying 67% of the weight of aluminum and 22% of the weight of steel. The specific gravity of magnesium is 1.74, and the vapor density is 0.84. Magnesite (CAS RN: 546-93-0, MW: 84.3 g/mol) is a white to yellowish-brown solid that is slightly water-soluble (0.01%) and has a specific gravity of 2.96. Magnesium oxide (CAS RN: 1309-48-4) is a fine, white, and slightly soluble (0.009%) powder that occurs naturally as the mineral periclase with a small amount of iron oxide; the molecular weight of MgO is 40.3 g/mol and the specific gravity is 3.58. High temperatures in production processes produce MgO as a fume. In saturated aqueous solutions, MgO combines with water to form $Mg(OH)_2$, producing a solution with a pH of 10.3.

EXPOSURE

Uses

Magnesium is one of the most common industrial metals with widespread applications as structural alloys in aircraft, tools, machines, engines, and office equipment. The reducing properties of magnesium are an important part of the production processes of beryllium, titanium, uranium, and zirconium. Other uses involve fireworks and flares (magnesium nitrate), organic chemical reactions, batteries, desulfurization of steel and iron, and corrosion prevention. Potential applications of magnesium oxide nanoparticles include the removal of contaminants from wastewater and drug delivery.[2] Pharmaceutical magnesium compounds include the administration of antacids (oxide and hydroxide) and cathartics (citrate and sulfate) as well as the treatment of a variety of illnesses (sulfate) including preeclampsia, asthma, migraine, depression, and dysthymias.

Production Processes

The production of magnesium metal is relatively small compared with the production of steel and aluminum; the production process primarily includes electrolytic reduction of magnesium chloride or thermal reduction of magnesium oxide. The most common production

TABLE 18.1. Average magnesium content of various foods. (Adapted from Gums).[27]

Content (mg/100 mL)	Sources (mg/100 mL)
High (>100)	All bran (420); cashews (267); soybeans (255); peanuts (174); whole wheat (147); chocolate (119); rice (106); shrimp (105).
Moderate (25–100)	Clams (89); coconut (80); apricots (65); dates (60); spinach (55); peaches (54); cheese (45); oysters (40); bananas (37); raisins (34); potatoes (29); liver (26); celery (25).
Low (<25)	Pork (24); broccoli (24); ham (20); chicken (19); mushrooms (16); cherries (14); milk (14); eggs (13); tomatoes (12); oranges (11); apples (10); onions (7); butter (1).

method is the electrolytic process that involves the heating of carbonaceous materials (e.g., coke, coal tar). Magnesium oxide forms from the filtering and burning of magnesium hydroxide, which precipitates from separation tanks containing dolomite and seawater. The heating of a mixture of pulverized coal or coke and magnesium oxide in the presence of chlorine gas produces pellets of magnesium chloride that feed electrolytic cells to form metallic magnesium. Following refining procedures, alloys of magnesium are formed with aluminum, beryllium, manganese, and zinc. During this process, potential chemical exposures include chlorinated aromatic hydrocarbons, chlorine gas, asbestos, carbon monoxide, sulfur dioxide, volatile coal tar products, and dust of magnesium oxide.[3]

Sources

Large natural deposits of magnesium exist in minerals (dolomite, magnesite, olivine), salt deposits, and seawater. Magnesium occurs in animal and plant tissue throughout nature, where chlorophyll a and b are magnesium chelates of porphyrin. An average daily diet contains about 300 mg (25 mEq) of magnesium. Table 18.1 lists the relative magnesium content of common foods in mg/100 mL.

ENVIRONMENTAL FATE

Typically, hard water contains high concentrations of calcium and magnesium ions that increase the capacity of the water (i.e., alkalinity) to neutralize acids by forming carbonate, bicarbonate, hydroxide, and occasionally borate, silicate, or phosphate compounds. Other dissolved divalent or multivalent metal cations also potentially increase water hardness including aluminum, barium, iron, manganese, strontium, and zinc. Monovalent ions (e.g., sodium, potassium) usually do not cause hardness; generally, hardness develops in groundwater as the water percolates through minerals containing calcium (limestone) or magnesium (dolomite). Soft water typically contains <60 mg Mg/L, whereas hard water has 120–180 mg Mg/L, and water containing >180 mg Mg/L is considered very hard. Desalinated water contains little calcium or magnesium.[4] In a Swedish study of 79 water samples from 18 municipalities, the magnesium concentrations ranged from 0 (water filtered) to 44.0 mg/L.[5]

DOSE EFFECT

Magnesium toxicity usually results from increased magnesium load (e.g., Epsom salts or $MgSO_4$) in the presence of renal dysfunction because the kidney effectively excretes moderate Mg excesses.[6] One tablespoon of Epsom salt contains ~35 g magnesium sulfate (3.4 g or 287 mEq elemental magnesium). A positive magnesium balance occurs in healthy patients with normal renal function when the daily Mg intake exceeds 6 g. The inadvertent intravenous infusion of 40 g $MgSO_4$ to a 28-year-old primigravida with preeclampsia caused somnolence, dyspnea, and ventilatory insufficiency.[7] She survived without sequelae following intubation, calcium bolus, and forced diuresis with furosemide.

Impaired Renal Function

Hypermagnesemia peaks during the early diuretic phase of renal failure without exogenous Mg loads. Accumulation of magnesium after exogenous administration occurs when the creatinine clearance falls below 10–30 mL/minute.[8] Iatrogenic hypermagnesemia with respiratory depression has been reported in patients with mild–moderate renal dysfunction who received doses of 10% hemiacidrin (Renacidin; 14.8% magnesium carbonate, 2.5% magnesium acid-citrate, pH = 3.9)[9,10], and magnesium citrate.[11] In an 87-year-old man with a creatinine clearance of 29 mL/minute on admission, the administration of 6.6 g Mg as magnesium citrate over 16 hours produced confusion, somnolence, and diminished deep tendon reflexes; the serum Mg concentration was 4.34 mEq/L (5.3 mg Mg/dL).[12]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

His admission serum creatine was 1.8 mg/dL. Both hypermagnesemia and hypercalcemia developed in two patients with hepatorenal failure after receiving magnesium sulfate enemas.[13,14] A 39-year-old woman presented to the emergency department after a tricyclic antidepressant overdose; the admission serum Mg concentration was 1.9 mEq/L.[15] She received ~58 g (5,017 mEq) Mg citrate via nasogastric tube over 72 hours, resulting in marked hyporeflexia, paralytic ileus, and respiratory arrest. She recovered after intensive supportive care.

Normal Renal Function

Although magnesium toxicity occurs rarely in patients with normal renal function, large Mg doses may produce magnesium toxicity in patients with normal renal function. Single doses of magnesium-containing cathartics usually do not cause statistically significant elevations in the serum magnesium concentrations of in patients with normal renal function.[16] Modest elevations of serum magnesium concentrations occurred in 102 adults with normal renal function treated for overdose with repetitive doses of magnesium citrate (mean = 960 mL (9.22 g Mg) over 24–48 hours).[17] The mean initial and final serum magnesium concentrations were 1.8 ± 0.03 mEq/L and 2.5 ± 0.05 mEq Mg/L, respectively; 12 patients had serum Mg concentrations of >3.0 mEq/L with no value higher than 4.0 mEq/L. The Mg citrate dose did not correlate with the serum Mg concentrations. In a study of 14 overdose patients receiving three 30-g doses of $MgSO_4$ (8.64 g, 720 mEq), 4 patients had peak serum magnesium concentrations of >3 mEq/L with a maximum of 5.0 mEq/L.[16] A patient with normal kidney function developed symptomatic hypermagnesemia (respiratory arrest, bradycardia) after receiving 90 g $MgSO_4$ (7,380 mEq Mg) over 18 hours.[18] Ingestion of 200 g magnesium sulfate by a hypothermic patient did not produce cardiovascular effects despite an admission serum Mg concentration of ~19 mEq Mg/L.[19] The ingestion of 17.5 g (140 mEq Mg) Epsom salt ($MgSO_4$) produced extreme musculoskeletal weakness and altered mentation,[20] whereas the ingestion of 50 g (400 mEq Mg) was associated with hypotension, coma, and cardiopulmonary arrest.[21] Both patients survived without sequelae. Neonates may be susceptible to hypermagnesemia as a result of immature renal function. A dose of ~380 mg Mg/kg/day for 3 days caused hypotonia, lethargy, and an initial serum Mg concentration of 7.6 mEq Mg/L in a 25-day-old neonate.[22]

TOXICOKINETICS

Absorption

Substantial interindividual variation occurs in the absorption of magnesium depending, in part, on the amount of magnesium present. In a metabolic study of eight healthy volunteers fed collards, turnip greens, leaf lettuce, and spinach grown in a nutrient solution containing radiolabeled magnesium, the estimated gastrointestinal absorption of radiolabeled Mg was ~40–60%.[23,24] The natural abundance of ^{26}Mg limits the sensitivity of determining the gastrointestinal absorption of magnesium by isotope studies. The amount of magnesium absorbed into the blood is dose-dependent with relatively less absorption occurring at higher than lower Mg concentrations.[25] Following the oral administration of 13.9 g (56.5 mmol) magnesium sulfate in four equal hourly increments to six healthy volunteers, the mean gastrointestinal absorption of Mg during the first 24 hours was 4.0 ± 2.9% (range: 0.8–8.7%) of the Mg sulfate dose and 6.9 ± 7.0% during a 72-hour interval, based on urinary Mg excretion (corrected for baseline excretion rate).[26] All subjects had mild-to-moderate diarrhea.

Distribution

The total body content of magnesium averages ~24 g.[27] Accumulation of magnesium in the bone accounts for ~60% of the total body content of magnesium in the following two pools: 1) a surface limited exchangeable pool in equilibrium with plasma magnesium (i.e., ~1/3 of the bone stores) and 2) a deep reservoir in the crystal mineral lattice portion of bone. The former, freely exchangeable pool acts as a reserve for maintaining extracellular magnesium concentrations.[28] Another 20% appears in the skeletal muscle with the remaining 20% distributed in a variety of organs including the heart, kidney, and liver. Only 1% of the total content of magnesium exists in the blood with ~30% bound to proteins.

Elimination

Elimination of magnesium occurs almost only by renal excretion. After the glomerulus filters magnesium, the proximal tubule and the ascending loop of Henle reabsorb ~95% of the filtered load. Glomerular filtration rates below 30 mL/minute predispose patients to hypermagnesemia. Both magnesium resorption and calcium resorption in the kidney are closely related because a

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

common carrier exists for calcium and magnesium. The fractional excretion of magnesium varies inversely with the serum magnesium concentration and, to a lesser extent, with the effects of diuretics and parathyroid hormone.[29] Hypercalcemia and high sodium intake increase magnesium excretion.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Magnesium is an essential, primarily intracellular cation with a wide range of functions including channel regulation (potential-dependent L-type calcium channels), membrane and nucleic acid stability, maintenance of the cell cycle, and a cofactor for many enzymes including Na^+/K^+ATPase. Magnesium is also an NMDA-receptor antagonist. This metal ion is the second most abundant intracellular cation after potassium and is involved in >600 enzymatic processes in the brain, heart, and skeletal muscles.[30] Within the cell, magnesium binds to ATP and proteins. Magnesium is an essential component of enzyme processes that involve protein synthesis, energy storage, and utilization (e.g., transfer of phosphate in nucleotide triphosphate reactions, ATP), DNA synthesis, metabolism, and the maintenance of cellular electrolyte balance. As a result of the role of magnesium in these biochemical reactions, magnesium is an important element in the control of neuromuscular transmission, neuronal activity, muscle contraction, and cardiac conduction.

Magnesium homeostasis and blood magnesium are tightly controlled because of the importance of magnesium in the pathogenesis of a variety of diseases including type 2 diabetes mellitus, osteoporosis, asthma, and cardiovascular diseases.[31,32] Although bone and intracellular magnesium are the primary storage areas for magnesium in the body, the kidney is the most important organ involved with magnesium homeostasis. The epithelial Mg channel (Melastatin 6) in the distal convoluted tubule functions as the gatekeeper for controlling Mg balance in the body by matching urinary magnesium excretion and the net entry of magnesium into the extracellular fluid.[33] Several mutations produce hypomagnesemia including mutations in transient receptor potential Melastatin type 6, renal tight junction protein claudin 16 (*CLDN16* gene), and cyclin M2 (*CNNM2*) gene, as well as mutations in Mg^{2+} transporter 1 linked to T cell deficiency and reduced cell viability.[30] Clinical features of hypomagnesemia include nystagmus, tremulous, hyperactive deep tendon reflexes, dysphagia, and dysrhythmias (premature ventricular contractions, multifocal atrial tachycardia, torsades de pointes, ventricular fibrillation). Hypokalemia strongly correlates to hypomagnesemia.

Mechanism of Toxicity

Hypermagnesemia affects primarily the cardiovascular and nervous systems in a dose-dependent relationship, resulting in stabilization of cell membranes, delayed nerve conduction, prolonged refractory period, and compromised muscle contraction. Alterations in extracellular magnesium levels cause impaired nerve conduction and synaptic blockade. Elevated Mg concentrations reduce impulse conduction at the neuromuscular junction by impairing the sensitivity of the postsynaptic junction to acetylcholine, decreasing acetylcholine release from the presynaptic terminals, and reducing the action potential produced by acetylcholine at the postsynaptic junction.[34] Hypermagnesemia probably does not directly slow motor and sensory nerve conduction velocities. Hypermagnesemia produces direct depression of atrioventricular conduction by suppressing the A–H interval. The latter interval approximates the conduction time through the AV node represented on the ECG by the time between the initial rapid deflection of the atrial wave (A) and the bundle of His (H); the typical A–H interval is 50–120 msec. Magnesium is a calcium antagonist that causes systemic and cerebral vasodilation, increases cyclic guanosine monophosphate, and modulates vasomotor tone by increasing nitric oxide and decreasing endothelin-1 concentrations.[35,36]

The kidney has a common transport system for the reabsorption of calcium and magnesium; consequently, hypercalcemia produces a concomitant increase in magnesium excretion.[37] Chronic diseases associated with hypercalcemia (e.g., milk-alkali syndrome, multiple myeloma, primary hyperparathyroidism, vitamin D intoxication) may cause hypomagnesemia.

Postmortem Examination

A 75-year-old woman was found dead in bed after ingesting magnesium-containing milk during the preceding several days.[38] Autopsy performed three days after death demonstrated congestion of the brain and lungs along with advanced arteriosclerosis and calcification of the coronary arteries, thoracic aorta, and abdominal aorta. The mildly enlarged heart weighed 480 g without evidence of myocardial infarction. Histological findings included fibril formations in the left

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ventricular wall, indurated glomeruli, and marked inflammatory cell infiltration in the kidney. The presence of advanced arteriosclerosis suggests the possibility of a fatal dysrhythmia secondary to hypermagnesemia.

After a 40-week gestation, a newborn aspirated meconium during delivery.[39] At 1½ hours after delivery, the newborn received 5 g (416 mEq) magnesium as $MgSO_4$ enema before being transported to a referral hospital. A respiratory arrest occurred 1½ hours after the enema followed by asystole. The Mg concentration was 4.6 mEq/L 4¼ hours after the enema and 7.6 mEq/L before exchange transfusion. An EEG was isoelectric 18 hours after the enema. The infant died 46 hours after delivery, despite resuscitative efforts and treatment for hypermagnesemia. The autopsy demonstrated evidence of moderately severe aspiration, cerebral edema, and hemorrhagic necrosis of the midbrain, pons, and inferior olivary nucleus of the brain stem. The presence of moderate pulmonary disease, pulmonary aspiration, and extensive hypoxic brain damage from her cardiac arrest confounds the interpretation of the clinical effect of hypermagnesemia.

CLINICAL RESPONSE

Acute Toxicity

Hypermagnesemia usually occurs in the setting of large iatrogenic doses or in the presence of renal failure with large magnesium loads (e.g., iatrogenic, rhabdomyolysis).[40,41] Progressive loss of neuromuscular, cardiovascular, and respiratory functions characterizes hypermagnesemia. Symptomatic hypermagnesemia appears rarely in the absence of intestinal or renal disease. Table 18.2 lists the common clinical settings of hypermagnesemia. The main symptoms involve neuromuscular (impaired conduction, synaptic blockade, loss of reflexes, paralysis), cardiac (hypotension, bradycardia, heart block), and respiratory (insufficiency, arrest). These signs and symptoms include central nervous system depression, respiratory depression, hypomotility of the bowel, muscle paralysis, hyporeflexia, and electrocardiographic changes similar to those in hyperkalemia (prolonged QRS, QT, and PR intervals, peaked T waves, interventricular conduction defects, atrioventricular block, and eventually asystole). In severe magnesium intoxication, patients manifest absent deep tendon reflexes, alteration of mental status progressing coma, dysrhythmias, refractory hypotension, and respiratory arrest.

Elevated serum magnesium concentrations may cause hypocalcemia because of decreased parathyroid hormone activity and decreased end-organ responsiveness,[19] especially in neonates born to preeclamptic mothers treated with magnesium sulfate.[42] Both preeclamptic mothers and their unborn children have survived accidental overdoses of magnesium sulfate without immediate evidence of sequelae.[43,44] The clinical presentation of hypermagnesemia is nonspecific; the differential diagnosis of hypermagnesemia includes primary central nervous system lesions, sepsis, bowel obstruction, and ethanol intoxication.

TABLE 18.2. Clinical settings associated with hypermagnesemia.

Frequency	Setting
Common	Acute renal failure, chronic renal failure with exogenous magnesium intake, magnesium sulfate therapy for toxemia.
Occasional	Chronic renal failure without exogenous magnesium intake, rectal administration of Mg-containing solutions.
Unusual	Acute diabetic ketoacidosis, Addison's disease, hyperparathyroidism with renal disease, hypothyroidism, lithium therapy, milk-alkali syndrome, neoplasm with bone metastasis, parasitosis with exogenous Mg intake, perforated viscus with exogenous Mg intake, pituitary dwarfism, viral hepatitis.

Environmental Exposure

There are few data to document the toxicity of excessive magnesium concentrations in the environment; most epidemiology studies examine the risk of cardiovascular disease and hypomagnesemia, calcium concentrations, and water hardness. Currently, there is inadequate evidence to justify the addition of magnesium to drinking water for preventive purposes.[45]

Occupational Exposure

Magnesium and magnesium alloys exhibit low toxicity. Magnesium oxide fumes form during the application of high temperatures to Mg-containing metals; however, experimental studies indicate MgO is substantially less toxic than oxides associated with metal fume fever (e.g., zinc oxide).[46] Exposure to these fumes may cause conjunctivitis, cough, and mild irritation of the nose and throat, but systemic symptoms (e.g., metal fume fever) occur rarely.[47,48] The latter reports do not provide sufficient exposure data to exclude other causes of the systemic complaints (i.e., confounding chemical exposures). Prolonged exposure to high doses of magnesium

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

carbonate at a magnesite production facility was associated with a 2.1% incidence of benign pneumoconiosis (cough, sputum, emphysema), but these effects could not be directly attributed to $MgCO_3$ because of the presence of silica and asbestos.[49]

Carcinogenesis

Magnesium is an essential cofactor for the proper functioning of numerous enzyme systems. Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program lists magnesium or magnesium compounds as suspected carcinogens. Magnesium production workers may be exposed to carcinogens (e.g., asbestos, coal tar pitch, chlorinated hydrocarbons). A cohort study of 2,391 male magnesium production workers detected a statistically significant excess of lung cancer with a relative risk of 1.8 (95% CI: 1.2–2.5), but not in the cohort with exposure to magnesium oxide (RR = 1.71, 95% CI: 0.6–3.7). Interpretation of the study is limited by the lack of adjustment for exposure to known carcinogens (e.g., coal tar, asbestos, smoke), crude exposure data, and the small number of cases.[3] A population-based, prospective study of 23,366 Swedish men aged 45–79 years with relatively high intakes of dietary magnesium did not detect an excess all-cause or cancer mortality after comparing the highest tertile of Mg intake (mean = 523 ± 38 mg/day) with the lowest tertile (mean = 387 ± 31 mg/day).[50]

DIAGNOSTIC TESTING

SI Conversion Units

1 mg/dL = 0.4114 mmol/L
1 mmol/L = 2.431 mg/dL
1 mg = 0.0823 mEq
1 mEq = 12.15 mg

Analytical Methods

Serum magnesium concentrations are common analytical measurements in clinical laboratories. In samples containing Mg in the mg/L range, the use of inductively coupled plasma/optical emission spectroscopy allows lower limits of quantitation in serum and whole blood in the range of 0.16 mEq/L and 0.8 mEq/L, respectively.[51] Preanalytic studies indicate magnesium is stable in whole blood, serum, and plasma for 6 hours at 25°C and 24 hours at 4°C.[52]

Biomarkers

Blood

General Population

The serum magnesium concentration does not always correlate well to clinical signs and symptoms because magnesium is primarily an intracellular cation with only ~1% of the body burden of magnesium in the blood.[25] Total serum magnesium concentration reflects the free or ionized form (55%), the protein-bound fraction (33%), and the chelated portion (12%).[53] Alterations in acid-base status and serum protein concentrations affect the active (free) fraction of magnesium similar to calcium.[54] A decrease in the serum albumin concentration lowers the total serum Mg concentrations without affecting the active (free) form of magnesium, whereas acidosis decreases protein binding and increases the active portion of magnesium. The mean serum magnesium concentration in 15 healthy Spanish adults aged 25–40 years was 1.65 mEq/L (0.83 mmol Mg/L).[55] Typical serum magnesium concentrations in the general population range from 1.5–2.5 mEq/L.

Toxic

Patients usually tolerate mildly elevated serum magnesium concentrations (2.5–3.25 mEq/L) without symptoms.[56] A 32-year-old woman with end-stage renal disease and a history of ingestion of magnesium oxide cathartics developed weakness and quadriparesis; her admission serum magnesium was 4.34 mEq/L (10.58 mg/dL).[57] A 56-year-old man developed coma, respiratory failure, and flaccid extremities after the ingestion of three tablespoons of Epsom salts and the iatrogenic administration of 2 g magnesium citrate; he survived with intensive supportive care.[58] His peak serum magnesium concentration was 9.43 mEq/L (23 mg/dL). A 56-year-old woman survived a cardiopulmonary arrest with supportive care after developing severe hypermagnesemia from multiple-dose $MgSO_4$ therapy; the initial serum Mg concentration was 21.3 mEq/L.[59] A 7-year-old boy sustained a cardiac arrest with asystole following the use of an Epsom salt enema earlier in the day.[60] He failed to respond to advanced cardiac life support that included the use of calcium; the admission serum Mg concentration reported after he was declared dead was 33.9 mEq/L. Table 18.3 outlines the clinical effects of hypermagnesemia associated with specific magnesium concentrations.

Postmortem

A 75-year-old woman developed muscle weakness and diarrhea after ingesting a home remedy for weight loss

TABLE 18.3. Clinical effects of specific serum magnesium levels. The typical serum magnesium concentrations in the general population are 1.5–2.5 mEq/L.

3.25–9.9 mEq/L	Erythema, nausea, vomiting, bradycardia, delayed cardiac conduction (↑ PR interval, ↑ QRS duration), hypotension, decreased reflexes, sedation
≥10–14 mEq/L	Muscle paralysis, respiratory depression, coma, hypotension with decreased ventricular conduction, ventricular arrhythmias
>14–15 mEq/L	Cardiac arrest, asystole

containing milk with magnesium chloride.[38] She was found dead in the morning; her heart blood contained a total magnesium concentration of 10.2 mEq/L. The mean postmortem magnesium concentration in heart blood from three autopsy cases with similar postmortem intervals and without excessive magnesium exposure was 6.6 ± 0.4 mEq/L; the femoral blood contained similar magnesium concentrations without evidence of significant postmortem redistribution.

Urine

Analysis of the 24-hour urinary magnesium is a good measure of total magnesium body burden that avoids the effect of circadian rhythms on magnesium excretion. In a study of 7,664 subjects mostly with a history of albuminuria, the mean urinary magnesium excretion was 4.24 ± 1.64 mmol/24 hours for men and 3.54 ± 1.40 mmol/24 hours for women.[61]

Abnormalities

Numerous factors affect the serum magnesium concentrations, as listed in Table 18.4. Fluid and electrolyte (hypokalemia, hypernatremia) imbalances may occur concurrently in patients with hypermagnesemia, but hypermagnesemia does not directly affect these concentrations. Some reductions in calcium concentrations develop during hypermagnesemia as a result of the effect of elevated magnesium concentrations on the secretion of parathyroid hormone.[62] Alkalosis decreases free magnesium in the serum by increasing protein binding, whereas acidosis increases free serum magnesium. Magnesium is usually an unmeasured cation; hence, in this situation, hypermagnesemia occurs with a low to normal anion gap. Hypermagnesemia causes PR interval widening and transient tachycardia progressing to third-degree heart block, bradycardia, and eventually asystole as the serum magnesium concentration increases.

TABLE 18.4. Factors altering serum magnesium concentrations. (Adapted from Gums).[27]

Serum Magnesium	Factor
Increased	↑ Serum phosphate; ↑ parathyroid hormone secretion
	↓ Serum magnesium (feedback loop); ↓ serum calcium
Decreased	Acute acidosis, acute pancreatitis, alcohol (inhibits Mg resorption), bowel resection, drugs (aldosterone, amphotericin, calcitonin, carbenicillin, cisplatin, digoxin, diuretics, gentamicin, growth hormone, protein pump inhibitors, tobramycin, thyroxine), ↑ sodium intake, hypercalcemia, ↑ extracellular volume, ↑ serum magnesium, malabsorption, osmotic diuresis, thyroid disease

For detection of magnesium-induced diarrhea, 24-hour fecal output of magnesium is the most sensitive indicator. The upper limits of the fecal output of soluble magnesium and fecal magnesium concentrations in a study of normal subjects were 14.6 mmol Mg/day and 45.2 mmol Mg/L/day, respectively.[63]

HEALTH SURVEILLANCE

Table 18.5 lists regulations and guidelines for exposure to magnesium oxide and carbonate. The US OSHA PEL–TWA for MgO fume is 10 mg/m^3 as total particulate in order to protect workers from irritation of the eyes and the throat. Workers with chronic renal disease are more susceptible to the accumulation of magnesium, but systemic symptoms are unlikely unless the exposure to MgO fumes is excessive. The US OSHA PEL–TWA (8-hour) for magnesite ($MgCO_3$) is 15 mg/m^3, total particulate, and 5 mg/m^3 for the respirable fraction. The ACGIH recommends a TLV–TWA of 10 mg/m^3 when the total dust does not contain asbestos and the crystalline silica content is <1% based on the lack of inflammatory effects following MgO exposure of volunteers to 100 mg/m^3.[46,64]

TREATMENT

Stabilization

Hypermagnesemia is potentially life-threatening with severe hypermagnesemia (>10–15 mEq Mg/L) causing sudden respiratory arrest and asystole; these patients should be followed closely with cardiac monitoring

TABLE 18.5. Regulations and guidelines for exposure to magnesium compounds.

Exposure Limit	Value
	OSHA
PEL–TWA (8-hour)	
MgO	10 mg/m^3 (total particulates)
$MgCO_3$	15 mg/m^3 (total particulates)
	5 mg/m^3 (respirable particulates)
	NIOSH
IDLH (30 minute, MgO)	750 mg/m^3
	ACGIH
TLV–TWA (8-hour)	
MgO	10 mg/m^3 (total particulates)
STEL–TWA (15-minute)	None
	US FDA
Bottled water allowable limit	None
MCL	None
US federal drinking water guidelines	None

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; MCL = Maximum contaminate level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average; US FDA = United States Food and Drug Administration.

and pulse oximetry for the development of bradycardia, progressive QRS widening, hypotension, and respiratory insufficiency. Generous saline replacement should precede the use of vasopressors. Frequently, hypotension responds to calcium administration. Serum electrolytes (i.e., potassium, calcium, phosphate) should be evaluated urgently because electrolyte abnormalities commonly occur with hypermagnesemia including hypocalcemia and hypokalemia.[65] With careful attention to fluid and electrolyte balance, the use of loop diuretics (e.g., furosemide) increases the renal excretion of magnesium; adequate hydration is necessary to enhance the renal elimination of magnesium.

Decontamination

Activated charcoal, emetics, and cathartics are not indicated in the treatment of hypermagnesemia.

Elimination Enhancement

Hemodialysis effectively removes magnesium; immediate hemodialysis may be necessary for severely intoxicated patients, particularly if the patient does not respond to calcium. Serum Mg concentrations of >8–10 mEq Mg/L suggest the need for dialysis in patients with renal dysfunction. The decision to institute hemodialysis in patients with normal renal function depends on clinical judgment because patients with normal renal function have survived severe hypermagnesemia without hemodialysis.[18]

Antidotes

Calcium is an antagonist of the membrane effects of hypermagnesemia. The exact mechanism of action is unknown, but calcium may displace magnesium from cell membranes. Treatment with intravenous calcium is indicated in symptomatic patients with serum magnesium concentrations of >5 mEq/L. The adult dose of calcium gluconate is 10–30 mL of a 10% solution (4.5–13.5 mEq elemental Ca^{2+}) over 10 minutes, depending on the severity of the symptoms. This dose may be delivered over 1 minute if the patient is *in extremis*. The dose may be repeated once; then, the serum calcium concentrations should be reevaluated to determine the need for more calcium and to prevent hypomagnesemia. Calcium chloride provides three times more elemental calcium (13.6 mEq/10 mL 10% solution) than the gluconate salt; however, intravenous calcium chloride is much more irritating to the vein and skin than calcium gluconate. The administration of repeat doses of intravenous calcium may require a central line, particularly calcium chloride.

Chapter 19

MANGANESE

ELEMENTAL AND INORGANIC MANGANESE

HISTORY

Manganese toxicity (manganism) is a rare central nervous system disease that results from chronic, high-dose occupational exposure to manganese dust or to manganese fumes.[1] In 1837, the Scottish physician, John Couper, published the first report of manganism in workers processing pyrolusite (mineral manganese dioxide). These mill workers inhaled manganese oxides while grinding ore at his father-in-law, Charles Tennant's bleach factory near Glasgow.[2] At that time, this factory was the world's largest hypochlorite bleaching powder plant.[3] Later reports documented similar neurological effects in Czechoslovakian manganese workers exposed to manganese-containing dust while pulverizing pyrolusite during the early 1900s.[4] In 1913, the Columbia University physician, Louis Casamajor, reported the first US cases of manganism in workers exposed to manganese-containing dust from the magnetic separation of zinc from ore also containing iron and manganese.[5] As the use of manganese in alloys, armaments, and welding increased manganese demand, other reports of manganism were published including those of Chilean manganese miners during the 1940s[6] and 1950s.[7] The inhalation of high doses of manganese initially produced an acute psychiatric syndrome in these workers called "manganese madness." Characteristic symptoms of this syndrome included compulsive and aberrant behavior, emotional lability, and hallucinations. Later reports associated a syndrome similar to Parkinson's disease (e.g., mask-like face, stooped posture, cogwheel rigidity, tremor, impaired speech, clumsiness) with workers exposed chronically to manganese.[8]

PHYSIOCHEMICAL PROPERTIES

Manganese is a very hard, brittle Group 7 (Group VIIB) transition metal that appears whitish-gray in color. Manganese is a constituent of many alloys because of its favorable physical properties. The outer electron shell of manganese can donate up to 7 electrons; therefore, there are 11 oxidation states (3− to 7+) with the most stable being Mn^{2+}, Mn^{4+}, and Mn^{7+}. Manganese is a cofactor in many enzymatic reactions. The divalent form (+2) is the most common valence state of manganese in biological systems, although the trivalent form (+3) is the oxidative state of manganese in superoxide dismutase and transferrin. Absorption of manganese from the diet occurs in the divalent and tetravalent states. Manganese oxide (tetravalent M_gO_2) is the most important tetravalent manganese compound. Most manganese salts are readily water-soluble, except for the limited water solubility of phosphate and carbonate salts.[9] Manganese oxides (dioxide, tetroxide) are also poorly water-soluble. Table 19.1 displays identifying information and physical properties of manganese and industrially important manganese compounds. At manganese concentration of >0.1 mg/L, this element stains plumbing fixtures, produces an undesirable

taste in beverages, and discolors laundry.[10] Black precipitate may slough from water pipes coated with manganese.

Manual and gas metal arc welding releases a complex mixture of welding fume particles with a dominant aerodynamic size of 0.1–2 μm;[12] X-ray diffraction of these particles indicates the manganese oxidation state in the aerosols is primarily divalent and trivalent with manganese oxides predominating in particles of <50 nm. Manganese compounds include MnO, Mn_3O_4, $KMnF_3$, and K_2MnO_4. In a study of 137 currently exposed manual and gas metal arc welders, the mean solubility of total Mn mass in welding aerosols collected in 237 personal air samples was 13.8% (range, 1–49%) as measured in the simulated lung lining fluid (Hatch solution).[13]

EXPOSURE

Production Processes

Manganese occurs in the environment combined with a variety of borates, carbonates, phosphates, oxides, sulfides, and silicates. The most important manganese-bearing mineral is pyrolusite (MnO_2, black oxide) with less common manganese ores including rhodanate (manganese silicate) and rodochrosite ($MnCO_3$). The mining of these ores occurs in shallow underground mines or open pits. Most of the uses of manganese ores involve the production of the manganese-iron alloy (ferromanganese) by the smelting of the ore in electric furnaces. For workers in the manganese alloy-producing industries, the predominant oxidation states of manganese in the respirable aerosol fraction are Mn^0 and Mn^{2+}.[14] The main manganese ores are manganese oxides that range in valence from +2 to +4. Fumes from the pouring and casting of molten ferromanganese are primarily manganese tetroxide. Low-purity manganese (97–98%) results from the aluminum reduction of low iron-containing manganese ores or from by-products of ferromanganese alloys.[15] Manganese compounds form from chemical reactions with metallic manganese or manganese ores. In nature, elemental manganese usually exists in an iron ore rather than the elemental form.

Uses

High-grade manganese ores occur in South Africa, the Commonwealth of Independent States (CIS), Gabon, Australia, Brazil, China, India, Mexico, Ghana, and Chile.[16] The principal use of metallic manganese is in the production of carbon and high-temperature steel to improve hardness and strength. Modern steel technology uses less manganese compared with the manganese consumption of older steel technologies. Table 19.2 displays some common uses of manganese compounds.[17]

Sources

Manganese is a ubiquitous constituent of the environment comprising about 0.1% of the earth's crust,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 19.2. Common uses of manganese compounds. (Based on Agency for Toxic Substances and Disease Registry).[17]

Manganese Compound	Uses
Manganese chloride	Dry-cell batteries, supplemental trace element in animal feed, catalyst for chlorination of organic compounds, precursor for manganese compounds
Manganese dioxide	Glass production, semiconductors, catalysts, ceramics, incendiaries, dry-cell batteries
Manganese sulfate	Ceramics, fungicides, nutritional supplements

primarily as carbonates, oxides, or silicates. This metal is a normal constituent of the human body. Crustal rock is the major natural source of manganese found in the atmosphere with other sources including vegetation, forest fires, volcanic activity, and ocean spray.[11] Food is the most important source of manganese for the general population, and daily intake ranges from 2–9 mg Mn depending on nutritional habits involving the consumption of high manganese-containing foods (e.g., tea).[17]

Occupational exposures result from metallurgical operations (e.g., ferrous/nonferrous alloys, iron, steel), mining, and ore-crushing. Welding is the most common source of occupational Mn exposure from the inclusion of this metal in steel production and the off-gassing of fumes from the steel welding processes (e.g., arc welding) involving manganese-containing base metal, welding rods, wire, or flux.[18] The extent of manganese exposure varies with the amount of Mn in the base metal, flux, rods, or welding wires, as well as the process and industrial hygiene factors. These processes produce respirable particles, primarily complex oxides that sometimes contain a silicon oxide shell. In contrast, manganese mining and ore milling produce much simpler forms of manganese-containing particles than welding processes. With the exception of cutting arc and hard-facing/burning processes, the manganese percentage in these fumes typically is low (i.e., 2%). Although elemental manganese and manganese oxides in these fumes are water-insoluble, some manganese absorption occurs after alveolar deposition.

Air

The background concentrations of manganese in rural and urban areas without point sources of manganese range from 0.01–0.07 μg Mn/m^3, whereas average ambient air concentrations of manganese near industrial sources range from 0.22–0.3 μg/m^3.[19] The anthropogenic sources of manganese in ambient air include the combustion of fossil fuels (20%) and the emission of manganese from industrial sources (80%).[17] Erosion of soil is the most important natural source of manganese in the ambient air, but little data are available to estimate the contribution of manganese from this source. Indoor and contiguous outdoor respirable Mn concentrations are usually similar. Despite higher respirable Mn concentrations in urban than rural areas, studies suggest that the higher ambient air concentrations do not produce relatively higher whole blood Mn concentrations in urban residents. In a Canadian study comparing Mn concentrations in ambient air and whole blood in five urban residents (Montreal) with five rural residents (Saint-Philippe), the mean whole blood Mn concentrations were similar (8.4 μg/L vs. 7.8 μg/L, respectively) despite differences in Mn concentrations in ambient air.[20] There was no correlation between blood Mn and duration of residence.

Canadian garage mechanics were exposed to a mean of 0.25 μg Mn/m^3 at work compared with a mean of 0.007 μg Mn/m^3 at their homes.[21] For taxi drivers, the mean was 0.024 μg Mn/m^3 compared with 0.011 μg Mn/m^3 at their homes. In general, the exposure of the general population to organic manganese from engine emissions is much lower than most exposures to manganese in the occupational setting.[22] Studies of Canadian subway systems suggest that internal Mn sources do not increase the ambient air concentrations of Mn in the subway above background (outdoor) concentrations.[23]

Water

Concentrations of manganese in seawater average about 2 μg Mn/L with higher Mn concentrations (1–200 μg/L, median ~10 μg Mn/L) occurring in freshwater.[24] A study of water samples from US rivers during 1974–1981 measured dissolved manganese; the median manganese concentration was 24 μg/L.[25] Manganese concentrations in drinking water vary substantially. A study of tap water samples from 278 homes in southwest Quebec demonstrated a mean Mn concentration of 6.4 μg/L (range, <0.1–159 μg/L).[26] Excluding samples from 16 wells, the range of Mn concentrations was 0.5–71.1 μg/L. In a study of drinking water in northwest Peloponnesos, Greece, the manganese concentration ranged from 3.6–14.6 μg/L to 1,800–2,300 μg/L.[27] Total manganese concentrations also reflect the amount of manganese adsorbed to sediment, but the bioavailability of manganese in sediment has not been established. Some manganese compounds ($MnCl_2$, $MnSO_4$) are soluble

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. in water; therefore, Mn exposure may result from the ingestion of manganese-containing water. Reducing conditions in lakes and groundwater favor high Mn concentrations. Generally, the contribution to overall daily Mn intake is smaller from drinking water than from food. High Mn concentrations (e.g., 400–800 μg/L) in ground or surface waters may result from industrial pollution. Contamination of well water by waste disposal produced concentrations near 2,000 μg Mn/L.[28]

Soil

Manganese exists in almost all types of soil. Concentrations of manganese in soil average 40–900 mg/kg with a mean of 330 mg/kg and maximum concentrations up to 7,000 mg/kg depending on the extent of mining activities.[24,29] Accumulation of manganese in soil usually occurs in the subsoil rather than the topsoil.[9]

Diet

Food is the most important Mn source in the general population with the daily intake from ambient air (i.e., ~0.04 ng) usually contributing several orders of magnitude less than the diet; homeostatic control mechanisms limit Mn absorption and manganese toxicity from dietary sources.[30] Food contributes ~95% of manganese absorbed from the diet (e.g., grains, tea, green leafy vegetables) with a small contribution from water consumption, except in areas with unusually high manganese concentrations (e.g., industrial pollution, contaminated wells).[31] Vegetarian diets typically contain higher manganese concentrations than animal-derived diets. The average daily intake is ~2–6 mg Mn,[32,33] ranging up to 11 mg Mn in vegetarian diets consisting of large portions of nuts and cereals.[34]

The highest manganese concentrations occur in nuts (18–46 ppm), grains (0.4–40 ppm), legumes (2.2–6.7 ppm), fruits (0.2–10 ppm), and vegetables (0.4–6.6 ppm), particularly avocados, blueberries, egg yolks, dried peas, green leafy vegetables, green tea, and seaweed.[35] Poultry, meat, refined foods, fish, and dairy products contain relatively small amounts (0.2–0.5 ppm Mn). A 1992 survey of bluefin tuna (*Thunnus thynnus*) from the Northwest Atlantic detected Mn concentrations ranging from 0.16–0.31 μg/g dry weight muscle with an average of 0.22 μg/g dry weight muscle.[36] Heavy consumption of green tea can significantly increase the daily Mn intake with the average cup of tea containing ~0.4–1.3 mg Mn.[37] The concentration of Mn in milk is relatively low with typical mean concentrations of ~5 μg/L in human breast milk and 25 μg/L in cow's milk.[38]

ENVIRONMENTAL FATE

Air

Release of manganese into the air occurs primarily as particulate matter with the fate and transport of the particles depending on size, density, and wind speed. Elemental manganese and manganese compounds have little vapor pressure, but transport of manganese into ambient air results from the emission of suspended manganese-containing particulates from industrial sources and the erosion of Mn-containing soils. About 80% of the manganese-containing particles possess a mean median equivalent diameter (MMED) of <5 μm with ~50% demonstrating an MMED of <2 μm.[9] Particle size varies by source. Large particles dominate near mining operations, whereas smaller particle sizes occur near ferroalloy production, iron and steel foundries, power plants, and dry-cell battery plants.[9] Gravitational settling and rain are the main mechanisms of manganese removal from the atmosphere. The half-life of these particulates in the atmosphere depends on the particulate size, density, wind speed, and wind directions with the half-life usually measured in days. Methylcyclopentadienyl manganese tricarbonyl (MMT) undergoes rapid photochemical degradation to manganese tetroxide (Mn_3O_4) and perhaps other forms of manganese with a half-life of ~15 seconds in sunlight.[39]

Water

Manganese exists in the aquatic environment as divalent and tetravalent forms with the dominant species determined by pH and redox conditions. Water solubility controls the transport of manganese in water. Divalent manganese, primarily in the form of $MnCO_3$, is the principal manganese source in water at pH 4–7; oxidation of manganese occurs at pH >8–9.[40] The limited solubility (i.e., 65 mg/L H_2O) of $MnCO_3$ restricts the amount of manganese present in water; the transport of manganese usually occurs by suspended sediment in rivers.[41] Anaerobic waters contain relatively high concentrations of dissolved Mn along with poorly soluble manganese sulfides. Reduction of Mn^{4+} to Mn^{2+} can occur in this environment with divalent form dominating at lower pH and redox potential. Significant bioconcentration of manganese exists in lower organisms (e.g., marine plants (10–20,000), invertebrates (10–40,000)). Manganese is an essential element for microorganisms, plants, and animals; this bioconcentration may reflect specific uptake mechanisms for manganese.[9] Significant bioconcentration of manganese occurs in aquatic biota

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

at lower trophic levels, but fish do not accumulate manganese to a similar extent as plants and microorganisms. Typical bioconcentration factors (BCFs) for marine and freshwater plants are 2,000–20,000 for plants and 2,500–6,300 for marine macroalgae, whereas the average BCFs for fish are ~100–600.[9] The relatively smaller bioconcentration of manganese in higher organisms suggests that biomagnification of manganese in the food chain is probably **not** significant.[15]

Soil

Adsorption of soluble manganese compounds to soils and sediments varies substantially depending on cation exchange capacity and the organic composition of the soil.[42] At low manganese levels, clay soils bind manganese tightly with little release of manganese into solution.[43] At higher concentrations, some desorption of manganese occurs as a result of ion-exchange mechanisms.

DOSE EFFECT

Inhalation

Cases of chronic manganese poisoning (manganism) result from the prolonged exposure of workers to high levels of manganese dust or fumes in ferromanganese foundries or manganese mines.[17] Most cases of manganism occur following exposure to air Mn concentrations of >20–30 mg/m^3,[44,45] typically in the range of 100–900 mg/m^3.[46] The development of clinical manganism is rare below exposures to manganese concentrations of <5 mg/m^3.[47] Recent cohort studies suggest early sub-clinical changes in neuropsychological parameters (hand tremor, reduced memory, prolonged reaction time) may occur in workers chronically exposed to manganese concentrations in the range of 1–5 mg/m^3 for 20 years.[48] A more recent retrospective risk assessment study of bridge welders suggests the possibility that mild cognitive impairment (working memory index, verbal intelligence quotient, verbal comprehension index, design fluency, Stroop color word test) may develop in workers exposed to manganese concentrations below current standards; however, most of these measures did not demonstrate a dose-rate response.[49] Chronic exposure of animals to manganese does not reproduce the effects seen in manganese workers,[50] although some behavioral changes develop after prolonged exposure to high concentrations (60–70 mg Mn/m^3).[51]

Ingestion

The estimated safe and adequate dietary intake of manganese as defined by the US National Research Council is 2–5 mg for adults.[52] The daily reference dose (R_fD) is 10 mg Mn based on estimates of the dietary intake of manganese as calculated by the US EPA. A cohort study[27] and a case report[53] associated the ingestion of contaminated well water (0.08–2.3 mg Mn/L and 14 mg Mn/L, respectively) with the development of chronic neurological symptoms characteristic of Parkinson's disease. However, the lack of accurate exposure data and the absence of a clear dose-response effect limit definite conclusions about the role of manganese in the occurrence of the symptoms in these patients. The US EPA used a lowest-observed-adverse-effect level of 4.2 mg Mn/day for the Kondakis' study as a basis for determining water standards for manganese.[52] Furthermore, a more recent cross-sectional German study of 41 individuals exposed to well water containing high Mn concentrations did not confirm the results of the Greek study.[54] The German cohort of rural residents was exposed over 10–40 years to concentrations ranging from 0.3–2.16 mg Mn/L in well water. Compared with the control group (<0.3 mg Mn/L well water), the exposed group displayed no significant differences on clinical examination, structured questionnaires, or tests of fine motor coordination. The clinical examiner was blinded to the exposure status of the individuals.

Manganese balance studies and excretion data indicate that low gastrointestinal absorption and rapid elimination of manganese limit the toxicity of manganese by the oral route as a result of homeostatic mechanisms (reduced absorption rates, increased presystemic elimination) that regulate manganese blood concentrations. Manganese concentrations in drinking water vary by several orders of magnitude depending on the amount of leaching from manganese in minerals and rocks in aquifers. Some cross-sectional studies suggest that higher manganese concentrations in drinking water are associated with a reduction in IQ in children living in these households. In a cross-sectional study of 362 Canadian children (age 6–13 years) living in households with a median manganese concentration of 34 μg/L (range, 1–2,700 μg/L), a 10-fold increase in the drinking water manganese concentration was associated with a decrease of 2.4 full scale IQ point (95% CI: −3.9 to −0.9 IQ, $P = 0.01$) after adjustment for confounding factors.[55] The diminution in full-scale IQ was present only at higher quintiles of manganese concentrations in the drinking water. However, the findings of studies on the effect of environmental manganese exposures on

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

intellectual functions are inconsistent, vary with exposure measures, and are subjected to confounding by factors with greater impact on the outcome measures. In a cross-sectional study of 299 Italian adolescents (aged 11–14 years) living in an industrialized area with ferroalloy plants, the whole blood manganese concentration (median = 10.9 μg/L; range, 4.00–24.1 μg/L) was not associated with cognitive (IQ) or behavioral (ADHD) outcomes.[56] The Canadian study did not detect an exposure-response relationship between Mn in drinking water and hyperactivity.[57]

TOXICOKINETICS

Absorption

Limited data are available on the retention and absorption of inhaled Mn particles; however, the solubility of MnO_2 and other inhaled manganese compounds is poor. Consequently, systemic absorption is restricted to a portion of those particles that reach the alveoli and are transferred to the stomach by mucociliary transport. Homeostatic mechanisms control Mn absorption of manganese compounds transferred to the stomach by mucociliary transport. Therefore, the amount of manganese absorbed depends on the amount ingested and the existing manganese concentrations. Manganese absorption occurs primarily in the small intestine as a result of the relative insolubility of manganese compounds in digestive fluids. Absorption of manganese from the gastrointestinal tract varies inversely with the amount of calcium in the diet and serum iron concentrations,[58] and directly with the water solubility of the manganese salt. Iron and manganese share the same transport system.[59] In a volunteer study, the concomitant administration of 7.5 mg or 15 mg manganese (as manganese chloride) with 3 mg iron (as ferrous sulfate) reduced manganese absorption by 20% and 34%, respectively, compared with the control (no manganese).[60] The amount of manganese absorbed from the diet averages about 3–5% based on ^{54}Mn isotope studies.[61] In a study of healthy miners, miners with chronic manganese poisoning, and anemic subjects, the amounts of absorption of $^{54}MnCl_2$ were 3%, 4%, and 7.5%, respectively.[62]

Distribution

Manganese occurs in all mammalian tissues with Mn concentrations varying from 0.3–2.9 μg/g wet tissue weight.[38] Manganese in the blood is highly bound (i.e., 80%) to β-globulin and albumin as Mn^{2+} with small amounts of Mn^{3+} complexed to transferrin.[63] The intracellular reaction with the superoxide anion converts the divalent form to the trivalent form present in enzymes. The β-globulin, transmanganin, transports part of the manganese in trivalent form to tissue stores. Additionally, some transport of the divalent forms of manganese bound to α-macroglobulin also occurs. A variety of transporters have potential roles in Mn transport including divalent metal transporter 1 (DMT1), the ZIP family metal transporters (ZIP-8, ZIP-14), the secretory pathway calcium ATPases (ATP13A2, SPCA1, SPCA2), ferroportin, transferrin/transferrin receptor complex (TfR), and the mutant SLC30A10 Mn transporter associated with familial hypermanganesemia, hepatic cirrhosis, and extrapyramidal motor disorder. However, the contribution of each of these transporters to Mn homeostasis remains unclear as none are specific transporters for Mn.[64] ATP13A2, ferroportin, SLC30A10, and SPCA1 transporters affect Mn homeostasis by transporting Mn out of cells. DMT1 is the main transporter for divalent Mn, whereas TfR is the primary transporter for trivalent Mn.[65] The transport of Mn across the blood–brain barrier involves both facilitated diffusion of the nonprotein-bound Mn^{2+} and active transport (e.g., divalent metal transporter 1-mediated transport, transferrin-dependent transporter).[66,67] The protein involved in the former transport mechanism is the intestinal protein responsible for iron regulation. Relatively higher diffusion of Mn across the blood–brain barrier occurs during iron deficiency.

The concentration of manganese in erythrocytes is at least five times higher than the Mn concentration in serum.[68] In a study of whole blood from 48 healthy adults, the plasma contained ~4% of manganese present in whole blood as measured by graphite furnace/atomic absorption spectrophotometry with Zeeman background correction.[69] The highest concentrations of manganese occur in the liver as a result of the efficient hepatic extraction of manganese, followed by the pancreas, the pituitary gland, bone, kidney, and portions of the brain (basal ganglia, cerebellum). Little accumulation of manganese occurs in the body with a majority of an average body burden of 8 mg distributed between the muscle and the liver.[70]

Elimination

Although manganese does not undergo biotransformation in the body, some changes in the manganese

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

oxidation state occur. In the diet, manganese typically exists in the divalent or tetravalent oxidation state, whereas most enzymes require the trivalent form of manganese.[71] The elimination of manganese occurs primarily (i.e., 98%) by biliary excretion into the feces. Following the administration of manganese to rats, some manganese crosses directly from the blood to the bile; however, most manganese is secreted into the bile.[72] Animal studies suggest that renal excretion of manganese is small (<0.1% over 5 days).[73] In a study of healthy subjects in northern Italy, the mean manganese concentration in urine samples was 1.02 ± 0.05 μg/L.[74] The biological half-life of manganese in blood ranges from ~12 days in healthy miners to ~40 days in healthy volunteers.[75] Animal experiments indicate the elimination of manganese from the whole body is much faster than from the brain, particularly the cerebrum.[76,77]

Maternal–Fetal Kinetics

Manganese is an essential element that crosses the placental barrier bidirectionally in animal species and humans;[24] however, rodent models suggest the Mn concentration in fetal brains is relatively stable without clear evidence of clinically significant accumulation of manganese prior to birth.[78] Manganese concentrations are typically higher in umbilical cord blood than maternal blood. In a Chinese study of 125 mother–infant pairs, the mean manganese concentration in umbilical cord blood was 78.75 ± 30.53 μg/L compared with 54.98 ± 22.68 μg/L in maternal blood at admission.[79] A prospective birth cohort study of biological markers of fetal and early childhood exposure to metal mixtures and psychosocial stress demonstrated a mean manganese concentration of 42 ± 16 μg/L in 470 umbilical cord blood samples compared with 24 ± 9.5 μg/L in maternal blood at delivery.[80] Both studies suggested an inverted U-shaped dose-response curve for maternal blood and birth weight. In the US study, there was a slight but statistically significant reduction in birth weight at maternal manganese concentrations of >3.1 μg/L after adjustment for potential biological and socioeconomic confounders. The relationship between admission maternal blood manganese concentrations and birth weight was not statistically significant (unadjusted) in the Chinese study. Breast milk contains Mn. Some infant formulas contain manganese concentrations up to 200 times greater than breast milk,[38] but the absorption of manganese from the formula is ~10 times less than Mn absorption from breast milk.[81]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Although there are no well-documented cases of manganese deficiency in humans, animal studies indicate that manganese is an essential cofactor for several important enzymes (e.g., phosphorylation, cholesterol, fatty acid synthesis), including arginase, glial cytoplasmic glutamine synthetase, phosphoenolpyruvate decarboxylase, hexokinase, mitochondrial superoxide dismutase, and xanthine oxidase.[82,83] Processes involving manganese-dependent enzymes include bone and cartilage formation, carbohydrate/lipid/amino acid metabolism, free radical detoxification, and, in the brain, ammonia clearance and neurotransmitter synthesis.[84] Specifically, manganese is a cofactor for arginase (hepatic urea production), superoxide dismutase (electron transfer process for limiting cellular oxidative stress), and pyruvate carboxylase (gluconeogenesis).

Manganese deficiency does not usually occur in humans because of the abundance of manganese in the diet. Most, but not all, men fed a manganese-deficient diet (0.1 mg Mn/day) for 35 days developed a fine, scaly, erythematous rash on the trunk along with biochemical changes (decreased plasma cholesterol, increased serum calcium, phosphorus, and alkaline phosphatase).[85] Deficiencies of manganese in animal studies produce abnormal glucose tolerance, impaired growth, skeletal defects, altered lipid and carbohydrate metabolism, ataxia, and reproductive abnormalities (i.e., reduced fertility and birth defects).[86,87]

The body strictly controls manganese concentrations through homeostatic mechanisms involving biliary excretion, various manganese importers (divalent metal transporter 1, citrate transporter, calcium channels, choline transporter, dopamine transporter, zinc transporters, transferrin receptor) and manganese exporters (ferroportin, secretory pathway Ca^{2+} ATPase 1, ATPase 13A2, solute carrier family 30 member 10).[65] These transports are permeable to other essential metals including iron and zinc. An autosomal recessive mutation in the *SLC30A10* gene is associated with a Mn transporter abnormality causing elevated blood manganese concentrations, hepatic cirrhosis, polycythemia, dystonia, and an extrapyramidal motor disorder.[88]

Mechanism of Toxicity

Pulmonary

Exposures to high Mn doses produce adverse effects, primarily in the lungs and brain. Inhalation of manganese

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dust leads to inflammation of the upper respiratory tract that is characteristic of nuisance dust. Animal studies indicate that the inhalation of manganese does not produce significant amounts of pulmonary fibrosis.[89]

Central Nervous System

Astrocytes are major sites of manganese accumulation in the brain as a result of the affinity of glutamine synthetase in these glial cells for manganese; this enzyme requires manganese as a cofactor. Ferromanganese workers and manganese miners develop a bradykinetic-hypertonic syndrome following long-term, high-dose manganese exposure (manganism) superficially similar to Parkinson's disease. Although Parkinsonism and chronic manganese exposure affect the basal ganglia, pathophysiological and clinical differences separate these two diseases. In contrast to the development of Parkinson's disease and reductions in dopamine synthesis, decreases in dopamine release occurs in manganism with preservation of dopamine synthesis. Pathological differences also separate chronic manganese poisoning from classic Parkinson's disease; manganese accumulates in the pallidum and striatum, whereas the hallmark of Parkinson's disease is the degeneration of the nigrostriatal dopaminergic neurons in the substantia nigra pars compacta that innervate the caudate and putamen.[90] Excessive manganese exposure produces neurological lesions (neuronal loss, gliosis) primarily in the output pathways distal to the dopaminergic projection (i.e., globus pallidus, striatum) rather than the midbrain dopamine neurons; consequently, the nigrostriatal dopaminergic pathway remains functional in manganism despite clinical evidence of Parkinsonian-like deficits.[91,92] Manganese also accumulates in the blood and basal ganglia of patients dying from liver failure.[93]

Manganism characteristically causes damage to the GABAergic cells of the caudate, putamen, and globus pallidus (i.e., primarily internal segment) with sparing of the substantia nigra pars compacta and the absence of Lewy bodies seen in Parkinson's disease. These changes correlate to early involvement of speech, gait and balance, minimal resting tremor, symmetrical changes in the globus pallidi, dystonia, and a poor response to levodopa.[94] In contrast to manganism, idiopathic Parkinson's disease is associated with the presence of intracellular inclusion bodies of α-synuclein protein (Lewy bodies), loss of striatal dopamine, and preservation of the pallidum. These changes correlate to resting tremor, asymmetry, and a good response to levodopa.

In experimental animals chronically exposed to manganese, this metal localizes in areas of the brain with high concentrations of non-heme iron (e.g., GABAergic cells in the globus pallidus and corpus striatum), impairing GABAergic signaling.[95,96] Primate studies indicate that neuropathological abnormalities are also present to a lesser extent in the caudate nucleus, putamen, and subthalamic nucleus-based MRI imaging of the brains of monkeys given $MnCl_2$ via inhalation.[77] Manganese toxicity probably results from the affinity of this element for neuromelanin along with the ability of manganese to disrupt the function of the dopaminergic systems. Hypotheses primarily involve alterations in dopaminergic transmission from some type of damage (e.g., increased production of free radicals through glutathione reduction, decreased glutathione peroxidase activity, the inhibition of mitochondrial respiration)[97,98] Some experimental evidence suggests the oxidation state of manganese affects the neurotoxicity of this element.[99]

Postmortem Examination

Autopsy findings in a 50-year-old man, who died from the daily ingestion of a liver-cleansing diet containing three tablespoons of manganese sulfate, demonstrated massive hemorrhagic necrosis in the liver and pancreas, diffuse hemorrhage of the gastrointestinal tract mucosa, and pulmonary edema. Microscopic abnormalities in the tissues involved characteristic changes of multiple organ failure (i.e., diffuse hepatocellular coagulative necrosis, acute tubular necrosis, alveolar hemorrhage).[100] Histopathological examination of a symptomatic Mn ore-crushing factory worker demonstrated gross atrophy and discoloration of the globus pallidus along with neuronal loss and moderately increased astrocytes in the corpus striatum; the substantial nigra was normal.[101] The nigrostriatal pathway remains intact following manganese toxicity in contrast to the damage to the substantia nigra seen in Parkinson's disease. Histopathological and immunochemical examination of a convenience sample of eight Mn miners without a history of neurological abnormalities also demonstrated a reduced ratio of astrocytes/microglial cells in the caudate compared with non-Mn mine workers.[102] A detailed exposure history was not available, but an industrial hygienist reviewing the available data suggested the miners were chronically exposed to relatively low Mn concentrations compared with published reports of symptomatic miners.

CLINICAL RESPONSE

Acute Ingestion

Both dermal and oral toxicity of manganese is low because of the low solubility of metallic manganese and limited gastrointestinal absorption;[103] consequently, case reports of acute manganese toxicity are rare, primarily involving the more water-soluble inorganic manganese salts. A healthy 50-year-old man developed nausea, vomiting, diarrhea, abdominal pain, weakness, and lightheadedness after ingesting an Epsom salt preparation containing manganese instead of magnesium.[100] Despite intravenous hydration, he progressed to fulminant hepatorenal failure, acute respiratory distress syndrome, coagulopathy, lactic acidosis, and refractory hypotension. He died 3 days after ingestion. A 48-year-old woman developed nausea and severe vomiting 10 minutes after undergoing dialysis with a dialysate contaminated with 3.2% manganese sulfate.[104] She subsequently developed acute pancreatitis with fat necrosis extending into the greater omentum, hypocalcemia, perioral numbness, abdominal pain, drowsiness, and fever; she recovered after a prolonged hospital course.

Acute Inhalation

Studies from the 1940s suggest exposure to high ambient air Mn concentrations can cause mild to moderate inflammation of the lungs (i.e., chemical pneumonitis).[105] An excess incidence of pneumonia has been associated with exposure to high Mn concentrations (210 mg/m^3) in the work environment; however, no known permanent pulmonary sequelae (e.g., fibrosis) developed after these exposures.[106] Later studies have not detected an excess incidence of pneumonia in workers exposed to manganese concentrations near current workplace standards. Metal fume fever (dry cough, thirst, nausea, headache, diaphoresis, fatigue, arthralgias, dyspnea) occurs after exposure to high concentrations of manganese oxide.[107]

Environmental Exposure

Manganism is not usually associated with environmental Mn exposures. Although some studies suggest a possible association, data are conflicting. The lack of a good biomarker for long-term exposure (Mn is excreted primarily in the bile) limits the epidemiological studies on the effect of environmental Mn exposures; currently, sufficient data are not available to determine the best Mn biomarker (e.g., blood, urine, nails, hair, dentin) for observational studies.

Central Nervous System

Adult Observational Studies

A cross-sectional study of 186 residents living near a ferromanganese smelter or an open-air Mn storage and packaging facility reported mild cognitive deficits in working/visuospatial memory (Rey-O Immediate, Rey-O Delayed) and verbal skills (Similarities) based on age-stratified normative data.[108] Exposure data were based on air-Mn site surface emissions method modeling (range, 0.03–1.61 $\mu g/m^3$). In a Mexican study of 288 adults living in a mining district with ambient air manganese concentrations of >0.05 $\mu g/m^3$ (EPA guideline for environmental exposure), air Mn concentration was a risk factor for attention impairment (OR = 1.75, 95% CI: 1.01–3.06).[109] The mean blood Mn concentration was 9.5 ± 4.14 µg/L; however, the blood Mn concentration did not correlate to any neuropsychological test. A pilot study of 29 residents living near an Ohio ferromanganese refinery detected a mild, subclinical impairment of postural balance.[110] Postural balance was correlated to hair Mn concentrations, but not whole blood Mn concentrations. The mean whole blood Mn was 9.4 µg/L (range, 4.2–21.7 µg/L). Analysis of data from the prospective Nurses' Health Study did not detect an association between Parkinson's disease and manganese exposure.[111] The fully adjusted hazard ratio comparing the risk of Parkinson's disease in the highest and lowest quartiles of Mn exposure was 1.04 (95% CI: 0.77–1.40).

Neurodevelopment/Childhood Studies

A systematic review of epidemiology studies identified seven studies reporting adjusted associations between Mn biomarkers and childhood intelligence as an outcome.[112] The observational studies differed in Mn biomarkers (blood, dentin, hair), setting (highly exposed/general community), design (cross-sectional, prospective), and results (positive, inverse, null). Although cross-sectional studies suggested an inverse, mostly statistically nonsignificant association between blood or hair manganese and childhood intelligence tests, the prospective cohort study reported mostly null and some positive associations between Mn dentin concentrations and child intelligence.[113] Overall, the authors concluded the scientific evidence did not provide sufficient proof of an inverse causal association between child intelligence and Mn exposure biomarkers, given the cross-sectional designs, lack of consistency, and potential for confounding and selection bias.

The Korean Mothers and Children's Environmental Study examined 232 infant–mother pairs for an association between peripartum maternal whole blood Mn concentrations (mean = 22.5 ± 6.5 μg/L) and Bayley Scales of Infant Development scores in 6-month-old infants.[114] After adjustment for potential confounders, the dose-response curve was U-shaped with lower scores on mental and psychomotor development indexes at low and high Mn blood concentrations. The inflection point between positive and negative outcomes in normal-weight infants occurred at whole blood Mn concentrations of 24–28 μg/L. In an agricultural area of California, where Mn-containing fungicide use was common, mental and performance development index scores on the Bayley Scales of Infant Development Test in 24-month-old Mexican-American infants were not associated with Mn dentin concentrations.[115] Small transient reduction of these scores occurred in girls 6 and 12 months old, particularly in infants with anemic mothers; however, the scores returned to the normal range by 24 months. A prospective birth cohort study examined the association between prenatal Mn concentration and mental/psychomotor development scores at age 2 years for infants living near the Tar Creek Superfund Site previously containing lead/zinc mines.[116] The maternal venous whole blood and infant cord blood Mn concentrations were 24.0 μg/L (IQR = 19.5–29.7 μg/L) and 43.1 μg/L (IQR = 33.5–52.1 μg/L), respectively. The maternal whole blood Mn interquartile range (19.5–29.7 μg/L) was associated with a reduction in the mental developmental index of −3.0 points (95% CI: −5.3 to −0.7 points) and −2.3 points (95% CI: −4.1 to −0.4 points) on the psychomotor developmental index. Cord Mn concentrations were not associated with neuro developmental scores. A study of children aged 7–9 years old recruited from residences near an Ohio ferromanganese refinery suggested a U-shaped association between the highest (>11.2 μg/L)/lowest (<8.2 μg/L) quartiles of whole blood Mn and the middle two quartiles for full IQ after adjustment for confounders.[117] Perceptual reasoning and processing speed were also negatively associated with the highest quartile when compared with the middle two quartiles. The lack of a good biomarker of the intensity of Mn exposure (e.g., whole blood reflects Mn exposure during the last few weeks) and selection bias limit conclusions about the effect of Mn exposure on cognitive function in this study.

A cross-sectional Korean study of 1,089 children aged 9–11 years compared neuropsychological scores of children with the highest (>21.4 μg/L) and lowest (<8.1 μg/L) blood Mn concentrations.[118] After adjustment for urine cotinine, blood lead, IQ, and other potential confounders, children with the highest blood Mn concentrations had lower scores in thinking, reading, and calculation. Other studies have not demonstrated a significant association between relatively low environmental Mn exposure and neuropsychological or developmental outcomes.[119] An Italian study used the Virtual Radial Arm Maze (VRAM) to assess visuospatial learning, reference memory, and working memory in 142 of 402 participants (35% participation rate) aged 10–14 years with naturally shed deciduous teeth available to examine prenatal and postnatal dentin Mn concentrations and neurodevelopment outcomes; the children resided near ferromanganese plants.[120] The results demonstrated a U-shaped dose-response curve between prenatal/early postnatal Mn exposure and VRAM outcome measures in girls, but not boys. The association between postnatal dentin MN concentrations and VRAM outcomes was null in girls and boys. In a Canadian study of 259 children aged 5.9–13.7 years consuming Mn-containing well water, drinking water, hair, toenail, and saliva Mn concentrations were not clearly associated with poor cognitive development in school-age children.[121] The percentage of children consuming Mn-containing water ranged from 4% (> 400 μg Mn/L) to 48% (<5 μg Mn/L) with 25% consuming drinking water containing >50 μg Mn/L. The association in girls was statistically significant only for toenail Mn and lower performance IQ ($\beta_{10\text{-fold}\uparrow Mn}$ = −5.65, 95% CI: −10.97 to −0.32), whereas the performance IQ results were positive and statistically significant for drinking water as well as positive and statistically nonsignificant for toenail Mn concentrations in boys. Verbal IQ was not associated with Mn biomarkers (water, hair, toenails, saliva) in girls or boys as measured by ICP-MS.

Case Report

A previously healthy 5-year-old girl developed behavioral changes (pica, incontinence, echolalia, emotional lability, apraxia), poor coordination, gait disturbances, subtle action tremor, polycythemia, and iron deficiency.[122] Her neurological abnormalities were attributed to manganese exposure based on an elevated serum manganese concentration (2.09 μg/L) and bilateral, symmetric hyperintense signals in the basal ganglia, brain stem, and cerebellum. Although the drinking water in the family vacation cabin had elevated manganese concentrations, no definite source for her manganese exposure could be identified, and her parents remained asymptomatic despite similar serum manganese concentrations.

Pulmonary

The risk of lung disease from Mn exposure in the environment is small; however, there is limited evidence that an increased prevalence of respiratory symptoms occurs near point sources of manganese, such as ferromanganese factories.[123]

Occupational Exposure

The primary target organs following chronic exposure to manganese are the lungs and brain.

Lungs

The mild to moderate inflammatory properties of manganese lead to an increased incidence of cough and bronchitis in workers exposed to manganese concentrations exceeding current standards.[48,124] Dusts and fumes of manganese do not possess significant fibrogenic properties. High mortality from pneumonia occurred among English workers exposed to manganese oxides during the manufacturing of potassium permanganate.[106] A mortality study of ferroalloy workers employed at a ferromanganese/silicomanganese plant did not demonstrate a significant increase in mortality from pneumonia (SMR = 1.03, 95% CI 0.75–1.38) or pneumoconiosis (SMR 1.65, 95% CI 0.04–9.20).[125] The cohort consisted of 14,730 men employed for at least 6 months during 1933–1990. Rare case reports associate occupational asthma with manganese exposure during welding based on airway hyperreactivity, positive skin prick test for manganese nitrate, and a single-blind, placebo-controlled specific inhalation challenge with 0.1% manganese chloride solution.[126]

Central Nervous System

Manganism is a progressive, disabling neurological syndrome that produces dull affect, altered gait, fine tremor, and occasionally psychiatric disturbances; serious cases of manganism occur exclusively following inhalation of Mn-rich dust.[24] A large case series of heavily exposed manganese miners suggests manganism symptoms typically begin after several years of exposure to dust containing high manganese concentrations; however, some individuals develop symptoms within several months.[46] The onset of symptoms of manganism more than a decade after manganese exposure is unusual. The initial symptoms are often nonspecific (i.e., generalized weakness, muscle stiffness, myalgias, anorexia, nervousness, irritability, headache).[47,62] Associated adverse effects include apathy, lethargy, loss of libido, and impotence.[46] Early neurological manifestations of manganism involve slow, halting speech, followed by dull facial expressions and retarded movement of the extremities.[7,46]

Mining

In manganese workers, slow deterioration of neurological function characterizes manganism; these symptoms begin insidiously as nonspecific symptoms and subclinical neurological signs. Clinical features of manganism include anorexia, apathy, arthralgias, myalgias, asthenia, headaches, irritability, lethargy, and weakness in the lower extremities. Gradually, dysfunction of the basal ganglia develops that is characterized by alterations of gait, loss of balance, fine tremor, loss of facial expressions, and speech disturbances. Finally, a severe, disabling, Parkinson's-like clinical condition develops characterized by widespread muscle rigidity, dystonias, a staggering gait, dysphagia, and a course intention tremor.[46] Although this disease resembles Parkinsonism, there are significant differences between the two diseases. Neurological characteristics favoring manganism include the following: psychiatric disturbances early in the course of the disease, early onset of speech and gait disturbances with dystonia including the "cock walk" (i.e., walking on toes with elbows flexed and spine erect), propensity to fall backward when pushed, relatively less resting tremor and more dystonias, relative symmetry of neurological abnormalities, and failure to respond to drugs (e.g., levodopa) during the late stages.[127] Neurological symptoms may improve after withdrawal from exposure; however, many symptoms (e.g., gait disturbances) persist or worsen after cessation of manganese exposure.[128] In a long-term study of five patients with chronic manganese intoxication, neurological symptoms (gait disturbances, rigidity, dysdiadochokinesias, writing) progressed over a 10-year period despite the return to normal tissue Mn concentrations and normal T1-weighted images on MRI.[129] Longer-term follow-up of these patients suggests the neurological effects of manganism stabilize in the decade after Mn exposure ceases.[130] Although asymmetry of neurological signs (cock gait, dystonia) suggests idiopathic rather than Mn-induced Parkinson's disease, some patients with the latter disease have persistent asymmetrical neurological signs. Early presentation of cock-walk suggests manganese toxicity.

A progressive psychiatric disturbance known as "manganese madness" may precede or accompany the onset of neurological signs. Psychiatric features of this syndrome include apathy, somnolence, confusion, bizarre behavior, visual hallucinations, increased lability, poor memory, anxiety, impotence, and decreased

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. libido.[131] Following exposure to high Mn concentrations, an acute psychiatric syndrome may develop characterized by aberrant behavior, emotional lability, and hallucinations.

Welding

Although case reports associate exposure of ferromanganese smelter workers to high ambient manganese concentrations with the development of manganism (atypical parkinsonism),[44] the association of the common form of Parkinson's disease with welding is more controversial. In contrast to manganese miners, the psychiatric and motor disturbances associated with clinical manganism are not well documented in welders exposed to manganese in welding fumes.[18,132] A meta-analysis of 13 epidemiological studies of welding and Parkinson's disease did not demonstrate an association between manganese exposure during welding and Parkinson's disease.[133] The pooled relative risk for all study designs (case-control, cohort, mortality) was 0.86 (95% CI: 0.80–0.92) for the association between welding and Parkinson's disease with similar effect measures (0.82–0.91) between study designs. The meta-analysis reported an absence of heterogeneity between studies ($I^2 = 0.0$). Although manganese exists in welding fumes, manganese exposures in welders are less than Mn exposures of miners and smelter workers with manganism.

A Swedish population-based study of welders and flame cutters in the 1960 and 1970 censuses ($n = 49{,}488$) did not detect an excess of basal ganglia or movement disorders (i.e., mostly in hospitalized patients) compared with the general population followed through 2003. The adjusted rate ratio for Parkinson's disease was 0.89 (95% CI: 0.79–0.99). Manganese exposure was based on a large survey of welding exposures conducted from 1974–1975 rather than direct measurements. Similarly, a retrospective cohort study of hospitalizations for neurodegenerative diseases in Denmark did not detect an excess of hospitalizations in welders or men in mild or stainless-steel welding departments.[134] The standardized hospitalization ratios for these 2 cohorts were 0.9 (95% CI:0.4–1.5) and 1.0 (95% CI:0.7–1.5), respectively. A follow-up study of bridge construction welders exposed to manganese in confined spaces for a mean of 16.5 months suggested some persistent depression, anxiety, and impairment of psychomotor speed, dominant postural hand tremor and body sway in these workers; however, the study design (e.g., confounding, low response rate) limited conclusions about the etiology of their abnormalities.[135]

Automotive Repair

A study of Canadian garage mechanics and blue-collar workers exposed to different Mn concentrations from methylcyclopentadienyl manganese tricarbonyl (MMT) combustion used personal air samplers, a dietary compilation, and residential water samples as measures of exposure. An epidemiological questionnaire and blood/hair samples did not detect a significant association between adverse health outcomes and chronic Mn exposure.[136]

Reproductive Abnormalities

Animal and human studies suggest that heavy consumption of manganese may produce developmental effects;[137] however, data are too limited to conclude that such effects exist in the human population as a result of Mn exposure.[17] No direct damage to testes in humans has been reported, but rodent studies suggest that manganese may produce degenerative changes in the testes at very high Mn concentrations.[138] Very high exposure to manganese has been associated with impotence,[139] but these reports involve seriously ill workers and there is little direct evidence of an effect on male reproduction. A cross-sectional study of alkaline battery workers exposed to manganese oxide (median atmospheric concentration of 0.71 mg Mn/m^3 as total manganese dust) for a mean of 6.2 years did not detect a reduced probability of live birth when compared with unexposed controls.[140] Although data are sparse, females appear less sensitive to the reproductive effects of manganese than males, based on rodent studies.[141]

Carcinogenesis

Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program recognizes manganese or its compounds as suspected human carcinogens. Although there are relatively few animal data on the carcinogenicity of manganese compounds, existing data indicate that manganese is not a significant carcinogen, despite some evidence of mutagenicity.[142] Exposure to dusts and fumes of manganese has not been identified as a risk factor for the development of lung cancer in workers exposed to manganese. Consequently, the potential for carcinogenic effects in humans appears small. A mortality study of 6,363 ferroalloy workers employed at a ferromanganese/silicomanganese plant did not demonstrate a significant increase in the overall incidence of cancer when compared with standardized rates for Norwegian men (SIR = 1.0, 95% CI: 0.93–1.17).[125] Although the

incidence of several cancers was statistically significant (pancreas, larynx, pleura), the presence of confounding exposures (asbestos, crystalline silica) limits conclusions.

DIAGNOSTIC TESTING

SI Conversion Units

1 μg = 0.0182 μmol = 18.20 nmol
1 μmol = 54.94 μg
1 mg/m^3 (25°C) = 0.4450 ppm
1 ppm = 2.247 mg/m^3

Analytical Methods

Methods for the determination of manganese in biological samples include atomic absorption spectrometry (AAS),[143,144] inductively coupled plasma atomic emission spectrometry (ICP/AES), and inductively coupled plasma mass spectrometry (ICP/MS).[145] Spectrophotometric procedures require careful sample preparation; this method is not very specific or sensitive. Flame atomic absorption spectrophotometry is a common, relatively simple method for the determination of manganese in biological samples, but sensitivity is limited; graphite furnace/atomic absorption spectrometry is a more sensitive method at very low manganese concentrations. Significant spectral interferences are minimal with AAS and ICP/AES, but ICP/MS requires high mass resolution instruments or a collision/reaction cell to reduce interference. Prior to quantitation, analysis of whole blood typically requires digestion with nitric acid at elevated temperature and pressure. Methods used to determine manganese concentrations (e.g., mass spectrometry, neutron activation analysis, spectrophotometry, X-ray fluorometry) measure total manganese concentrations; therefore, these methods do not distinguish between various valences or compounds.[9] Most methods require wet digestion, derivation, and/or extraction prior to analysis. Detection limits range from <0.01–0.2 μg/g for biological fluids to 5–10 μg/m^3 in air and 0.01–50 μg/L in water. Nuclear magnetic resonance is a more sensitive method (<2 ng/L water) than spectrophotometric methods.[146]

Biomarkers

Diagnostic tests used to identify excessive manganese exposure primarily include estimation of Mn concentrations in urine, blood (whole, serum, plasma), dentin, toenails, and hair; less common testing involves a positive response to $CaNa_2EDTA$ chelation and reversal/improvement after *L*-dopa treatment. None of these tests are highly specific or sensitive for manganese toxicity; blood and urine Mn concentrations do not accurately reflect the total body burden as >95% of Mn elimination occurs via the bile/feces.[147] Manganese accumulates in toenails, fingernails, and hair; however, there are few data correlating manganese concentrations in these matrices to environmental exposures. A study of 46 apprentice welders assessed for manganese exposure by personal gravimetric samples suggested manganese concentrations in pooled toenail clippings correlated to the calculated cumulative manganese exposure index for the preceding 7–12 months.[148] The correlation of toenail manganese concentrations to whole blood manganese concentrations was poor. The median airborne manganese concentration of the personal samples during the work shift was 12.89 μg/m^3 (range, 2.02–137.41 μg/m^3). Other potential biomarkers of Mn exposure include erythrocyte Mn, the Mn/Fe ratio in plasma or erythrocytes, and the pallidal index comparing the pallidus and subcortical frontal white matter intensity in axial T1-weighted magnetic resonance images.[149]

Blood

Following absorption, sequestration of manganese occurs in tissues and intracellular compartments rather than the blood; additionally, the elimination half-lives of Mn in tissues including the brain, are substantially longer than blood Mn. Efficient homeostatic mechanisms regulate the absorption and excretion of manganese; these mechanisms limit the whole blood manganese concentration to a specific range. Consequently, blood Mn concentrations are a measure of recent exposure rather than the cumulative Mn burden. Blood manganese concentrations distinguish exposed from unexposed individuals on a group basis, but the blood Mn concentration is less sensitive for discriminating one individual from the rest of the study population. Issues of methodological differences and contamination complicate the interpretation of manganese concentrations in the older literature. Past manganese concentrations in whole blood measured by spectrometry are an order of magnitude higher compared with whole blood concentrations measured by atomic absorption or neutron activation.

General Population

Whole Blood The whole blood manganese concentration measured by inductively coupled plasma/mass spectrometry (ICP/MS) averaged ~9 μg/L (range,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

~4–18 μg/L) in 130 German adults without occupational Mn exposure.[150] The mean Mn concentration in whole blood samples from a control group of 90 Danish adult males (mean 59 years, range 40–79 years) was 8.7 μg/L with a range of 4.1–19.0 μg/L as measured by atomic absorption spectrometry with Zeeman background correction.[151] The 95% upper limit for whole blood Mn concentrations in an expanded adult Danish reference group (n = 189) was 15 μg/L (271 nmol/L).[152] Manganese concentrations in infants are usually slightly higher than in older children and adults.[38] Smoking, gender, and alcohol consumption did not significantly affect the blood Mn concentration. Regular use of underground subways increases blood manganese concentrations.[153] Liver failure elevates blood Mn concentrations because biliary excretion is an important route of Mn elimination. A study of 11 patients with moderately severe cirrhosis demonstrated a statistically significant difference (P = 0.0013) in the whole blood manganese concentration between the cirrhosis group (20.6 ± 10.2 μg/L) and healthy, age-matched controls (7.2 ± 2.7 μg/L) as measured by graphite furnace/atomic absorption spectroscopy.[154] The mean whole blood Mn concentration in 10 patients with liver cirrhosis was 34.4 μg/L compared with a mean whole blood Mn concentration of 10.3 μg/L in 10 controls (no liver disease).[93] This difference was statistically significant (P = 0.0058).

Serum/Plasma Mn concentrations are substantially higher in whole blood than plasma or serum. Hemoglobin in erythrocytes binds ~85% of the manganese in blood; therefore, average plasma and serum manganese concentrations are much lower than whole blood Mn concentrations. In a study of 48 healthy adults, plasma contained ~4% of the manganese in whole blood as measured by Zeeman graphite furnace atomic absorption spectrophotometry after digestion with nitric acid and hydrogen peroxide.[69] A study of 1,000 Swedish adults aged 70–79 years reported a mean whole blood/serum Mn ratio of 5.06 as measured by inductively coupled plasma/sector field mass spectrometry[155] compared with 14.7 in healthy Italians as measured by graphite furnace/atomic absorption spectrometry.[74]

The mean plasma Mn concentration in 68 healthy adult blood donors was 0.79 ± 0.3 μg/L (14.3 ± 5.7 nmol/L).[156] In a study of 250 healthy adult inhabitants of Barcelona, Spain, where methylcyclopentadienyl manganese tricarbonyl (MMT) is an approved gasoline additive, the geometric mean serum manganese concentration was 1.1 μg/L with a range 0.3–2.5 μg/L (95% upper CI: 1.8 μg/L) as measured by graphite furnace/atomic absorption spectrometry.[157]

Hemolysis of blood samples will falsely elevate the plasma and serum manganese concentrations in blood samples. In a study of 31 healthy volunteer blood donors, the mean serum Mn concentration was 0.6 ± 0.16 μg/L (10.8 ± 3.0 nmol/L) as measured by atomic absorption spectrometry.[158] Studies on the course of Mn in patients developing renal failure are in conflict with some studies demonstrating increasing plasma concentrations with progressive renal failure,[159] whereas other studies suggested the serum Mn decreases with decreasing glomerular filtration rate.[160] Alterations in serum protein concentrations (e.g., malnutrition, inflammation) may account for some of the differences in these studies.

Environmental Exposure

There is no scientifically confirmed biological indicator of cumulative manganese exposure. Average whole manganese concentrations reflect the total body burden on a group basis, but not on an individual basis. The rapid clearance of manganese from the body limits the correlation between chronic health effects and the blood manganese concentration, particularly after Mn exposure ceases.[161] Hence, whole blood concentrations document recent exposure (1–2 weeks), but little correlation exists between past Mn exposure and current whole blood Mn concentrations.[162] In a study of 273 non-occupationally exposed residents from a province that contained a former manganese alloy production plant, the whole blood Mn concentration ranged from 2.5–15.9 μg/L with a median concentration of 7.3 μg/L.[163] Higher Mn concentrations (>7.5 μg/L) were associated by MANOVA analysis with poorer upper limb coordination, recall, and learning as well as slower hand rotation. There were no identifiable sources of excessive manganese exposures in these residents other than proximity to the former manganese alloy plant; regression analysis indicated that location and the ingestion of leafy vegetables and cereal accounted for <7% of the variability in blood Mn concentrations.[164]

Toxicity

Toxic concentrations of manganese are not well defined. A 48-year-old woman developed gastrointestinal distress, hypocalcemia, and acute pancreatitis after undergoing dialysis with a manganese-contaminated dialysate.[104] Her serum manganese concentration on the day following the incident was 252.5 μg/L (4.55 μmol/L). Blood manganese concentrations associated with neurotoxicity have not been defined. Of the seven children on long-term parenteral nutrition including manganese supplements, four children had increased T1-weighted

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

signal intensity in the globus pallidus and subthalamic nuclei.[165] Whole blood manganese concentrations ranged 13.8–28.6 μg/L (249–516 nmol).

Postmortem

A 50-year-old man died 3 days after inadvertently ingesting a preparation containing manganese sulfate.[100] His postmortem blood manganese concentration was 6,650 μg/L; his bile contained 376,000 μg Mn/L.

Urine

Manganese excretion in urine samples is low (i.e., <1% of the absorbed dose); urine Mn concentration reflects very recent exposure to manganese. Urinary manganese concentrations in spot samples from the general population without occupational exposure to manganese typically are <1–3 μg/L.[74] In a study of the US population (National Health and Nutrition Examination Survey, NHANES III), the 95th percentile Mn concentration was 3.33 μg/L as measured by inductively coupled argon plasma/mass spectrometry.[166]

Hair

Hair Mn concentrations are attractive, noninvasive measures of Mn exposure, but this biomarker is not a validated measure of Mn exposure. Several occupational studies suggest that proximal hair Mn concentrations increase with the duration of employment. In a study of dry-cell battery workers, the auxiliary hair Mn concentrations increased with the intensity of Mn exposure on a group basis; however, the wide variation in hair Mn concentrations in the controls limits the use of hair Mn concentrations on an individual basis. Interpreting the significance of dramatically elevated Mn hair concentrations in smelter workers was complicated by external contamination.[167] Scalp hair Mn concentrations did not correlate to neurological abnormalities in Mn-exposed Aborigines on an individual basis.[168]

Abnormalities

Neuropsychological Testing

Occupational Exposure

Overall, analysis of individual data on neuropsychological performance of manganese-exposed workers (male welders and non-welders) suggests some slowing of motor speed (simple reaction time), fine motor performance (pursuit aiming), dexterity (Santa Ana), and short-term/working memory (Digit Span) in these workers.[169] However, interpretation of the neurological effects of low-dose manganese exposure is conflicting, primarily as a result of the following factors: 1) difficulty matching the demographics of control (age, education, IQ) and Mn-exposure workers; 2) controlling for exposure to other neurotoxins along with a lack of validated biomarkers of exposure; 3) variability in sample size and neuropsychological tasks; 4) differences in Mn exposure; and 5) lack of dose-response relationships. Manual dexterity and visual recognition were not affected by these analyses.

A meta-analysis on 41 variables from 19 neuropsychological studies of Mn-exposed workers demonstrated the highest effect size for clerical substitution tasks, finger tapping endurance, digit span, and Swedish Performance Evaluation System "Additions" reaction times.[170] However, the effect size for these tasks did not exceed the effect size for education or aptitude; there was no dose-response relationship between exposure and effect size. A meta-analysis of 20 peer-reviewed published neuropsychological studies of occupational exposures to manganese suggested a small deleterious effect of manganese exposure on cognitive and sensory motor performance when comparing exposed and nonexposed workers.[171] Cohen's d statistic yielded a statistically significant weighted mean effect size of −0.17 ($P < 0.0001$) for manganese exposure, but this effect is too small (1/6 standard deviation) to detect on an individual basis. Although this study suggested slight impairment, the lack of a dose-response effect and abnormalities in the normally robust verbal comprehension domain indicated that current studies lack proper control of confounding variables and misclassification. In a cross-sectional study of 143 workers from an Australian ferroalloy smelter with estimated average cumulative manganese exposure of 3.51 mg-years/m^3 inhalable and 1.19 mg-years/m^3 respirable, correlation and hierarchical regression analyses demonstrated statistically significant relationships between increased exposure to inhalable/respirable manganese and tests of subcortical function (Digit Symbol Coding, Stroop color-work, Trail Making Part A).[172] However, the magnitude of the effects was smaller than the standard error of measurement, indicating that the demonstrated relationships were not clinically significant.

A meta-analysis of 13 studies examining 958 exposed (i.e., primarily metal alloy, Mn production) and 815 unexposed workers detected significant overall effects in some measures of motor speed (finger tapping) and information processing (simple reaction time, digit symbol).[173] The mean inhalable Mn concentration in these studies ranged from 0.05–1.59 mg/m^3, whereas the whole blood Mn concentration ranged from 8.1–48.4 μg/L. The size of the negative effects correlated to inhalable Mn

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

concentrations rather than whole blood Mn concentrations. Refinement of the meta-analysis using individual participant data rather than aggregated data from 579 exposed men and 433 referents demonstrated lower performance of the exposed workers on speed of movements and processing speed, whereas manual dexterity and recognition of memorized visual material were not consistently affected.[169] The association between concurrent blood manganese concentrations (sample type not reported) and performance on cognitive and motor tasks was weak and inconsistent. Cross-sectional studies of active workers exposed long-term (mean 10–20 years) to concentrations near 5 mg Mn/m^3 demonstrate subtle, sub-clinical reductions on neuropsychological testing of rapid, alternating motor movements (finger tapping),[48] hand steadiness,[48,174] and postural tremor.[175] In cross-sectional studies of manganese workers, tests of motor function (e.g., performance of coordinated, rapid, and sequential movements) appear more affected by Mn exposure compared with intellectual functions.[176] Less consistent reductions occurred in some studies including tests of response speed (simple reaction time),[177] short-term memory (digit span),[178] and diadochokinesia[179] when the results from these tests were compared with controls. Other studies have not detected significant differences in the scores on tests of simple reaction time[176,178] or memory.[176] These studies have not demonstrated a clear dose-response effect between exposure parameters and specific neuropsychological abnormalities.[180] Although a follow-up study of Canadian ferroalloy plant workers detected elevated T-scores for depression and anxiety among the former Mn-workers compared with a normative population,[181] studies of Danish steel workers did not detect a causal relationship between cognitive/neuromotor function and chronic Mn exposure.[182,183] Therefore, these neuropsychological tests provide supportive data, but there is no diagnostic group of tests that provides definitive proof of chronic manganese poisoning. Longitudinal studies of ferroalloy workers suggest most abnormalities on neuropsychiatric testing resolve over time with the exception of hand movements and cognitive flexibility (Trail Making B, Symbol Digit Modalities Test, Stroop Color-Word Test) in older workers.[184] In a study of retired former welders (mean exposure time, 28 years, 18 years since last exposure), the former shipyard welders and referents (matched for age) performed similarly on neurobehavioral tests of tremor, motor speed, manual dexterity, diadochokinesis, eye-hand coordination, and postural stability with the exception of the grooved pegboard test.[185] The welders performed slightly better than referents on tests evaluating hand steadiness. There were no airborne measurement data available for manganese.

Environmental Exposure

Data on the effects of manganese on children are limited, primarily involving cross-sectional studies; available studies on the neurodevelopment effect of manganese exposure suggest a negative or U-shaped association with Full Score IQ, particularly in the verbal domain. A meta-analysis of four studies using hair Mn concentrations as a surrogate for Mn exposure demonstrated a significant decrease ($P < 0.001$) of −0.70 point (95% CI: −1.07 to −0.34) in Full Scale IQ of children aged 6–13 years for each 50% increase in hair Mn concentrations. In a case-control study of 18 children aged 5–15 years with attention deficit and hyperactivity disorder (ADHD) and 74 controls matched for age and gender, the risk of ADHD increased with increasing whole blood Mn concentrations.[186] The mean whole blood Mn concentration was not reported; the study examined 12 heavy metals, and whole blood Mn concentrations are measures of recent Mn exposure (i.e., few weeks). Logistic-regression analyses indicated the risk of ADHD significantly increased for increasing blood lead, manganese, and zinc concentrations (type of sample not reported), but the risks were not adjusted for multiple confounders. Stepwise multi-logistic regression suggested that zinc concentration was a better predictor of ADHD than lead or manganese. A cross-sectional study of elementary school children (8–11 years) in Bangladesh detected a negative correlation between mathematic achievement scores and Mn concentrations in water.[187] Mn water concentrations exceeding 400 μg/L (median = 1,302 μg/L) were associated with a 6.4% reduction in mathematic test scores after adjustment for socioeconomic factors and arsenic concentrations. There was no correlation between Mn water concentrations and language scores, arsenic water concentration, or urinary total arsenic concentration as measured by graphite furnace/atomic absorption spectrometry. Interpretation of these studies is complicated by methodological issues including the lack of a validated biomarker of the manganese body burden or Mn exposure in the distant past.

Manganese–Methcathinone Encephalopathy

The clinical features from the use of intravenous manganese-contaminated methcathinone vary in severity with pronounced motor disabilities and limited cognitive deficits. Determination of the domains affected by this drug of abuse is complicated by the rarity of this encephalopathy, comorbidities (e.g., HIV, hepatitis C), small sample sizes, and limited follow-up.

A cross-sectional study of 14 methcathinone users (12 men, 2 women) and 14 age/education/sex-matched, healthy controls evaluated the 27 neuropsychological tests involving the Wechsler Adult Intelligence Scale with tests of attention, memory, motor skills, visuospatial skills, and executive abilities.[188] About half the users were actively using drugs with occasional use of other drugs (heroin, amphetamine). All users were positive for hepatitis C virus and six users were positive for HIV. The users displayed a Parkinson-like syndrome with dystonias, symmetric bradykinesia, and impairment of gait, posture, and speech; their Unified Parkinson's Disease Rating Scale (UPDRS) score as 43.0 ± 18.3 ranging from mild to severe disease. Although the cognitive performance of the users was slightly lower than that of the controls, the main differences involved motor skills. After adjustment for multiple comparisons, the users demonstrated modestly lower scores on executive abilities (verbal fluency), Grooved Pegboard tests (motor skills), and WAIS Object Assembly subtest (visuomotor skills).

Neuroimaging Studies

Welders

The pattern of MRI abnormalities in workers with manganese intoxication includes abnormal, bilateral, symmetrical signal hyperintensity in the corpus striatum (caudate and lentiform nuclei) and globus pallidus on T1-weighted images.[189,190] The thalamus and ventral pons are typically spared along with the nigrostriatal dopaminergic pathway.[191] In some studies of cross-sectional data on manganese workers, the relative T1-weighted magnetic resonance signal hyperintensity of the globus pallidus relative to frontal white matter (pallidal index) was correlated to Mn-exposure variables (blood, ambient air) and performance on neurobehavioral tests[192] as well as a positive dose-response association with cumulative Mn exposure.[193] There is no alteration of T2-weighted images;[194] T1 changes usually resolve within 6 months following cessation of manganese exposure.[195]

The MRI signal intensity increases following Mn accumulation from its strong paramagnetic properties that shorten T1 relaxation time; most earlier studies used T1-weighted images to estimate brain Mn accumulation because measuring T1 relaxation time required specific MRI sequences. The T1 relaxation time is more specific than the pallidal index because the former does not depend on Mn concentrations in the globus pallidus. Several cross-sectional studies of welders using T1 relaxation sequences suggest Mn accumulation in basal ganglia structures (globus pallidus, substantia nigra, caudate nucleus, anterior prefrontal lobe) is associated with early subtle cognitive changes (executive/verbal function), alteration of motor function, and modulation of movement.[196,197] The 3-month cumulative exposure index did not correlate to any neuropsychological test score. Manganese accumulation may occur in a nonlinear relationship requiring a critical exposure level to produce effects; however, these concentrations are not well-defined. Additionally, welding fumes contain several metals in addition to manganese (e.g., iron and copper) that may influence welding-associated neurotoxicity through competition with carrier-mediated transporters (e.g., transferrin, divalent metal transporter-1, ZIP8), particularly at low Mn exposures.[198,199]

A magnetic resonance imaging (MRI) study of a patient with manganese encephalopathy demonstrated that increased manganese concentrations in the basal ganglia and hypothalamus normalize within 5–7 months.[200,201] This pattern is similar to the MRI abnormalities seen in the scans of patients with chronic liver failure.[202] The intensity of images depends on the exact image parameters; therefore, the pallidal index varies between studies and is a semi-quantitative measure of Mn concentrations in the brain. Other causes of high-intensity signals on T1-weighted images include hepatic cirrhosis with portosystemic shunt, primary biliary cirrhosis, congenital biliary atresia, Rendu-Osler-Weber syndrome with diffuse intrahepatic portosystemic shunt, patent ductus venosus, total parenteral nutrition, Mn exposure during welding, lipid deposition, hemorrhage, iron and copper deposits, and neurofibromatosis.[203] Most welders with high signal intensity on T1-weighted images are asymptomatic.[204] Studies on *in vivo* dopaminergic presynaptic nerve terminal function within the nigrostriatal system are conflicting. In contrast to patients with idiopathic Parkinson's disease including those conditions induced by methylphenyltetrahydropyridine (MPTP), some studies on positron emission tomography (PET) scans with 6-fluorodopa have not demonstrated abnormalities of the nigrostriatal dopaminergic projections in manganese workers with mild Parkinsonism-like symptoms.[205,206] In a welder with clinical manganism, the ^{18}F-DOPA PET scan was normal, demonstrating the integrity of dopamine production and secretion up to the site of the damaged dopamine receptors in the putamen.[207] A case series of 27 Mn-exposed welders reported a modest reduction in ^{18}F-DOPA uptake in the caudate nucleus indicating presynaptic dopaminergic dysfunction in the nigrostriatal system; however, the study detected no clear dose-response association

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. between Mn exposure or Parkinson (UPDRS3) scores and ^{18}F-DOPA uptake.[208]

Manganese–Methcathinone Encephalopathy

In Russia and Eastern Europe, the chronic, intravenous use of methcathinone (2-methylamino-1-phenylpropan-1-one, ephedrone, Jeff) prepared by adding pseudoephedrine to the oxidant, potassium permanganate, in the presence of acetic acid was associated with a neurological disease similar to manganism.[209,210] These individuals have MRI abnormalities in the globus pallidum and striatum along with speech impairment, typical cock-walk gait, symmetrical bradykinesia, dystonias, and difficulty with backward motion. MRI imaging of active intravenous ephedrone users indicates that the primary Mn deposits in the brain occur in the globus pallidus based on hyperintense T1-weighted images; increased signal intensities also may develop in the substantia nigra, periaqueductal gray matter, and cerebral pedunculi.[211] Typically, less signal intensity occurs in the dorsal striatum (caudate nucleus, putamen), internal capsule, and white matter; however, some abnormalities may develop in the white matter of active users.[212]

HEALTH SURVEILLANCE

Risk Assessment

The US EPA established the RfC for exposure to inhaled manganese of 0.05 μg/m^3 based on neurobehavioral and psychomotor impairment (finger tapping, hand steadiness) in workers exposed to manganese dioxide at a Belgian battery factory.[213] The estimated lowest-observed-adverse-effect level (LOAEL) was 150 μg Mn/m^3; this concentration was adjusted for nonoccupational lifetime exposure and an uncertainty factor (1,000) to yield an R_fC of 0.05 μg Mn/m^3. Based on benchmark dose methodology, safe occupational exposure guidelines for manganese are ~0.1–0.3 mg/m^3 as an 8-hour time–weighted average of the respirable particulate fraction only.[214] The US EPA reference dose (RfD) for oral manganese exposure is 0.14 mg/kg/day based on the upper range of dietary essentiality (10 mg/day)/70 kg.

Environmental Monitoring

Environmental monitoring of total and respirable dust remains the best method for monitoring workers exposed to manganese. The US OSHA PEL for manganese and manganese compounds is a ceiling limit of 5 mg/m^3 as the fume and a PEL–TWA of 1 mg/m^3 as dust. A cross-sectional study of manganese workers chronically exposed (mean exposure, ~20 years) to ambient air manganese averaging ~0.2 mg/m^3 did not detect any subclinical neurological effects as measured by the prevalence of neurological symptoms and neuropsychological testing.[215] NIOSH established an REL–TWA for manganese compounds and manganese fume of 1 mg elemental Mn/m^3 and a REL–STEL of 3 mg elemental Mn/m^3. The IDLH level was defined as 500 mg Mn/m^3. Table 19.3 outlines current occupational and environmental standards. In 2013, the ACGIH reduced the recommended TLV–TWA for

TABLE 19.3. Occupational and environmental exposure standards for manganese.

Exposure Limit	Value
OSHA	
PEL-TWA (8-hour)	
Mn (fumes)	0.2 mg/m^3
PEL–STEL (15-minute)	
Mn (fumes)	3 mg/m^3
Inorganic Mn	3 mg/m^3
PEL-Ceiling	
MMT	5 mg/m^3
NIOSH	
REL–TWA (10-hour)	
Inorganic Mn	1 mg/m^3
MMT	0.1 mg/m^3
REL–STEL (15-minute)	3 mg/m^3
IDLH	500 mg/m^3
ACGIH	
TLV–TWA	
Mn (respirable particulates, mostly <4 μm)	(8-hour, skin notation) 0.02 mg/m^3
Mn (inhalable particles, some >4 μm)	0.1 mg/m^3
MMT	0.1 mg/m^3
BEI	None
US EPA	
RfC (chronic inhalation exposure)	5×10^{-5} mg/m^3
RfD (chronic oral exposure)	0.14 mg/kg/day
Drinking Water Guidelines	
US EPA	0.05 mg/L
WHO	0.4 mg/L

Mn to 0.02 mg Mn/m^3 (respirable particulate matter), 0.1 mg/m^3 (inhalable particulate matter), and 0.1 mg/m^3 for inorganic manganese compounds to reduce the potential for subclinical effects on neurological and neurobehavioral function. This recommendation is based on the reported development of subclinical effects (e.g., hand steadiness, finger tapping, hand-eye coordination, reaction time) in workers exposed to manganese fumes at concentrations below 1–5 mg/m^3.[213,216,217] The US OSHA established a PEL–TWA for manganese cyclopentadienyl tricarbonyl of 0.1 mg Mn/m^3 with a skin notation. The US EPA established a 50 μg/L limit for manganese in drinking water to prevent visual discoloration and undesirable taste associated with Mn concentrations above this guideline.

The World Health Organization increased the recommended manganese drinking water guideline to 0.4 mg/L based on a tolerable daily intake of 0.06 mg/kg body weight by dividing a NOAEL of 11 mg/day[218] by an uncertainty factor of 3 and an adult body weight of 60 kg.[30] Frequently, the presence of discoloration and/or a disagreeable odor limits consumer acceptability of drinking water containing Mn concentrations above 0.05 mg/L. The Mn guideline for children remains controversial because of concern about the effect of manganese on cognitive and motor function in the developing brain.[219,220]

Biological Monitoring

Blood

No practical biological marker (e.g., homovanillic acid)[221] accurately reflects the intensity of manganese exposure because the primary route of manganese excretion is the bile; additionally, efficient homeostatic mechanisms limit the fluctuation of manganese in the blood. Monitoring of blood manganese confirms recent Mn exposure (i.e., few weeks) based on the relatively short half-life of Mn in the blood, but correlation of these concentrations to cumulative exposure or chronic manganese poisoning depends on the type of exposure.[222] The high variability of whole blood manganese concentrations limits the usefulness of these biomarkers on an individual basis; however, blood Mn concentrations reflect current average daily air Mn concentrations when exposures are relatively consistent or cumulative exposure when exposures are highly variable in time and concentration.[223] Field studies of foundry furnacemen suggest the blood Mn concentrations return to baseline ~5 weeks after cessation of Mn exposure.[151] Because of large interindividual variation, the interpretation of biological monitoring data should be done on a group basis.

Dry-Cell Battery Production

In a cross-sectional study of 100 workers in a dry cell battery manufacturing plant, the mean whole blood concentration was significantly higher in samples from Mn-exposed workers than unexposed controls.[224] The mean whole blood Mn concentration in blood samples from controls was 7.5 ± 2.7 (range, 2.6–15.1 μg/L) compared with 13.8 ± 4.4 μg/L (range, 6.1–23.3 μg/L) for samples from workers exposed to a mean ambient air Mn concentration of 0.4 mg/m^3.

Ferroalloy Smelters

In a study of 94 ferroalloy production workers exposed to manganese oxides (mean airborne Mn concentration, 202.6 μg/m^3; range, 5–740 μg/m^3) and 87 maintenance workers matched by age and smoking habits, the whole blood Mn concentrations were 10.3 ± 3.8 μg/L and 5.9 ± 1.7 μg/L, respectively.[225] For the exposed group, the whole blood Mn correlated to airborne Mn concentrations, but there was very high variability in this correlation between workers. The study did not demonstrate a correlation between blood Mn and measures of cumulative Mn exposure. A study of blood Mn concentrations in ferroalloy smelter workers indicated that whole blood Mn concentrations of <10 μg/L were associated with exposure to airborne Mn concentrations of <200 μg/m^3.[226]

Welders

In a study of 96 welders exposed to air manganese concentrations ranging from 3–4620 μg/m^3 (geometric mean = 97 μg/m^3), the arithmetic mean of manganese in whole blood samples from the welders was 8.6 μg/L with a range of 3.7–24 μg/L.[227] This arithmetic mean was statistically different from the whole blood manganese concentration (mean controls = 6.9 μg/L; range, 2.5–14 μg/L) in turners and fitters from the same plant without exposure to welding fumes.

Urine

Urine Mn concentrations, plasma Mn concentrations, and serum prolactin concentrations are not reliable measures of exposure to Mn.[223] A cross-sectional study of ~100 workers exposed to manganese dioxide up to 794 μg/m^3 was not able to distinguish exposed workers and referents based on spot urine manganese concentrations.[224]

Medical Monitoring

The medical examination should focus on abnormalities in the pulmonary and central nervous systems. Useful measures for screening tests include pulmonary function tests, simple reaction times, and hand tremor.[213] Neuropsychological testing must be used with caution because these tests are not specific, and the normal ranges are not well defined for specific populations.

TREATMENT

Treatment for chronic manganese toxicity is primarily supportive. There are no effective chelating agents available for clinical use during manganese intoxication.[228] Chelation therapy with $CaNa_2EDTA$ increases the urinary excretion of manganese; case reports suggest symptoms of an acute manganese-induced psychosis may improve following chelation.[229] However, the use of chelation therapy including $CaNa_2EDTA$, does not usually alter chronic neurological symptoms.[216,230] During a 21-day course of dimercaptosuccinic acid (DMSA), no significant improvement in symptoms or reduction of blood manganese concentrations occurred in two workers with chronic manganism.[231] A case report associated the use of para-aminosalicylic acid with improvement in two cases of chronic manganese poisoning,[232] but there is little experimental or clinical data to support the use of para-aminosalicylic acid at the present time. Occasionally, L-dopa and Sinemet (carbidopa/levodopa 25/250) may reverse some neurological symptoms (e.g., cogwheel rigidity, tremor), but these anti-Parkinson drugs are typically not effective,[233] particularly for dystonias.[147,234]

POTASSIUM PERMANGANATE

PHYSIOCHEMICAL PROPERTIES

Permanganates are strong oxidizing agents with +7 valence. Table 19.4 lists some physiochemical properties of potassium permanganate. The ingestion of potassium permanganate crystals/solution produces brown-black stains on the hands, lips, and oropharynx.

TABLE 19.4. Identifying information and physical properties of potassium permanganate.

Property	Value
Synonyms	Permanganic acid, potassium salt; Chameleon mineral
Chemical formula	$KMnO_4$
CAS RN	7722-64-7
Mass (g/mol)	158.04
Color	Purple
Physical state	Solid
Melting point (°C)	240–270
Boiling point	Decomposes
Solubility	Soluble in water (64 g/L at 20°C), acetone, and sulfuric acid

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.

EXPOSURE

The electrolytic oxidation of MnO_2 in KOH produces potassium permanganate. This compound is a corrosive, water-soluble cleansing and antiseptic agent for suppurative wounds; other uses include metal cleaning, bleaching, and as a preservative for flowers and fruits. Potassium permanganate is available as a 300-mg tablet or dark purple bronze crystals. Medicinally, a 1:10,000–1:20,000 dilution of potassium permanganate is applied to an oozing dermatitis for mild antiseptic and drying properties. Commercial applications of potassium permanganate involve the photographic, pharmaceutical, and chemical industries. Historical uses for potassium permanganate include the induction of abortion, urethral irrigation for gonococcal urethritis, stomach lavage for alkali poisoning, and treatment of snake envenomation.[235]

DOSE EFFECT

Solutions of potassium permanganate of >1:5,000 are corrosive. Most toxic exposures result from the mistaken ingestion of topical compounds with most deaths resulting from edema of the epiglottis or circulatory failure.[236] The estimated minimal lethal adult dose is ~10 g of solid $KMnO_4$ (1.5 teaspoons of the crystals) based on the corrosive effects of $KMnO_4$ on the upper airway rather than systemic effects.[237,238] A patient survived the ingestion of 25 g $KMnO_4$ powder with the development of esophageal strictures.[239] A fatal hemorrhagic pancreatitis was associated with the ingestion of an estimated dose of 20 g $KMnO_4$.[240]

The ingestion of two 325-mg potassium permanganate tablets followed by saline lavage produced a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

first-degree chemical burn of the esophagus and stomach without sequelae.[241] E. Gruyz-Harday described a 68-year-old man who consumed 15–20 g potassium permanganate, vomited, and died within 40 minutes.[242] The use of potassium permanganate as an abortifacient was fatal, probably as a result of hemorrhage and perforation of the gastrointestinal tract.[243] The subcutaneous injection of 7 g potassium permanganate resulted in hypermagnesemia (21.7 mg Mn/L 4 days after administration), local irritation, mild elevation of hepatic aminotransferase levels, and ultrastructural changes in the liver.[244]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Potassium permanganate is a powerful oxidizing agent that produces coagulation-type necrosis similar to that produced by an acid. A brown, purplish, or black stain forms on the skin or pharyngeal surfaces as a result of the formation of manganese dioxide. The brown stains are frequently difficult to differentiate from corrosive burns.[245] Perforation of the gastrointestinal tract is unusual. In rare circumstances, hepatorenal damage may result from systemic absorption. An autopsy of a patient dying 6 days after the ingestion of 5–10 g potassium permanganate crystals demonstrated severe fatty change of the liver, subcortical and papillary petechial hemorrhages of the kidneys, renal tubular necrosis, severe esophagitis, hemorrhagic gastritis, and cerebral petechial hemorrhages.[246] Rarely, the ingestion of potassium permanganate causes clinically significant methemoglobinemia that produces cyanosis and hypotension. Ingestion of herbal preparations containing potassium permanganate produced severe methemoglobinemia in two adults.[247]

CLINICAL RESPONSE

Ingestion of concentrated solutions or tablets of potassium permanganate causes local corrosion manifested by burning of the mouth, chest pains, abdominal pain, nausea, and vomiting. Deliberate ingestion of concentrated potassium permanganate may cause methemoglobinemia, hypotension, with cyanosis, metabolic acidosis, hemolysis, altered mental status (hallucinations, coma), and pancreatitis. In severe cases, disseminated intravascular coagulation, hepatorenal failure, acute respiratory distress syndrome, and cardiogenic shock may occur within 36 hours of ingestion.[248] Perforation of the gastrointestinal tract and septic shock may complicate the clinical course of potassium permanganate poisoning or the use of this compound as an abortifacient.[249,250] Dyspnea and stridor are serious clinical effects that indicate epiglottic and/or tracheal edema. Although the accidental ingestion of potassium permanganate is not usually associated with long-term sequelae,[251] strictures and perforations of the gastrointestinal tract occasionally occur following intentional ingestion of concentrated solutions. Pyloric stenosis developed after the ingestion of 8 g of potassium permanganate tablets by a suicidal patient, who initially presented with epigastric pain and vomiting.[252] A fatal hemorrhagic pancreatitis was associated with the ingestion of a large dose of $KMnO_4$.[240]

The mistaken ingestion of an 8% potassium permanganate solution over 4 weeks (cumulative dose, 10 g) produced initial gastrointestinal distress (the abdominal cramps remitted after several doses), hair loss, paresthesias, diaphoresis, decreased concentrating ability, somnolence, visual impairment, and muscle fasciculations.[253] Nine months post-ingestion, the patient developed parkinsonian syndrome. Gastrointestinal injury may occur without systemic toxicity.

DIAGNOSTIC TESTING

Although elevated manganese concentrations may appear in blood and urine after potassium permanganate toxicity, poisoning may exist without elevated Mn concentrations. Five days after the reported ingestion of 5–10 g potassium permanganate crystals, the whole blood Mn level was 90.5 μg/L (1.63 μmol/L), and 30 hours later, the Mn concentration decreased to 42.2 μg/L (0.76 μmol/L).[246] Shortly after the last Mn concentration was drawn, the patient died from fulminant hepatic failure.

After the unintentional cumulative ingestion of 10 g KMnO4 over 4 weeks and during $CaNa_2EDTA$ chelation, a 66-year-old man developed a resting tremor, paresthesias, hyperreflexia, poor concentration, and abdominal distress. His peak blood manganese concentration was 150 μg Mn/L (normal value 48 ± 20 μg Mn/L) as measured by flameless atomic absorption spectrometry.[253] The whole blood values should be interpreted cautiously because of methodological limitations and the timing of the specimen. In severe intoxication, methemoglobin levels, serum hepatic aminotransferase levels, serum creatinine, and complete blood count should be determined. Albuminuria may develop after the ingestion of concentrated (4–5%) $KMnO_4$ solutions.

TREATMENT

Management is primarily supportive. The immediate life-threatening problems following intoxication with potassium permanganate are epiglottic edema, hemolysis, hemorrhage, metabolic acidosis, and hypotension. In unusually severe cases with evidence of methemoglobinemia, methylene blue therapy for methemoglobinemia may be necessary. Potassium permanganate ingestions should be treated similarly to acid ingestions. Do not induce emesis. Most accidental exposures require only dilution with water. Decontaminate the eyes and skin with copious saline irrigation. Areas of exposure display the characteristic dark purple staining that turns brown after the formation of MnO_2. Dilute oxalic acid removes the brown stain by converting the manganic ion to the colorless manganous ion. Currently, no effective measures are available to enhance manganese elimination. Neither dimercaprol (BAL) nor $CaNa_2EDTA$ increases manganese excretion.[244] Endoscopy within 12–48 hours of ingestion may be necessary as a method of evaluating the severity of the chemical burn when clinical evidence of upper gastrointestinal tract burns (drooling, dysphagia, abdominal pain) or large suicidal ingestions occurs. No studies are available to guide the clinical use of steroids in the management of potassium permanganate burns.

ORGANIC MANGANESE

HISTORY

There is little history on organic manganese because of limited exposure to organic manganese compounds. The risk of exposure to low concentrations of manganese is being reevaluated as a result of the potential exposure of the general population to manganese released from the combustion of unleaded gasoline containing the anti-knock agent methylcyclopentadienyl manganese tricarbonyl (MMT).

PHYSIOCHEMICAL PROPERTIES

The industrially important organometallic compounds are methylcyclopentadienyl manganese tricarbonyl

TABLE 19.5. Identifying information and physical properties of organic manganese compounds. (Data from International Programme on Chemical Safety).[11]

	MMT	Maneb	Mancozeb
Synonyms	Methylcyclopentadienyl manganese tricarbonyl, Methyl-cymantrene, Antiknock-33, Manganese tricarbonyl methylcyclopentadienyl	Manganese ethylene-bis-dithiocarbamate, Trimangol 80, Ethylene-bis (dithiocarbamic acid), manganous salt Dithane	Manganese ethylene-bis-(dithiocarbamate) (polymeric) complex with zinc salt, Dithane M-45, Manzate, Manzaeb, Zimaneb
Chemical formula	$C_9H_7MnO_3$	$C_4H_6MnN_2S_4$	$C_4H_6MnN_2S_4{\cdot}C_4H_6N_2S_4Zn$
CAS RN	12108-13-3	12427-38-2	8018-01-7
Mass (g/mol)	218.10	265.31	541.03
Color	Dark orange-red	Yellow-brown	Grayish-yellow
Physical state	Liquid	Powder	Powder
Melting point (°C)	1.5	Decomposes on heating	Decomposes without heating
Boiling point (°C)	232.8	Decomposes on heating	Decomposes
Solubility	Practically insoluble in water (0.029 g/L at 25°C); completely soluble in hydrocarbons	Slightly soluble in water; soluble in chloroform	Practically insoluble in water (0.006 g/L at 25°C) as well as most organic solvents
Log K_{ow}	3.7		1.33
HLC	0.019		

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number; HLC = Henry's Law constant; K_{ow} = octanol–water partition coefficient.

(MMT) and cyclopentadienyl manganese tricarbonyl (CMT). MMT is a yellow, water-soluble, volatile liquid with an herbal odor. Table 19.5 lists identifying information and physical properties of industrially important organic manganese compounds.

EXPOSURE

Uses for organomanganese compounds include an anti-knock additive in leaded gasoline, fuel oil additive, smoke inhibitor, and fungicide. The organomanganese additive for gasoline (MMT) is produced by the reaction of manganese chloride, cyclopentadiene, and carbon monoxide in the presence of manganese carbonyl. Although the use of MMT decreases the release of carbon monoxide, the US EPA originally banned the use of MMT because MMT increases hydrocarbon emissions from catalytic converters.[254] However, a US Federal Court decision allowed the use of MMT in the US beginning in December 1995. Recent risk analysis by the US EPA suggests that exposure to substantial portions of the urban population would exceed the RfC of 0.05 μg Mn/m^3 if all unleaded gasoline contained MMT at a concentration of 0.031 g Mn/gal.[39] MMT has been a fuel additive (maximum allowable, 0.018 μg Mn/L or 0.68 μg Mn/gal) in Canada since 1976.[136]

ENVIRONMENTAL FATE

The contribution of organometallic manganese compounds to ambient air Mn concentrations is relatively small (13 ng Mn/L) even in urban air because the use of these compounds is limited to anti-knock agents in leaded and unleaded gasoline.[255] Combustion products of MMT-containing gasoline in exhaust represent <15% of the Mn in gasoline.[256] Emissions from MMT in gasoline appear in submicron particles (mass median aerodynamic diameter <1 μm); the tailpipe exhaust products include manganese phosphate, manganese sulfate, and Mn_3O_4 that may disperse widely in inhalable forms.[257] Manganese oxides represent <20% of these combustion products. In countries (e.g., Canada) using MMT in gasoline, the air concentrations of manganese depend on the concentration of MMT in gasoline and the gasoline consumption patterns. From 1989–1992 (i.e., after the replacement of leaded gasoline with MMT), the Canadian air manganese concentrations as measured in particulate matter with an aerodynamic diameter ≤2.5 μm remained relatively constant. The ambient air concentrations during this period ranged from 0.11–0.013 μg/m^3 in small cities to 0.02–0.025 μg/m^3 in larger cities without industrial Mn sources (e.g., silicomanganese and ferromanganese facilities).[258] A year-long population-weighted study of personal exposures to particulate matter ($PM_{2.5}$) in Toronto, Canada, suggested the preponderance of personal Mn exposure was derived from non-MMT sources.[259] The mean and median exposure of participants to $PM_{2.5}$ Mn were 14 ng/m^3 and 8.5 ng/m^3, respectively; however, the omission of participants with non-MMT sources of Mn (e.g., tobacco smokers, metal workers, subway riders) reduced the mean and median $PM_{2.5}$ Mn exposure to 8.3 ng/m^3 and 7.0 ng/m^3, respectively. Although the use of MMT as an anti-knock agent increases the exposure of specific subsets of the general population to manganese in these countries, the exposure of these populations remains below international standards.[31]

DOSE EFFECT

Although current data indicate that exposure to manganese as a result of the combustion of MMT in gasoline is small compared with occupational exposure to manganese, there are few data that delineate the risks of the use of MMT in fuels.[260]

TOXICOKINETICS

There are few data on the toxicokinetics of organic manganese compounds in humans. Rodent studies suggest MMT is well absorbed from the gastrointestinal tract and excreted primarily as hydroxylated metabolites in the urine.[261] These studies indicate the gut absorbs most MMT excreted in the bile, and the kidney excretes most of the absorbed dose of MMT. Consequently, little MMT appears in the feces.

CLINICAL RESPONSE

MMT in car exhaust degrades to manganese salts (sulfate, phosphate, tetroxide). There are few human data on MMT toxicity; however, human exposures should be consistent with inhalational exposures to manganese salts.

Chapter 20

MERCURY

Mercury exists in three forms: elemental mercury (Hg^0), inorganic mercury (Hg^+, Hg^{2+}), and organic mercury ($C_nH_nHg^+$). The sources, type of exposure, toxicokinetics, and biological effects vary between these different forms. The most common exposures to mercury result from metallic mercury vapor in occupational processes and use of dental amalgams, methylmercury in edible fish tissues, and ethyl mercury in preservatives (e.g., multidose vaccine vials). The latter has been removed from most vaccines in the United States.

ELEMENTAL MERCURY

HISTORY

Since early times, mercury has fascinated man; the mining of cinnabar (mercury sulfide) dates back at least to the late Neolithic/Chalcolithic period (3,400–2,100 BC) near Almadén, Spain.[1] Aristotle named metallic mercury quicksilver; this term has been associated with the misconception that mercury quickens a boxer's punches.[2] Later, Pliny recognized the severe illnesses associated with mining mercury ores. During the Arab domination of Spain, mercury was an important constituent in medicines and the extraction of gold (alchemy). The King of Spain established a penal colony at these mines in the 16th century to provide a labor force for mercury production. The penal colony was closed in 1801; however, mercury production continued there until 2000, when the Almadén mines became uneconomical as mercury prices fell.

Although inorganic mercury was the main chemotherapeutic agent, elemental mercury was also a treatment for syphilis during the 500 years before the introduction of less toxic heavy metals (bismuth, arsenic) in the late 1800s and the advent of penicillin therapy in the 1940s.[3] Paracelsus (Philippus von Hohenheim) and other physicians in the Middle Ages were early proponents of mercury chemotherapy for syphilis including the administration of elemental mercury vapor by fumigation as well as oral inorganic mercury salts (e.g., mercurous chloride).

Medicinal and dental uses of elemental and inorganic mercury became widespread in the 19th century.[4] The French dentist, Auguste Taveau, introduced the use of silver and mercury amalgams for filling dental cavities in 1826.[5] Silver, copper, and tin were the first metals used in various ratios for dental amalgam; however, many other metals were added later to amalgam including gold, platinum, zinc, bismuth, cadmium, nickel, manganese, indium, lead, and aluminum. With the discovery of *Treponema pallidum* in 1905 and the publication of the Oslo Study on untreated syphilis indicating many syphilitic cures attributed to mercury chemotherapy probably resulted from the natural fluctuation of cutaneous luetic infections, the use of mercury for this disease declined.[3] Bismuth replaced mercury after World War I as a more effective and less toxic alternative. Subsequently, the synthetic arsenicals (salvarsan, Neosalvarsan) became the mainstay of syphilis treatment; however, mercury chemotherapy remained in use until penicillin became the standard agent around 1940.

PHYSIOCHEMICAL PROPERTIES

Mercury is a member of Group 12 (Group 2B) of the periodic table along with cadmium and zinc. Elemental mercury (Hg^0, CAS RN: 7439-97-6) is a silver-white, odorless liquid at room temperature with high surface tension. Synonyms for elemental mercury include colloidal mercury, hydrargyrum, liquid silver, metallic mercury, and quicksilver. Mercury is the only metal that is a liquid at room temperature. Above that temperature, elemental mercury quickly vaporizes. Thus, elemental mercury is the main volatile form of mercury in air. At 20°C, a saturated atmosphere of elemental mercury contains 15 mg Hg/m^3; this concentration is several hundred times higher than current occupational standards for elemental mercury as an 8-hour TLV–TWA.[6] Table 20.1 lists the identifying information and physical properties of elemental mercury. Mercury is a non-essential metal with no known physiological function in the human body.

Valuable commercial properties of elemental mercury include high specific gravity, uniform expansivity, electrical conductivity, fluidity at room temperature, and ability to alloy with metals.

EXPOSURE

Uses

Chloralkali plants use large quantities of mercury as cathodes in the electrolysis of sodium chloride solutions during the production of caustic soda and chlorine gas, resulting in the release of elemental mercury into ambient air. By-products (e.g., hydrogen, sodium hypochlorite, hydrochloric acid) of this process all contain mercury. Mercury is also a constituent of processes that produce dyes, urethane foam, and vinyl chloride monomers. Commercial applications of mercury-containing compounds include light sources (mercury vapor lamps), arc rectifiers, battery cells, control instruments (barometers, switches, thermostats), disinfectant and stool preservatives, and medical instrumentation. Liquid elemental mercury is a component of some gold extraction processes, particularly those processes used in small "cottage" industries.[7] Gold ores are ground mechanically to a fine powder with the addition of liquid mercury to bind the gold into a gold-mercury amalgam; heating the amalgam vaporizes the mercury and leaves a raw gold sponge. The latter step exposes the workers (amalgam burners) to high concentrations of elemental mercury. Nonspecific neuropsychiatric symptoms were associated with occupational exposure to mercury in a worker who repaired sphygmomanometers in a poorly ventilated shop.[8] A study of children from workers in a mercury thermometer manufacturing plant revealed elevated urine mercury concentrations; however, physical examination of these children revealed no obvious evidence of mercury toxicity.[9]

In the United States, dentists use >100 tons of mercury annually; individual dentists in private practice use ~2–3 pounds of mercury per year.[10] The use of mercury amalgams has decreased with the increasing use of composite materials. The exact mercury content of amalgam varies from 42% (conventional "dry" mouths) to 60% mercury ("wet"). Conventional silver amalgam typically contains 50% mercury, 35% silver, and 10% tin by weight, as well as traces of copper and zinc. Alternatives to dental amalgam include the following: 1) composites of plastic material, 2) porcelain, and 3) gold. The average life span of amalgam is ~10 years.

Many potential sources of mercury exposure exist in a dental office including the following: accidental spills, poor mercury hygiene, normal milling to express excess mercury for freshly mixed amalgam, mechanical amalgamators, ultrasonic analgesic condensers, heating of the amalgam carrier to dislodge set particles, failure to use high-vacuum suction while removing old amalgam restorations, and improper dry heat sterilization of amalgam-contaminated instruments. Depending on the procedure for handling amalgam and the type of ventilation, the mercury concentration in ambient air of some dental operation rooms may exceed current US occupational standards (50 µg Hg/m^3).[11] In a study of Swedish dental clinics with relatively low airborne mercury vapor concentrations (median, 3.6 µg/m^3 in private clinics), the urine mercury concentrations of the dental personnel were similar to the general population; there was no correlation

TABLE 20.1. Identifying information and physical properties of elemental mercury. (Based on International Programme on Chemical Safety).[6]

Physical Characteristic	Value
CAS RN	7439-97-6
Synonym	Quicksilver, mercury, elemental mercury, mercury vapor
Atomic weight (g/mol)	200.59
Melting point (°C)	−38.87
Boiling point (°C)	356.72
Density (25°C)	13.534 g/cm^3
Water solubility (25°C)	0.28 µmol/L
Vapor pressure (mmHg 25°C)	2×10^{-3}

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.

between the prevalence of symptoms and urine mercury concentrations.[12]

Production Processes

Mining of elemental mercury involves the underground collection of mercury ore in the form of cinnabar (mercuric sulfide) followed by filtration, re-distillation, and electrolytic processing to purify the mercury in cinnabar. The Almadén mercury mine in Spain produced 90% of the total output of mercury for the European Community. Following the closure of mercury mines in the United States during the 1990s, recycling of mercury-containing products (e.g., mercury batteries, dental amalgams, switches/thermostats, manometers, chloralkali wastewater sludges, chemical solutions, fluorescent light tubes[13]) and by-products of gold mining became the primary sources of mercury.[14]

Sources

Mercury is ubiquitous in the environment. Comparing estimates of the amount of mercury contributed to the environment by anthropogenic sources (i.e., from human activity) and natural sources is complicated by the difficulty in estimating emissions from terrestrial and marine systems as well as the "recycled" anthropogenic sources. Some estimates suggest natural sources emit up to three times more mercury than anthropogenic sources.[6] Important human (i.e., anthropogenic) sources of mercury include combustion of fossil fuel[15] and household waste, smelting of metal sulfide ores, refining of gold, production of cement, and industrial metal applications.[16] The major natural sources of mercury include evaporation of elemental mercury from water, emissions from volcanoes, and off-gassing of mercury vapors from the soil. The major potential source of exposure to mercury and mercury compounds in the general population includes the inhalation of elemental mercury from the air, the ingestion of contaminated water and food, and dental and medical therapy (e.g., Ayurvedic medicines).[17] Rasa Shastra is the Ayurvedic practice of combining herbs with gems, metals, and minerals. Analysis of Ayurvedic medicines sold via the Internet indicated these Rasa Shastra medicines contained substantially higher total Hg concentrations than non-Rasa Shastra medicines.[17] For the general population, the three major sources of mercury include fish consumption (methyl mercury) and dental amalgams (elemental mercury); most vaccines in the United States no longer contain ethyl mercury.[18] Dental amalgam fillings release mercury vapor with a daily intake in the range of several micrograms of mercury; this relatively small amount is significantly below Hg exposures producing adverse effects.

Air

Elemental mercury vapor is the main chemical form of mercury released from anthropogenic sources into the atmosphere; the estimated daily mercury absorption from air is <1 μg in urban residents. Ambient air concentrations of elemental mercury are unlikely to exceed 0.05 $\mu g/m^3$, but the presence of point sources (e.g., smelters, mercury mines, application of mercury-containing fungicides) may increase the mercury concentration in ambient air near these sources to ~10–15 $\mu g/m^3$.[19]

The mercury concentration in the work environment may exceed general environmental concentrations. A survey of a mining operation revealed mercury concentrations ranging from 160–4,890 $\mu g/m^3$,[20] whereas some air samples from a milling operation exceeded 1,200 $\mu g/m^3$.[21] The average elemental mercury vapor concentration in 21 chloralkali plants during the early 1970s was 65 $\mu g/m^3$ with 85% of the values of <100 $\mu g/m^3$.[22] Heating mercury in a confined space (e.g., gold extraction processes in nonindustrial settings) may release high elemental mercury concentrations into the air, particularly in artisanal gold mining areas (e.g., rural Columbia, Brazil, Venezuela, Ecuador, Tanzania, Ghana) when the process involves adding Hg to the gold ore prior to milling (i.e., amalgamation of whole ore).[23,24] Inhalational mercury toxicity and pneumonitis also occur during the extraction of gold from recycled jewelry and electronic equipment by using heated Hg in homes in developed countries.[25]

Soil/Spills

Local spills of mercury in the home or work environment represent a potentially serious hazard.[26,27] The complete volatilization of 3 g (1/5 mL) Hg in a 10′ × 10′ × 8′ room can substantially exceed current mercury standards. Attempts to remove the mercury by vacuuming may result in the dispersal of the mercury over a larger surface area.[28] Even though visible traces of liquid mercury are not present, low ambient air concentrations of mercury may persist for several weeks.[29] Mercury in elemental form or an amalgam is necessary to generate ultraviolet radiation in fluorescent lamps via ultraviolet excitation of luminescent powder. Compact fluorescent lamps contain milligram quantities of mercury (i.e., up to 2.5–5 mg) that disperse into the surrounding air following breakage depending on room

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. size, ventilation, room temperature, age of lamp (elemental mercury oxidizes to HgO with use), and location in the room, particularly during the first 4 hours after breakage.[30,31] In contrast to liquid mercury spills, modeling of releases from broken lamps suggests airborne mercury concentrations do not significantly exceed current recommendations, particularly following ventilation and clean-up.[32] More liquid mercury occurs in new than older fluorescent tubes.[33] Mercury vapor bulbs (self-extinguishing or "T"-type, non-self-extinguishing or "R"-type) are long-lasting, bright sources of light in gyms, sports arenas, banks, stores, and street lights.

Elemental mercury is volatile; the rate of evaporation depends on the temperature and surface area of the mercury spill.[34] Young children are particularly susceptible to the development of mercury toxicity including acrodynia following exposure to mercury vapor because of several factors including: 1) closer physical proximity to the source of mercury vapors in carpeting, 2) increased respiratory rate resulting in increased absorption of mercury vapor, and/or 3) decreased body size.[35,36] Volatilization of mercury from broken switches in incubators may increase the absorption of mercury by neonates, but symptoms of mercury toxicity do not usually develop.[37]

Water

Natural weathering of mercury-bearing minerals in igneous rocks directly releases mercury into the surface and underground water sources. Surface runoff transports mercury from the soil into surface waters, particularly from soils with high humic content.[38] The amount of elemental mercury in drinking water typically is toxicologically insignificant (i.e., ~0.05 μg/day).

Diet

For the general population, the most common source of mercury is methylmercury in fish; the amount of elemental mercury in the diet is very small. Uptake of mercury vapors from dental amalgam accounts for most of the exposure to mercury in persons without occupational or dietary exposures.

ENVIRONMENTAL FATE

The natural cycling of mercury involves evaporation of elemental Hg from soils and surface waters, followed by atmospheric transport, deposition of mercury on land and surface waters, and the absorption of mercury to soil or sediment particulates.[14] Figure 20.1 demonstrates

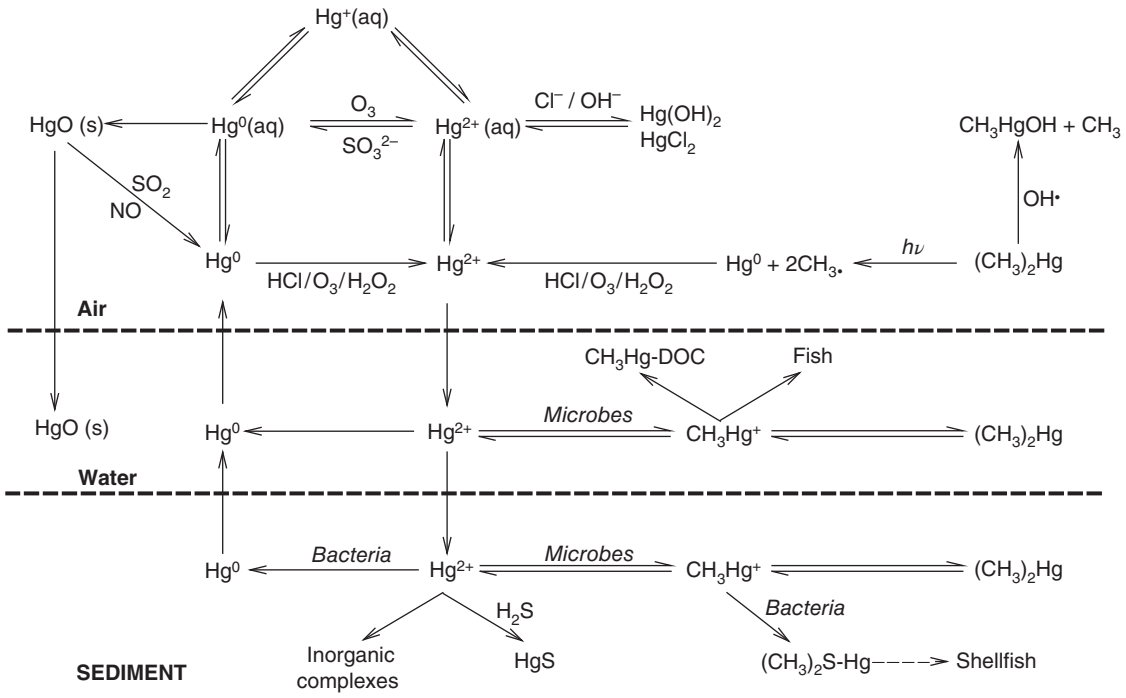

FIGURE 20.1. Mercury transformation in air, water, and sediment. Dashed lines are boundaries between environmental compartments of air, water, and sediment. *Abbreviations:* aq = associated with aqueous environment; DOC = dissolved organic carbon; hν = energy from light; s = solid. (Agency for Toxic Substances and Disease Control).[14]

the global cycle of mercury. Elemental mercury vapor is the dominant form of mercury in the atmosphere with anthropogenic sources for ~25–50% of the total, primarily from the burning of fossil fuels.[39] This form is chemically stable; the residence time of mercury vapor in the atmosphere ranges from 0.4–3 years.[6] In the atmosphere, metallic mercury vapor (Hg^0) undergoes oxidation to divalent Hg by ozone before being removed from the atmosphere by precipitation.

Elemental mercury may travel long distances before wet or dry deposition deposits the mercury on soil or surface waters. Models of the transport of mercury indicate that sources up to 2,500 km away may account for mercury in precipitation.[40] Deposition of the mercury with precipitation accounts for the removal of about 2/3 of the mercury present in the atmosphere;[41] wet precipitation is probably the source of most mercury in lakes that do not receive industrial effluents.[42] In surface waters, biotransformation is the most important transformation process in the environmental fate of mercury. The source of most mercury in groundwater is the atmosphere as a result of the limited leaching of mercury adsorbed to the soil.[43]

Mercury is a highly mobile metal. Simulated studies of the transport of mercury from air to the soil indicate that the penetration of elemental mercury from the atmosphere is limited to the first 3–4 cm of topsoil.[44] In the soil, particulate-bound mercury enters several different pathways including formation and precipitation of insoluble mercury sulfide, off-gassing of volatile or soluble forms of mercury, or bioaccumulation in aquatic and terrestrial food chains.[14]

DOSE EFFECT

Acute Toxicity

Inhalation

Several case reports associate exposure to high elemental mercury concentrations with the development of fatal pulmonary damage similar to acute respiratory distress syndrome; however, the reports did not include airborne mercury concentrations.[45,46]

The accidental exposure of workers to estimated airborne mercury concentrations (>5–10 mg Hg/m^3) for a few hours produced an acute febrile illness with interstitial pneumonitis, gastrointestinal tract irritation, and inflammation of the oral cavity characterized by cough, chest pain, dyspnea, stomatitis, gingivitis, nausea, diarrhea, and salivation.[47,48] Animal studies in rabbits indicate that the inhalation of mercury concentrations of 28.8 mg Hg/m^3 over 4–30 hours produces mild to moderate pathological changes in the lungs, mild to marked cellular degeneration of the colon, marked cellular degeneration with some necrosis of cardiac muscle, moderate to severe liver necrosis, marked degeneration of the kidney, and necrosis of brain tissue.[49] Exposure of these rabbits to the same concentration of mercury vapor for 1–4 hours produced mild to moderate pathological changes in these organs.

Wounds/Injection

Case reports indicate that the absorption of elemental mercury over several days from subcutaneous wounds is relatively small.[50] A 1-mL (13.6 g) injection of elemental mercury caused no symptoms and an increase in the whole blood mercury concentration to 62 µg/L.[51] A 20-mL elemental mercury injection resulted in pleuritic chest pain, dyspnea, and malaise that resolved over several weeks with supportive care. Although the pulmonary embolization of mercury was extensive, no acute or chronic systemic symptoms developed.[52]

Ingestion

The oral bioavailability of elemental mercury is extremely low; therefore, toxicity from the ingestion of elemental mercury is unusual unless large elemental mercury doses are retained within the gastrointestinal tract or released into the peritoneum. A 17-year-old boy ingested 204 g of elemental mercury without systemic toxicity.[53]

Chronic Toxicity

Target Organs

The central nervous system is probably the most sensitive target organ for toxicity following exposure to elemental mercury vapors. Behavioral changes, gingivitis, and tremor occur without pulmonary symptoms following repeated exposure to airborne mercury concentrations near 1 mg/m^3. A study of chloralkali workers exposed to elemental vapor concentrations up to 0.1 mg/m^3 did not demonstrate any effects attributable to mercury exposure.[22] In a study of plant manufacturing thermometers, workers with mean Hg exposure to 0.076 mg/m^3 (range, 0.026–0.27 mg/m^3) demonstrated a greater incidence of static tremor and heel-to-toe gait disturbances compared with workers without occupational exposure to mercury.[54] In a cross-sectional study of 43 chloralkali workers and 22 age-matched, unexposed referents, there were no significant associations

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

with current or cumulative mercury exposure and measures of eye-hand coordination or diadochokinesis.[55] The median mercury exposure time for the exposed workers was 13 years (range, 2–32 years) with a mean current urine mercury concentration of 7.7 μg/g creatinine (range, 1.3–25 μg/g creatinine) compared with 0.9 μg/g creatinine (range, 0.2–4.1 μg/g creatinine) for referents.

Few data support the liver or kidneys as target organs of mercury toxicity, particularly in humans. In rats exposed to elemental mercury vapor of 3 mg/m^3, 3 hours/day, 5 days/week for 15–42 weeks, behavioral changes included a decline in conditioned avoidance response and increased latency in the pole climb shock escape response. Pathological examination demonstrated slight degenerative changes (lysosomal inclusions, black intracellular deposits in tubular epithelium) developed in the kidneys without any detectable liver injury.[56]

Dental Amalgam

Dental amalgam is a solid emulsion composed of ~50% elemental mercury with the remainder consisting of a metallic powder (silver, tin, copper, indium, palladium, zinc).[57] For the general population, elemental mercury vapor released from dental amalgams is the second most common mercury source after methylmercury in fish; however, the amount of mercury vapor released during mastication remains substantially below concentrations associated with mercury toxicity. Three potential mechanisms for the release of mercury from fillings include: 1) a corrosive process that liberates mercury ions from the effect of saliva and oxygen on the amalgam; 2) mercury absorption from the dissolution of solid corrosion products and amalgam debris in the gastrointestinal tract; and 3) inhalation of vaporized mercury during mastication, dental filling procedures, or the removal of old amalgam restorations.[58] Abrasion of the dental amalgam is the primary process causing mercury release from the amalgam; this mechanism accounts for three times the mercury release from amalgam fillings than corrosion.[59] Chewing causes a several-fold increase in the release of mercury vapors from dental amalgam with the mercury concentrations returning to baseline after ~90 minutes.[60] Solid or dissolved forms of mercury enter the gastrointestinal tract where elemental mercury absorption is minute. Based on similar ratios of mercury in the erythrocytes and plasma of mothers and their fetuses, fetal exposure to elemental mercury vapor from dental amalgam probably does not exceed maternal exposure.[61]

Absorbed Dose

Even though the amount of mercury absorbed from dental amalgams is extremely small and clinically insignificant, the contribution of dental amalgams to the average mercury exposure of the general population may be a substantial portion of the average daily Hg uptake from all sources. Several studies correlated the number and surface area of dental fillings to mercury content in tissues.[62,63]

Accurate estimation of mercury uptake by the human body is complicated for technical reasons and substantial individual variation including the number of total and occlusal amalgam surfaces. Earlier estimates of daily mercury uptake from dental amalgams substantially overestimated the absorbed Hg dose (2.5–17.5 μg/day);[64] however, later estimates were lower (e.g., 1.4 μg Hg) from better instrumentation (intraoral flow rate, collection volume) and approximation of physiological Hg release rates without (i.e., nasal breathing) and with eating (i.e., saliva-covered surfaces), intraoral flow rate, and inspiratory volume per breath.[65,66] Estimates of daily mercury intake from dental amalgam based on volunteer studies range from 1–2 to 5–9 μg for subjects with an average number of dental amalgam.[67] A Norwegian study suggests individuals with over 26 restorative amalgam surfaces absorb 10–12 μg Hg/day,[68] whereas the estimated daily absorbed Hg dose from a randomized, controlled, three-armed trial comparing treatment and non-treatment strategies ranged from 2.3–2.7 μg for a medium amalgam load (median = 25 surfaces) to <7.4 μg for a high amalgam load (45 surfaces).[69] The European Commission's Scientific Committee on Emerging and Newly Identified Health Risks concluded dental amalgam already in place is not a health risk for the general population; they recommended against removing amalgam restorations as a preventive measure.[70] In some situations (e.g., large cavities, cavity susceptibility), dental amalgam remains the preferable choice.

Mercury Kinetics

The release of mercury from amalgam restoration is relatively small with peak concentrations occurring shortly after amalgam placement in the dental cavity, then declining to a lower steady-state concentration within 10–15 days.[71] Although there was considerable interindividual variation, *serum* inorganic mercury concentration in 29 elderly women increased by ~0.02 μg/L/amalgam tooth surface corresponding to a daily Hg uptake of 0.2 μg/amalgam surface.[72] Following placements of up to eight new amalgam restorations, urine mercury concentrations were below recommended standards

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(<50 μg Hg/L whole blood; <30 μg Hg/L urine).[59] Complete removal of dental amalgams produces a transient rise in plasma mercury concentrations followed by a reduction in the plasma Hg concentration (i.e., elimination half-life ~30–60 days) to baseline values.[73,74] In an observational study of 12 healthy adults undergoing amalgam removal (mean amalgam surfaces = 18; range, 13–34), peak *plasma* mercury concentrations occurred within 48 hours.[75] Peak *plasma* mercury concentrations were an average of 32% higher than pre-removal plasma Hg concentrations. By 60 days after removal, the plasma mercury concentration had declined exponentially to ~60% of the pre-removal value. Methods to reduce Hg absorption during amalgam removal include high-speed cutting, water cooling, high-volume evacuator use by dental assistants, and rubber dam placement.[76,77] A 1-year observational study followed plasma and urine Hg concentrations in 18 subjects undergoing removal of all amalgam restorations during a single treatment session using a rubber dam and 10 subjects without a rubber dam.[76] The number of occlusal amalgam surfaces was similar in the two groups (12.9 ± 3.6 and 11.3 ± 3.6, respectively), whereas the mean number of total amalgam surfaces for the rubber dam group was 42.8 ± 13.3 compared with 19.9 ± 11.5 in the non-rubber dam group. The peak (1-day) plasma Hg concentration increased by 0.56 ± 1.65 μg/L in the rubber dam group compared with 2.67 ± 3.13 μg/L in the non-rubber dam group ($P = 0.012$). By 1 year, the reduction in plasma and urine Hg concentrations in the two groups was not statistically different (power not reported). Although some health complaints attributed to amalgam restorations may improve following amalgam removal,[78] no convincing scientific evidence supports the benefit of removing normally functioning dental amalgams to relieve non-dental-related symptoms other than the placebo effect.[79]

Dose Response

Despite lay concern about the release of some elemental mercury from occlusal surfaces containing mercury amalgam during mastication, no cases of acrodynia or other toxic effects are clearly caused by the presence or removal of mercury amalgam. Although chewing releases vaporized Hg^0 into the oral cavity, the release rate is probably too small to cause mercury toxicity. A review of 14 studies on these release rates indicated the mercury dose from fillings (i.e., <10 μg/day) is substantially below acceptable daily intakes even in symptomatic patients who believe their amalgam restorations cause toxicity.[80] Using direct measurements of intraoral mercury vapor, a Swedish case series compared 10 consecutively selected patients referred for evaluation of subjective symptoms they believed were caused by their amalgam restorations (mean occlusal surfaces = 13.0 ± 4.5, mean total amalgam surfaces = 44.4 ± 13.6) and 8 controls (mean occlusal surfaces = 12.9 ± 2.4, total amalgam surfaces = 40.9 ± 13.4).[81] The calculated daily uptake of inhaled mercury vapor and urine/blood Hg concentrations were similar in both groups. The 24-hour Hg uptake was 2.0 ± 1.4 μg in the symptomatic group and 2.4 ± 1.9 μg in the control group. The DMSA group reported a statistically significant decrease in fatigue-inertia; however, the symptom did not correlate to increased urinary Hg excretion or reduced blood Hg concentrations. The Hg uptake represented <5% of the 1991 WHO acceptable daily Hg uptake. Hg uptake in the range of 1–3 μg would require the presence of 450–530 amalgam surfaces in non-gum chewing patients to exceed the urine concentration (30 μg/g creatinine) associated with subtle, preclinical effects in the most sensitive individuals by the World Health Organization.[82] These numbers are consistent with the lack of a clear relationship between amalgam load and health effects in these studies. A retrospective case report suggested extensive grinding of old amalgam restorations during 12 visits over 2½ months was possibly associated with the development of stomatitis and other neurological symptoms; however, the urine Hg concentrations did not confirm a causal relationship.[83]

TOXICOKINETICS

Absorption

The systemic absorption of elemental mercury (Hg^0) is much higher from the lungs (~70–80%) compared with the gastrointestinal tract (i.e., ~0.01%).[67,84] In a study of nine healthy volunteers exposed to 400 μg/m^3 mercury vapor, the median pulmonary retention of Hg^0 was 69% (range, 65–72%).[67] The uptake of elemental mercury vapor by the skin is small (<1%) compared with pulmonary absorption based on studies in human volunteers. In a study of five male subjects, the calculated Hg^0 uptake was 0.01–0.04 ng/cm^2 skin surface/min for each ng Hg/cm^3 air based on the dermal application for <1 hour.[85] Large oral doses (200 g) of elemental mercury are required to produce toxicity, although occasionally the ingestion of mercury in broken thermometers may cause local tissue reactions from the incorporation of mercury into the intestinal wall.[86] In a study of 11 volunteers ingesting mercury-containing amalgam, the estimated absorbed fraction of the administered dose was ~0.04%.[87] Intravascular elemental

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mercury injections produce pulmonary mercury granulomas but little acute systemic toxicity as a result of the relatively poor absorption of elemental mercury.[88]

Distribution

The kidney is the major storage site of the elemental mercury (Hg^0) following absorption into the body with mercury causing relatively limited bioaccumulation.[84] Animal studies indicate that ~50–90% of the mercury body burden resides in the kidneys after administration of elemental Hg vapor.[6,89] Other tissues with an affinity for mercury include the brain, liver, ovaries, testes, pancreas, prostate, and thyroid. Studies of dental personnel document elevated mercury concentrations in the pituitary gland, but this low-grade chronic mercury exposure does not produce dysfunction of the pituitary gland; storage of mercury as the biologically inactive mercuric selenide may account for the lack of significant toxicity.[90] The high lipid solubility of elemental mercury allows the rapid transfer of this form of mercury across the blood–brain barrier where oxidation of elemental Hg to Hg^{2+} in the central nervous system limits back diffusion across the blood–brain barrier. Erythrocytes also oxidize Hg^0 to the divalent form. Mercury concentrations following Hg^0 vapor exposure are ~2 times higher in red blood cells than plasma. Total mercury concentrations from the consumption of mercury in the diet average several hundred ng/g tissue in the kidney and liver, whereas the mercury concentrations in the cerebrum, cerebellum, heart, and spleen average several tens of ng/g tissue.[91] For the general population, the average total mercury concentrations in the kidney, liver, and brain are ~0.3 μg/g, 0.05–0.1 μg/g, and 0.01–0.02 μg/g, respectively.[63,92,93] Renal mercury concentrations are much higher (i.e., up to 50–100 times) in Hg-exposed workers than in the general population.

Animal studies suggest the distribution of mercury to the brain is relatively higher (and correspondingly lower to the kidneys) following exposure to elemental mercury than mercury salts. In a study of squirrel monkeys, the mercury concentration of the brain was 25% higher and the kidneys 78% lower following the inhalation of mercury vapors than following the ingestion of an equivalent dose of mercuric salts.[94] Moderate alcohol concentrations considerably reduce the oxidation of elemental mercury vapor in the body.[95]

Elimination

Following absorption in the lungs, elemental mercury undergoes oxidation to divalent mercury by the hydrogen peroxide-catalase pathway. These reactions occur primarily in the red blood cells; however, some oxidation also occurs in the brain, liver, and lungs. Most absorbed elemental mercury leaves the blood within 2–4 days. Following the short-term exposure of nine workers to ambient air mercury concentrations exceeding 100 μg/m^3, the estimated whole blood half-lives were 3.1 days for the fast compartment comprising ~80% of the absorbed dose and 18 days for the slow compartment.[96] Elimination of mercury from whole blood appears somewhat longer after long-term mercury vapor exposures compared with short-term exposure for the fast and slow compartments. Measurement of whole blood mercury concentrations in 14 chloralkali workers exposed to mercury vapors for a median of 10 years (range, 1–24 years) demonstrated half-lives of 3.8 days for the fast phase and 45 days for the slow phase.[97] The fraction of mercury eliminated during the slow phase is ~50% following long-term exposure compared with 20% during the slow phase of elimination following short-term exposure. The mercury half-life in the plasma is relatively shorter during the fast phase compared with the mercury half-life in erythrocytes, whereas the opposite occurs during the slow phase.

Excretion of elemental mercury occurs primarily in the urine and feces with a half-life of 40–60 days following short-term exposure and ~90 days after long-term exposure. The intravenous administration of up to 60 g ascorbic acid did not significantly increase the urinary excretion of mercury in 89 adult volunteers with low blood Hg concentrations when compared with a placebo infusion of saline.[98] Expiration of elemental mercury is a relatively small (<7%) portion of the elimination pathway; little mercury excretion occurs 5–7 days after exposure to Hg vapors.[99]

Maternal–Fetal Kinetics

Elemental mercury (Hg^0) easily crosses the placenta and accumulates in the fetus. The limited data available indicate that maternal and cord blood are similar at delivery following *in utero* exposure to elemental mercury.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Mercury is a non-essential element. Elemental mercury is highly lipophilic, resulting in rapid penetration

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

through the blood–brain barrier. Conversion of elemental mercury to the monovalent mercurous and divalent mercuric cations limits the ability of Hg in these forms to exit the nerve cell. Consequently, divalent inorganic mercury probably is the proximate toxic species producing the CNS effects associated with elemental mercury poisoning because elemental mercury does not react with tissue ligands.[100] Mercury in all forms will bind sulfhydryl (–SH) groups in thiols or proteins; several amino acids contain sulfur including cysteine, cystine, methionine, and taurine. Binding of mercury to amino acid residues in receptor or transport proteins alters the metabolic functions dependent on these proteins. The inhibition of a wide variety of enzymes and protein-transport mechanisms following the binding of divalent mercury to sulfhydryl groups probably accounts for mercury toxicity; however, the precise target for mercury is unclear.[100] Alteration of the tertiary and quaternary structures of various proteins by the binding of divalent Hg to SH-groups can affect cellular signaling, receptor binding, and cell membrane function. Mercury also forms strong bonds with other ligands (e.g., amine, phosphoryl, carboxyl groups) that may contribute to mercury toxicity.[101]

Pathological Changes

Central Nervous System

In addition to methylmercury, the central nervous system is a target organ of elemental mercury toxicity; however, the pathological changes in the brain following the inhalation of elemental mercury are generally mild compared with the changes following the chronic ingestion of organic mercury compounds. Exposure to elemental mercury vapor usually causes mild, reversible changes in the central nervous system. Although elevated mercury concentrations may persist for years in the brain, histological examinations of the brain of workers recovering from Hg^0-induced encephalopathy are frequently normal (i.e., no loss of granular cells in the cerebellum) despite the presence of mercury in central nervous system neurons.[102] In contrast to organic mercury toxicity, destruction of the endoplasmic reticulum and neurons does not usually occur. Additionally, pathological damage also develops in organs outside the central nervous system. Autopsies of four workers dying after exposure to elemental mercury vapors for 2 weeks demonstrated infarctions in the brain along with disseminated intravascular coagulopathy, renal cortical necrosis, and diffuse organized pneumonia.[103]

Kidney

The kidney is not a critical target organ even following acute, massive elemental mercury poisoning, except for the production of usually mild, transient proteinuria.[104] However, elemental Hg undergoes rapid oxidation to inorganic salts in the body that may cause acute tubular necrosis. Additionally, elemental mercury exposure has been associated with glomerular dysfunction ranging from proteinuria to nephrotic syndrome. Case series associate the development of a nephrotic syndrome with an immunological response that manifests as an immune complex (membranous) glomerulonephritis following chronic occupational exposure to mercury vapors.[105] The proteinuria primarily involves high-molecular-weight proteins that leak through damaged glomeruli.

Respiratory System

The inhalation of large amounts of elemental mercury produces capillary damage and pulmonary edema along with desquamation and hyperplasia of the bronchiolar lining, progressing to fibrosis and the obliteration of alveoli. The histology of the pulmonary tissue depends on the severity of the exposure and the time since the exposure ended. Acutely, erosive, necrotizing bronchitis and interstitial pneumonitis with hyaline membrane develop.[45,106] Obstruction from desquamation of bronchiolar epithelium results in severe ventilation/perfusion defects and hypoxemia similar to acute respiratory distress syndrome with postmortem examinations demonstrating various stages of fibrosis depending on the length of survival.[107] Histological changes include alveolar dilatation resulting from ruptured septa, exudation of inflammatory cells, hyperplastic pneumocytes, alveolar macrophages, and progressive interstitial fibrosis.[103] A follow-up 22 years after aspiration of elemental mercury demonstrated progressive fibrosis with pleural effusions, pulmonary granulomas, and bronchiectasis that was associated with local irritation from aspirated elemental mercury.[108]

Postmortem Examination

The smelting of mercury amalgam in poorly ventilated home environments is associated with the development of progressive, fatal acute pulmonary injury with histological changes related to the postexposure survival period. Extra-pulmonary changes do not usually occur in this setting. Postmortem examination of four fatal cases of elemental mercury vapor inhalation revealed severe diffuse alveolar damage, acute proximal renal tubular necrosis, vacuolar hepatotoxicity,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and a variety of changes in the central nervous system including vasculitis, multifocal ischemic necrosis, and gliosis.[107] Postmortem analysis of tissue from a thermometer worker committing suicide 4 weeks after leaving a 14-year job involving mercury vapor exposure revealed the following mercury concentrations: kidney, 25 μg/g; liver, 1.2 μg/g; lung, 0.72 μg/g; and brain, 0.014–0.018 μg/g.[109]

CLINICAL RESPONSE

Acute Toxicity

Inhalation

Acute elemental mercury toxicity usually results from the heating of liquid mercury in a poorly ventilated space. The inhalation of toxic doses of elemental mercury produces the syndrome of mercurialism that primarily affects the central nervous system and lungs. Dyspnea is the initial symptom that typically develops within 1–4 hours. Additional clinical features include fever, chills, nausea, nonspecific chest pain, cough, and headache similar to acute metal fume fever[35,48] as well as diarrhea, abdominal cramps, and decreased vision.[110] Severe cases of elemental mercury poisoning may resemble toxic shock syndrome with progression to noncardiogenic pulmonary edema (dyspnea, cyanosis, extensive bilateral infiltrates, progressive respiratory failure) within several days.[111,112] Complications include subcutaneous emphysema, pneumomediastinum, pneumothorax, and death.[113]

The issue of whether or not large, acute exposures to elemental mercury cause permanent neurological sequelae remains unresolved. A 3-month follow-up report on a cohort of workers with acute, massive elemental mercury toxicity revealed that some workers demonstrated persistent, nonspecific neurological symptoms and reduced scores on some tests of visuomotor function (Trailmaking A and B, Stroop Color Word Test).[35] However, the lack of well-defined control groups, the use of normative data rather than pre-exposure test scores, and selection bias limit the interpretation of this study.

Elemental mercury vapor toxicity may simulate mucocutaneous lymph node syndrome (Kawasaki's disease). This disease is an acute febrile multiorgan vasculitis seen predominately (i.e., 75–80%) in children of <5 years of age with many symptoms and diagnostic criteria similar to acrodynia.[114] These two diseases share the susceptibility marker of glutathione *S*-transferase depletion. Although some case reports document elevated urine mercury concentrations in Kawasaki's disease patients,[115] most of these patients have normal urine mercury concentrations with some increased susceptibility in Asian children.[116] The etiology of Kawasaki's disease remains unknown.

Injection

Subcutaneous injections of elemental mercury cause local abscesses and granulomas; however, systemic symptoms are unusual,[117,118] despite the blood and urine mercury concentrations substantially exceeding normal concentrations.[119] Sequelae of intravenous elemental mercury injections include local and embolic complications (thrombophlebitis and granuloma formation); the development of elemental mercury poisoning is rare. A 35-year-old man injected Hg^0 subcutaneously into his right shoulder, creating a reservoir of elemental mercury under the skin. One year later, he presented with gait ataxia, nystagmus, diplopia, dysarthria, vertigo, headache, vomiting, left third nerve and bilateral sixth nerve palsies, and a large plaque in his right shoulder; the serum mercury concentration was elevated (84 ng/mL) at presentation.[120] Case reports associate pleuritic chest pain, exertional dyspnea, fatigue, low-grade fever, a low posterior pleural rub,[121] tremors, lower extremity weakness,[122] and persistent hemoptysis[123] with the intravenous administration of elemental mercury.[124] The oxidation of elemental mercury to the soluble mercuric ion is slow following the intravenous administration of Hg^0; this slow oxidation to the biologically active mercuric ion probably accounts for the relative rarity of mercurialism after intravenous injection of Hg^0. Elemental mercury causes local chronic inflammation with progressive fibrosis at the sites of elemental mercury globules without the development of pulmonary dysfunction from the mercury emboli. A follow-up examination of a patient 11 years after injecting elemental mercury revealed decreased diffusing capacity (55% of estimated normal) and reduced sperm motion, but the nerve conduction velocities, neuropsychological tests, and renal function were normal.[125]

Ingestion

The clinical course following elemental mercury (Hg^0) ingestion is typically benign unless pulmonary aspiration occurs after massive Hg^0 ingestion[126] or disruption of the gastrointestinal tract causes Hg^0 extrusion into the peritoneum with development of granulomas and/or abscesses;[127,128] consequently, systemic mercury toxicity is unusual.[129] Although rare care reports associate acute appendicitis with the filling of the appendix with Hg^0,[130] appendicitis does not usually result from Hg^0 retained

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in the appendix, depending on the risk of obstruction.[131] Intraperitoneal mercury contamination in a 64-year-old morbidly obese diabetic during a Roux-en-Y gastric bypass did not cause acute mercury toxicity.[132] His peak blood mercury and urine mercury concentrations were 146 μg/L (day 22) and 227 μg/L (day 43), respectively. The only observed sequela was an increase in his total urinary protein concentration from 480 mg/24 hours (preop) to 2,301 mg/24 hours (88 days postoperation). Although these patients had multiple complaints (abdominal pain, alopecia, dizziness, fatigue, gait disturbances, headaches, insomnia, irritability, loss of balance, proteinuria, pruritus), the presence of multiple comorbidities limits conclusions about the toxic effect of mercury absorption from the peritoneum.

Dermal

Broken non-self-extinguishing ("R"-type) mercury vapor light bulbs may emit sufficient UV radiation to cause keratoconjunctivitis and skin erythema.[133]

Environmental Exposure

For the general population, the elemental mercury vapor released from dental amalgams is the second most common source of mercury exposure after methylmercury in fish. There is no clear evidence that the Hg concentrations produced by dental amalgam cause adverse health effects, including renal damage or neurobehavioral abnormalities.[134] Furthermore, blood or urine concentrations of total and inorganic mercury do not separate asymptomatic adults with amalgams from adults with multiple, nonspecific complaints they attribute to amalgams.[135] In a study of 40 females claiming serious health damage from mercury in dental amalgam and 43 females without health complaints, there was no statistically significant difference in the median mercury concentration in blood or urine samples.[136] Clinical experience indicates the release of mercury from dental amalgam is less likely to cause allergic reactions than copper or silver.

Analysis of data from the Seychelles Child Development Nutrition Study did not detect an association between maternal amalgam surfaces and infant scores on mental or psychomotor development indices of the Bayley Scales of Infant Development administered 9 and 30 months after birth.[137] Several randomized clinical trials of children requiring dental restorations did not detect any statistically significant neurobehavioral or neuropsychological effects when comparing children with mercury amalgam and children with resin composites.[138,139] These trials involved annual follow-up for 7 years; the testing was designed to detect a difference of three to five IQ points. A randomized controlled trial of 534 6–10-year-old rural and urban children annually assessed the children with a battery of tests including attention, intelligence, language, achievement, learning, executive function, fine motor function, verbal fluency, and visual-spatial skills.[140] Although the group with dental amalgams had a higher average urine mercury concentration than the composite group (i.e., 0.9 μg/g creatinine vs. 0.6 μg/g creatinine), the neuropsychological test scores of the two groups during the 5-year follow-up period were statistically similar. A 5-year prospective study of children of 6–10 years of age demonstrated a higher prevalence of urinary albumin (>30 mg/g creatinine) in the amalgam group ($n = 267$) compared with the composite group ($n = 267$) at follow-up 3 years and 5 years after enrollment in the study.[141] The odds ratio (OR) was 1.8 (95% CI: 1.1–2.9). However, there was no dose-related increase in albuminuria between the number of amalgam fillings and albuminuria; therefore, chance could not be excluded as the cause of the results. There were no statistically significant differences in markers of renal tubular function (α-1-microglobulin, *N*-acetyl-β-D-glucosaminidase). Dental amalgams remain an option for the treatment of caries in children.

Occupational Exposure

Studies of occupational exposure to elemental mercury involve primarily neurological and renal effects. The classic triad of occupational exposure to elemental mercury in the range of 100–600 μg Hg/m^3 includes inflammation of the oral cavity (gingivitis, salivation, stomatitis), tremor, and behavioral/personality changes.[142] The latter involves excessive shyness, emotional instability, anxiety, irritability, loss of confidence, pathological fear of ridicule, vivid dreams, poor memory, insomnia, and anorexia. Erethism is a historical term applied in the early 19th century to describe all the clinical features of mercury vapor toxicity; however, the diagnostic utility of this term is limited by poorly defined behavioral changes and nonspecific features. The psychological effects of mercury vapor exposure differ from the clinical features of acute psychoses (hallucinations, delirium, suicidal ideations) because the patient retains some self-control and sense of reality.[100] Clinical features of chronic mercury toxicity of workers (e.g., amalgam burners in gold processing) exposed to high ambient air concentrations include ataxia, incoordination, tremor, excessive salivation, and metallic taste.[143]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Primary hypersensitivity to elemental mercury is rare;[144] however, contact dermatitis has been associated with chronic exposure to elemental mercury.[145] The high incidence of false-positive patch tests complicates the interpretation of the significance of these case studies. The immune system is not a major target organ for elemental mercury toxicity. A cross-sectional study of 36 workers at a chloralkali plant occupationally exposed to mercury vapor did not demonstrate any abnormalities in immunological parameters (white blood cell count, cytokines, interleukin 1, tumor necrosis factor alpha, IgM, IgG, IgA) when compared with several groups of controls that included patients with mercury hypersensitivity.[146] The median blood mercury concentrations were >3-fold higher than controls.

Central Nervous System

Central nervous system symptoms are the most prominent adverse effects of chronic elemental mercury intoxication. The exposure of three workers to metallic mercury while gilding for <1–2 months was associated with the development of anxiety, restlessness, memory impairment, insomnia, depression, anorexia, weight loss, metallic taste, and dyspnea.[147] The patients had elevated urine mercury concentrations with normal nerve conduction velocities and electromyograms. All symptoms resolved within 6 months of cessation of mercury exposure. Chronic elemental mercury exposure may cause behavioral and personality changes as well as gingivitis and tremor.[148] The latter involves a rapid resting or an intention tremor abolished by sleep.[149,150] The most common tremors in workers exposed to elemental mercury are fine resting tremors with intention tremors more common in Minamata's disease (methylmercury toxicity).[151,152]

In the case series, psychological complaints of workers exposed to elemental mercury include depression, emotional lability and anxiety,[153] and decreased short-term memory.[154] A cross-sectional study of workers with moderate exposure to elemental mercury vapor for an average of 5 years revealed an increased prevalence of memory disturbances, depressive feelings, fatigue, and irritability, but the prevalence was not dose-related and neuropsychological tests did not reveal statistically significant differences between workers and unexposed controls.[155] Upon cessation of elemental mercury exposure, the motor impairments generally improve, but the cognitive disturbances (e.g., memory loss) often do not resolve.[156] Although the children of workers exposed to mercury may have increased urine mercury concentrations compared with unexposed controls, signs of chronic mercury poisoning typically do not occur in these children.[9]

Studies of workers exposed to mercury vapors suggest some subclinical differences in the color discrimination thresholds between exposed workers and controls in the blue-yellow and the red-green chromatic systems.[157,158] However, conclusions about a causal relationship between mercury vapor and these effects are limited by the lack of a clear dose-response relationship between exposure duration and mean urinary mercury concentration.

Peripheral Nervous System

Chronic over-exposure of workers to elemental mercury vapor may produce a mild sensorimotor neuropathy (weakness, paresthesias, muscle cramps) as defined by prolonged distal latencies on nerve conduction tests, even though urinary mercury concentrations may not be significantly elevated (average, <0.5 mg/L).[159,160] Cross-sectional studies of workers exposed to elemental mercury suggest that this neuropathy may be subclinical.[161] The common neurological abnormalities involve diminished vibratory sensation and hypoactive Achilles reflexes in the lower extremities that are consistent with the involvement of the large nerve fibers.[162] Examination of a cohort of 205 former workers with high cumulative elemental mercury exposure demonstrated persistent changes in motor nerve conduction velocity, motor nerve F-wave latency, and resting tremor, but cumulative mercury exposure did not correlate to cognitive neurobehavioral test outcomes when compared with the control group.[163]

Kidneys

The occurrence of renal changes (proteinuria, nephrotic syndrome, tubular dysfunction) following chronic elemental mercury exposure is uncommon.[164] The nephrotic syndrome is an idiosyncratic reaction to mercury involving edema and albuminuria. Studies of workers exposed to elemental mercury do not demonstrate consistent changes in renal function. Some, but not all, studies of mercury workers suggest that chronic elemental mercury exposure can cause reversible tubular dysfunction in active workers. A study of 53 miners (33 active and 20 retired) from the Idrija Mercury Mine demonstrated a statistically significant correlation between urinary α_1-microglobulin and the mean integrated exposure intensity in active workers.[165] The mean annual time–weighted mercury exposure was 0.29 mg/m^3, the mean integrated exposure intensity

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

was 1413 mg/m^3/hours, and the average urine mercury concentration in miners was 68.24 μg/L. There was no similar correlation between measures of chronic mercury exposure and other measures of renal tubular function (*N*-acetyl-β-D-glucosaminidase) or glomerular function (urinary albumin, IgG). Measures of renal tubular and glomerular functions did not correlate with estimates of elemental mercury exposure in retired workers. Other studies have not demonstrated statistically significant differences in urinary measures of renal tubular and glomerular function of chloralkali workers chronically exposed to mercury vapor.[166,167] A cross-sectional study of 49 chloralkali workers with previous exposure to mercury vapor did not demonstrate any statistically significant differences in biomarkers of kidney function when compared with 49 age-matched referents.[168] These biomarkers included serum creatinine, urine albumin, urine alkaline phosphatase, urine *N*-acetyl-β-D-glucosaminidase, and serum anti-glomerular basement membrane. The mercury exposure of the chloralkali workers ceased a mean of 4.8 years (range, 4–25.4 years) prior to the study.

Reproductive Abnormalities

Currently, there is little evidence that elemental mercury produces reproductive or developmental effects at concentrations present in the current work environment or the general population. A pregnant woman in her third trimester developed elemental mercury toxicity following exposure to mercury vapors during the heating of mercury-gold amalgam.[169] She delivered a healthy infant without clinical signs of Hg toxicity 26 days after exposure. The blood mercury concentrations were similar in mother and infant (36 ng/mL and 34 ng/mL, respectively). A Swedish study of 8,157 infants born of dentists, dental assistants, or dental technicians suggests that there is no effect on spontaneous abortion rates, perinatal survival, or birth weight distribution that could be explained by occupational exposure in dentistry work.[170]

Carcinogenesis

Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program (NTP) lists elemental mercury as a potential human carcinogen.

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 4.985 nmol/L
1 μmol/L = 200.6 μg/L
1 μg/g creatinine = 0.5638 μmol/mol creatinine
1 μmol/mol creatinine = 1.773 μg/g creatinine
1 ppm = 8.204 mg/m^3
1 mg/m^3 = 0.1219 ppm

Analytical Method

Most techniques for the determination of mercury concentrations utilize atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (AFS), or neutron activation analysis (NAA). During analysis with these methods, the mercury in the sample is reduced to elemental mercury, resulting in the measurement of total mercury. The most common method of analyzing blood and urine for mercury content involves cold vapor AAS after digestion of the samples with acids and the reduction of bivalent inorganic mercury to mercury vapor with stannous chloride. The possibility of contamination by natural mercury compounds exists at all phases of sample preparation; elemental mercury is relatively volatile, resulting in the potential loss of mercury during sample preparation and analysis. NAA is the most sensitive method of detecting Hg; this method is usually considered the reference standard. Atomic absorption spectrophotometry with the cold vapor technique is a relatively sensitive (0.5 ppb in 1-g sample), precise (<10% relative standard deviation) procedure for the detection of mercury in body fluids.[171,172] Simple, rapid techniques involving acid pressure decomposition followed by flameless atomic absorption spectrophotometry can detect mercury at 1 ng/mL.[173] Extensive mercury losses can occur from aqueous solutions of mercury compounds during storage.[174]

The preferred collection container is a Vacutainer-style evacuated blood collection tube for trace elements (royal blue-top) containing EDTA anticoagulant. Most analyses from routine EDTA tubes are usually adequate if the specimen is analyzed within 2–3 days of collection. If standard Vacutainer® are used, additional blank tubes should be sent to the laboratory to confirm the absence of mercury contamination. Blood specimens that contain visible clots do not provide an adequate sample for analysis of whole blood mercury.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Substantial inter-individual and intra-individual variation in the urine mercury concentration occurs. Measures that help reduce this variability include correction of the sample for specific gravity or creatinine, collection of the sample at the same period during the workweek, and procurement of the samples during direct exposure following a time period sufficient to reach steady state.[175] Accurate measurement of urine mercury concentrations requires the collection of urine samples in glass or plastic containers that do not contain mercury (e.g., acid-washed). Urine samples should contain creatinine concentrations between 30 and 300 mg/dL.

Biomarkers

Inhalation of elemental mercury usually affects the lungs and central nervous system, whereas the kidney and central nervous system are critical organs for inorganic mercury in humans. In an analysis of kidney cortex biopsies, 24-hour urine collections, and blood samples from 109 living kidney donors, the total mercury concentrations in the kidney and creatinine-adjusted 24-hour urine collections were strongly correlated (Pearson correlation coefficient, $r_P = 0.80$, $P = < 0.001$) and approximately linear. The correlation with whole blood mercury was weaker ($r_P = 0.29$, $P = 0.002$).[176] The mean kidney/24-hour urine ratio was 0.22 compared with 0.19 for whole blood Hg. The mean 24-hour creatinine-adjusted mercury excretion was higher in women (1.9 μg/g creatinine) than men (1.4 μg/g creatinine).

Blood

Total mercury in whole blood is the sum of inorganic mercury (primarily elemental mercury vapor) and organic mercury (primarily methylmercury from fish). Elemental mercury does not persist in the blood as a result of the rapid oxidation of elemental mercury to inorganic mercury (Hg^{2+}) in red blood cells.[177] Although total mercury concentration in whole blood is the best biomarker of recent (i.e., within several days) Hg exposure,[178] total whole blood Hg concentrations reflect primarily methylmercury because whole blood contains primarily methylmercury (i.e., >80%). The vast majority of the methylmercury resides in erythrocytes; therefore, plasma and serum Hg concentrations primarily reflect exposure to inorganic Hg species including Hg^0. Although whole blood Hg concentrations increase in the first day after DMPS administration, the increase is not a reliable diagnostic biomarker to assess total mercury body burden or distinguish patients with and without symptoms attributable to dental amalgam.[179]

General Population

The main mercury sources for the general population are elemental mercury vapor (atmosphere, dental amalgam) and methylmercury in the diet, particularly fish. The mean total mercury concentration in whole blood of 51 asymptomatic Norwegian referents was 5.66 μg/L (range, 3–12.8 μg/L) with elemental/inorganic and organic mercury accounting for ~20% and ~80% of the total mean mercury concentration, respectively.[180] In a French study of 106 hospital staff volunteers, the mean total whole blood Hg concentration was 5.8 μg/L (median, 1.72 μg/L, 95% CI: 0.59–5.12 μg/L) as measured by inductive coupled plasma/mass spectrometry.[181] The corresponding mean plasma Hg concentration was 2.69 μg/L (median, 0.36 μg/L, 95% CI: 0.09–1.01 μg/L). In a study of 1,127 male US military personnel (mean = ~53 years), the mean whole blood concentration of *organic* mercury was 2.01 ± 2.69 μg/L compared with 0.54 ± 0.48 μg/L for *inorganic* mercury as measured by cold vapor AAS.[182] The average number of amalgam surfaces in the subjects was ~20 surfaces (range, 0–66 surfaces).

Toxicity

Subperitoneal deposition of elemental mercury resulting from the breakage of a rectal thermometer in a 10-month-old infant was confirmed by radiographic imaging; a surgical attempt to remove the mercury was unsuccessful.[183] The serum Hg concentration was 23.4 μg/L. Prior to dimercaprol chelation, the serum Hg concentration in a 40-year-old woman 6 days after smelting silver-mercury amalgam was 127 μg/L; she died of acute respiratory failure 21 days after exposure.[45]

Postmortem

Four adults attempted removal of silver from a silver-mercury amalgam by heating the mixture in a small smelter at the home of a family member.[45] All four died of acute respiratory failure despite intensive supportive care and dimercaprol chelation. The postmortem serum Hg concentration in the 88-year-old woman (survival, 15 days) was 212 μg/L, whereas the postmortem serum from the 69-year-old man (survival, 11 days) was 368 μg/L.

Urine

Analysis of urine mercury concentrations is a simple, rapid test for identifying patients with excessive exposure to elemental and inorganic mercury. Total mercury concentrations in urine probably reflect mercury accumulation in the kidneys, which accounts for ~80% of the body burden. Corrections of spot samples throughout

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a 24-hour period include adjustment for creatinine, osmolality, and specific gravity. Correction for creatinine is slightly more effective than other corrections to estimate 24-hour urine Hg excretion from spot urine samples; however, individual corrected Hg values may still vary 6-fold.[184]

The administration of chelating agents (e.g., DMSA, DMPS) produces a relative transient increase in urinary and blood mercury excretion above baseline levels that is not related to previous mercury exposure, specific symptoms, or clinical toxicity, probably as a result of the limited Hg bioaccumulation. The kidney excretes almost all absorbed Hg^0 in the urine.[84] Consequently, urine DMSA or DMPS chelation challenge tests are not useful biomarkers of past mercury exposure.[185,186] Collection of urine samples in close proximity to chelating agents (i.e., <24 hours) increases the excretion of various metals including essential metals (e.g., Cu, Zn) necessary for normal human function. Additionally, most of the metal excretion occurs soon after chelator administration (i.e., <6 hours), whereas creatinine excretion remains stable over 24 hours. The maximum DMSA-induced excretion of mercury occurs ~2 hours after DSMA administration.[35] Furthermore, standard reference ranges obtained from the general population are inappropriate to interpret the significance of post-provocation urine mercury concentrations; hence, there are no normal reference ranges for provoked urine metal concentrations in healthy asymptomatic individuals.[187] Consistent with recommendations by the Agency for Toxic Substances and Disease Registry (ATSDR) and the Centers for Disease Control and Prevention (CDC),[188] the American College of Medical Toxicology recommends against the use of post-challenge urinary metal testing in clinical practice or the use of challenge tests as an indication for further chelation based on: 1) lack of scientific validation with the absence of well-documented reference ranges and unpredictable exposure-response relationship;[189] 2) no demonstrated benefit; and 3) potential harm (e.g., chelation of essential metals, hypersensitivity, misdiagnosis).[190,191]

General Population

The elimination half-life ranges from ~40–60 days after short-term exposure and about 90 days after long-term exposure.[99,192] Baseline total urine mercury concentrations in subjects with no unusual exposure to mercury range from 1–25 μg/L with the vast majority of the urine concentrations <5–10 μg/L. The mean total urinary Hg in 1,642 Tokyo children without specific sources of Hg exposure was 1.9 μg/L (1.9 μg/g creatinine) for boys and 2.1 μg/L (2.0 μg/g creatinine) for girls.[193] In a study of 130 Japanese men, the mean total mercury concentration in urine samples was 2.33 ± 1.5 μg/L (1.51 ± 0.68 μg/g creatinine) with a range of 0.27–10.26 μg/L (0.39–4.21 μg/g creatinine).[194] Inorganic mercury accounts for almost all of the Hg in urine samples.[195]

The amount of dental amalgam (i.e., amalgam surfaces) correlates weakly but positively to total urine mercury concentrations. In a study of a US military population, the urine mercury concentration increased by ~1 μg/L for every 10 surfaces of amalgam.[182] The number of dental amalgam fillings explained <1.5% of the total variance of urinary Hg in the Japanese study of 1,642 children.[193] The filling of cavities with dental amalgam produces a small, transient increase in the renal excretion of mercury. In a study of 43 children receiving dental amalgam, the urinary mercury concentrations before and 9–12 days after an amalgam filling were 3.38 ± 2.45 μg/L and 5.14 ± 3.14 μg/L, respectively.[196]

Toxicity

Urine mercury concentrations document mercury exposure; however, these values do not correlate well to specific symptoms of mercury toxicity. After intravenous injection of mercury, urine total mercury concentrations were elevated (600–1,050 μg/L).[123] A subperitoneal mercury deposit could not be surgically removed from a 10-month-old infant. The random urine mercury concentration 5 days after the incident was 21.8 μg/L. The urine mercury concentration did not change immediately after surgery; by 10 months post-incident, the random urine mercury concentration was 8.4 μg/L (reference <10 μg/L). The child remained asymptomatic despite the presence of residual mercury on CT imaging. Unprovoked urine mercury concentrations below 20 μg/L are usually not associated with adverse health effects.[14]

Hair

Potential external contamination and sorption limit the usefulness of hair analysis to determine past inorganic Hg exposures in occupational settings, particularly in the presence of ambient air containing elemental Hg vapor (e.g., chloralkali plants, small-scale artisanal mining operations). Other factors complicating the use of hair analysis include the effects of age, gender, hair color, and permanent hair treatments on the Hg concentration in hair. Elemental mercury concentrations in hair probably are not robust markers of dietary exposures to elemental Hg.[197] A 10-year follow-up study analyzed the mercury concentrations in the hair of residents living near a hazardous-waste-treatment plant.[198] The study detected a slight increase in the median mercury

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

concentration in hair with mercury emissions from the plant occasionally exceeding 50 μg/m^3; however, the minimal increase in the mercury concentrations was not associated with a significant health risk. In a study of 20 dental students exposed to elemental mercury vapor during a 6-week operating dental course, Hg concentrations were analyzed in hair, erythrocytes, plasma, and urine at baseline, the end of the 6-week exposure, and 3 months after the exposure ceased. At baseline, hair mercury concentrations correlated moderately with erythrocyte Hg (Spearman's rank order correlation coefficient, r = 0.686) and slightly with monthly fish consumption (r = 0.448). Erythrocyte, plasma, and urine Hg concentrations did not correlate to hair Hg at the end of the 6-week course. After 3 months, only the erythrocyte Hg concentration had a slight correlation to the hair Hg concentration (r = 0.492).

Abnormalities

Following intravenous administration of elemental mercury, case reports associate a restrictive pattern and normal FEV_1/FVC with the presence of Hg emboli on X-ray.[200] A ventilation/perfusion scan in this patient demonstrated ventilation/perfusion deficits.

Imaging

Following the intravenous injection of elemental mercury, the chest radiograph may exhibit multiple, fine, radiodense, spherical particles in the lungs and a pooled elemental density in the right ventricle by echocardiography.[2] Despite the striking radiographic appearance, embolization of mercury in the lung does not typically produce significant vascular obstruction based on angiography. Pelvic and abdominal X-rays may indicate mercury in the paraspinal and pelvic areas in addition to the injection site. Radionuclide V/Q imagery differentiates the accidental intra-bronchial aspiration of the ruptured, mercury-filled intestinal tube from pulmonary arterial mercury emboli. Embolized mercury can coalesce and pool in the lumen of the apex of the right ventricle, whereas extravasated mercury at the venipuncture site in the extremities suggests embolization. The presence of small metallic beads in the colon suggests the ingestion of elemental mercury.

Neuropsychological Testing

Potential tests for chronic, symptomatic elemental mercury exposure include neuropsychological testing, peripheral nerve conduction, and measures of renal function (e.g., serum creatinine, glomerular filtration rate, lysosome enzymes). The results of these tests are not specific to mercury toxicity; the results must be interpreted in relation to the history and physical examination. Separation of the effects of elemental and inorganic mercury on neuropsychological test scores is complicated by: 1) the tendency to include exposures of elemental Hg and inorganic Hg together in epidemiology studies, 2) relatively small sample sizes, and 3) the intracellular conversion of elemental mercury to inorganic mercury.

A meta-analysis of 12 studies (1980–1999) involving 14 neuropsychological tests with 20 different tasks suggested the possibility of adverse effects on memory, attention, construction, and motor performance following inorganic Hg exposure producing urine mercury concentrations of <100 μg/g creatinine (mean = 32 ± 37 μg/g creatinine).[201] However, the lack of a clear dose-response relationship for specific tests and the lack of premorbid data limit conclusions regarding causation. A meta-analysis of 36 peer-reviewed studies of neuropsychological testing in workers exposed to mercury (elemental, inorganic) indicated that the prevalence of neuropsychological deficits following chronic occupational Hg exposure is small (weighted study-mean effect size = −0.23, $P < 0.0001$); consequently, these effects (i.e., mean shift of ¼ standard deviation) are difficult to detect on an individual basis.[202] The largest impairment occurred in psychomotor skills, whereas occupational mercury exposure had the smallest effect on verbal comprehension. These studies did not include occupational exposure to organic mercury.

A cross-sectional study of former chloralkali workers with past exposure to mercury vapor suggested that slight persistent neurological effects, mainly involving motor function and attention, may result from chronic exposure to mercury vapor when compared with unexposed, age-matched controls.[203] Neuropsychological testing demonstrated statistically significant differences between these two groups for scores on simple reaction time, grooved pegboard, and the Benton visual retention test. There were no significant differences in scores for measures of memory and learning, hand-eye coordination, hand steadiness, visuospatial ability, and perceptuomotor speed.

Neuropsychological testing during an epidemiological study of dentists indicated that early, subclinical changes may include motor speed (finger tapping), visual scanning (Trail making A), visuomotor coordination and concentration (digit symbol), and visual

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

reproduction.[204] Two adolescent siblings developed behavioral problems, irritability, declining school performance, tremor, rash, headache, sleep disturbances, paresthesias, and anorexia, after an accidental 3-month exposure to excessive mercury vapors (50–400 μg/m^3) from an unsuspected mercury spill in their home.[205] Both adolescents received chelation with DMSA. Repeat neuropsychological testing 1 year after chelation demonstrated persistent deficits in visuoperceptual and constructional skills (Block Design), conceptual abstraction, and nonverbal memory (Rey-Osterrieth Complex Figure). Full-scale IQ during this testing was consistent with premorbid testing for both children. Specific comparisons between pre- and postexposure domains were not reported. The 15-year-old boy repeated the first and sixth grades; the 13-year-old half-sister repeated the first grade and required reading assistance.

HEALTH SURVEILLANCE

Risk Assessment

The ATSDR established a minimal risk level (MRL) of 0.2 μg/m^3 for chronic-duration inhalation exposure (i.e., ≥365 days) to elemental mercury vapor based on hand tremor measurements in a study of 26 mercury vapor-exposed workers from 3 industries (fluorescent tube factories, chloralkali plant, acetaldehyde production) and 25 unexposed controls (same factories without Hg exposure).[149] The mean duration of Hg exposure for the workers was 15.3 years (range, 1–41 years). The mean total urinary Hg concentrations in the exposure workers and controls were 19.2 ± 2.0 μg/g creatinine and 5.8 ± 1.2 μg/g creatinine, respectively. The US EPA has not derived an RfD value for elemental mercury. The EPA inhalation reference concentration (RfC) for elemental mercury is 3×10^{-4} mg/m^3 based on an LOAEL of 25 μg/g from adverse effects (hand tremors, ↓ memory testing, slight autonomic dysfunction) detected in epidemiology studies of exposure workers.

Environmental Monitoring

Table 20.2 lists the guidelines and regulations for exposure to mercury vapor (primarily elemental mercury). The US OSHA PEL–TWA for mercury vapor was 50 μg/m^3 with a skin notation; however, the 11th Circuit Court of Appeals vacated the regulation in 1992. These exposure levels were promulgated in 1989 to prevent systemic toxicity including subclinical neuropathies.[206] A study of chloralkali workers exposed to mercury vapors did not detect clinical evidence of chronic mercury toxicity at ambient air Hg concentrations of <100 μg/m^3.[22] The ACGIH recommends the same limit as the previous OSHA limit for mercury vapor exposure. NIOSH has established a Hg concentration immediately dangerous to life or health (IDLH) of 10,000 μg/m^3. Currently, there are few data to indicate the presence of elementary mercury concentrations in the current work environment sufficient to cause reproductive abnormalities, especially in males. For residential settings, the ATSDR guidelines recommend mercury concentration of <1 μg/m^3 in air samples following decontamination of mercury spills and the isolation of areas with airborne mercury concentrations exceeding 10 μg/m^3.

TABLE 20.2. Mercury vapor guidelines and regulations.

Exposure Limit	Value
OSHA	
PEL–TWA[a] (8-hour)	None
PEL-Ceiling	100 μg/m^3
NIOSH	
REL–TWA (10-hour)[b]	50 μg/m^3
IDLH	10,000 μg/m^3 (as total Hg)
ACGIH	
TLV–TWA (8-hour)[b]	25 μg/m^3 (as Hg)
US FDA	
Bottled water allowable limit	2 μg/L
US EPA	
RfC (chronic inhalation exposure)	0.3 μg/m^3
EPA carcinogenic unit risk (daily)	None
MCL	2 μg/L
ATSDR	
MRL (chronic inhalation exposure, ≥365 days)	0.2 μg/m^3

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfC = reference concentration; RfD = reference dose; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time–weighted average; US EPA = US Environmental Protection Agency; US FDA = US Food and Drug Administration.

Biological Monitoring

Urine

Elemental mercury (Hg^0) rapidly crosses the alveolar membranes, resulting in the oxidation of elemental mercury to inorganic mercury (Hg^{2+}) in red blood cells; consequently, little elemental mercury (Hg^0) exists in the blood. In a study of workers from a thermometer manufacturing plant exposed to average ambient air mercury concentrations exceeding 100 μg/m^3, the urinary Hg^0 concentrations in urine samples from these workers ranged from 0.05–1.7 μg/L.[207] Elemental mercury accounted for <1% of the inorganic mercury present in the urine samples. Most occupational studies use total urine Hg concentrations as the biomarker of Hg exposure because peak urine mercury concentrations occur about 2–3 weeks after an acute exposure; urinary Hg elimination half-lives for short-term and long-term exposures are ~40–60 days and 90 days, respectively.[96]

In a study of chloralkali workers without kidney damage, the biological half-life of mercury in urine following mercury vapor exposure was ~3 months (mean = 90 days; range, 69–108 days).[208] In a study of 119 chloralkali workers retired at least 1 year before the examination, the 24-hour urine mercury concentration did not correlate to historical measures of mercury exposure.[185] The mean Hg excreted in the 24-hour urine samples was 4.3 μg. These studies suggest that after discontinuation of mercury vapor exposure, the urine mercury concentration reflects the amount of mercury stored in the kidney.

The ratio between mercury in air (μg/m^3) and mercury in urine (μg/L) ranges from 1:1–1:1.22. Recent data using personal samplers suggests that this ratio is closer to 1:1. Roels et al.[209] found a ratio of 1 μg/m^3 in air to 1.22 μg/g creatinine, whereas Lindstedt et al. reported a ratio of 1 μg/m^3 in air to 1.16 μg/L.[210] Although mercury concentrations in air and urine samples are correlated below 50 μg/m^3, urinary mercury is not an accurate measure of environmental exposures below 10 μg/m^3 because of the interference of other sources (fish, dental amalgam).[211]

Total Mercury

The process of mining and the heat extraction of gold from amalgam (gold-mercury alloy) during small-scale (artisanal) mining operations expose miners and smelters to elemental mercury vapor.[212] Typically, mercury exposure increases in the following order: residents, miners, millers, smelters, and refiners; however, individual mercury exposure varies between studies depending on extraction methods and work practices including the use of protective devices.[213] Analysis of convenience urine samples from two groups of Indonesian miners (i.e., panning) demonstrated median total mercury concentrations of 5.33 μg/L (n = 30; range, 0.60–788 μg/L) and 7.80 μg/L (n = 17; range, 0.79–57.6 μg/L) as measured by cold vapor/atomic absorption spectrometry.[214] For workers involved with smelting and vaporizing the mercury-containing amalgam, the median total mercury concentration in urine samples was 10.24 μg/L (n = 69; range, 0.43–5,249 μg/L) and 22.40 μg/L (n = 60; range, 0.72–564 μg/L).[215] After correction for creatinine, the median total mercury concentration in these samples ranged from 3.55–10.24 μg/g creatinine. The median total mercury concentration in urine samples from the local control group was 0.73 μg/L (n = 21; range, 0.10–3.16 μg/L). Approximately 24–43% of miners had signs of chronic mercury intoxication compared with 55–62% of the smelter workers.

The impact of occupational Hg exposure on dental personnel depends on several factors including local conditions, the number of amalgams restored, and the amount of Hg in the amalgam. On average, the urine mercury concentration following mercury exposure in dental personnel is similar to the mercury concentration of a person with 19 amalgam surfaces.[216] In general, the urine mercury concentrations of dentists correlate to the number of hours of practice/week and the number of amalgam restorations per week. In a cohort of dentists and dental nurses in Stockholm, the mean urine mercury concentration was ~3.5 μg/L compared with 0.5 μg/L in a control sample of an amalgam-free population with no occupational exposure to mercury.[217] In a study of dentists, the mean urinary mercury concentration was 14.2 μg/L urine with ~1.3% of these dentists having urine mercury concentrations exceeding 100 μg/L.[10] In a study of 234 university staff and students exposed to elemental mercury vapor during laboratory experiments (geometric mean = 1.61 μg Hg/g creatinine; range, 0.30–9.31 μg Hg/g Cr), multiple regression analyses did not detect a correlation between urinary Hg concentration and the number of amalgam fillings or surface area of these fillings in the workers and students.[218]

Effects

Central Nervous System The urinary mercury concentration following occupational exposure to mercury is ~2 orders of magnitude higher than the mercury concentration in urine from subjects with dental amalgams.[219] The presence of urine mercury concentrations of >500–850 μg Hg/L in workers was associated with the development of reversible polyneuropathies manifested by tremors, unsteadiness, and poor coordination.[153] Early neurological symptoms may appear at urine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mercury concentrations of >150 μg/L. More recent data focus on subclinical effects on renal function and neuropsychological tests.

Kidney Clinical evidence of renal dysfunction is less common following exposure to elemental mercury vapor compared with inorganic mercury exposure. Increased urinary excretion of high-molecular-weight proteins and lysosomal enzymes may occur following exposure to elemental mercury that yields urine mercury concentrations of >50–60 μg Hg/L.[220] No glomerular or tubular dysfunction was detected in chloralkali workers exposed to elemental mercury vapor at concentrations producing urine mercury concentrations near 25 μg/L.[221]

Biological Exposure Indices

Occupational studies suggest a correlation between the intensity of recent Hg vapor exposure and total urine Hg concentrations following at least 1 year of exposure; a latent period is necessary while the body accumulates Hg, primarily in the kidney.[222] Clinical signs of acute Hg poisoning usually do not appear at urine Hg concentrations of <300 μg/L,[153] whereas some studies indicate increased prevalence of neuropsychological symptoms, tremor, and increased urinary *N*-acetyl-β-D-glucosaminidase, concentrations following urinary Hg concentrations of <100 μg/L.[155] Urine Hg concentrations are the preferred measure for long-term, integrated mercury vapor exposure. Recommendations for biological exposure indices following chronic mercury vapor exposure range from 20 μg/g creatinine in pre-shift urine based on adverse, subclinical renal and neuropsychological effects (ACGIH)[223] to 50 μg/g creatinine.[105,224] Urine Hg concentrations exceeding 100 μg/g creatinine indicate the need to remove the worker from Hg exposure; this value suggests the Hg vapor concentration in ambient air exceeds 80 μg/m^3.[222] Because of the large inter- and intraindividual variation in urine mercury concentrations, decisions regarding workers should be based on an average of several measurements rather than a single value. The creatinine adjustment method is the most sensitive method of reducing variation in the content of urine mercury samples used for biological monitoring. The steady-state urinary Hg concentration does not change significantly over the weekend in chronically exposed workers.

Blood

Concentrations

Occupational exposure to elemental mercury occurs primarily in the chloralkali industry, the manufacture of thermometers and fluorescent light tubes, and dental services. Elemental mercury (Hg^0) rapidly crosses the alveolar membranes; oxidation of elemental mercury to inorganic mercury (Hg^{2+}) occurs rapidly in red blood cells. Consequently, the Hg^0 concentration in plasma, serum, and whole blood is relatively small. In end-of-shift blood samples drawn from thermometer manufacturing workers exposed to elemental mercury vapors, the Hg^0 concentration in whole blood ranged from non-detectable to 0.22 μg/L compared with inorganic mercury concentrations of 22–230 μg/L.[177] A study of 42 chemical workers exposed to elemental mercury vapor revealed a rough correlation between the ambient air concentration of mercury (100 μg/m^3) and the whole blood mercury concentration up to 50 μg/L, but not with symptoms.[225] Whole blood mercury concentrations in chloralkali workers ranged from a mean of 11 μg/L (range, 3–60 μg/L) in Swedish workers[226] to a mean of 28.5 μg/L in Taiwanese workers.[227]

Effects

In a study comparing 89 chloralkali workers with 75 unexposed chemical workers matched for age, education, and verbal comprehension, the median whole blood mercury concentrations were 11 μg/L (3–60 μg/L) and 3 μg/L (range, 0.2–13 μg/L), respectively.[228] Although the exposed group had increased somatic complaints (tiredness, confusion), there were no statistically significant differences between groups for scores on hand-eye coordination, finger tapping, simple reaction time, symbol-digit, or digit span. Analysis of these studies indicates that smoking and alcohol consumption do not alter blood mercury concentrations. A study of 42 chemical workers exposed to elemental mercury vapor did not detect a correlation between total whole blood mercury concentrations up to 50 μg/L and neuropsychological symptoms.[225]

Biological Exposure Indices

The intensity of *recent* Hg vapor exposure correlates to the whole blood mercury concentration at the end of a work shift;[208] the urine Hg concentration is less responsive to recent Hg vapor exposure than whole blood concentrations. Several factors limit the usefulness of whole blood Hg concentrations as a BEI including the rapid initial elimination half-life of mercury in the blood (i.e., ~2–4 days)[99] and the influence of methylmercury in the diet on the total whole blood Hg concentration.

Medical Monitoring

Preemployment physical examinations should focus on the documentation of baseline renal and central

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nervous system function including a urinalysis. Subsequent examinations should emphasize the detection of signs and symptoms of central nervous system dysfunction (personality changes, tremors, gait disturbances, insomnia, weight loss, ataxia).

TREATMENT

Decontamination

Medical

Accidental elemental mercury ingestion is usually nontoxic; therefore, gastrointestinal decontamination measures are unnecessary. If technically feasible, local foci of elemental mercury remaining after the parenteral injection may require excision to avoid a reservoir for continued slow Hg absorption into the blood, depending on the location of the mercury.[2]

Environmental

Procedures for mercury cleanup depend on the amount of mercury spilled and the type of surface. Mercury-containing clinical thermometers are silver, whereas red thermometers contain dibutyl phthalate. The decontamination of mercury spilled from a broken thermometer can usually be accomplished in the home without professional help. Collection of the mercury on nonporous surfaces (e.g., kitchen counters, linoleum floors) requires the use of stiff paper (e.g., index cards) to gather the mercury into glass jars or zip-lock plastic bags. Neither vacuum cleaners nor brooms should be used to collect the mercury; gold jewelry should be removed prior to the cleanup.[229] Heat increases mercury volatility; therefore, heaters and house ventilation should be turned off prior to cleanup. The mercury should be discarded through the local hazardous waste program. Additional ventilation for several days in the area of the spill is desirable to reduce ambient mercury levels.

Larger spills of mercury or spills of mercury on porous surfaces (e.g., furniture, carpet, unfinished wood) may require special equipment/expertise to avoid the formation of toxic Hg concentrations including the creation of an insoluble compound (i.e., solidifying mercury with sulfide powder to form mercuric sulfide) or amalgamation (i.e., mixing with one or more metals to form a solid). The skin absorbs elemental mercury; therefore, dermal contact with elemental mercury should be minimized. The local health department or private consultants are resources for decontamination measures. The US EPA recommends that the ambient air Hg concentration should be reduced to $<1\ \mu g/m^3$.

Antidotes

Animal studies indicate current chelating agents do not efficiently remove elemental mercury from the brain but may reduce the renal accumulation of elemental mercury.[230] The chelating agent of choice for symptomatic chronic Hg^0 toxicity is probably DMPS; however, data on efficacy are very limited with existing data suggesting efficacy decreases with increasing time since exposure. BAL is an option in acute mercury vapor intoxication if administered soon after exposure. Clinical data on the efficacy of DMSA are weak. Rodent studies indicate most chelators do not cross the blood–brain barrier or remove metals directly from brain tissue.[231]

DMPS

2,3-Dimercaptopropane-1-sulfonate (DMPS) is an investigational oral analog of BAL that may be less toxic than DMSA; however, there is limited availability of this drug in the United States because this chelating agent is not approved by the US FDA for Hg or Pb poisoning. American pharmacies can compound DMPS (usual daily dose, 3–10 mg/kg body weight).[232] The typical oral adult dose is up to 300 mg three times daily for 7 weeks. DMPS may be administered intravenously in 0.9% saline with reported doses in severe poisoning of 250 mg q4h for the first 48 hours, 250 mg q6h for the next 48 hours, and then 250 mg q8h. Duration of treatment depends on clinical improvement, blood/urinary Hg concentrations, and the ability to switch to oral therapy. Adverse effects of DMPS include back pain, nausea, rash, and leukopenia. Essential minerals (Cu, Mg, Se, Zn) should be monitored; replacement of these essential metals may be necessary.[233]

There are inadequate clinical data to determine the effect of DMPS on the clinical outcome of elemental mercury poisoning; however, several case reports suggest improved outcomes following DMPS chelation after Hg^0 exposure. The urinary excretion half-life of mercury decreased from an average of 33.1 to 11.2 days in 2 workers with elevated mercury concentrations after an excessive elemental mercury vapor exposure.[234] The initial 24-hour Hg excretion of both workers exceeded 500 μg; the symptomatic worker was significantly improved after his course of chelation. A 36-year-old jewelry producer developed tremors, slurred speech, headaches, and poor coordination after chronic exposure to mercury vapors (blood Hg = 116 μg/L).[235] Three 5-day courses of 30 mg DMPS/kg/d in three divided doses over 9 weeks were associated with substantial improvement in speech and tremor; total urinary excretion of Hg during this period was about 49 mg. Although

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

oral DMPS (1,200 mg on day 1, followed by 200 mg bid from day 2 on) initially increased urinary Hg excretion after the intentional injection of elemental Hg, the renal elimination of mercury was extremely small compared with the total Hg^0 dose.[236]

Dimercaprol (BAL)

Although BAL removes inorganic mercury from the kidney during severe acute inorganic mercury poisoning, the use of BAL for elemental mercury exposure is questionable. The administration of dimercaprol (BAL) is an option in severe, acute elemental mercury poisoning depending on clinical judgment of the potential risks and benefits;[237] however, there are no clinical data to confirm the effectiveness of chelation therapy in improving the toxic effects of elemental mercury. Some,[238,239] but not all,[240] rodent studies suggest BAL may redistribute mercury to the heart, lung, and brain when administered 24 hours after exposure. Case reports document the survival of patients after severe, acute elemental mercury poisoning without chelation.[23] The effectiveness of BAL decreases with time since acute exposure, particularly when initiated more than a few months after acute exposure.

DMSA (Succimer®)

DMSA (meso 2,3-dimercaptosuccinic acid) is a water-soluble analog of BAL. The advantages of DMSA compared with BAL include oral administration and mild adverse effect profile (e.g., nausea, vomiting, diarrhea, flatus, transient elevation of serum hepatic aminotransferases). Although DMSA is a potential chelating agent for mercury, this drug has not been officially approved for the treatment of mercury intoxication. Current data supporting the use of DMSA for the treatment of toxicity related to mercury vapor exposure are weak. A review of the medical literature recommended the use of DMPS rather than DMSA in elemental mercury toxicity based on experimental[241] and limited human data.[242] In studies of chloralkali workers given DMPS[243] and DMSA,[208] the increased urinary mercury excretion was not clinically significant when administered more than several months after the cessation of mercury exposure.

Case reports indicate that DMSA is a safe chelating agent that reduces the plasma mercury elimination half-life and increases the urinary excretion of mercury 2- to 3-fold following acute mercury toxicity.[244] Peak Hg urinary excretion occurs about 2–4 hours after the administration of DMSA;[245] however, at the present time, there is insufficient evidence that chelation therapy improves clinical outcomes, particularly when initiated more than a few months after cessation of mercury exposure. In studies of chloralkali workers given DMPS[243] and DMSA,[208] the increased urinary mercury excretion was not clinically significant when administered more than several months after the cessation of mercury exposure. A group of chloralkali workers developed a wide range of symptoms (e.g., fatigue, weakness, headache, irritability, anxiety, sleep changes, congestion, tremor, diarrhea) following exposure to mercury vapor lasting up to 16 hours.[246] Chelation of a sub-cohort of the workers with the highest mercury concentrations using DMSA (30 mg/kg every 8 hours) resulted in a ~3-fold increase in urine mercury excretion; however, the mercury excreted represented a small fraction of the total Hg dose. Chelation of these workers demonstrated no clear benefit. Similarly, the administration of a 5-day oral course of DMPS (200 mg q8h) followed by a 3-day rest period and then a 5-day oral course of DMSA (500 mg daily divided into three doses) eliminated negligible mercury from the injection of 1.5 mL Hg^0 by a 27-year-old man.[247] The total amounts of mercury excreted in the urine over the two 5-day courses were 8 mg and 3 mg, respectively. Animal studies indicate DMSA removes mercury from the kidney but does not efficiently reduce mercury content in the brain following inhalation exposure to elemental mercury vapor.[248] Rodent studies indicate the use of chelation with DMSA 1 week after exposure to elemental mercury vapors does not reduce mercury concentrations in the brain.[231]

Observation studies of patients with symptoms they attribute to dental amalgams do not provide strong scientific support for the administration of chelating agents (DMSA, DMPS) to alleviate self-related symptoms or assess Hg body burden.[249] Twenty subjects complaining of a variety of symptoms related to their dental amalgams received either a placebo or 20 mg DMSA/kg/day for 14 days.[250] Their symptoms and mood states were evaluated during the study and at a 3-month follow-up. Although DMSA treatment resulted in an average 65% increased urinary Hg excretion, and a 0.04 µg/L/day decreased blood Hg concentration, no dose-response related change occurred in subjective symptoms or mood state at the 3-month checkup. Urinary Hg excretion returned to baseline. A double-blind, randomized placebo-controlled trial involving 50 consecutive patients with self-diagnosed environmental illnesses related to dental amalgams demonstrated improvement in symptoms following enrollment in the trial.[251] Although symptoms decreased in the DMSA-treatment group, there was no statistical difference in the clinical response between the treatment and

placebo groups. Analysis of the Symptom Check List revealed overall distress, somatization, depression, anxiety, and obsessive-compulsive symptoms were above the reference ranges in these patients at baseline.

D-Penicillamine and NAP

This oral compound is probably not a useful antidote for mercury vapor toxicity as a result of the adverse effect profile and lack of supportive clinical data. D-Penicillamine chelates copper, zinc, and iron in addition to mercury. The use of penicillamine is contraindicated in penicillin-sensitive patients. *N*-acetyl-D,L-penicillamine (NAP) is an investigational analog of D-penicillamine. Several case reports suggest some clinical improvement after administration of NAP following chronic elemental mercury toxicity;[252,253] however, chelation of 53 construction workers exposed to mercury vapor with NAP and DMSA resulted in the mobilization of a small fraction of the total estimated body mercury.[35]

Supportive Care

Supportive tests based on clinical symptomatology following acute elemental Hg intoxication include a complete blood count with platelets,[254] serum electrolytes, glucose and baseline creatinine, chest X-ray, arterial blood gases, hepatic enzymes, and prothrombin time depending on the amount of Hg^0 ingested. In serious mercury poisoning, electrocardiographic abnormalities (e.g., ST depression, QT prolongation, dysrhythmias) often occur.[255] Data on the benefit of prophylactic appendectomy for retained appendiceal Hg^0 is sparse based on rare case reports; recommendations are conflicting depending on the risk of obstruction and spillage of the Hg^0 into the peritoneal cavity during laparoscopy.[256] Whole bowel lavage and/or endoscopic aspiration often do not remove sufficient amounts of Hg^0. The risk of a subsequent inflammatory reaction producing acute appendicitis is unpredictable and sometimes delayed.[257]

INORGANIC MERCURY

HISTORY

In prehistoric times, cinnabar was a constituent of color drawings on cave walls; early Chinese workers used cinnabar to produce red ink. The transformation of cinnabar (mercuric sulfide, HgS) into a shining metallic fluid fascinated the Chinese Taoists, who believed that cinnabar represented the *One* (i.e., the nuclear energy of yang and yin). The belief in the immortal benefits of cinnabar resulted in the deaths of many Taoists, particularly the Tang emperors, during the early 9th century. Recognition of mercury toxicity predates the birth of Christ. The Romans used only slaves and criminals to mine cinnabar in the notorious Almadén mines in Spain. A number of Greek and Roman authors (e.g., Hippocrates, Pliny, Galen, Discoides, Aetius) considered mercury a toxic substance;[258] however, as early as 500 BC, mercury compounds were recommended drugs for chronic dermatological and infectious illnesses.[4] In Ayurvedic medicine, metal-containing medicines were common because the practitioners believed purified metal did not react adversely with tissues. Derived from cinnabar, *Rasasindura* was used in Ayurveda therapeutics as a metallic herb to treat deafness, insomnia, fever, pneumonia, and syphilis.[259]

Inorganic mercury was the main chemotherapeutic agent for the treatment of syphilis during the 500 years before the introduction of less toxic heavy metals (bismuth, arsenic) in the late 1800s and the advent of penicillin therapy in the 1940s.[3] Paracelsus (Phillipus von Hohenheim, 1493–1541) recommended both elemental mercury vapors and inorganic mercury salts for the treatment of syphilis. Calomel (85% mercurous chloride, Hg_2Cl_2) was the most frequently administered mercury salt. In addition to being used as an anti-syphilitic agent, calomel was a diuretic, teething powder, and cathartic. Mercuric chloride (corrosive sublimate, $HgCl_2$) was a less common form of medicinal mercury that produced local ulcerations on application to skin lesions, resulting in the name corrosive sublimate. Physicians in the 16th century used large doses of mercury to treat syphilis because they believed the diuretic action of mercury was necessary to excrete the "bad humors" from the body. Eventually, the dose of calomel was reduced after physicians realized the therapeutic action of the drug did not require the induction of drastic side effects (e.g., salivation, gingivitis, polyuria). Topical and systemic mercury probably reduced gummas and aided the healing of cutaneous lesions containing spirochetes; however, the use of mercury was not effective for the large numbers of spirochetes in secondary syphilis.

Medicinal and dental uses of inorganic mercury became widespread in the 19th century.[4] President Andrew Jackson's physicians used calomel for a variety of ailments; some authors suggested that President Jackson's tooth loss, renal dysfunction, irritability, mood shifts, and mistrust resulted from lead and mercury

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. exposure.[260] Other authors believe his death was probably not due to heavy metal poisoning based on hair sampling;[261] however, the validity of hair sampling for inorganic Hg exposure is equivocal. Mercurous chloride (calomel) was a popular teething powder, anthelmintic, disinfectant, and cathartic during the 19th and early 20th centuries, particularly for children. Some of these children developed acrodynia (Feer syndrome, pink disease, erythredema polyneuropathy), an illness characterized by the insidious onset of anorexia, irritability, insomnia, sweating, and photophobia, followed by the appearance of swelling, paresthesia, and a painful pink, desquamating rash on the extremities. Although Swift first described the clinical features of acrodynia in 1914, the connection between the ingestion of mercurous chloride and acrodynia was not recognized until the late 1940s, in part because of the highly variable course and the occurrence of acrodynia in only a few of the children exposed to mercurous chloride or other mercury compounds (phenylmercury, elemental mercury vapor).[262] Between 1950 and 1953, the General Register Office recorded 174 deaths in children attributed to acrodynia.[263,264] In 1980, three sentinel cases of acrodynia alerted health authorities in Buenos Aires, Argentina, to the exposure of ~12,000 infants to phenylmercuric fungicide-contaminated diapers.[265,266] Various forms of mercury (e.g., mercury vapor, mercurous/mercuric salts, phenylmercuric compounds) cause acrodynia from the conversion of these compounds to inorganic mercury. This disease now occurs rarely, primarily as a result of exposure to elemental mercury vapor.[267]

Following the revocation of the Treaty of Nantes in 1685, many Huguenots immigrated to England, where they brought their process for treating felt hats with mercuric nitrate. Some writers believe the Mad Hatter in *Alice's Adventures in Wonderland* was based on English hatters, who frequently were exposed to heated inorganic mercury and potentially mercury vapors during the felting process when acidic solutions of mercuric nitrate and heat were applied to hairs from animal fur. In 1938, a study of hatters exposed to inorganic mercury in the fur-cutting industry reported an excess incidence of behavioral changes, tremors, and hyperreflexia.[268] Although shyness and timidity characterize mercury-induced behavioral abnormalities, Lewis Carroll (*nom de plume* for Charles Lutwidge Dodgson) knew an eccentric furniture dealer who more closely resembled his fictional character, the Mad Hatter.[269] He also regularly observed inmates at mental health facilities while traveling with his uncle and close friend, Skeffington Lutwidge.

In 1955, the English psychiatrist John Todd first published Alice in Wonderland syndrome to portray the bizarre illusions of size, shape, and motion (metamorphopsia) appearing to the fictional character Alice in her long, strange dream.[270] The etiology of these bizarre changes in perception includes infections, mind-altering drugs, complex partial seizures, and migraine headaches. Lewis Carroll long suffered from severe migraine headaches.[271]

PHYSIOCHEMICAL PROPERTIES

The common valences of inorganic mercury are Hg^{+} (mercurous) and Hg^{2+} (mercuric). Mercurous ions form a unique structure consisting of two mercury atoms possessing an overall divalent (+2) charge. This bond easily breaks to form elemental mercury and divalent inorganic mercury.[272] Mercurous chloride (Hg_2Cl_2, calomel) is an odorless, heavy, white powder. Mercuric compounds possess a high affinity for sulfhydryl groups common in important components of enzymatic processes in the body as well as selenium in the reduced form (selenide, Se^{2-}). Mercuric selenide is highly insoluble. Mercuric chloride ($HgCl_2$, corrosive sublimate, bichloride of mercury) is an odorless, white, crystalline powder that is the most corrosive mercury salt. Mercuric sulfide (HgS, cinnabar, quicksilver vermillion) is a black or grayish-black crystalline powder. In general, mercuric oxides and sulfides are water-insoluble, whereas water-soluble mercury salts include bromides, chlorates, chlorides (except mercurous chloride), cyanide, fluorides, and nitrates. Some mercuric compounds (e.g., mercuric chloride) are corrosive to mucous membranes.[142] Table 20.3 lists the identifying information and physical properties of several inorganic mercury salts.

EXPOSURE

Uses

Although mercury has many unique physical properties (e.g., ease of alloying with other metals, uniform expansion over wide temperature range, high surface tension, fluidity) for industrial applications, domestic consumption of mercury has decreased since the early 1970s including use in batteries and switching devices.[14] The production of galvanic cells in button batteries involves the use of mercuric oxide anodes in combination with zinc or cadmium cathodes. Mercury is an important part of alkaline batteries.

TABLE 20.3. Identifying information and physical properties of inorganic mercury compounds. (Based on Satoh).[142]

Property	Mercuric Chloride	Mercuric Sulfide	Mercurous Chloride
CAS RN	7487-94-7	1344-48-5	10112-91-1
Molecular weight (g/mol)	271.52	232.68	472.09
Molecular structure	$HgCl_2$	HgS	Hg_2Cl_2
Valence	+2	+2	+1
Melting point (°C)	277	446 (sublimes)	400–500 (sublimes)
Boiling point (°C)	302	502 (Predicted)	384
Density	5.4 g/cm^3 (25°C)	7.55–7.70 g/mL (black)	7.15 g/mL
Water solubility	69 g/L (20°C)	Insoluble	0.002 g/L (25°C)
Vapor pressure (mmHg)	136.2°C	~0	NA

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number; NA = not available.

Mercury bichloride solutions previously were administered in the United Kingdom as a lavage solution to kill abdominal metastatic cancer cells, resulting in toxicity.[273] Dark-skinned people use mercury-containing soap (mercuric iodine) and cream (1–10% ammoniated mercury) to lighten their skin color.[274,275] Copper is required for tyrosinase activity and melanocyte production; inorganic mercury produces lightening of the skin by replacing copper, resulting in the inhibition of tyrosinase activity. Many countries now ban the use of inorganic mercury-containing skin lightening creams as a result of case reports associating the use of these agents with inorganic mercury toxicity;[276] however, some African countries still produce soaps that typically contain 1–3% mercuric iodide.[6]

Sources

Environment

In contrast to ambient air where elemental mercury is the dominant species, inorganic mercury salts are the dominant Hg species in drinking water and soil; however, the inorganic mercury absorption from water is limited. The strong binding of inorganic mercury to organic matter substantially limits the availability of inorganic mercury to microorganisms for conversion to the more soluble methyl mercury. In soil and surface water, mercury exists in the form of mercuric (Hg^{2+}) and mercurous (Hg^{+}) salts. The predominant form of mercury in surface water is mercuric complexed or chelated with ligands. Overall, the concentrations of mercury species in water are low. Although considerable local variation occurs, average mercury concentrations in aquatic systems are as follows: rivers and lakes, 0.001–0.003 µg/L; coastal seawater, 0.002–0.015 µg/L; and open seas, 0.0005–0.003 µg/L.[277] Drinking water usually contains <0.025 µg Hg/L; however, in a survey of US groundwater, the mercury concentrations exceeded 0.5 µg/L in 15–30% of the wells tested.[278] The WHO guideline for Hg in drinking water is 1 µg/L, whereas the US EPA standard for drinking water is 2 µg/L. The mercury concentration in most terrestrial foodstuffs is low (<20 µg/kg), consisting primarily of inorganic mercury.

The mercury content in minerals is usually low (<50 µg/kg); the amount of mercury present in soil solution is also low (20–625 µg/kg) because mercury binds strongly to organic matter.[277] Higher mercury concentrations occur in surface soil compared with subsurface soil, urban soil compared with rural soil, and organic soil compared with minerals. Human uptake of mercury from cinnabar (HgS) in soil is limited because cinnabar ore is relatively insoluble;[279] the diet is a much stronger determinant of urine mercury concentrations than residence near sources of mercury-contaminated soil.[280] Higher mercury concentrations (255–360 mg/L) may occur in sediment from lakes near point sources (e.g., coal-fired power plants); however, the mercury concentration in sediment does not correlate with the mercury concentrations of fish swimming in the water above the sediment.[281] In a highly industrialized coastal marine ecosystem (Taranto Gulf, Ionian Sea, Italy), the mean total mercury concentration in samples from 2 inlets was 2,777 µg/kg dry weight (range, 36–7,730 µg/kg dry weight).[282]

Diet

The bioavailability of inorganic mercury in the diet is poor; therefore, this form of mercury probably contributes little to the overall mercury intake by the general population. Although animals in the food chain concentrate inorganic and organic mercury, humans absorb a much greater amount of methylmercury in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

their diet than inorganic mercury (90% vs. 10%, respectively). Consequently, methylmercury, rather than inorganic mercury, is the dominant Hg species absorbed by humans consuming fish.

ENVIRONMENTAL FATE

The migration of mercury in the soil depends on the Hg species. The dominant process in the distribution of mercury compounds in the environment is the sorption of inorganic mercury into soil, where mercury exists as complex ions of divalent mercuric and monovalent mercurous compounds with varying water solubilities. Particulate matter and sesquioxides strongly adsorb inorganic mercury at pH 4–9, forming mercuric sulfide in the presence of adequate sulfide stores; therefore, the transport of inorganic mercury in soil is very limited.[283]

Although leaching is a relatively insignificant transport process, surface runoff is an important means of moving mercury-containing particulate matter into water. A substantial portion of mercury deposited in coastal sea areas precipitates as a result of the very low solubility of inorganic mercury compounds; however, acidic conditions favor the formation of methylmercury as a result of decreasing sulfide ion activity. Most inorganic mercury binds to colloids, high-molecular-weight organic matter, and particles. Sediment is the principal sink for inorganic mercury. Bacterial activity converts some inorganic mercury to methyl mercury. Limited demethylation of organic mercury to inorganic Hg occurs in the cold layers of the sediment and lakes during winter. Inorganic mercury is rapidly eliminated from organisms; therefore, little inorganic mercury accumulates in animals.

DOSE EFFECT

The effects of mercury depend on the dose and form of mercury. Inorganic mercury affects the nervous system (central and peripheral) and the renal tubules.

Acute Toxicity

The low vapor pressure of inorganic mercury compounds limits exposure via inhalation to toxicologically insignificant concentrations. The lethal dose of mercuric chloride or mercuric acetate ranges from 10–42 mg Hg/kg. Consequently, the lethal dose of these two inorganic compounds is about 1–4 g based on the percentage of Hg in these salts (73% and 63% by weight, respectively). A 39-year-old woman vomited twice immediately after ingesting 0.675 g mercuric chloride. Within 2 hours, she received 5 mg BAL/kg; subsequently, she remained asymptomatic.[284] A 26-year-old woman survived after ingesting 0.9 g mercuric chloride after developing hematemesis, melena, and acute renal failure,[285] whereas a 27-year-old man ingested 6 g mercuric chloride and died after developing hypovolemic shock, acute renal failure, and necrosis of his stomach.[286] The ingestion of 7 g mercuric chloride by a 23-year-old female resulted in her death from progressive acute respiratory distress syndrome despite chelation, plasma exchange, and intensive supportive care.[287] The kidney is the critical target organ for the ingestion of inorganic mercury. A single ingestion of 15.8 mg Hg/kg as mercuric chloride produced nephrotoxicity including proteinuria in an 18-year-old; no permanent renal damage developed.[288]

Chronic Toxicity

At the present time, there is insufficient evidence to conclude that inorganic mercury concentrations typically present in the environment cause any adverse effects in the general human population; however, the general consensus of most regulatory organizations is the minimization of mercury exposure where practical.[289] The most sensitive target organs are the fetal and neonatal central nervous system, the kidneys, and the thyroid gland.

Neurotoxicity from the ingestion of inorganic mercury in humans usually results from the abuse of mercury-containing medications. A case report associated the development of dementia and irritability with the chronic ingestion (0.72 mg Hg/kg/d) of a mercurous chloride-containing laxative over many years.[290] A 14-day study in rats gavaged with mercuric chloride revealed a NOAEL of 0.93 mg Hg/kg/day, whereas a 6-month rodent study demonstrated a NOAEL of 0.23 mg Hg/kg/day based on the development of foci of tubular regeneration and thickened tubular basement membranes.[291]

TOXICOKINETICS

Absorption

The gastrointestinal tract is the primary route of inorganic Hg absorption with animal studies indicating the rate of absorption ranges from 2–40% depending on age and the solubility of the particular type of inorganic compound.[292] The bioavailability of mercuric chloride averages ~5–7%; this inorganic mercury compound

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

accounts for most cases of inorganic mercury poisoning. The ingestion of mercury disk batteries may increase blood Hg concentrations following decomposition. An 18-month-old infant ingested a large mercury-containing disc battery. She remained asymptomatic during and after the 48-hour passage of split casing and a large amount of mercury following an enema.[293] Her physical exam and laboratory values were normal. *In vitro* human skin studies and case reports of elevated urine Hg concentrations in individuals using mercurous chloride-containing cosmetics indicate that transcutaneous absorption of this inorganic mercury compound may occur.[294]

Distribution

The distribution of inorganic mercuric (Hg^{2+}) is similar to that of elemental mercury with most inorganic mercury residing in the kidney and to a much lesser extent in the liver and intestines. Inorganic mercury concentrations increase with age in the cerebrum and heart. Unlike elemental mercury, the poor lipid solubility of mercuric mercury limits the amount of Hg^{2+} that crosses the blood–brain barrier; however, primate studies indicate the occurrence of some metabolism to inorganic mercury following absorption of elemental or organic mercury in the brain.[295,296] In the plasma, Hg^{2+} does not diffuse easily because of the binding of Hg^{2+} to albumin and globulins; consequently, inorganic Hg concentrations are similar in plasma and red blood cells.[297]

Elimination

Following the absorption of large doses of inorganic mercury, the urine is the principal route of elimination; the amount of inorganic mercury excreted in the feces is much smaller than the urine. Reductase and dismutase enzymes convert small amounts of inorganic mercury to elemental mercury with resultant elimination in expired air;[100] however, the expiration of elemental mercury after reduction of Hg^{2+} to Hg^0 accounts for only a very small portion of the elimination pathway. The elimination of inorganic mercury follows a complicated model with the biological half-lives depending on the tissue and time since exposure. The overall elimination rate of inorganic mercury follows the elimination rate of mercury from the kidney with a biological half-life of 40–60 days; the elimination rate from the blood and brain follows a biphasic pattern with an initial rapid phase of several days.[298] A fraction of the body burden of mercury probably has a long half-life including inorganic mercury in the brain,[299] but the toxicological significance of this prolonged half-life remains unclear because of the storage of at least some of this mercury in a biochemically inactive form (e.g., mercury selenide).[6]

Maternal–Fetal Kinetics

Only a small fraction of Hg^{2+} enters fetal blood as a result of limited lipid solubility; however, Hg^{2+} can accumulate in the placenta.[6] In a study of maternal guinea pigs injected with 1 mg $HgCl_2$/kg body weight, total Hg concentrations in their milk were lower than maternal plasma on days 3, 5, and 10 postpartum.[300]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The mechanism of toxicity for inorganic mercury and organic mercury appears similar, resulting from the disruption of sulfhydryl-containing enzymes. Mercury impairs intracellular homeostasis of oxidation/reduction reactions with subsequent enhancement of oxidative stress, primarily in the kidney, brain, and liver.[301] Although the binding of mercury to thiol groups affects intracellular mercury transport and kinetics (distribution, excretion), this effect does not explain intracellular oxidative changes or alteration of calcium homeostasis. *In vitro* studies suggest selenoproteins in glutathione peroxidase and the thioredoxin system (thioredoxin reductase 1/2) are primary cellular targets of mercury toxicity.[302] The affinity of thiol groups is several orders of magnitude higher for selenium than mercury; consequently, the binding of mercury to selenoproteins (e.g., K, P, T) enhances oxidative stress by impairing the thioredoxin system and disrupting the cellular redox environment. Mercury induces a relative selenium deficiency depending on the form of mercury and selenium, dose, and organ; subsequent toxicity produces disturbances of calcium homeostasis, lipid peroxidation, mitochondrial injury, disruption of protein repair processes, and increased apoptosis.[301] Valence and chemical state influence mercury kinetics, target organs, and chemical processes (e.g., thioredoxin system) with inorganic mercury compounds being less potent inhibitors of the thioredoxin system than methylmercury.[303]

At relatively low doses, mercuric chloride produces nephropathy in the S_1 segment of the proximal tubule that spreads to the S_2 and S_3 segments as the dose increases. This action results at least partly from the selective distribution of enzymes and transport

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

proteins (e.g., apical γ-glutamyl transpeptidase, the basolateral organic anion transport system) that affect Hg uptake into the proximal tubule.[304] Acrodynia (pink disease) may involve hypersensitivity; however, the immune system is not a major target organ for inorganic mercury toxicity. Although total urine mercury concentrations are always elevated in these children, neither the occurrence nor the severity of this disease is dose-related to mercury exposure.[6] Hypertension associated with acrodynia results from the inactivation of *S*-adenosylmethionine with subsequent inhibition of catecholamine-*O*-methyltransferase and increased epinephrine, norepinephrine, and dopamine concentrations.

Pathological Changes

The kidney is the main target organ following acute exposure to inorganic mercury, whereas exposure to elemental or organic mercury seldom causes renal dysfunction.[305] Acute inorganic mercury salt ingestion produces oliguric renal failure secondary to acute proximal tubular necrosis. Damage following inorganic mercury ingestion typically involves the distal renal tubule; renal biopsy 2 weeks after the ingestion of ~500 mg mercuric chloride demonstrated markedly dilated renal tubules with intratubular cell debris, interstitial edema, and mild inflammatory infiltrates in the interstitium consistent with acute tubular necrosis.[306] Histological changes in the renal vascular system, collecting ducts, and glomeruli are usually minimal.[307] Occasional case reports associate the use of inorganic mercury-containing compounds with nephrotic syndrome. These case reports describe an idiosyncratic, immunological response that manifests by an immune complex (membranous) glomerulonephritis. The exposures to inorganic mercury compounds include the use of teething powders by pediatric patients, application of skin-lightening creams by black African women, and occupational Hg exposure at an electrolysis unit in a chemical plant.[308] The proteinuria of membranous glomerulonephritis primarily includes high-molecular-weight proteins that leak through damaged glomeruli. Although glomeruli are normal by light microscopy, immunohistochemical studies demonstrated confluent finely granular epimembranous deposits of IgG and C3. Severe mucosal necrosis results from acute inorganic ingestion.

Postmortem Examination

A 36-year-old woman intentionally ingested mercuric chloride; she developed hemorrhagic nasopharyngeal mucosa, airway obstruction, respiratory failure, and hemodynamic instability with hepatorenal failure.[309] She died ~12 hours after ingestion. The postmortem examination demonstrated the following Hg concentrations: kidney, 284.3 μg/g; liver, 65.1 μg/g; spleen, 56.3 μg/g; lungs, 38.5 μg/g; myocardium, 16.9 μg/g; cerebral cortex, 1.4 μg/g; and cerebellum, 1.2 μg/g. The findings are consistent with the difficulty of inorganic mercury penetrating the blood–brain barrier.

CLINICAL RESPONSE

Inorganic mercury toxicity usually results from occupational exposure or the intentional/unintentional misuse/use of Hg-containing medicines. Classically, acute inorganic mercury toxicity (excluding elemental mercury vapor) involves divalent mercuric chloride (corrosive sublimate) and, previously, monovalent mercurous chloride (calomel, 85% Hg_2Cl_2). The former causes corrosive injury to the GI tract, renal damage, and secondary infections, whereas the latter produces acrodynia (pink disease) characterized by diaphoresis, weight loss, weakness, apathy, and a diffuse, painful rash. Mercuric chloride does not easily pass the blood–brain barrier, limiting CNS toxicity. The low solubility of mercurous chloride limits GI absorption and toxicity.

Acute Toxicity

Burning mouth, sore throat, nausea, and vomiting with severe gingivitis, stomatitis, and esophageal erosions develop after ingestion of large quantities of inorganic mercury. Abdominal pain, weakness, fatigue, pallor, hematemesis, hematochezia, shock, and vascular collapse may also occur. Severe ingestions cause acute tubular necrosis and acute renal failure. A 26-year-old woman was anuric for 14 days after ingesting mercuric chloride; she survived with hemodialysis, and normal renal function returned 4 months after ingestion.[310] A patient survived the injection of mercuric chloride in spite of the development of nausea, vomiting, darkened gums, abdominal pain, and anemia.[311]

Environmental Exposure

During the 1940s, case reports of young children (<5 years old) associated acrodynia (pink disease, Feer disease, erythredema polyneuropathy) with exposure to mercurous chloride (calomel, 85% H_2Cl_2) in teething powder and ointments.[262] Although acrodynia typically

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

affects infants and young children exposed to mercurous chloride, adolescents and adults may develop acrodynia following exposure to elemental mercury vapor from broken thermometers or fluorescent light bulbs,[312] organic phenylmercuric compounds in latex paint, or other inorganic mercury compounds (mercuric chloride in diaper rinse;[313] ammoniated mercury (HgH_2NCl) ointment[27]). The highly variable clinical features of this disease include dermatological, cardiovascular, and neurobehavioral abnormalities. Acrodynia (pink disease) means painful extremities referring to the presence of an edematous, pink, painful, paresthetic, and desquamating rash on the extremities.

The onset of this illness is often insidious with anorexia, hypotonia, and irritability. Profuse sweating, photophobia, and hypertension often develop along with a prominent miliaria rash. Secondary infections may develop as a result of the traumatic denudation of the skin of the hands. In severe cases, dehydration and tooth loss occur along with ulceration of the gums. Clinical findings are less severe in older children. The extremities are not as pink in older children with acrodynia because the palms and soles are thicker. Antisocial behavior, poor school performance, tremor, fatigue, insomnia, and alopecia are more prominent in older children with acrodynia compared with infants. In adults, common presenting symptoms include insomnia, thirst, abdominal pain, aching extremities, and psychological disturbance. The differential diagnosis of acrodynia includes Kawasaki disease (mucocutaneous lymph node syndrome), measles, pheochromocytoma, and other viral exanthems. Lymphadenopathy, mucous membrane lesions, and conjunctival injection are much less common in acrodynia than Kawasaki disease.[267]

Occupational Exposure

Although some *in vitro* and animal data suggest mercuric chloride exposure may increase some serum cytokines and autoimmune responses,[314,315] insufficient evidence are available in epidemiology studies to link mercury exposure with autoimmune diseases.[316] Renal dysfunction (proteinuria) may develop; less commonly, the proteinuria progresses to the nephrotic syndrome with continued inorganic mercury exposure. Stomatitis and gastrointestinal distress also may occur. The appearance of a brown anterior band in the lens indicates the deposition of mercury on the anterior surface of the lens (mercurialentis).[317]

Developmental Abnormalities

Currently, there is little evidence that inorganic mercury exposure produces reproductive or developmental effects at mercury concentrations present in occupational or environmental settings. A case report associated a spontaneous abortion with the maternal ingestion of a large dose of mercuric chloride.[318]

Carcinogenesis

Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program (NTP) lists inorganic mercury compounds as potential human carcinogens. The former agency lists elemental and inorganic mercury in Group 3 (not classifiable as to their carcinogenicity in humans). A 2-year study by the NTP revealed a statistically significant incidence of squamous cell papillomas in the forestomach of male Fischer 344 rats gavaged with 1.9 and 3.7 mg Hg/kg/d as mercuric chloride, but there was equivocal evidence for squamous cell papillomas in female rats.[291] Additionally, there was a marginal increase in the incidence of thyroid follicular cancer in male rats, but not in female rats or mice. The US EPA classifies mercuric chloride as class C (possible human carcinogen) based on limited rodent data and no human data, whereas other inorganic mercury salts are class D (not classifiable) compounds.

DIAGNOSTIC TESTING

Analytical Method

Most techniques for the determination of mercury concentrations utilize atomic absorption spectrometry (AAS), atomic fluorescence spectrometry (AFS), or neutron activation analysis (NAA). In most methods, the mercury in the sample is reduced to elemental mercury. The most common method of analyzing blood and urine for mercury content involves cold vapor AAS after digestion of the samples with acids and the reduction of bivalent inorganic mercury to mercury vapor with stannous chloride. Gas chromatography/atomic fluorescence spectrometry can separate individual mercury species. *In vitro* studies indicate inorganic mercury is stable in whole blood at −70°C to –23°C for 1 year, whereas deterioration occurs at body temperature (37°C) after 2 weeks.[319]

Biomarkers

Blood

Inorganic mercury distributes relatively evenly between serum and erythrocytes, whereas erythrocytes are the primary location of methylmercury.[320] Consequently, inorganic Hg concentrations in plasma, serum, and whole blood are similar. Although data are very limited, case reports suggest the body probably does not convert substantial amounts of inorganic Hg to organic Hg compounds following inorganic Hg poisoning. A 39-year-old man died 49 days after the intentional ingestion of ~50 g mercuric chloride; the postmortem blood contained total Hg and methylmercury concentrations of 11,700 μg/L and 150 μg/L, respectively.[321] The total Hg concentration in whole blood 1 day after admission was 6,750,000 μg/L. Potential biomarkers of a biologically effective dose include depletion of intracellular glutathione and induction of metallothionein; however, other metals and compounds affect the concentration of these substances complicating and confounding the results of analytical methods to detect glutathione and metallothionein.

General Population

The diet is the primary source of mercury with methylmercury in fish accounting for a major portion of the mercury in fish-eating populations. The typical total whole blood Hg concentration in non-fish-eating population is ~2 μg/L.[322] The total whole blood Hg/plasma Hg ratio depends on the Hg species involved with the mercury exposure. A study of unexposed referents and 40 Swedish chloralkali workers exposed primarily to elemental Hg demonstrated a mean whole blood Hg concentration of 7 μg Hg/L and a plasma Hg concentration of 6 μg/L.[323] The whole blood/plasma ratio for the general referent population (i.e., nonoccupational controls exposed primarily to methylmercury in fish) was 2.38 compared with 1.17 for chloralkali workers exposed primarily to mercury vapor. The higher whole blood/plasma Hg ratio in the controls reflects relatively lower plasma inorganic Hg than in the chloralkali workers.

Toxicity

A 31-year-old man complained of nausea, vomiting, and abdominal pain 4 hours after ingesting mercuric oxide.[324] The whole blood samples drawn during the first 24 hours after admission demonstrated total mercury concentrations of 0.13 mg/L (130 μg/L) and 0.185 mg/L (185 μg/L). He underwent chelation with BAL and DMSA; he developed only mild elevation of serum hepatic aminotransferases without specific complaints. Whole blood mercury concentrations returned to baseline within 1–2 months of acute poisoning. A 19-year-old woman presented with nausea, blood-stained vomitus, diarrhea, and abdominal discomfort after the suicidal ingestion of 2–4 g mercuric chloride powder.[325] The whole blood mercury concentration 3 and 24 hours after ingestion was 3.58 mg/L (3,580 μg/L) and 2.13 mg/L (2,130 μg/L), respectively. Dimercaprol was initiated within 2 hours of presentation along with supportive care. She developed mild hemodynamic instability, metabolic acidosis, hypokalemia, leukocytosis, and fever with symptoms improving within 48 hours of admission; the 48-hour post-ingestion whole blood mercury concentration was 1.77 mg/L (1,770 μg/L). She recovered without sequelae.

Postmortem

A 66-year-old woman ingested an undetermined amount of mercuric chloride and methyprylon; she developed rigidity and was taken to the emergency department, where she died shortly after admission.[326] The whole blood total mercury concentration was 22 mg/L (22,000 μg/L) as measured by flameless atomic absorption spectrophotometry; the postmortem methyprylon concentration was 0.6 mg/L. The postmortem blood from two patients dying after undergoing peritoneal lavage with mercuric chloride-contaminated fluid was 1,700 mg/L (1,700,000 μg/L) and 2,100 mg/L (2,100,000 μg/L) as measured by neutron activation analysis.[327]

Urine

General Population

Analysis of urine mercury concentrations is a simple, rapid test for identifying patients with excessive exposure to elemental and inorganic mercury. Elemental Hg rapidly oxidizes to inorganic mercury; consequently, total urine Hg concentrations reflect exposure to elemental and inorganic mercury; the kidney excretes little methylmercury from the diet. In the general population without occupational Hg exposure or excessive fish consumption, the total urine mercury concentrations average <5 μg/L.

Toxicity

Urine mercury concentrations document exposure to mercury and help monitor the effectiveness of chelation therapy, but urine total mercury concentrations do not correlate to specific symptoms of inorganic mercury toxicity. Spot urine collections are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

less reliable than 24-hour urine collections for mercury concentrations because glomerular filtration rates and creatinine clearance vary. Typically, signs of acute mercury poisoning do not usually occur until the urine mercury concentration exceeds 300 µg/L. Baseline urinary excretion of mercury can be normal in patients with overt acrodynia, depending on the timing of the urine sample.[328] A nonrandom survey of 150 women tested within 120 days after the use of a mercury chloride-containing beauty cream demonstrated a mean urine mercury concentration of ~147 µg/L (maximum, 1,170 µg/L).[274] Many of these women had health complaints consistent with mercury intoxication; however, there were inadequate data to correlate urine mercury concentrations to the dose of mercury or health complaints.

Hair

Accumulation of inorganic mercury in hair is limited. Typically, inorganic Hg including elemental forms represents <10% of the total Hg in hair. The simultaneous analysis of multiple (e.g., 15–39) metals in hair samples to provide vitamin supplements or chelation therapy is not a reliable method to determine the presence of toxic concentrations of heavy metals including mercury.[329,330] In contrast to methylmercury, there are limited data on the incorporation of inorganic mercury during hair growth. Correlating blood mercury concentrations with inorganic or elemental mercury concentrations in hair is more complex than methylmercury, particularly when volatile species of inorganic or elemental mercury in the environment contaminate the hair. Inorganic and elemental mercury concentrations in hair are probably not robust markers of dietary exposure to these mercury species; thus, hair and nail sampling are not recommended methods to evaluate inorganic mercury toxicity.[197]

Abnormalities

Urine

Mercury blocks catechol methyl transferase, the enzyme that converts catecholamines to metanephrine. Consequently, elevated levels of epinephrine and norepinephrine may appear in the urine along with increased concentrations of vanillylmandelic acid and homovanillic acid. Glucosuria may also result from the accompanying sympathetic hyperactivity following acute mercury intoxication.

Imaging

The MRI of a 38-year-old worker with the development of anxiety, tremulousness, chills, diffuse red rash, joint swelling, myalgias, and headache following a 5-day exposure to phenylmercury ammonium acetate demonstrated hypermetabolism of the posterior cingulate cortex; the changes correlated with attention/concentration deficits and marked anxiety on neuropsychiatric testing.[331] The CT scan of the brain was normal. The T2-weighted MRI images of a 10-year-old child with acrodynia, seizures, and visual impairment following chronic elemental mercury poisoning demonstrated multiple hyperintense lesions in the cerebral white matter (paracentral gyrus, posterior frontal region, parietal region, posterior cingulate gyrus), left globus pallidus, and putamen.[332] These findings resolved over 9 months with resolution of neurological symptoms and normalization of blood mercury concentrations. Sural nerve biopsy from a patient with chronic mercury toxicity secondary to exposure to ammoniated mercury salts demonstrated a mixed pattern of axonal degeneration and demyelination.[333]

Neuropsychological Testing

Neither blood nor urine mercury concentrations correlated to neuropsychological testing in 42 chemical workers from a plant producing inorganic mercury compounds; the major processes were production of mercuric oxides, mercury chlorides, and phenyl mercuric acetate along with drying and formulation operations.[225] A meta-analysis of 18 occupational studies (1,106 exposed, 1,105 controls) assessing the effect of inorganic mercury on neuropsychological tests suggests chronic exposure to inorganic mercury impairs motor performance (e.g., steadiness, grooved pegboard, Purdue pegboard, tapping, Santa Ana, eye-hand coordination) to a greater extent than memory or attention tests.[334] The mean total urine Hg concentration in these cross-sectional studies ranged from 3–192 µg/g creatinine. The lack of prospective studies, imprecise historical exposure information, and limited information on baseline test scores limit conclusions regarding exposure-response relationships.

HEALTH SURVEILLANCE

Risk Assessment

The ATSDR established an MRL of 7 µg Hg/kg/day for acute-duration oral inorganic mercury exposure

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(≤14 days) based on an NOAEL of 930 µg Hg/kg for renal effects (i.e., ↑ absolute and relative kidney weights) in rats gavaged with mercuric chloride for 14 days.[335] The MRL for intermediate-duration (15–364 days) oral exposure to inorganic mercury was 2 µg mercury/kg/day based on an NOAEL of 230 µg Hg/kg for renal effects (i.e., ↑absolute and relative kidney weights) in rats gavaged with mercuric chloride.[336] The US EPA established an oral RfD of 3×10^{-4} mg/kg/day (0.3 µg/kg/day) for mercuric chloride based on weight-of-evidence approach analyzing LOAELs of 226, 317, and 633 µg/kg/day of mercuric chloride derived from three studies demonstrating immunoglobulin deposits in glomeruli and intestinal glands of Brown Norway rats.[337,338,339]

Environmental Monitoring

Table 20.4 lists the guidelines and regulations for inorganic mercury exposure. These values are similar for elemental and inorganic Hg because the body converts almost all absorbed Hg^0 to inorganic mercury with subsequent urinary excretion of the inorganic mercury. The US OSHA regulation for inorganic mercury compounds is 100 µg/m^3 as a ceiling limit with a skin notation. This exposure value was promulgated to prevent systemic toxicity including subclinical neuropathies.[206] The ACGIH guideline for inorganic mercury compounds is a TLV–TWA of 25 µg/m^3 rather than a ceiling limit. The previous 100 µg/m^3 level was based on pharmacokinetic data that indicated inorganic mercury compounds deposit little mercury in the brain; subsequent concern about subclinical renal and neuropsychological effects resulted in the lowering of the ACGIH recommendation.[223] Currently, there are few data to indicate that inorganic mercury levels in the current work environment produce reproductive abnormalities, especially in males.

TABLE 20.4. Inorganic mercury guidelines and regulations.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	None
PEL-Ceiling	100 µg/m^3[a]
NIOSH	
REL–TWA (10-hour)	100 µg/m^3
IDLH	10,000 µg/m^3 (as total Hg)
ACGIH	
TLV–TWA (8-hour)[a]	25 µg/m^3 (elemental + inorganic)
BEI (urine)	20 µg/g creatinine, (as Hg)[b]
BEI (whole blood)	None[b]
US FDA	
Bottled water allowable limit	2 µg/L
US EPA	
RfD (chronic oral exposure)	0.3 µg/kg/day
MCL	2 µg/L
ATSDR	
MRL (acute oral exposure, ≤14 days)	7 µg/kg/day
MRL (intermediate duration oral exposure, 15–364 days)	2 µg/kg/day
WHO	
Drinking Water Guideline	1 µg/L

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; BEI = biological exposure indices; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfD = reference dose; TLV = threshold limit value; TWA = time–weighted average; US EPA = US Environmental Protection Agency; WHO = World Health Organization.

[a] Skin notation; [b] Total inorganic mercury in pre-shift urine sample; the total inorganic mercury at the end of shift at the end of workweek whole blood sample (15 µg/L) was withdrawn in 2013 because of the effect of dietary organic mercury on the whole blood Hg concentration.

Biological Monitoring

Urine

Total Mercury

The presence of urine mercury concentrations >500–850 µg Hg/L in exposed workers is a good predictor of the development of polyneuropathies manifested by tremors, unsteadiness, and poor coordination.[153] Early neurological symptoms may appear at urine mercury concentrations of >150 µg/L. More recent data focus on subclinical effects on renal function and neuropsychological tests. Chronic occupational exposure to inorganic mercury may produce alterations in the renal tubules and glomeruli. Most of these structural or functional changes occur when the urine mercury concentrations exceed 50 µg/g creatinine (28 µmol/mol creatinine).[340] Marked reductions in the urinary excretion of prostaglandin E_2 occur at concentrations near 35 µg Hg/g creatinine, but these changes appear reversible following a reduction in mercury exposure.[341]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Increased tremor, reduced hand steadiness, increased reaction time, and poor hand-eye coordination have been associated with total urine mercury concentrations of >200 μg/L in workers chronically exposed to inorganic mercury.[342,343] Some, but not all, studies suggest that subclinical neurological effects (e.g., reduced short-term memory, verbal intelligence) may develop following chronic mercury exposures producing urine mercury concentrations exceeding 50–100 μg/L.[154] A small cross-sectional study compared workers chronically exposed to inorganic mercury with unexposed controls using the WHO test battery to detect preclinical signs of central nervous system impairment.[344] The results suggested that decrements in short-term memory (but not in other tests on the panel) may occur in workers with urine mercury concentrations near 25 μg Hg/L. However, there are inadequate data to determine a specific threshold of urine mercury for neurological abnormalities.

Some epidemiology studies have not detected abnormalities in neuropsychological testing in workers with urine mercury concentrations near 50 μg Hg/L.[155] In a study of chemical workers exposed to inorganic mercury, an increased prevalence of neuropsychological symptoms and elevated urine *N*-acetyl-β-D-glucosaminidase (a lysosomal enzyme present in renal tubular cells) were associated with urine mercury concentrations exceeding 100 μg/L when compared with unexposed controls.[225] There was also a reduction in the mean motor conduction velocities in the highly exposed group; however, abnormal nerve conduction did not correlate to neurological symptoms. Neuropsychological test scores also did not correlate to urine mercury concentrations.

Tubular Proteins

Tubular proteinuria consists of a variety of proteins and enzymes. Many of these potential biomarkers are low-molecular-weight proteins (e.g., β_2-microglobulin, retinol-binding protein) that are normally filtered through the glomerulus and reabsorbed in the proximal tubules. Other proteins (e.g., the enzyme, *N*-acetyl-β-D-glucosaminidase, NAG) are released directly into the urine from damaged proximal tubule cells. Several different urine proteins have been evaluated as biomarkers of renal injury; however, the specificity and predictive value of these biomarkers as early indicators of a more serious renal disease remain unclear. The pattern of urinary excretion of tubular proteins (structural proteins, prostaglandin metabolites, growth factors) is not unique to specific toxins including mercury. Tubular proteinuria increases in a variety of diseases (e.g., diabetes, hypertension, alcoholism, drug use, lupus erythematosus).[345] Other sources of variability in the urinary concentrations of tubular proteins include age, gender, urine flow rate, and circadian rhythms. Environmental exposure to mercury in contaminated condominiums did not produce tubular proteinuria, despite urine mercury concentrations averaging 26 ± 4.5 μg/g creatinine.[345] *Serum* concentrations of β_2-microglobulin (B_2G) do not correlate well with measures of chronic mercury exposure.[54]

Beta$_2$ Microglobulin This microglobulin (B_2G) is a low-molecular-weight protein with a molecular weight of ~10.8 kD. The glomerulus freely filters B_2G proteins. Individuals with normal proximal tubular renal function excrete ~0.3% (<370 μg/day) of the filtered load of B_2G. Increased excretion of B_2-microglobulin suggests but does not imply impairment of renal function.[288] Following the ingestion of 1.5 g mercuric chloride by an 18-year-old, B_2-microglobulins in the urine rose to 42,400 μg/day. The increased excretion of high-molecular-weight (albumin) and low-molecular-weight (B_2-microglobulin) proteins indicates the presence of both tubular and glomerular lesions.

N-Acetyl-β-D-Glucosaminidase (NAG) This high-molecular-weight (130–140 kD) protein is a lysosomal enzyme present in renal tubular cells; therefore, NAG is not normally filtered at the glomerulus. Elevated urinary NAG concentrations indicate tubular dysfunction following mercury exposure, producing urine mercury concentrations of 100–250 μg/L.

Biological Exposure Indices

The Biological Exposure Indices (BEI) recommended by the ACGIH for total urinary (i.e., primarily inorganic) mercury is 20 μg/g creatinine in a pre-shift urine sample as listed in Table 20.4. Although substantial interindividual variation in urine mercury concentrations occurs, urine mercury concentrations exceeding 50 μg/L indicate the need to investigate the individual's work environment; concentrations exceeding 100 μg Hg/L suggest the need to remove the worker from the work environment. Overt clinical evidence of mercury toxicity may not occur in mercury-exposed workers despite the presence of urine mercury concentrations of >100 μg/g creatinine.[346] Because of the large inter- and intraindividual variation in urine mercury concentrations,[210] decisions regarding workers should be based on an average of several measurements rather than a single value.[347] The creatinine adjustment method

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

is the most sensitive method of reducing variation in the content of urine mercury samples used for biological monitoring.[348]

Blood

Most occupational studies use urine mercury rather than whole blood Hg concentrations as the biomarker of long-term inorganic Hg exposure because peak urine mercury concentrations occur ~2–3 weeks after acute exposure, and the urinary elimination half-lives for short-term and long-term exposures are ~40–60 days and ~90 days, respectively.[96] Additionally, methylmercury in the diet affects the whole blood Hg concentration, but not the urine Hg concentration.

Medical Surveillance

Preemployment physical examinations should focus on the documentation of baseline renal and central nervous system function including a urinalysis. Subsequent examinations should emphasize the detection of signs and symptoms of central nervous system dysfunction (personality changes, tremors, gait disturbances, insomnia, weight loss, ataxia).

TREATMENT

Decontamination

Studies reported in the 1940s suggest activated charcoal reduces the absorption of mercuric chloride in rats and *in vitro* solutions.[349] Although activated charcoal in the usual doses for ingestions of inorganic mercury is a therapeutic option, activated charcoal is not routinely recommended for inorganic mercury because there are no clinical data to confirm the efficacy of using activated charcoal in this setting, particularly when corrosion of the gastrointestinal tract occurs.

Enhancement of Elimination

Hemodialysis

Hemodialysis and hemofiltration remove relatively small amounts of mercury compared with the total body burden of mercury; therefore, the role of hemodialysis in the treatment of inorganic mercury toxicity is limited to the support of patients in renal failure.[350,351] In an adult developing anuria after the ingestion of mercuric chloride, 42 courses of hemodialysis did not increase the clearance of mercury.[286] The BAL-mercury complex is dialyzable, but the combination of chelation therapy and hemodialysis adds little to Hg clearance in patients with adequate renal function.

Experimental methods to improve the efficiency of hemodialysis include extracorporeal regional coupling hemodialysis (ERCH) and equilibrium dialysis. The insertion of dimercaptosuccinic acid into an arterial bloodline during the hemodialysis of a patient following the ingestion of mercuric chloride 6 days earlier resulted in a 10-fold increase in the amount of mercury in the dialysate compared with hemodialysis alone. However, an 80-minute treatment of DMSA-ERCH removed only ~1 mg of mercury from this anuric patient.[352] *In vitro* equilibrium hemodialysis with *N*-acetylcysteine and dimercaptosuccinic acid is an experimental method for the removal of mercury from the body during hemodialysis for acute mercury poisoning. *In vitro* studies with this method suggest that *N*-acetylcysteine enhances the transfer of mercury into the dialysate more than other chelates;[353] the efficacy of this procedure remains unclear.

Charcoal Hemoperfusion

Charcoal hemoperfusion and hemodialysis are ineffective methods to enhance the removal of mercury, even after the patient has been treated with dimercaprol (BAL).[354] Charcoal hemoperfusion does not offer a useful alternative to accelerate mercury elimination.[346,354,355]

Plasma Exchange/Exchange Transfusion

Although plasma exchange removes a relatively small amount of mercury, the removal of mercury by plasma exchange is larger than other methods used to enhance elimination. Following the ingestion of 6 g mercuric chloride, six plasma exchanges recovered 17 mg of mercury.[286] However, blood mercury concentrations rebounded after each plasma exchange similar to hemodialysis. Plasma exchange is most effective when instituted early, together with chelation therapy.[346]

Antidotes

Although chelating agents are often used to increase mercury excretion in severe acute inorganic mercury poisoning, the effectiveness of these drugs in organic and elemental mercury poisoning remains unclear. The initiation of chelation more than 1 month after an acute episode of mercury poisoning or the treatment of chronic mercury intoxication probably is not efficacious. Unlike lead, mercury undergoes relatively little bioaccumulation; the excretion half-life of mercury is ~1–2

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

months.[97] Although chelating agents bind inorganic mercury and increase renal elimination of mercury, there are insufficient data from randomized clinical trials to confirm improved outcomes. Furthermore, current recommendations for chelation are based on clinical judgment and anecdotal data rather than consensus guidelines. Patient compliance is particularly important to prevent long-term sequelae of acute inorganic mercury toxicity (e.g., memory impairment, dementia, peripheral neuropathy).

Dimercaprol (BAL)

Previously, BAL (British Anti-Lewisite) was the primary chelating agent for the treatment of inorganic mercury poisoning; however, some,[238,239] but not all,[240] rodent studies suggest BAL may increase Hg distribution to the brain, heart, or lungs. As a result of these concerns and limited data on the efficacy of BAL therapy, the precise indications for BAL therapy or the use of other chelating agents are not well-defined. The decision to institute chelation therapy depends on clinical judgment regarding the severity of anticipated symptoms, the presence of toxic Hg concentrations in the urine or blood, and the adverse effects of BAL therapy. BAL is available only in intramuscular form solubilized in peanut oil.

The typical course of BAL is 4 mg BAL q4h for 5 days with 7–10 days of rest between courses. The duration of treatment depends on the chronicity of toxicity, the persistence of symptoms, the amount of mercury excreted in the urine, and the development of adverse effects. Because mercury is a non-essential metal in body function, urine mercury concentrations should be reduced to the lowest concentration possible (<10–20 µg/L) without inducing adverse effects as soon as possible after exposure. The frequent occurrence of multiple adverse effects (e.g., pain at the injection site, nausea/vomiting, abdominal pain, irritability, anxiety, paresthesias, headache, lacrimation, conjunctivitis, sore throat, myalgias, fever, hypertension) often requires the substitution of oral chelating agents (DMSA). Unfortunately, data are limited on the efficacy of oral chelating agents.

DMSA

DMSA (meso 2,3-dimercaptosuccinic acid, Succimer®) is a water-soluble analog of BAL. Although DMSA is a potential chelating agent for mercury, this drug has not been officially approved for the treatment of mercury intoxication;[356] however, animal studies support the use of DMSA for acute inorganic mercury toxicity when administered soon (minutes to hours) after poisoning as a method to reduce renal toxicity.[357] Although DMSA or DMPS increase renal excretion of mercury and reduce mercury concentrations in some tissues, the efficacy of chelation for chronic inorganic mercury is unproven.

Advantages of this drug are oral administration, mild adverse effect profile, and lack of redistribution of mercury to the brain. DMSA (Succimer®) is classified as a Category C agent for which the potential for adverse reproductive effects is not known. The most common adverse effects reported in clinical trials of children and adults have been primarily gastrointestinal including nausea, vomiting, diarrhea, and appetite loss. Rashes have been reported in about 4% of adults. Mild transient elevations in serum aminotransferase concentrations have been observed in 6–10% of treated patients.[358] The typical oral dose is 10 mg/kg twice a day for 14 days, followed by a rest period (of 2–3 weeks). Depending on the persistence of symptoms and the urinary response to chelation, a second round of DMSA may be needed.

DMPS

2,3-Dimercaptopropane-1-sulfonate (DMPS) is an investigational oral analog of BAL that may be less toxic than DMSA, but there is limited availability in the United States and few clinical data on the efficacy of DMPS during mercury toxicity. In oral doses of 100 mg three times daily, DMPS significantly increases the urinary excretion of some essential metals (e.g., copper, zinc, mercury).[359] Although the use of DMPS increases the urinary excretion of mercury,[360,361] there are few data on the effect of chelation therapy on clinical outcomes. A review of the medical literature recommended the use of DMPS for inorganic mercury toxicity based on experimental and limited human data, whereas DMSA was the preferred chelator for organic mercury poisoning.[241] Animal studies suggest that DMSA and DMPS appear superior to BAL and NAP (*N*-acetyl-D,L-penicillamine) in alleviating acute toxicity and preventing the undesirable distribution of orally administered mercuric chloride, especially to the kidney.[362] Complications of the maximum 15-day course were limited to a few patients with skin rashes. In a patient with serious ingestion of mercuric chloride, the administration of DMPS was associated with a reduction in the terminal half-life of mercury from 60 days to ~8 days.[363] However, the pharmacokinetic analysis indicated nonrenal mechanisms eliminated of >80% of the mercury; consequently, the clinical effectiveness of the DMPS treatment was not clear.

The usual course of treatment is 100 mg DMPS bid or tid for 21 days followed by a rest period.[364] Side effects

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

observed during treatment with DMPS include erythema multiforme, maculopapular rashes, and mucous membrane reactions (mouth ulcers).

N-Acetylcysteine (NAC)

Animal studies suggest that the nephrotoxic effects of mercuric chloride (both functional and biochemical) are either enhanced by glutathione depletion or prevented by glutathione augmentation. A synergistic effect may exist between the direct effect of mercury and renal glutathione deficiency. *N*-acetylcysteine promotes a significant increase in renal nonprotein sulfhydryl content.[365] The use of NAC remains experimental because there are no clinical data regarding the effect of NAC on clinical outcomes.

D-Penicillamine and NAP

This oral compound may be useful in less severe symptomatic inorganic and elemental mercury inhalation exposures; however, the role of D-penicillamine in the treatment of mercury poisoning remains unclear without clinical studies. The use of D-penicillamine is based on case reports. D-Penicillamine reverses sulfhydryl binding in the blood and chelates copper, zinc, iron, and lead in addition to mercury. The use of penicillamine is contraindicated in penicillin-sensitive patients.

N-acetyl-D,L-penicillamine (NAP) is an investigational analog of D-penicillamine that was associated with improvement in patients with inorganic mercury-induced neuropathies (tremor, ataxia).[366] These case reports suggest that NAP may improve the outcome of patients with mercury intoxication. In both cases, urinary mercury, zinc, and copper excretion increased significantly. Both patients also had partial resolution of their neurological symptoms after chelation and removal from mercury exposure. The pediatric dosage is 30 mg/kg/day up to a maximum of 1 g, while the adult dosage is 250–500 mg/day.

ORGANIC MERCURY

HISTORY

In contrast to the long history of medicinal and industrial use of inorganic and elemental mercury, the use of organic mercury compounds dates back a little more than one century. The toxicity of organic mercury compounds was recognized in the 1860s when two laboratory technicians died of dimethylmercury poisoning in London.[367] Despite the recognition of severe central nervous system toxicity as an adverse effect of organic mercury compounds used for treating syphilis, organic mercurial diuretics were developed near the end of World War I. For the next 30 years, mercurial diuretics were the drugs of choice to enhance fluid excretion from the body until more effective and safer diuretics were discovered. During this period, the antibacterial and antifungal properties of many organic mercury compounds were discovered with applications including seed dressings for cereals. Contamination of food sources by methylmercury is associated with several public health disasters that resulted in irreversible central nervous system damage.

During the 1950s and 1960s around Minamata Bay of the Yatsushiro (Shiranui) Sea in Kumanoto Prefecture, Japan, methylmercury accumulated in fish from contaminated effluent discharge by a chemical plant producing methylmercury chloride as a byproduct of acetaldehyde production.[368] The chemical composition of the contaminants was never documented, but the effluent contained other toxins (e.g., arsenic) in addition to methylmercury. Initially, this contaminant was released into Minamata Bay; however, as the production of acetaldehyde increased to meet the demand for plastics, the drainage site changed from Minamata Bay to the mouth of the Minamata River. The change in the drainage site resulted in the contamination of fish in the Yatsushiro Sea; the release of the unusually high amounts of methylmercury into the seawater ceased in 1968. Methylmercury contamination of fish also occurred during the 1960s near the Agano River in the Niigata prefecture of Japan. The first reported cases of Minamata disease appeared in 1953; by 2000, the Japanese government recognized 2,264 patients as victims of methylmercury poisoning.[369] Ataxia, cerebral palsy, chorea, mental retardation, seizures, and tremors developed in the offspring of mothers eating large amounts of methylmercury-contaminated fish; these mothers developed only mild paresthesias.[370] Currently, consumption of fish contaminated by natural biomethylation processes has not been identified as a cause of methylmercury poisoning.[100]

Three epidemic outbreaks of organic mercury poisoning occurred in Iraq from 1955–1956, 1959–1960, and the largest from 1971–1972.[371] During the first two outbreaks from 1955–1960, rural residents unknowingly consumed bread prepared from contaminated grains that contained ethylmercury *p*-toluene sulfonanilide fungicides in seeds intended for planting. The identity

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of the exact organomercury compound causing these two epidemics was not well described. The last and largest Iraqi organic mercury epidemic was attributed to methylmercury, resulting in a slightly different clinical presentation.[372] Consumption of this contaminated bread by local women led to severe mental retardation and more subtle developmental effects (e.g., delayed developmental milestones) in offspring.[373] Approximately 6,500 cases of organic mercury intoxication occurred, resulting in ~450 deaths. Epidemiology studies did not detect an increased incidence of congenital defects; however, some children developed cognitive abnormalities, delayed speech, marked visual/hearing loss, and impaired sensorimotor function.

PHYSIOCHEMICAL PROPERTIES

Organic mercury compounds contain at least 1 carbon atom covalently bound to a mercuric ion. The common organic mercury compounds include short-chain alkyl (e.g., methylmercury, ethylmercury), long-chain alkyl, and aryl (e.g., phenylmercury) forms. Mercuric acetate, methylmercuric chloride, and phenylmercuric acetate are white or white-to-cream crystalline powders, whereas dimethylmercury is a colorless liquid with high vapor pressure. Alkyl mercury compounds possess a high affinity for sulfhydryl groups commonly present in important components of enzymatic processes in the body. Divalent mercury covalently binds to carbon atoms to form organic, relatively stable mercury compounds; however, some organisms metabolize these compounds in the environment. Table 20.5 lists the identifying information and physical properties of common organic mercury compounds.

Short-chained alkyl mercury compounds (methyl, ethyl, propyl) contain a mercury-carbon bond that is much stronger than other organic mercury compounds. The mercury-carbon bonds in aryl and alkoxyalkyl mercury compounds are less stable than similar bonds in alkyl mercury compounds (e.g., methylmercury); toxicity related to the former compounds primarily results from the release of divalent mercury. In contrast to most inorganic and organic mercury compounds, dialkyl mercury compounds (R–Hg–R) volatilize in sufficient quantity to occur in the atmosphere near sources.[374] Thimerosal (sodium ethylmercurithiosalicylate) is ~50% mercury by weight; this compound degrades in the tissues into ethyl mercury and thiosalicylate.

EXPOSURE

Uses

In the United States, organic mercury compounds are no longer commonly used as biocides in rice, marine and household paint, or laundry products. During the 1990s, some multi-dose, inactivated infant vaccines (e.g., hepatitis B, diphtheria-tetanus-acellular pertussis, *Haemophilus influenzae* type b) contained the ethyl mercury-containing preservative, thimerosal, to avoid bacterial overgrowth following repeated entry into multi-dose vials. Thimerosal is an ethyl mercury radical attached to the sulfur group of thiosalicylate that undergoes biotransformation to ethyl mercury.[375,376] Infants receiving several vaccinations may receive an ethyl mercury dose up to 175 mg; however, the rapid blood elimination (i.e., mean $t_{1/2}$ = 7 days) of ethyl mercury limits mercury exposure below estimated safe concentrations.[377] The use of thimerosal as a preservative is now limited by the adoption of single-dose packaging that does not contain thimerosal. Clinical studies have not supported the efficacy of chelation treatment for autism[378] or a causal role of thimerosal in a variety of neurodevelopmental disorders including autism.[379,380] There are limited uses for organic mercury compounds as antiseptic compounds

TABLE 20.5. Identifying information and physical properties of organic mercury compounds.

Property	Mercuric Acetate	Methylmercuric Chloride	Dimethyl Mercury	Phenylmercuric Acetate
CAS RN	1600-27-7	115-09-3	593-74-8	62-38-4
Molecular weight (g/mol)	318.70	251.1	230.66	336.75

because of the development of safer, more efficacious anti-infective agents. Case reports associate the use of mercurochrome (0.2% aqueous methyl mercury) on the omphalocele of a neonate with mercury toxicity.[381] Less common uses include laboratory-based research and antifungal thimerosal agents on seed, bulb plants, and vegetation.[382] In some parts of the world, organic mercury compounds remain part of anti-fouling and mildew-proofing paints. The US EPA suspended the use of mercury compounds in interior paint in 1990.

Sources

For the general population, the major source of organic mercury is the consumption of large, predatory fish (e.g., pilot whales);[383] elephant seals, mink, and river otters also contain methylmercury.[384,385] Vaccines are no longer a significant source of exposure for the US population. In some countries, vaccines contain ethyl mercury in the form of the preservative thimerosal. With the exception of some flu vaccines, the switch from thimerosal-containing multi-dose vials to single-dose vials without thimerosal eliminated most childhood exposure to thimerosal in US vaccines.

Environment

Elemental mercury is the principal form of mercury in the air with negligible amounts of organic mercury. The only source of methylmercury in the environment is the methylation of inorganic mercury by microorganisms.[39] The amount of methylmercury depends on conditions within the lake or river, but usually, methylmercury constitutes a small portion (1–6%) of the total amount of mercury. Microorganisms in lake sediments possess the ability to methylate mercury; the amount of methylated mercury depends on overall microbial activity.[368] At a near-neutral pH, methylmercury is the dominant product of this methylation; the output of methylmercury doubles for each 10-fold increase in the amount of inorganic mercury.[277] The formation of new lakes may increase the production of methyl mercury, but this increase is usually temporary.[386]

Diet

The estimated daily intake of mercury in a US study averaged 2.3–3 μg/day (50 ng/kg/day),[387] whereas the daily intake in Belgium averaged 6.5 μg/day.[388] The provisional tolerable daily adult Hg intake of the World Health Organization (WHO) is 50 μg/day (i.e., ~5 μg Hg/kg body weight/ week). Cooking does not eliminate mercury from food; frying may increase the Hg concentration up to 2-fold as a result of water loss from the sample based on observational studies.[389] Methylmercury is the dominant species of mercury absorbed by humans following the consumption of fish; fish consumption accounts for almost all of the methylmercury present in the diet of the general population, particularly fish at the highest trophic levels (i.e., benthic and predatory pelagic species) that accumulate methylmercury in kidney, brain, muscle, and liver.[390,391] Methylmercury has a high affinity for protein sulfhydryl groups, resulting in the easy accumulation of this compound along the food chain. Consequently, large, long-lived predators (e.g., king mackerel, seals, swordfish, tilefish, blue-fin tuna, whales) have high Hg concentrations, as animals in the food chain concentrate both inorganic and organic mercury.[94] Dietary mercury content varies primarily with fish consumption and the mercury concentration in the fish. In general, seafood low in mercury includes catfish, cod, sardines, salmon, shrimp, tilapia, freshwater trout, and canned tuna.[392]

Freshwater and marine fish are the main sources of mercury in the diet. In a Japanese study, tuna and mackerel were the most common fish associated with elevated total hair mercury in 189 adults and children from the Karakuwacho Peninsula;[393] a study of Asians in Chicago also associated tuna consumption with elevated hair Hg concentrations.[394] Although mackerel typically contains low mercury concentrations, the authors attributed high intake as the etiology of the correlation between mackerel consumption and elevated total hair mercury. Typical total mercury concentrations in various fish species usually range from 0.01–4 mg/kg, depending on the surrounding environment (pH, redox potential), species, age, and size. In a study of UK seafood, the highest concentrations of total mercury occurred in swordfish, marlin, and shark with mercury concentration in five samples of sharks ranging from ~1–2.2 mg/kg.[395] Almost all samples of tuna contained total mercury concentrations below the European Commission limit of 1 mg/kg for predatory fish species. Canned tuna contained substantially lower (i.e., <0.5 mg/kg) total mercury concentrations.

Methylmercury accounts for most mercury (i.e., ~40–90%) in these fish with other organic mercury compounds (e.g., ethylmercury, phenylmercury) comprising the remaining portion. Humans absorb a much greater amount of methylmercury than inorganic mercury (90% vs. 10%, respectively). Additionally, the longer biological half-life of methylmercury than inorganic mercury favors the accumulation of methylmercury in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

fish.[277] Through natural processes and direct commercial discharge, most mercury species settle in the marine environment; consequently, some waters naturally contain high mercury concentrations. The Mediterranean basin contains large deposits of cinnabar; marine organisms from the Mediterranean have substantially higher total mercury concentrations compared with similar species in the Atlantic Ocean.[396]

Lifestyle

Phenylmercuric acetate (PMA) is a latex (water-based) paint additive that prolongs the shelf-life of these paints by inhibiting the action of bacteria and mildew. Elemental mercury vaporizes from these paints during the drying process with ambient air concentrations in some homes painted with interior latex containing >200 mg PMA/L exceeding the recommended ambient air Hg concentrations.[397] The actual Hg exposure depends on several factors: time since application, time spent in the painted room, minute ventilation, and the rate of air exchange in the painted room. A 4-year-old child developed acrodynia within 10 days of the painting of the inside of his home with latex paint containing ~950 mg PMA/L.[398] In a study of houses painted with organic mercury-containing paint ~30 days before testing, the average mercury concentration in ambient air was 2 μg/m^3 (range, <0.1–10 μg/m^3). The mean ambient mercury concentration substantially exceeded the recommended residential concentration of 0.5 μg/m^3.[399]

ENVIRONMENTAL FATE

Dimethylmercury is the only volatile form of mercury other than elemental Hg; however, the concentration of this compound in the atmosphere is small.

Soil

Methylmercury results from the biotransformation of elemental mercury deposited in water and soil. Methylation of inorganic mercury occurs mostly on sediments in fresh and ocean waters as a result of the non-enzymatic methylation of Hg^{2+} by methyl cobalamin compounds produced by bacterial synthesis. The solubility and mobility of methylmercury in soil allow methylmercury to enter the food chain rapidly. Very little mercury accumulates in terrestrial food chains with the exception of edible mushrooms (*Pleurotus ostreatus*) grown on compost containing mercury.[400] These mushrooms may present a health risk following heavy consumption as a result of estimated Hg bioaccumulation factors of 65–140. Most mercury reaching the ocean via wet deposition is recycled to the atmosphere with <10% reaching the sediment and ~2% methylated in biota.[401] The bottom sediment of the ocean is the ultimate sink for mercury, where the mercury exists as the highly insoluble mercuric sulfide.

Water

Most aquatic species contain methylmercury that undergoes biomagnification in long-lived predatory fish. The biomethylation of inorganic mercury to methylmercury occurs in lakes and wetlands, primarily as a result of microbial activity in the warm upper layer of sediment and the warm surface waters of lakes during the summer months.[402] Only a small percentage (i.e., ~2%) of the methylated mercury vaporizes into the atmosphere, primarily as dimethylmercury.[403] The most common organic form of mercury is methylmercury; this soluble, mobile form accumulates more rapidly in biological tissue than inorganic mercury.[404] Once released from microorganisms in surface waters, methylmercury quickly enters the food chain by rapid diffusion, binding to proteins in aquatic organisms.

Large predatory species at the top of the food chain (king mackerel, barracuda, bass, pike, trout, large tuna, marlin, scabbard, swordfish, walleye, shark), seals, and toothed whales contain the highest concentration of methylmercury as a result of biomagnification that produces mercury levels 10,000–100,000 times the concentrations of mercury found in ambient water.[19] In highly polluted environments, the Hg concentrations in liver and gonads increase relatively more than the mercury concentration in muscle tissue, particularly for predatory fish.[405] The relatively greater bioavailability of methylmercury compared with inorganic mercury also promotes the biomagnification of methylmercury in the food chain. Low pH, reduced oxygen concentrations, high levels of mercury in sediment, and conditions favoring the growth of microorganisms increase the amount of methylmercury present in water.[406] Other factors include temperature, calcium concentrations, total hardness, and conductivity.[407] The relocation or redirection of bodies of freshwater indirectly increases methylmercury concentrations by increasing the amount of humic material available for the growth of microorganisms.[408] Acid conditions favor the formation of methylmercury, probably by inhibiting the generation of insoluble mercuric sulfide that provides a sink for inorganic mercury in the sediment.

DOSE EFFECT

The effects of mercury depend on the dose and form of mercury. Organic mercury exposure in adult populations and methylmercury exposure in children exposed *in utero* may cause neurological effects. The unborn fetus exposed to methylmercury is probably the most sensitive part of the general population; however, the thresholds for these effects are not well-defined.[409]

Acute Toxicity

Inhalation

There are little data on the inhalation of organic mercury compounds in humans as a result of the low volatility of most organic mercury compounds. In the 1940s and 1950s, no respiratory symptoms developed in workers exposed to undetermined levels of alkyl mercury compounds (e.g., methylmercury) over several months; however, these workers demonstrated evidence of neurological dysfunction characterized by ataxia, unsteady gait, tremor, dysarthria, paresthesia, irritability, short-term memory deficit, and constricted visual fields.[410,411,412]

Ingestion

Very limited data are available on the acute lethal dose of organic mercury compounds. Estimated fatal doses of methylmercury based on tissue Hg concentrations during epidemics of methylmercury poisoning range from 10–60 mg Hg/kg with mercury accounting for 80% of the dose of methylmercury by weight. The ingestion of 20 mL 2% mercurochrome by a 15-year-old female was associated with the development of nausea, vomiting, abdominal pain, and dizziness, along with slightly elevated urine mercury concentrations.[413] A 44-year-old man ingested 83 mg thimerosal/kg as the alkyl aryl organic mercurial bactericide, sodium ethylmercurithiosalicylate.[414] He developed renal tubular dysfunction (maximum serum creatinine, 2.4 mg/dL), delirium, gingivitis, coma, polyneuropathy, gastritis, and respiratory failure despite chelation therapy with DMSA. After 148 days, sequelae were limited to sensory deficits in the toes.

Injection

There is no convincing evidence that the use of thimerosal-containing vaccinations causes adverse neurological or psychological effects based on prospective cohort studies of vaccinated children,[415,416] particularly autism.[417]

Chronic Toxicity

Animal studies indicate methylmercury is a more potent neurotoxin than inorganic mercury compounds. Two deaths were associated with occupational exposure to an estimated 1 mg diethyl mercury/m^3.[418] A study of workers exposed to Hg concentrations of 10–100 μg/m^3 as alkyl mercury did not reveal any specific symptoms attributable to the exposure to alkyl mercury.[419] Based on studies on the consumption of methylmercury-contaminated bread in Iraq, the estimated lethal dose of methylmercury was ~200 mg.[371] In this study, paresthesia began when the total body burden exceeded 40 mg Hg.

Studies of fish-eating populations in the Republic of Seychelles off the east coast of Africa (779 infant-mother pairs) and the Faroe Islands north of Scotland (1,022 singleton births) did not confirm an association between low-dose, prenatal exposure to methylmercury (as measured by segmental hair analysis) and delayed developmental milestones; the latter study did report subclinical deficits in the language, attention, memory, and visuospatial domains on neuropsychological testing, primarily when maternal hair concentrations exceeded 10 ppm (μg/g).[420,421] These populations consumed substantially more fish than US populations with mercury concentrations in the range of 0.05–0.2 ppm (μg/g); the mean maternal hair total mercury concentration in the Faroe study group was 6.8 ppm.[422] The source of the fish in Seychelles was ocean fish, whereas the source in the Faroe Islands was pilot whale blubber that is potentially contaminated by PCBs. An Italian study of a birth cohort living near a mercury-contaminated coastal site did not detect a statistically significant difference in full scale, verbal, or performance IQ between 7-year-old children born to mothers with total mercury hair concentrations above or below 2 ppm;[423] however, the mean scores on these tests were four to five points lower in the former children than the latter. No neurological abnormalities were detected in 327 7-year-old Japanese children with hair mercury concentrations of <6.9 μg/g.[424] The estimated mercury concentration in methylmercury-contaminated fish associated with Minamata disease was 3–30 ppm compared with the US EPA maximum regulatory concentration of 1 ppm.[425,426] Based on regression coefficients and analysis of cord samples from Minamata, the estimated median daily maternal Hg intake was ~225 μg, and the estimated median maternal Hg hair concentration was 41 μg/g; the estimated median cord blood of the affected infants was 216 μg/L.[427]

TOXICOKINETICS

Absorption

The gastrointestinal tract almost completely absorbs (i.e., up to 90%) an oral dose of methylmercury, whereas the absorption of phenyl mercury is less.[428] Little data exist on the systemic absorption of methylmercury from the lungs, but indirect evidence in animals suggests that the lungs easily absorb organic mercury compounds.[429,430] Dermal absorption of organic mercury compounds is small (<2%), but rarely mercury toxicity (tremor, fever, desquamation of the skin, renal dysfunction) may occur after the application of organic mercury compounds (e.g., Mercurochrome) to susceptible areas like the omphalocele of a premature infant.[431,432] Elevated mercury concentrations occur in infants exposed to diapers sprayed with phenyl mercury fungicide, but mercury toxicity is not clinically apparent.[266]

Distribution

Methylmercury diffuses across cell membranes as a small molecular-weight thiol complexed with L-cysteine and attached to neutral amino acid carriers. This transport is stereo-selective and competitively inhibited by large neural amino acids (e.g., methionine).[433] The highly lipophilic properties of methylmercury allow the diffusion of this compound across the blood–brain and placental barriers. As a result of the conversion of organic to inorganic mercury in the brain, most (i.e., >75%) of mercury in the brain appears in the form of inorganic mercury, even though the primary source of mercury is methylmercury. This conversion also results in the accumulation of Hg in the kidneys. Demethylation of methylmercury to inorganic mercury is species-, tissue-, dose-, and time-dependent.

From a toxicological perspective, there are two types of organic mercury compounds. The alkyl mercury group (e.g., methyl mercury) is readily lipid-soluble and distributes more uniformly throughout the body.[434] Methylmercury accumulates in red blood cells following the oxidation of methylmercury to less soluble mercurous and mercuric oxides via the catalase-hydrogen peroxidase pathway. After the ingestion of fish containing methylmercury, the erythrocyte/plasma ratio of methylmercury ranges 10–20.[435] The distribution of methylmercury compounds is usually complete within 4 days, but several more days may be necessary to reach equilibration in the brain.

In contrast to these compounds, phenylmercury and methoxyethylmercury behave pharmacokinetically, resembling inorganic mercury compounds in the body. Although phenyl mercury and methoxyethylmercury compounds are more easily absorbed than inorganic salts, once inside the body, these organic mercury forms undergo biotransformation by splitting the carbon–mercury bond to release inorganic mercury. Although the initial distribution of phenylmercury is similar to that of methylmercury, phenylmercury partitions to a greater extent into the erythrocyte compared with plasma. Additionally, phenylmercury deposits primarily in the liver rather than the kidney. The blood–brain barrier is less permeable to phenylmercury than to methylmercury. Consequently, phenylmercury and methoxyethylmercury toxicity more closely resemble poisoning with inorganic mercury salt than alkyl mercury poisoning.

Elimination

There is no definite evidence of the synthesis of organic mercury compounds in mammalian tissue.[436] The conversion of methylmercury to divalent mercury compounds is the key process for the excretion of methylmercury from the body. Because methylmercury easily penetrates the intestinal mucosa, a prominent enterohepatic circulation develops unless methylmercury is converted to the more poorly absorbed inorganic form. The major route of excretion of methylmercury is through the bile into the feces; this pathway accounts for most (i.e., ~90%) of the elimination of methylmercury in the form of inorganic mercury. Alkyl (methyl) mercury compounds accumulate in red blood cells where entrapment prolongs the excretion of these compounds, whereas aryl (phenyl) mercury compounds undergo conversion to inorganic mercury and more rapidly leave the body than alkyl Hg compounds.[428] The clearance of methylmercury from the blood and the body is longer than the clearance of inorganic mercury compounds. The elimination half-life of methylmercury in the blood averages ~50–65 days,[435] whereas the elimination half-life of the body averages ~70–80 days.[437] Enterohepatic recirculation accounts for the somewhat longer elimination half-life of organic mercury compared with inorganic and elemental mercury (30–60 days).

The clearance of ethylmercury from the body is >3-fold faster than that of methylmercury.[438] In a study of 15 patients receiving a thimerosal-containing vaccine monthly for several years, the estimated mean elimination half-life of ethylmercury from the blood was 5.6 days (95% CI: 4.8–6.3 days).[439] There was no evidence of accumulation of ethylmercury in the blood of these patients.

Maternal–Fetal Kinetics

The alkyl mercury compounds easily pass the placental barrier and demonstrate a high affinity for fetal hemoglobin. Animal studies suggest that methylmercury concentrations are slightly higher in fetal blood than in maternal blood.[440] An epidemiological study of mothers and their offspring in Greenland revealed methylmercury concentrations in the blood of infants were 40% higher than maternal blood; however, biases in the study limit conclusions about the source of this difference.[441] Breast milk does not appear to be a major source of mercury exposure for infants. A study of women ingesting large quantities of fish indicated mercury does not accumulate in breast milk; Hg concentrations in breast milk and the plasma of breast-fed infants were similar to maternal plasma Hg concentrations.[442] Although most of the ingested mercury was methylmercury, only 20% of the total mercury in the breast milk was organic mercury.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Although differences in toxicokinetics produce dissimilar clinical effects from exposure to methyl and ethylmercury, the mechanisms of toxicity are similar. Methylmercury and ethylmercury bind sulfhydryl (–SH) groups in thiols, sulfur-containing amino acids (cysteine, methionine, cysteine-derivative taurine), and proteins. Methylmercury combines covalently with sulfhydryl (thiol) groups and selenoproteins to cause inhibition of sulfhydryl-containing enzymes).[443] The mechanism of toxicity for organic mercury and inorganic mercury appears similar; the differences in toxicity probably result from the differential accumulation of these Hg forms in sensitive tissue that results from variations in their toxicokinetics including the ability of methylmercury to disrupt the thioredoxin system and enhance oxidative stress.[301] Methylmercury forms a complex (MeHg-L-cysteine) with cysteine following absorption that mimics the molecular structure of methionine.[433] Subsequently, the L-type amino acid transport system enhances the uptake of methylmercury by the brain. Ethylmercury (e.g., thimerosal, merthiolate) does not share the same transport system as methylmercury; additionally, ethylmercury elimination is much more rapid than methylmercury.

The exact mechanism of organic mercury toxicity is complex and remains unclear. Potential mechanisms include the following: 1) impairment of calcium channels and intracellular calcium homeostasis from inhibition of sulfhydryl-containing enzymes; 2) over-activation of NMDA-type glutamate receptors and production of excessive calcium concentrations and cell death; 3) reduction of glutathione concentrations and increased generation of reactive species (e.g., hydrogen peroxide, nitric oxide) resulting in oxidative damage to nucleic acids, proteins, and lipids; generation of arachidonic acid; 4) overproduction of nitric oxide from increased nitric oxide synthase, particularly in the cerebrum and cerebellum; and 5) damage of the spindle apparatus during mitosis.[444,445] Methylmercury produces focal damage to specific areas of the adult brain and also destroys microtubules that are important for cell division and migration in the developing brain.[446] Methylmercury alters brain ornithine decarboxylase (an enzyme associated with cellular maturity) and neurotransmitter uptake at both presynaptic terminals and postsynaptic adrenergic receptor binding sites.[447]

Pathological Changes

The primary target organ of toxicity following exposure to methylmercury is the central nervous system, particularly cortical damage in the central and occipital cortex along with varying degrees of damage to the granular layer of the cerebellum.[448] High doses of methylmercury produce irreversible changes in the visual cortex and cerebellum, leading to permanent narrowing of the visual field and ataxia.

Postmortem Examination

Autopsies of adults with methylmercury poisoning indicate that central nervous system damage occurs in specific focal areas of the cerebral and cerebellar cortexes. Pathological changes include a granular cell-type cerebellar atrophy involving the granule cells of the neocerebellum with relative sparing of the Purkinje cells. Bilateral cortical atrophy also occurs, particularly in the calcarine fissures of the occipital lobe (visual cortex), pre- and postcentral cortex (motor and sensory centers), and temporal cortex (auditory center).[449] Disruption of the blood–brain barrier results in the extravasation of plasma protein. Postmortem examination of a chemical worker dying after exposure to dimethylmercury demonstrated similar changes in the cerebral cortex with loss of nerve cells and diffuse astrogliosis in the occipital and insular cortex; there was only slight pericellular edema and gliosis in the frontal and parietal cortex along with sparing of the subcortical

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

white matter.[450] Although there was also degeneration in the cerebellar cortex, particularly the vermis, the loss of Purkinje cells occurred in the molecular layer with slight degenerative changes in the granular layer and sparing of the cerebellar white matter. A case report associated progressive cerebellar ataxia, dysarthria, generalized weakness, and stupor with exposure to ethylmercury at an insecticide manufacturing plant.[451] The worker died after developing infectious complications of lungs and kidneys; postmortem examination demonstrated pathological changes primarily in the corpus callosum, calcarine cortex, and the Purkinje cells in the cerebellum.

Autopsies of patients with Minamata disease demonstrated localized mercury deposits in microglial cells (macrophages) over wide areas of the brain in addition to mercury deposits in the calcarine fissures, pre- and postcentral cortex, temporal cortex, and the cerebellum.[452] The clinical features of Minamata disease (dysarthria, ataxia, deafness, constriction of visual fields, abnormal gait) correlate to the pathological damage detected on postmortem examinations.[453] Little or no deposition of mercury occurs in the Purkinje cells of the cerebellum or the epithelial cells of the choroid plexus. Histological changes in autopsies of patients dying within 2 months of the onset of Minamata disease demonstrated neuron loss with reactive proliferation of glial cells, microcavitation, vascular congestion, edema, and petechial hemorrhage in the calcarine, pre and postcentral, and transverse temporal cortices in the cerebrum along with loss of granule cells (but not Purkinje cells) in the cerebellar cortex.[103] Pathological lesions also appeared in the peripheral nervous system, manifested by the destruction of the anterior horn cells of the dorsal roots and the myelin sheaths. Degeneration is more prominent in sensory than motor neurons, perhaps as a result of the disruption of cellular metabolism. Postmortem analysis of these offspring indicated that the prenatal effects result from the incomplete and abnormal migration of the neuronal cells to the cerebral and cerebellar cortices.[454] Although seafood consumption correlated to elevated blood Hg concentrations in the brains (inferior/temporal/midfrontal cortex, cerebellum) of deceased participants in the Memory and Aging Project clinical neuropathological cohort study, the total mercury concentrations as measured by neutron activation analysis did not correlate to brain neuropathology or the presence of Alzheimer's disease.[455]

CLINICAL RESPONSE

Organic mercury poisoning usually develops from the consumption of methylmercury-contaminated food sources (e.g., Minamata Bay from consumption of fish contaminated by industrial discharges).[101] The clinical features of methylmercury and other organic mercury compounds typically involve the central nervous system. The classical signs of methylmercury compounds involve constriction of visual fields, cerebellar ataxia, and dysarthria (Hunter-Russell triad).[456] Some organic mercury compounds (e.g., phenylmercury) readily break down within the body into inorganic compounds, whereas alkyl mercury compounds (e.g., methylmercury) metabolize more slowly into inorganic mercury compounds. This difference in metabolism may account for the fact that acrodynia has been associated with phenylmercury poisoning but not with methylmercury poisoning Japan and Iraq. Ethylmercury organic compounds rapidly convert to inorganic mercury compounds, resulting in renal damage and CNS effects compared with methylmercury organic compounds that almost exclusively produce CNS effects.[100] Although elevated mercury concentrations may occur in the temporal lobes of patients with Alzheimer's disease,[457] no statistically significant difference in the blood mercury concentrations was demonstrated in a study of 18 patients with Alzheimer's disease when compared with controls.[458,459]

Acute Toxicity

The intentional ingestion of a large dose of thimerosal by a 44-year-old man caused gastritis, gingivitis, anuria, polyneuropathy, delirium, coma, and respiratory failure requiring intubation; there was no evidence of direct brain damage.[414] He recovered following supportive care with only minor paresthesias of the feet. A 48-year-old chemistry professor presented to the hospital with a 5-day history of rapidly progressive encephalopathy characterized by deterioration of balance, gait, visual fields, and speech.[460] Five months previously, she accidentally spilled dimethylmercury in her polyvinyl chloride-gloved hand while working under a ventilated hood. She was asymptomatic until 2 months before hospitalization, when she developed intermittent nausea, vomiting, abdominal pain, and weight loss. Her whole blood initial mercury concentration 154 days after exposure at the beginning of her neurological symptoms was 4,000 μg/L. Within the next 2 months, she became comatose with spontaneous episodes of agitation and crying. She failed to respond to supportive therapy and died 298 days after the dimethylmercury exposure. The medical investigation discovered no other mercury source. Another laboratory worker developed rapid, progressive neurological deterioration after using dimethylmercury for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. several months. The clinical features included severe nausea, anorexia, paresthesias, visual field constriction, dysarthria, and ataxia, followed by incontinence and coma; he developed pneumonia and died despite the early use of supportive care and chelation with D-penicillamine.[450]

Environmental Exposure

The clinical manifestations of organic mercury poisoning depend on the type of mercury compound involved. The classic presentation for methylmercury in Minamata disease includes paresthesias, tremor, ataxia, gait disturbances, bilateral concentric constriction of visual fields, speech/hearing impairment, and muscle weakness.[461] Aryl organic mercury compounds (e.g., phenylmercury, methoxyethylmercury) produce a pattern of toxicity similar to that associated with inorganic mercury salts. The alkyl mercury compounds (e.g., methylmercury, dimethylmercury) cause a toxic encephalopathy (psychiatric disorders, blurred vision, hearing impairment, olfactory and gustatory disturbances, ataxic gait, dysarthria, somatosensory changes) that includes a severe congenital form resulting from prenatal exposure based on epidemiological data from 1971–1972 Iraqi epidemic.[462,463] Both aryl and alkyl mercury compounds are potent skin sensitizers that produce a classic type IV cell-mediated delayed hypersensitivity reaction. Thimerosal (sodium ethylmercurithiosalicylate, CAS RN: 54-64-8) is a preservative in ophthalmological preparations that was the third most common sensitizer in a survey of the etiology of contact dermatitis in North America during the 1960s and 1970s.[464] Additionally, ammoniated mercury is a common sensitizer.[6]

Methylmercury

The classic triad of methylmercury toxicity is dysarthria, ataxia, and visual field constriction. Visual acuity, ocular movements, and pupillary reflexes are usually normal. Early symptoms manifest as sensory neuropathy with distal paresthesias, ataxia, and loss of position sense. Spasticity, hearing defects, intention tremor, slurred speech, insomnia, muscle weakness, decreased smell and taste, depression, emotional lability, loss of concentration, personality changes, intellectual disabilities, akinetic mutism, cerebellar ataxia (dysmetria, dysdiadochokinesia, gait disturbances), and somatosensory disturbances (distal paresthesias, hypesthesias, hypalgesia, poor two-point discrimination, decreased stereognosis) also occur. Tendon reflexes usually are preserved; sensory changes result from damage to the somatosensory cortex rather than damage to peripheral nerves.[369] Paresis usually does not occur, and hepatorenal function remains normal. The mean latent period in the last Iraqi epidemic from methylmercury poisoning was 3 weeks (range, 10–150 days).[372]

Studies of Samoan fishermen and tuna-packers with heavy fish consumption did not detect neurological abnormalities despite the daily fish consumption of up to ~10 oz.[465] The mean mercury concentration in hair samples from the fishermen and the tuna-packers was 17 ppm (maximum, 48 ppm) and 8 ppm (maximum, 24 ppm), respectively. Alkyl mercury poisoning may mimic amyotrophic lateral sclerosis.[466] Although fatty liver has been associated with exposure to methylmercury, an epidemiological study of 1,406 persons aged 50–69 living in a methylmercury-polluted area did not demonstrate an increased incidence of liver disease attributable to the methylmercury.[467] There is little evidence that exposure to moderate amounts of methylmercury from fish consumption increases the risk of cardiovascular disease (coronary heart disease, hypertension, stroke) based on exposure assessment by analyses of toenail mercury concentrations in 2 US cohorts totaling over 172,000 participants.[468,469] The studies did not differentiate organic from inorganic mercury.

Ethylmercury

Based on epidemics of methylmercury in Japan along with methylmercury and ethylmercury poisonings in Iraq, ethyl mercury (7.7% ethylmercury *p*-toluene sulfonanilide, Granoson M®, total mercury 3.2% w/w, Dupont) is a prominent renal toxin and a less potent neurotoxin compared with the prominent neurotoxicity and lack of renal toxicity associated with methylmercury exposures.[470,471] Clinical features involving the cardiovascular, gastrointestinal, hematopoietic, and urinary systems were more common in the earlier Iraqi epidemic of ethylmercury than in the later methylmercury epidemic.[372] During the Iraqi epidemic, the latent period between the end of exposure and onset of symptoms typically beginning with paresthesias was relatively long (weeks to a few months).

Reproductive Abnormalities

Congenital Minamata Disease

The fetal brain is substantially more susceptible to organic mercury poisoning than the adult brain. Children born to mothers with methylmercury toxicity

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

develop severe derangement of the developing central nervous system that manifests as psychomotor retardation (delayed developmental milestones, seizures, spasticity) based on observations of children born to mothers exposed to methylmercury during the two major outbreaks of methylmercury poisoning in Iraq and Japan (congenital Minamata disease). The latter disease resembled cerebral palsy. The exact composition of the contaminated effluent discharged into Minamata Bay was not documented; however, the effluent probably contained other toxins (e.g., arsenic). The fetus is more sensitive to the effects of methylmercury than the mother; therefore, severe retardation may develop in the offspring of a mother without clinical features of serious methylmercury poisoning. A descriptive study of infant and birth outcomes in the Minamata area in 1950–1974 suggested the impact of prenatal exposure to contaminated discharge on infant mortality was equivocal.[472]

Maternal Fish Consumption

Neurocognitive Development

Studies on women with methylmercury exposure from high fish consumption have not demonstrated consistent findings in regards to the adverse effects on cognitive and behavioral development following large maternal fish consumption (i.e., 10-fold higher than typical US fish consumption).[473] Reviews of these studies suggest higher gestational methylmercury exposures are associated with lower neurological scores on some tests (e.g., finger tapping, naming tests, visual recognition memory scores), whereas other studies demonstrate either no dose-related effect or high scores on other neurodevelopmental tests.[474,475] Analyses of the three major epidemiology studies on methylmercury ingestion (Faroe Islands, Seychelles Islands, and North Island, New Zealand) suggested the size of the effect on child intelligence quotient points/μg methylmercury increase/g maternal hair ranged from −0.18 points (95% CI: −0.378 to −0.009)[476] to −0.7 points (plausible range, 0–1.5 points).[477] A cross-sectional analysis of 182 singleton term births in the Faroe Islands detected a statistically significant ($P = 0.03$) reduction in a measure of neonatal neurological function (neurological optimality score) with increasing cord whole blood Hg concentrations after adjustment for gestational age and PCB concentrations.[478] Although a study of 149 children from a Madeiran fishing community with high methylmercury consumption demonstrated some reduction in the brainstem visual and auditory evoked potentials, the changes were not related to measures of methylmercury exposure (e.g., hair-mercury concentrations in offspring).[479] Other epidemiological studies have not supported an association between high maternal fish consumption (i.e., methylmercury) and neurodevelopmental abnormalities in offspring. A study of 131 mother–infant pairs from a Peruvian coastal village found no association between prenatal exposure to methylmercury and infant development or neurological examination.[480] The mean maternal methylmercury concentration in hair samples was 7 ppm (μg/g) with a range of 0.9–28 ppm.

The longitudinal Seychelles Islands study did not detect an adverse association between prenatal exposure to methylmercury and six developmental outcomes (cognitive ability, receptive and expressive language, reading and math readiness, visual-spatial ability, social and adaptive behavior) when the children were tested at 66 months of age.[481] The mean methylmercury concentration in maternal hair was ~60% higher (median = 5.9 μg/g; range, 0.5–26.7 μg/g) in mothers from the Seychelles cohort than the Faroe Islands cohort. In addition, diets differed between the two populations with the Seychelles cohort ingesting primarily fish with no whale meat and less fats; factors that mitigate Hg toxicity may differ between these two populations including the presence of selenium and long-chain polyunsaturated fatty acids (e.g., docosahexaenoic acid, eicosapentaenoic acid). A follow-up longitudinal study of the Seychelles Islands cohort through age 11 years also did not detect any significant associations between prenatal methylmercury exposure and any of the study endpoints including a measure of developmental quotient or IQ (global cognition).[482] Analyses of postnatal mercury exposure in this cohort did not detect a consistent pattern suggestive of a causal relationship between methylmercury exposure from fish and adverse neurocognitive effects, as measured by the exposed children's intelligence quotient at 107 months.[483]

In a study of 780 US children enrolled in the Treatment of Lead-Exposed Children Trial, stratified, spline regression and generalized linear model data analyses did not detect an adverse effect of background methylmercury concentrations on the children's intelligence quotient or behavior.[484] The children were tested at ages 2, 5, and 7 years; the geometric mean organic mercury concentration of the group was ~0.5 μg/L (95% CI: 0.48–0.56 μg/L). In this study, blood lead concentrations (range 20–44 μg/dL) were associated with adverse effects on cognitive and behavioral development.

Available data indicate that the neurodevelopmental benefits of breastfeeding of infants outweigh the risk of methylmercury neurotoxicity from prenatal or postnatal maternal fish consumption, assuming exposure to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

methylmercury commonly found in fish.[485] In a study of Spanish children and their mothers during pregnancy, the geometric mean of the total mercury concentration in cord blood was 8.8 μg/L (95% CI: 8.4–9.2 μg/L). Testing of general cognition with the McCarthy Scales of Children's Abilities at age 4–5 years demonstrated improved scores with doubling of the cord blood mercury concentration (β = 1.29, 95% CI: 0.28–2.31).[486] The test scores of children from mothers consuming <3 fish serving/week during the first trimester tended to decrease with increasing cord blood Hg concentrations, suggesting maternal nutritional factors during the first trimester affect children's test scores.

Birth Outcomes

Studies on birth outcomes and maternal fish consumption are conflicting with some cohort studies suggesting a negative effect of mercury concentrations on birth weight,[487] whereas other studies demonstrate no negative Hg-related effects on birth weight.[488] In a community-based study of 1,024 in the Pregnancy Outcomes and Community Health (POUCH) study, the median total hair mercury concentration was 0.23 μg/g (range, 0.1–2.50 μg/g).[489] Compared with women delivering at term, women with very premature deliveries (i.e., <35 weeks gestation) had a higher risk of total hair mercury concentrations exceeding the 90th percentile (≥0.55 μg/g). The adjusted odds ratio was 3.0 (95% CI: 1.3–6.7) with covariates including total fish consumption, maternal age, ethnicity, Medicaid status, and community. Compared with women delivering full-term infants, the adjusted OR for high hair total mercury concentrations was not significantly elevated for all women delivering preterm infants (adjusted OR = 1.55, 95% CI: 0.7–2.9) or women delivering 35–36-week premature infants (adjusted OR = 0.4, 95% CI: 0.1–1.9). In a study of 367 Japanese mother–newborn pairs using total mercury in hair as a biomarker of MeHg exposure, the mean birth weight was 3,073 ± 37 g and the incidence of babies small for gestational age weight was 4.9%.[490] Multiple regression analysis with adjustment for confounding factors did not detect an overall association between mercury hair concentrations and birth weight/length or chest/head circumferences.

Carcinogenesis

The International Agency for Research on Cancer (IARC) lists methylmercury as Group 2B (possibly carcinogenic to humans) based on sufficient evidence of carcinogenicity in experimental animals and inadequate evidence in humans. The US National Toxicology Program (NTP) does not list organic mercury compounds as potential human carcinogens. A mortality study of a historic cohort of patients with Minamata disease did not demonstrate an increased risk of mortality from all cancers. Analysis of site-specific cancer using a Poisson regression model detected a statistically significant decrease in mortality from stomach cancer (RR = 0.49, 95% CI: 0.26–0.94) and an increase in the risk of death from leukemia (RR = 8.35, 95% CI: 1.61–43.3).[491] However, the increased risk of leukemia was not clearly related to methylmercury exposure alone as reflected in the wide confidence interval.

DIAGNOSTIC TESTING

Analytical Method

Typically, the determination of organic mercury concentrations in biological samples involves subtracting the results of the inorganic Hg concentration from the total Hg concentration. The latter analysis comprises complete conversion of all mercury to the volatile elemental form by harsh digestion (e.g., nitric acid/perchloric acid or bromate/bromide) and reduction of ionic mercury to the elemental form followed by cold vapor/atomic absorption spectrometry, whereas the determination of inorganic mercury involves milder digestions (HCl, sulfuric acid) and reduction. The use of gas chromatography/electron impact/mass spectrometry combined with inductively coupled plasma/mass spectrometry or gas chromatography/mass spectrometry with D_3-methylmercury as the internal standard allows the quantitation of methylmercury directly in whole blood samples with lower limits of quantitation of 0.3 μg/L and 0.5 μg/L, respectively.[492] At whole blood methylmercury concentrations of 10 μg/L, the precision of these methods is <6% and <3%, respectively. In contrast to the above methods, the results from isotope dilution/gas chromatography/mass spectrometry are not affected by incomplete recovery or matrix effects.[493] The use of high-pressure liquid chromatography to separate mercury species and triple spike isotopic dilution with solid-phase microextraction coupled to inductively coupled plasma/dynamic reaction cell/mass spectrometry allows the determination of organic and inorganic species in blood and urine samples.[494] Capillary electrophoresis (CE) is an alternative to chromatography for the separation of various mercury species; CE may be combined with electrothermal atomic absorption spectrometry, inductively coupled plasma/optical emission spectrometry, inductively coupled plasma/mass spectrometry, or atomic fluorescence spectrometry for mercury speciation.[495] Sample preservation is important because methylmercury is volatile.

In vitro studies indicate methylmercury and ethylmercury are stable in whole blood −70°C to 23°C for 1 year, whereas deterioration occurs at body temperature (37°C) after 2 weeks.[319] Although freeze-drying may prevent methylmercury losses, repeat freezing-thawing cycles of biological samples may cause methylmercury losses depending on the matrix.[496] Acidification removes oxidizing agents that degrade methylmercury.

Biomarkers

Blood

In general, blood is superior to urine in the assessment of body burdens for metals with long biological half-lives (i.e., mercury) as a result of reduced variability in mercury concentrations.[494] Additionally, the feces eliminate almost all absorbed organic mercury (e.g., methylmercury and ethylmercury) with little organic Hg excretion in the urine.[320] Analysis of data from the National Health and Nutrition Examination Survey (NHANES 2007–2010) suggests BMI is inversely related to whole blood Hg concentrations after controlling for methylmercury exposure through fish/shellfish consumption and other confounders.[497] Compared with overweight/normal weight adults, the whole blood mercury concentration of obese adults averaged 22% (95% CI: 33% to −8.2%) lower than that of other adults; differences between obese and nonobese children were not statistically significant. In the general population without occupational mercury exposure, methylmercury accounts for ~80–95% of mercury present in blood; the remainder is inorganic mercury.[498] Consequently, total whole blood Hg concentrations reflect recent organic Hg (i.e., methylmercury) exposure. The short-chained alkyl mercury compounds (e.g., methylmercury) are relatively resistant to biotransformation; therefore, these compounds are toxicologically different than aryl or alkoxyalkyl mercury compounds. These latter compounds liberate inorganic mercury in the body.

General Population

Depending on the number of dental amalgams and the amount of fish in the diet, most whole blood total mercury concentrations in the general population are <10–20 μg/L with the mean whole blood mercury concentration <3–4 μg/L (15–20 nmol/L).[6,499] The consumption of large quantities (>4 meals/week) of predator fish may increase the total whole blood mercury concentrations 20 times above mean whole blood mercury concentrations depending on the Hg concentration in the fish.[500] A study of residents near the Elb River in Germany revealed a mean whole blood mercury concentration of ~12 μg/L with a range up to 79 μg/L in a fisherman.[501] In a study of 56 Japanese women without occupational Hg exposure, the mean total whole blood Hg concentration was 18.2 ± 9.9 μg/L (range 3.9–56.8 μg/L) as measured by reductive vaporization/gold amalgam capture/atomic absorption spectrophotometry.[194] Fish consumption was not reported, but presumably, fish was a prominent part of their diet.

In a study of US women, the geometric mean total Hg concentration in whole blood was 1.02 μg/L (95% CI: 0.85–1.20 μg/L).[502] About 8% of these women had whole mercury concentrations exceeding the US Environmental Protection Agency reference dose of 5.8 μg/L. This dose corresponds to the lower 95% confidence limit of the benchmark dose estimated to double the proportion of children with an abnormal score on a developmental assessment tool *and* an uncertainty factor of 10.[503] The geometric mean whole blood mercury concentration in samples from women of childbearing age during the US National Health and Nutrition Examination Survey (NHANES) 1999–2002 was 0.92 μg/L (upper 95% CI: 6.04 μg/L).[504] About 5.6% of the women aged 16–49 years had blood mercury concentrations exceeding the EPA reference level of 5.8 μg/L. In the 2009–2010 NHANES IV study of 5,765 subjects 20 years or older, the geometric mean total whole blood Hg concentration was 1.04 μg/L (95% CI, 0.956–1.14) with an upper 95% CI of 5.75 μg/L (5.14–6.50 μg/L).[505] Females had lower total Hg whole blood concentrations than men.

Toxicity

Four hours after the acute ingestion of 83 mg thimerosal/kg (5 g), the Hg concentration was 14 mg/L in whole blood and 1.7 mg/L in serum as determined by cold vapor/atomic absorption spectrometry.[414] The patient developed renal dysfunction, neuropathy, coma, and respiratory failure, but he recovered after 6 months with slight paresthesias in the toes.

Early symptoms (paresthesias, sensory disturbances) of acute methylmercury toxicity in adults initially appear at whole blood mercury levels near 200 μg Hg/L. In Iraq, paresthesias developed in persons with whole blood mercury concentrations >240 μg/L 65 days after exposure ceased.[506] Based on a biological half-life of 65 days for methylmercury in the blood, the minimal peak blood concentration associated with the development of paresthesias was 480 μg Hg/L. The fetus is very sensitive to methylmercury; therefore, the critical values for mercury in fetal blood are lower (e.g., 50 μg Hg/L) than adults.[507]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Postmortem

The average concentration of total mercury in postmortem blood from two fatal cases of ethyl mercury toxicity from contaminated Iraqi grains was 15 mg/L (15,000 μg/L) as measured by flameless AAS.[508]

Urine

General Population

In contrast to inorganic mercury, the kidney excretes a very small portion (i.e., <10%) of the absorbed dose of methylmercury; therefore, whole blood or hair concentrations are better biomarkers of the organic Hg body burden than urine. Experimental studies do not support the use of chelation with DMSA as a method to evaluate organic or inorganic mercury toxicity. In a study of 24 healthy physicians assigned to 3 groups (non-fish eaters, 1–2 fish meals/week, ≥3 fish meals/week), there was no statistical difference in pre-chelation urinary mercury excretion (range, 0.12–2.2 μg/g creatinine, $P = 0.37$).[509] All groups demonstrated increased urinary mercury excretion with statistically significant differences ($P = 0.04$) between the three groups with higher Hg excretion in fish eaters. Using multiple linear regression, the only variable that predicted the post-chelation mercury concentration was the baseline whole blood mercury concentration ($P = 0.001$). The authors concluded that the increased Hg excretion over baseline after provoked DMSA chelation was not a reliable diagnostic indicator of mercury poisoning.

Toxicity

Urine total mercury concentrations document total Hg exposure, but urine mercury concentrations do not correlate to specific symptoms of mercury toxicity. Infants exposed to phenylmercuric acetate paints may develop acrodynia despite urine total mercury concentrations <50 μg Hg/g creatinine.[510]

Hair

The most prominent mercury species in hair and blood is methylmercury. In a Swedish study of 28 volunteers, the mean percentage of organic Hg species in hair was 91% (range, 79–95%) with the remainder being divalent inorganic mercury.[511] High inorganic mercury percentages suggest external mercury contamination and/or demethylation of methylmercury. The interindividual variation between total blood and hair mercury concentrations was very large, depending primarily on fish consumption. Typically, total Hg concentrations in terminal hair range from <1 μg/g (non-fish eaters) to ~30 μg/g in individuals frequently consuming Hg-contaminated fish.[512] In a study of 59 Japanese women with no occupational exposure to mercury, the mean total mercury concentration was 1.51 ± 0.91 μg/g (95% CI: 0.49–3.60 μg/g) in closely cut scalp hair compared with 0.86 ± 0.66 μg/g creatinine (95% CI: 0.28–2.06 μg/g creatinine) in morning urine samples.[513] Based on estimated daily mercury intakes from fish and other seafood using a food frequency questionnaire, fish accounted for ~30% of the total mercury in hair samples.[514] The arithmetic mean of total Hg concentrations in the hair of 118 Japanese children aged 3–6 years in 5 Japanese regions was 1.02 ± 0.63 μg/g (range, 0.17–3.20 μg/g). The study detected significant differences in the total hair Hg concentrations between the five regions consistent with traditional regional patterns of eating fatty fish (e.g., swordfish, tuna); however, the total Hg concentration did not vary significantly with age, sex, dental amalgams, or other types of seafood/shellfish. In a study of Louisiana anglers with relatively high fish consumption, the median total hair Hg concentration was 0.81 μg/g (n = 398; range, 0.02–10.7 μg/g) with 40% of participants exceeding the US Environmental Protection Agency's reference dose of 1 μg/g.[515] In contrast to the consumption of primarily commercial seafood by the general US population, ~74% of the angler's estimated Hg intake came from recreationally caught seafood based on interviews and Internet surveys; many of the fish species were unique to the region.

Hair analysis is an alternative to blood mercury concentrations for screening subjects with methylmercury exposure through seafood, particularly as a means to provide supplemental information to reconstruct prior methylmercury exposure. The usefulness of analyzing inorganic or elemental Hg concentrations in hair has not been established.

Sampling

The preferred sample is terminal hair from the occipital-neck junction, clamped to preserve strand alignment. Full-length hair strands (~100 g) from the occiput area should be collected with sharp scissors that cut the hair shaft close to the skin.[512] Terminal hair has a larger diameter and longer length than intermediate type (intermediate length and diameter found on arms and legs) and vellus type (small hairs on eyelids, forehead, bald scalp). The initial 0.5 cm adjacent to the scalp represents methylmercury exposure ~1–3 weeks before collection. Longitudinal analysis of hair for mercury suggests the approximate time of acute ingestion, based on average hair growth rates (~1 cm/month with a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

10-day lag period for the formation of the hair and a range of 0.6–3.4 cm/month).[285,516]

Hair/Blood Mercury Ratio

The hair (μg/g)/blood (mg/L) Hg ratio of 250:1 is a commonly used measure of past methylmercury exposure in nonoccupational environments;[517] however, estimating this ratio is a complex calculation that depends on a variety of factors including age, sex, diet, season, and analytical method. Frequently, these calculations differ from estimates based on the history of food consumption and methylmercury concentrations in ingested foods.[518] Consequently, total hair Hg concentrations do not always correlate to total whole blood Hg concentrations or Hg toxicity, particularly on an individual basis following chronic methylmercury exposure. In a study of paired hair and blood mercury samples from 1,000 children at birth, ages 7 and 14 the mean ratio at birth using cord blood was ~200.[519] The hair/blood mercury ratios of this cohort at 7 and 14 years of age were 360 and ~250, respectively. In a Canadian study of 1,333 individuals from aboriginal communities in Northern Quebec using ANOVA and Estimated Marginal Means, the error at the community level in blood Hg estimated from hair Hg using the 250:1 ratio was −25% to +25% with mean underestimation in females of −8.4% and mean overestimation in males of +5.8%.[520] The corresponding error at the individual level was −98.7% to +1,040%, resulting in observed hair/blood ratios of 3–2,845. Although properly handled hair samples are surrogate biomarkers for blood mercury concentrations in epidemiological studies of large groups exposed to methylmercury, the utility of hair testing for individuals in the clinical setting is limited because the correlation between hair and blood mercury concentrations varies substantially. In the clinical setting, hair mercury concentrations should be confirmed by measurement of mercury in blood samples as a result of the potential overestimation of the actual mercury concentration.[330] Even in the setting of epidemiology studies, there is substantial imprecision (i.e., coefficient of variation near 30%) in the maternal hair to cord blood mercury ratio; therefore, calibration of this ratio should be confirmed by analysis of cord blood in each study.[519] External contamination is a potential source of inaccurate analysis, particularly with methylmercury compounds that absorb more readily on the hair shaft than inorganic mercury compounds.[521]

General Population

Typically, total hair mercury concentrations (i.e., primarily methylmercury) are <1 μg/g in individuals with little fish consumption; however, this value may increase to >30 μg/g when the diet contains frequent amounts of fish with high Hg concentrations.[512] In a study of 559 human head hair samples from fish-eating populations around the world, the mean mercury concentration ranged from 0.5 ppm in Germany to 3.9 ppm in Japan.[522] The mean hair mercury concentration varied with fish consumption, ranging from 1.4 ppm for <1 fish meal/month to 11.6 ppm for ≥1 fish meal/day.

Toxicity

Methylmercury poisoning occurred around Minamata Bay, Japan (1940s–1950s) with the identification of the toxin in 1959; consequently, dose-response relationships between hair mercury concentrations and neurological disease were not well-characterized during the most prevalent time of the disease. Mercury concentrations in hair of >50 μg/g (ppm) suggest the possibility of the development of sensory disturbances based on analysis of patients with methylmercury poisoning in Niigata, Japan from eating contaminated fish from the Agano River during the 1960s;[507] however, retrospective analysis of methylmercury poisoning in Niigata suggested the occurrence of this disease in patients with hair Hg concentrations of <50 μg/g *at* the time of initial neurological examination.[523] In addition to the validity of hair analysis, the issue of the time of the poisoning in relation to the hair analysis complicates the interpretation of the latter study. Analysis of data obtained from 473 patients clinically diagnosed with methylmercury poisoning several months after eating contaminated Iraqi wheat and barley did not detect neurological symptoms when the total Hg hair concentration was <300 μg/g; however, neither whole blood total Hg nor total hair Hg correlated well to neurological symptoms.[524] The study did suggest that the fetus is particularly susceptible to the effects of methylmercury. The longitudinal Seychelles Child Development Study did not detect a relationship between prenatal Hg exposure and 21 endpoints for neurodevelopmental deficits; the study followed the 553 children to age 19 years.[525] Their mean prenatal Hg hair concentration was 6.9 μg/g, whereas the mean recent postnatal Hg Hair concentration was 10.3 μg/g. The Seychelles mothers averaged 12 fish meals/week.

The Faroe Islands Study enrolled 1,022 singleton births with neuropsychological testing at 7 and 14 years.[526] Pilot whale meat was the primary source of mercury in the mothers. The geometric mean of their prenatal hair Hg concentration was 4.2 μg/g with a range of <0.2–40 μg/g. Regression analysis indicated prenatal methylmercury exposure correlated to deficits in finger

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tapping speed, reaction time on a continued performance task, and cued naming; postnatal methylmercury exposure did not produce a discernible effect on the test results. Follow-up of 847 members of the cohort at 22 years of age indicated the cognitive deficits observed were smaller than at examinations at younger ages; deficits in Boston Naming Test (BNT) and other tests of verbal performance were significantly (negatively) associated with the cord-blood mercury concentration, whereas most other neuropsychological tests did not reach statistical significance.[527] A hierarchical model of general intelligence suggested a 2.2 IQ point reduction for a 10-fold increased prenatal methylmercury exposure. The issue of how to adjust for these exposures complicates the interpretation of the results of the Faroe Islands study.[528] The presence of co-contaminants (e.g., PCBs) or nutritional differences may account for some of the differences between the Seychelles and Faroe studies.

Abnormalities

Imaging

Abnormalities of fetal brains on CAT scanning following methylmercury poisoning are relatively mild compared with the clinical features of the disease. CAT scans of the brain do not effectively differentiate cerebral palsy from methylmercury poisoning.[529] For patients followed long-term with Minamata disease, the MRI demonstrates lesions of the calcarine area, cerebellum, and postcentral gyri that correlate to neurological abnormalities of visual field constriction, ataxia, and sensory deficits, respectively.[530] The slightly hypointense, T1-weighted images and the hyperintense, T2-weighted images of the visual cortex suggest status spongiosus. In alcoholism, the superior vermis of the cerebellum is more severely affected compared with the inferior vermis in the Minamata disease.

Neuropsychological Testing

There are few data on the effect of low mercury concentrations on cognitive function in adults. A cross-sectional study of 474 urban volunteers 50–70 years of age did not detect significant impairment of total whole blood Hg concentrations on neurobehavioral test scores in 7 domains (nonverbal reasoning and intelligence, language, verbal memory, visual memory, visuoconstruction and visuoperception, motor and manual dexterity, executive function).[531] The median total whole blood mercury concentration was 2.1 μg/L with a range of 0–16 μg/L. In the US Treatment of Lead-Exposed Children study of 780 children with elevated blood lead levels, whole blood methylmercury concentrations were measured simultaneously with high-performance liquid chromatography/inductively coupled plasma/mass spectrometry.[532] The geometric mean total methylmercury concentration was 0.56 μg/L (95% CI: 0.52–0.59 μg/L). Linear regression models did not suggest adverse neuropsychological effects from methylmercury. A 1 μg/L increase in methylmercury concentration was associated with an increase of 2.1 Full-Scale IQ points (95% CI: 0.4–3.8 points).

HEALTH SURVEILLANCE

Risk Assessment

The US Agency for Toxic Substances and Disease Registry (ATSDR) reduced the chronic-duration (≥365 days) minimal risk level (MRL) for methylmercury to 0.3 μg/kg/day based on neurodevelopmental outcomes in children exposed *in utero* to methylmercury from maternal fish ingestion.[14] The previous value was based on a no-observed-adverse-effect-level (NOAEL) of 0.23 mg/kg/d derived from a rodent study that detected developmental effects on operant behavioral performance in the offspring of rats given methyl mercuric chloride on gestation days 6–9. In addition, the previous calculation used data from developmental measurements in Iraqi children of mothers consuming bread contaminated with mercury-containing fungicide. The estimated maternal exposure sufficient to cause biological damage in offspring was 1 μg/kg body weight daily, based on maternal mercury concentrations of 10 ppm in hair samples.[373] More recent data from the Seychelles Child Development Study demonstrated no decrements in neurobehavioral tests of children born to mothers with 15.3 ppm mercury in maternal hair.[422] The overall uncertainty factor for the recent MRL was 4.5, consisting of 1.5 for variability in hair-to-blood ratios, 1.5 for interindividual variability, and 1.5 for extrapolation from a population outside the United States.

The US EPA also considers the developing human nervous system as the most sensitive end point for determining safe levels of exposure to mercury compounds. The previous chronic oral R_fD was 0.3 μg/kg/day based on paresthesias in Iraqi adults eating methylmercury-contaminated grain.[533] The current R_fD is 0.1 μg/kg/day based on a benchmark dose of 11 ppm methylmercury in maternal hair causing congenital neurological abnormalities in Iraqi children born to mothers consuming methylmercury-contaminated bread. The

ratio of 250:1 (μg Hg/mg in hair to μg methylmercury/mL blood) was used to derive the R_fD critical dose and convert the maternal hair concentration to 44 μg/L fetal blood.[534]

The WHO tolerable limit for mercury in hair is 5 ppm based on the estimated threshold effect of 50 mg/kg and a safety factor of 10 for the greater estimated sensitivity of the developing brain.[535] Although some methylmercury may be converted to inorganic mercury in the environment, almost all mercury in water is inorganic; hence, exposure guidelines for water are based on total Hg consisting primarily of inorganic mercury. Examination of methylmercury concentrations in the cord blood of residents of Minamata indicated a dose-response relationship between methylmercury concentrations and the development of congenital Minamata disease.[536] The lowest no-observed-effect-level (NOAEL) in the Iraqi outbreak of methylmercury poisoning was ~400 μg/g hair as measured by the maximum hair mercury level of the mother during pregnancy.

Environmental Monitoring

Table 20.6 lists the guidelines and regulations for organic mercury. Organic mercury compounds contain at least one carbon atom covalently bonded to mercury. Because of the conversion of aryl (e.g., phenyl) and alkoxyalkyl (e.g., methoxyethyl) mercuric salts to inorganic mercury in the body, recommendations for exposure to these mercury compounds follow the guidelines for inorganic mercury. Short-chained alkyl Hg compounds (e.g., methylmercury, ethylmercury) are very stable compounds that resist biotransformation. US OSHA establishment of a PEL–TWA of 100 μg/m^3 and a STEL of 30 μg/m^3 for alkyl mercury compounds along with a skin notation was vacated by the 11th US Circuit Court of Appeals in 1992. The recommendations of ACGIH and most other countries are similar to the vacated OSHA values. NIOSH defines the level immediately dangerous to life (IDLH) as 2,000 μg/m^3 for alkyl mercury compounds.

TABLE 20.6. Short-chain alkyl organic mercury guidelines and regulations. For these compounds, mercury binds directly to simple straight-chain groups (e.g., methyl, ethyl) rather than to more complex carbon configurations.

Exposure Limit	Value
OSHA	
PEL–TWA[a] (8-hour)	10 μg/m^3[b]
PEL-Ceiling[a]	40 μg/m^3[b]
NIOSH	
REL–TWA (10-hour)[a]	10 μg/m^3 (as Hg)
STEL[a]	30 μg/m^3 (as Hg)
IDLH[a]	2,000 μg/m^3 (as Hg)
ACGIH	
TLV–TWA (8-hour)[a]	10 μg/m^3
STEL-Ceiling[a]	30 μg/m^3
US EPA	
RfD (chronic oral exposure, methylmercury)	0.1 μg/kg/day
ATSDR	
MRL (chronic oral exposure, ≥365 days)	0.3 μg/kg/day
US FDA	
Methylmercury (maximum edible seafood)	1 μg/g
WHO	
Tolerable weekly intake methylmercury[c]	1.6 μg/kg body weight
Tolerable limit hair methylmercury	5 μg/g (ppm)

Biological Monitoring

Urine

As a result of the primary excretion of alkyl mercury compounds (e.g., methylmercury) in the feces and very small amounts of these compounds in the urine, urine Hg concentrations do not correlate to the intensity of exposure to these compounds. Consequently, monitoring mercury concentrations in urine is not a practical method to evaluate alkyl mercury exposure. Aryl and alkoxyl mercury compounds behave pharmacologically similar to inorganic mercury compounds. The use of chelating agents to estimate the total body burden is not recommended because of the lack of baseline values, interindividual variability, and inadequate data on clinical efficacy.[188]

Blood

For workers chronically exposed to mercury, the intensity of exposure to mercury correlates to the whole blood Hg concentration at the end of a work shift.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Organic mercury concentrates in the erythrocytes; therefore, serum and plasma mercury concentrations do not reflect the total body burden of mercury. The usefulness of whole blood mercury concentrations as biomarkers is limited to recent exposure because the initial elimination half-life of mercury in the blood is ~2–4 days. Although whole blood Hg concentrations correlate to the methylmercury body burden, the presence of alkyl mercury compounds in the diet complicates the interpretation of the results and limits the sensitivity of the whole blood mercury concentration following occupational exposure to low ambient air Hg concentrations. The ACGIH does not recommend a specific BEI for methylmercury or other organic Hg compounds.

Medical Monitoring

Preemployment physical examinations should focus on the documentation of baseline renal and central nervous system function including a urinalysis. Subsequent examinations should emphasize the detection of signs and symptoms of central nervous system dysfunction (personality changes, tremors, gait disturbances, insomnia, weight loss, ataxia).

TREATMENT

Decontamination

There are no specific clinical data to guide gut decontamination in the treatment of organic mercury poisoning.

Enhancement of Elimination

A 2-hour exchange transfusion removed ~6% of the estimated body burden of mercury from two children severely poisoned by methylmercury; however, no dramatic improvement occurred in the clinical condition of these two patients.[537]

Dimercaprol (BAL)

Although the use of BAL is indicated in severe acute inorganic mercury poisoning, the effectiveness of BAL in organic mercury poisoning remains questionable. Dimercaprol does not reverse the chronic neurological effects of alkyl mercury poisoning; however, BAL is an option for the treatment of acute ingestions of aryl organic mercury compounds (e.g., phenylmercuric acetate) that are converted to inorganic mercury in the body.

DMPS

2,3-Dimercaptopropane-1-sulfonate (DMPS) is an investigational oral analog of BAL that appears less toxic than DMSA. Based on a comparison of half-lives, DMPS was the most effective chelating agent in a series of 16 patients treated during the outbreak of methylmercury poisoning in Iraq based on reduction in blood elimination half-lives; the amount of methylmercury removed was not reported.[538] Treatment with DMPS (Dimaval®, Heyl and Co., Berlin) was associated with the resolution of hematuria and the reversal of electromyographic abnormalities in patients with methylmercury intoxication.[234]

DMSA

A review of the medical literature recommended the use of DMSA (meso 2,3-dimercaptosuccinic acid, Succimer®) in organic mercury toxicity based on greater Hg excretion in clinical studies than DMPS;[241] however, these studies did not document improved clinical outcomes. Although this water-soluble BAL analog is a potential chelating agent for mercury, this drug has not been officially approved for the treatment of mercury intoxication. Unlike elemental and inorganic mercury, organic mercury forms a thermodynamically stable bond with the deprotonated thiol group that limits DMSA effectiveness.[539] Animal and clinical studies suggest that pretreatment with DMSA chelation removes mercury primarily from the main peripheral site of deposition (i.e., the kidney) but not from the brain.[208,248]

There are few data on the use of DMSA in organic mercury poisoning. Despite the initial excretion of large amounts of mercury (39,800 µg/24 hours) following DMSA therapy, a 48-year-old chemist with suspected dimethylmercury poisoning died 4 months after the initiation of chelation.[460] Chelation began 14 days after neurological symptoms developed; 8 days later, she became comatose. The half-lives of mercury in the blood ranged from 29–37 days during chelation. During the treatment of severe thimerosal toxicity, the administration of both DMSA and DMPS did not significantly increase the renal excretion of mercury; the patient recovered with supportive care.[414]

Analysis of blood samples from 67 children receiving Succimer® (DMSA) in the Treatment of Lead-Exposed Children Trial demonstrated a modest decrease in the organic mercury concentration in blood samples compared with untreated children.[540] After three 26-day courses of DMSA, the organic mercury concentrations

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in the DMSA group ($n = 31$) were ~80% of the placebo group ($n = 33$); however, the difference was not statistically significant ($P = 0.19$) after adjustment for age, sex, race, center, and earlier organic mercury concentrations. DMSA treatment produced an initial reduction in the organic mercury concentration and slowed but did not reverse the accumulation of organic mercury. The average total mercury concentrations of the treated children were ~70% higher than children in the National Health and Nutrition Examination survey (0.56 ng/mL vs. 0.34 ng/mL, respectively). The clinical benefit of the use of succimer® for reducing organic mercury concentrations in this setting is equivocal.

N-Acetylcysteine (NAC)

In a study of mice fed methylmercury-contaminated water, the administration of NAC in the drinking water beginning 48 hours after the beginning of the experiment increased Hg excretion in the treatment group.[541] For the subsequent 48 hours, the treated group excreted 47–54% of the ^{203}Hg in the urine compared with 4–10% for the untreated (control) group. This compound increased the urinary organic mercury elimination rate in one case of acute methylmercury ingestion,[123] but the use of NAC remains experimental because there are no clinical data regarding the effect of NAC on clinical outcome.

Chapter 21

MOLYBDENUM

HISTORY

The Greek name, *molybdos*, translates as lead-like; the Greeks and Romans did not distinguish molybdenum from lead, graphite, or other similar compounds. Analysis of 14th-century Japanese swords indicates molybdenum (Mo) was used in the production of weapons. The Swedish scientist, Carl Wilhelm Scheele, first discovered molybdenum as a substance different from graphite in 1778. Shortly thereafter, his colleague, Peter Jacob Hjelm, prepared an impure, black powder from an oxide of molybdenite that he called molybdenum. The pure form of molybdenum was not produced until Moissan separated the pure metal in 1893.[1] The physical properties of molybdenum allow the replacement of tungsten in some steel alloys; the use of molybdenum as an alloying metal in armaments containing plate steel began in the late 1800s. Commercial production of molybdenum started in 1885 with the opening of the Knaben Gruver mine in southern Norway. The shortage of tungsten during World War I accelerated the search for molybdenum sources, culminating in the opening of the massive Climax molybdenum deposit in Colorado in 1918.

PHYSIOCHEMICAL PROPERTIES

Molybdenum is a member of the Group 6 (Group VIb) series of the periodic table along with chromium and tungsten. Molybdenum does not exist naturally in its pure metallic state as a result of the association of molybdenum with other elements. Of the five oxidation states (2–6), the dominant oxidation states are Mo^{4+} and Mo^{6+} with the latter being the most stable. Molybdenum shares many physiochemical properties with tungsten.[2] Of the commonly available metals, only tungsten and tantalum have higher melting points. Molybdenum alloys with tungsten and several lighter alloys (aluminum, chromium, cobalt, iron, silicon) to increase strength and reduce weight of the alloys. The chemistry of molybdenum is complex with this metal forming a very complex series of compounds with the exception of some simple halides, oxides, and sulfides. The dominant form of molybdenum in dilute solutions (e.g., soil, natural waters) is the molybdate anion (MoO_4^{2-}).[2] In solutions containing moderate to high concentrations of molybdenum, this element readily polymerizes into a wide variety of complex structures involving polymolybdates.

Molybdenum exists as a silver-white to dark-gray/black powder, whereas molybdenum trioxide (CAS RN: 1313-27-5) is a white powder that converts to a yellow material when heated. The mineral molybdenite (molybdenum disulfide, MoS_2) is a gray, lustrous, and poorly water-soluble powder. Water-soluble molybdenum compounds include ammonium paramolybdate, ammonium molybdate (400 g/L, 20°C), calcium molybdate, sodium molybdate, and molybdenum trioxide. Water-insoluble molybdenum compounds include elemental Mo, molybdenum dioxide, lead molybdate, and molybdenum disulfide. Table 21.1 lists the identifying information and physical properties of common molybdenum compounds.

TABLE 21.1. Identifying information and physical properties of molybdenum and molybdenum compounds.

Physical Characteristic	Molybdenum	Calcium Molybdate	Sodium Molybdate	Molybdic Oxide	Molybdenum Disulfide
CAS RN	7439-98-7	7789-82-4	7631-95-0	1313-27-5	1317-33-5
Molecular formula	Mo	$CaMoO_4$	Na_2MoO_4	MoO_3	MoS_2
Molecular weight (g/mol)	95.95	200.01	205.92	143.94	160.08
Valence	0	6	6	6	4
Color	Silver-white, dark-gray/ black	White	White	Colorless to white-yellow	Gray
Physical state	Powder	Powder, crystalline	Granular	Powder, dry	Powder
Density (g/mL)	10.28 (20°C)	4.35 (25°C)	3.28 (18°C)	4.70 (26°C)	4.8 (14°C)
Melting point (°C)	2629	965	687	795	1185
Boiling point (°C)	4612	ND	ND	1115[b]	1450[b]
Water solubility (g/L, 25°C)	Insoluble	Insoluble[a]	Insoluble	1.07 (18°C)	Insoluble

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number, ND = No data
[a] Decomposes in hot water; [b] Sublimes.

EXPOSURE

Production Processes

The United States is the world's largest producer of molybdenum as a result of large natural reserves in the western mountain regions. The major sources of metallic molybdenum include primarily mining operations and by-products of copper and tungsten mining operations. Molybdenum salts are by products of uranium mining. Molybdenite (MoS_2), ferrimolybdite ($Fe_2[MoO_4]_3$), and jordisite (amorphous molybdenum disulfide) are the most abundant and commercially important ores for the production of molybdenum with molybdenite the most important source. Less economically important molybdenum-containing ores in decreasing order of importance are as follows: powellite ($CaMoO_4$), wulfenite ($PbMoO_4 \cdot 8H_2O$), and ilsemanite (molybdenum oxysulfate).

Roasting of molybdenite ores produces technical-grade Mo oxides used in steel. Conversion of technical-grade Mo oxide to its purer form requires sublimation that requires precise temperature control to prevent material losses from sublimation and volatilization at temperatures of >700°C.

Uses

The vast majority of molybdenum is used in metallurgical applications (e.g., stainless steel, cast iron alloys, iron-based construction steel, high-temperature and tool steel alloys). Stainless steel typically contains 1–3% Mo. The addition of molybdenum to steel alloys improves the commercial characteristics of the alloy by increasing the strength, thermal resistance, and corrosion resistance of the alloy. Examples of the commercial applications of molybdenum-containing alloys include gas and steam turbines in power generation, missiles, and aircraft. Molybdenum exposure usually occurs during the production and fabrication of molybdenum-containing products in the form of elemental Mo oxides and Mo sulfides in dust or fumes.

Metallic molybdenum enhances the adherence of siliceous material to metals; therefore, molybdenum is useful in metal–ceramic composites. Molybdenum trioxide is a corrosion inhibitor, a reagent for chemical analysis, and a blue dye for ceramic glazes and enamels. Zinc molybdate provides stabilizing and anticorrosive properties for paint. Molybdenum acetylacetonate is a catalyst for the polymerization of ethylene and the production of polyurethane foam. Molybdenum disulfide possesses a sheet-like structure similar to graphite, commercially useful in dry lubricants and chemical catalysts. Fertilizers for leguminous plants contain molybdenum salts; standard commercial fertilizers have ~2–6 ppm Mo. Ammonium tetrathiomolybdate is an experimental chelating agent for conditions that increase copper concentrations (e.g., Wilson's disease).[3,4]

Sources

Molybdenum is a rare earth metal. Most Mo exposure results from the use of Mo in steel alloys and less commonly as biocides and constituents of photovoltaic technology. The major anthropogenic sources of molybdenum in the environment include combustion of coal, municipal sewage sludge, and industrial or mining

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

operations. The daily intake of molybdenum from the air and drinking water is negligible compared with the absorption of molybdenum from the diet, except in molybdenum-mining areas.[5]

Air

The molybdenum concentrations in the ambient air are normally low compared with other trace elements (e.g., cadmium, copper, lead, zinc). Higher Mo concentrations occur in the ambient air of urban areas compared with rural areas (0.01–0.03 μg/m^3 vs. 0.001–0.0032 μg/m^3, respectively).[6] Although the release of molybdenum from natural sources far exceeds the release of molybdenum from anthropogenic sources, the mobilization of molybdenum from fossil fuel may produce substantial elevation of molybdenum in the immediate vicinity of the combustion site. Residues from the combustion of coal are important anthropogenic sources of molybdenum in the environment.[1] The Mo concentration in fly ash ranges from 7–160 mg/kg.[7]

Soil

Although the Mo concentration in soil averages ~1,000–2,000 μg/kg, the Mo concentration varies considerably depending on the particular type of geological materials present in the soil and soil pH.[1] Sedimentary-related material (e.g., shale) contains high Mo concentrations, whereas acidic soils are often deficient in molybdenum. Generally, molybdenum-deficient and molybdenum-excessive soils are defined by Mo concentrations of <200 μg/kg and > 700 μg/kg, respectively.[5] Uptake of molybdenum by plants depends on a variety of factors in the soil including mineral content (manganese, phosphorus, sulfur), moisture content, sesquioxide content, pH, and organic matter.[1] Mo uptake by plants occurs mostly from alkaline or neutral soil with Mo concentrations in plants grown in acidic soil (e.g., pH = 5.5) substantially lower than those grown in neutral or alkaline soil. Molybdenum commonly contaminates municipal sewage sludge with Mo concentrations averaging ~15,000 μg/kg and ranging from ~1,000–40,000 μg/kg.[8]

Water

Most natural waters contain low Mo concentrations in the range of <2–3 μg/L, unless local anthropogenic sources contaminate the water. Near industrial sources (e.g., molybdenum mining areas), the Mo concentration in surface water may reach 200–400 μg/L and 25,000 μg/L in groundwater.[9] Molybdenum concentrations in well water may vary significantly over short distances. In streams draining areas with high Mo content, the Mo concentration in water is usually <6,000 μg/L, similar to the Mo concentrations in streams that drain areas with low molybdenum concentration.[1] Increased water pH increases Mo solubility and leachability, whereas acidic conditions decrease the transfer of molybdenum from soil to water. The Mo concentrations in acidic groundwater in contact with soil containing 800 mg Mo/kg were <200 μg/L.[10]

Diet

The diet is the major source of molybdenum for most people. The average daily Mo intake ranges from 100–500 μg, although water contaminated by industrial Mo sources may increase the daily intake to 1,000 μg.[11] Daily adult intake of Mo typically ranges from ~50–240 μg. Analysis of the daily molybdenum intake of 56 German adults demonstrated a range of 47–89 μg as measured by the dithiol and Sandell–Kolthoff procedure.[12] In a study of adult residents in Denver, the daily dietary Mo intake ranged from 120–240 μg with a mean of 180 μg.[13] A study of older children and adults in the northeastern US demonstrated a daily Mo intake ranging from 74–126 μg.[14] The average daily Mo intake (i.e., ~225 μg) in Japanese residents is higher than in Western cultures as a result of the relatively higher intake of rice and soybean products.[15] The WHO estimates the minimum daily Mo requirement is 2 μg/kg body weight.

Molybdenum concentrations in plants range widely (<0.5 to over 100 mg/kg dry weight). Generally, foodstuffs from aboveground plant material (e.g., legumes, leafy vegetables, cauliflower) contain relatively high Mo concentrations compared with food from tubers or animals. The richest sources of molybdenum in the diet include beans, cereal grains, kidney, leafy vegetables (e.g., spinach), legumes, nuts, liver, and milk.[16] Fruits, sugars, oils, stem and root vegetables, and muscle from animals (cod, chicken, anchovies, sardines) usually contain relatively low Mo concentrations. The adult Recommended Daily Allowances (RDA) range is 150–500 μg/day. Tobacco contains small Mo concentrations (0.3–1.76 μg/g); therefore, smoking is probably not a significant Mo source.[17]

DOSE EFFECT

Humans

Molybdenum is an essential element for plants and animals, with molybdenum possessing relatively low

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. toxicity. A balance study of 24 girls aged 7–9 years ingesting 75 μg Mo/day demonstrated elevated urinary Mo concentrations; the abstract of the study did not identify any adverse effects.[18] Rarely, deficiencies of dietary molybdenum are associated with adverse effects; however, the ubiquity of molybdenum in plants and animals significantly limits the ability to produce molybdenum-deficient diets. During prolonged parenteral nutrition, a patient developed amino acid intolerance, irritability, altered consciousness, and biochemical abnormalities (hypermethioninemia, elevated urinary xanthine and sulfite, reduced urinary uric acid and sulfate).[19] These abnormalities resolved after the administration of 160 μg Mo/day.

Animals

Molybdenum toxicity in animals depends on a variety of factors including age and species of the animal, previous dietary history, and the relative amounts of copper, sulfur, and molybdenum in the diet.[16] Ruminants (e.g., sheep, cows) develop adverse reactions to feed containing 2–30 μg/g Mo, whereas horses and pigs tolerate feed with Mo concentrations of >1,000 μg/g Mo. Low copper and sulfur concentrations in the diet enhance molybdenum toxicity; the clinical features of Mo toxicity are similar to those of copper deficiency. Chronic exposure of animals to molybdenum oxide fumes of 53 mg/m^3 for 1 hour daily produced pulmonary irritation and fatty changes in the liver and kidney; all animals survived.[20]

TOXICOKINETICS

Absorption

The gastrointestinal tract readily absorbs soluble, but not insoluble molybdenum compounds. The absorption rate of molybdenum from the diet of patients and healthy volunteers averaged ~50% in two patients with pancreatic insufficiency[21] and 88–93% in a study of patients receiving 22–1,490 μg Mo/day for 24 days.[22] Animal studies indicate that the poorly soluble compound, molybdenum disulfide, is not well absorbed in the lungs or the gastrointestinal tract compared with the more soluble hexavalent molybdenum compounds. The ingestion of Mo in food decreases the bioavailability of Mo compared with purified Mo. In a study of four men receiving labeled and unlabeled molybdenum, the mean bioavailability of food-bound Mo was 83%.[23]

Distribution

In the blood, molybdenum binds to α_2-macroglobulins in the form of molybdate. The binding of molybdenum to the protein, spectrin, also occurs on the erythrocyte membrane. Based on analysis of postmortem tissues, the highest concentrations of molybdenum appear in the kidney and liver with smaller concentrations found in the adrenal glands and long bones.[24] Little molybdenum exists in the brain and gastrointestinal tract (except the jejunum). Retention of molybdenum probably is small.

Elimination

Animal and volunteer studies indicate elimination of absorbed molybdenum compounds occurs rapidly, primarily via renal excretion with urinary Mo excretion increasing as the Mo dose increases. In a study of four adults, the mean renal excretion of Mo over 12 days increased from 26.7% after ingesting 23.8 μg Mo/day to 84.5% when fed 1,378 μg/day.[22] Very little excretion of molybdenum into the bile occurred in a volunteer study following the administration of daily Mo doses up to 1,500 μg. In a radiotracer study of five volunteers, Mo elimination was biexponential with plasma half-times ranging from 4–70 minutes for the fast component and 3–30 hours for the slow component.[25] The presence of high concentrations of copper and sulfates in the diet enhances the elimination of molybdenum by blocking protein carriers and inhibiting tubular Mo reabsorption.[26] Elimination is usually complete within several weeks.

Maternal–Fetal Kinetics

The correlation of umbilical cord blood Mo concentration in newborns with maternal concentrations of molybdenum suggests molybdenum compounds easily cross the placental barrier with similar values between the umbilical cord and maternal serum. The mean plasma Mo concentration in 33 mothers was 1.44 μg/L with a range up to ~3 μg/L, similar to their infants (mean = 1.44 ± 0.89 μg/L, r = 0.48) as measured by flameless atomic absorption spectrophotometry.[27] The mean Mo concentration in 29 maternal serum samples was 0.7 ± 0.3 μg/L (range, 0.3–1.4 μg/L) compared with 0.8 ± 0.3 μg/L (range, 0.4–1.6 μg/L) in umbilical cord blood from their infants, as measured by inductively coupled plasma/mass spectrometry.[28] The mean Mo concentration in colostrum obtained from 27 of these mothers between postpartum days 1–3 was 7.0 ± 3.8 μg/L (range, 3.4–18.8 μg/L). The mean Mo concentration in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

breast milk in a study of six French mothers breastfeeding during the first month of their babies lives was ~10 μg/L at birth with the Mo concentration in breast milk decreasing to ~1 μg/L 2 months postdelivery.[29] The mean Mo concentration in breast milk from 13 postpartum women decreased from 15.0 ± 6.1 μg/L on postpartum day 1 to a stable concentration of ~2 μg/L at 1 month.[30] In this study, the estimated daily Mo intake of seven breastfeed infants at 35 ± 3 days after birth was 2.1 ± 1.5 μg. A 28-year-old breastfeeding mother underwent a metal-on-metal hip implant 13 weeks after delivery.[31] During the first 3 months after surgery, breast milk Mo concentrations peaked at 5 days postop (1.32 μg/L) and 77 days postop (1.67 μg/L), whereas the serum Mo concentration peaked at 5 days (5.46 μg/L). The serum and breast milk Mo concentrations did not correlate.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Molybdenum is an essential metal for humans and most forms of life except blue-green algae because several important enzymes contain molybdenum including xanthine oxidase/dehydrogenase, aldehyde oxidase, and sulfite oxidase. The former two enzymes are involved with the terminal metabolism of purines and the oxidation of aldehydes, whereas the latter enzyme is involved with the oxidation of sulfite to sulfate. Enzymes containing molybdenum (molybdoflavoproteins) catalyze basic metabolic reactions in the carbon, sulfur, and nitrogen cycles. In plants, molybdenum acts as an enzyme activator for nitrogen metabolism via reactions with nitrogenase, a nitrate reductase that reduces nitrogen to ammonia. Consequently, molybdenum deficiency in legumes produces effects similar to those of nitrogen deficiency.[1] All these molybdenum-containing enzymes catalyze oxidation-reduction reactions. The two major types of reactions involving molybdenum-containing enzymes are as follows: 1) the transfer of oxygen atoms to/from the electron pair of a substrate (DMSO reductase, sulfite oxidase), and 2) oxidative hydroxylation of aldehydes and aromatic compounds (xanthine oxidase, aldehyde oxidoreductase).[32] The cofactor, molybdopterin, anchors the molybdenum atom to the active site of a protein in reactions involving the sulfur and carbon cycles.[16] Deficiency of this cofactor has been associated with seizures, mental retardation, severe cerebral atrophy, and early death.[33,34] Substantial variation in aldehyde oxidase activity occurs between species with humans demonstrating the highest activity, rats and mice low activity, and dogs with no detectable activity, whereas xanthine oxidoreductase activity is common among animal species.[35]

Mechanism of Toxicity

Molybdenosis (teart) is a disease affecting primarily ruminants (cattle, sheep) that occurs during grazing on pastures with high molybdenum and sulfate content with low copper availability.[36] In animals, the clinical appearance of molybdenum toxicity is similar to the disease of copper deficiency. The formation of trithiomolybdate by the replacement of oxygen by sulfide in the stomachs of ruminants probably alters the affinity of copper for competing ligands; this reaction produces disturbances in copper distribution and elimination.[37] Signs of molybdenum toxicity in animals include anemia, anorexia, profound diarrhea, joint abnormalities, osteoporosis, hair discoloration, reduced sexual activity, and death. Diets low in sulfates and copper enhance the toxicity of molybdenum,[38] whereas copper supplementation reduces the prevalence of molybdenosis in cattle grazing on soil heavily contaminated with Mo.[39]

CLINICAL RESPONSE

Little data on human molybdenum toxicity are available. The acute toxicity of Mo and Mo compounds is very low.

Environmental Exposure

Exposure to molybdenum from environmental sources is negligible because this metal rarely occurs naturally. In 1961, Kovalskii et al. associated a gout-like syndrome with excessive environmental Mo exposure (10–15 mg molybdenum/day).[40] The disease occurred in Armenians living in areas rich in molybdenum. The predominant clinical features associated with increased Mo intake included hyperuricemia, arthralgias, erythema, edema, and deformity of the knees, hands, and feet. The exact cause of this disease remains unclear as a result of serious study limitations. In this study, the mean serum copper concentration of 1.13 mg/L in the 52 subjects was significantly below the normal mean serum copper concentration of 1.83 mg/L in the 5 controls.[41]

Occupational Exposure

A self-employed, overweight, 36-year-old industrial electrician developed acute arthritis with hyperuricemia

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and elevated serum C-reactive protein; the family history was positive for rheumatoid arthritis, but not gouty arthritis.[42] A limited reconstruction of the patient's workshop demonstrated total Mo dust concentrations of 2–10 mg/m^3 with background concentrations of 1 mg/m^3 from the cutting, grinding, and heating of molybdenum-containing metals. No other cause for his arthritis was established; however, his serum uric acid level remained elevated 1 year after the cessation of his Mo exposure. There is a lack of case reports and epidemiological studies on the occurrence of gouty arthritis in individuals with heavy occupational Mo exposure.

High Mo concentrations may irritate the upper respiratory tract. A 1963 Soviet study associated the development of pneumoconiosis in 3 of 19 workers exposed over 4–7 years to 1–19 mg Mo/m^3 as metallic molybdenum and molybdenum trioxide.[11] Nonspecific symptoms (anorexia, arthralgias, fatigue, headache, weakness) occurred in workers receiving an estimated Mo exposure of 10 mg/day as dust in a molybdenite roasting plant, but the lack of control groups and adequate follow-up complicates the interpretation of the clinical significance of this study.[43] These workers did not report arthritis-related symptoms despite elevated plasma/urine Mo concentrations, low urine copper concentrations, and moderately elevated serum uric acid concentrations compared with controls. This study did not detect any permanent sequelae.

Carcinogenesis

Neither the IARC nor the US Toxicology Program lists elemental molybdenum suspected carcinogens; however, the IARC added molybdenum trioxide to the list of possible carcinogens (Group 2B) based on sufficient evidence of carcinogenicity in animals (i.e., ↑ bronchioloalveolar carcinomas in mice) and inadequate evidence in humans.[44] A hypothesis-generating, hospital-based, retrospective case-control study demonstrated a statistical association (adjusted OR = 2.1, 95% CI: 1.2–3.7) between jobs with ever-exposure to molybdenum and lung cancer after adjustment for smoking, age, marital status, and socioeconomic status.[45] Evaluation of exposure involved both self-reporting (21 cases/12 controls) and job-task exposure matrices (52 cases/34 controls). The only duration of exposure of >21 years was associated with a statistically significant increased odds ratio (OR = 3.3, 95% CI: 1.3–8.3; 19 cases/12 controls) for lung cancer; however, self-reported Mo exposure did not correlate to an increased lung cancer risk. The poor exposure data, the uniqueness of these findings, and the multiple comparisons in this study prevent any conclusions regarding cancer causation. In this study, the association between chromium exposure and lung cancer was not statistically significant.

DIAGNOSTIC TESTING

SI Conversion Units

1 mg = 10.42 μmol
1 μmol = 95.95 μg

Analytical Methods

Older techniques for determining the molybdenum concentration in environmental samples include colorimetry (e.g., thiocyanate) and dithiol methods;[46] whereas atomic absorption spectrometry was the common method for analyzing Mo in biological samples.[47] Currently, neutron activation analysis and inductively coupled plasma/mass spectrometry or atomic emission spectrometry are the current methods of choice for confirmation of Mo concentrations in biological samples. The use of double-focusing magnetic sector/inductively coupled plasma/mass spectrometry operated in medium-resolution mode allows the detection of Mo in the range of 0.06 μg/L.[48] Using ion-exchange chromatography/inductively coupled plasma/mass spectrometry, the limit of detection for Mo in plasma samples was 1 ng/L with a coefficient of variation of <2%.[49] Potential contamination from glassware, reagents, syringes, and the environment complicates the interpretation of Mo concentrations in biological samples.

Biomarkers

Blood

There are few data comparing plasma and whole blood Mo concentrations; some Mo binding to the erythrocyte membrane and plasma proteins occurs.[50] In a study of 998 Swedish adults in their 70s, the mean whole blood/serum Mo ratio was 0.73 as measured by inductively coupled plasma/sector field mass spectrometry.[51] The mean whole blood/plasma Mo ratio in blood from 106 healthy French subjects was 0.90 (3.57 vs. 3.98 μg/L) as measured by inductively coupled plasma/mass spectrometry/collision cell technology.[52]

Balance studies in metabolic units suggest plasma Mo concentrations reflect Mo exposure over the preceding 14 days at daily Mo intake up to 1,500 μg with plasma Mo concentrations correlating well to dietary Mo intake.[53] Prior to 1973, some studies reported mean whole blood Mo concentrations up to ~150 μg/L in subjects from areas rich in molybdenum including molybdenum mining areas. In a study of 26 residents of Missoula, Montana, the mean Mo concentration in 26 whole blood samples was 157 μg/L with a range of 5–410 μg/L as measured by fluorometry;[54] however, the reliability of these early methods is equivocal.

General Population

Most people in the general population have low whole blood Mo concentrations (i.e., <5 ng/mL); however, substantial individual variation in the blood Mo concentration occurs in the general population depending on the local Mo concentrations and diet.[55] The geometric mean whole blood Mo concentration in samples from 418 Venezuelan blood donors was 2.66 ± 0.66 μg/L (range, 1.20–4.80 μg/L).[56] In general, the average daily Mo intake is higher in Japanese residents than in residents of Western cultures. The geometrical mean and median serum Mo concentrations in blood samples from 70 healthy Japanese adults were 1.21 ± 1.34 μg/L and 0.90 μg/L, respectively, with a range of <0.1–9.11 μg/L as measured by inductively coupled plasma/mass spectrometry.[57] A majority (55.7%) had serum Mo concentrations of <1 μg/L and only 8.6% ($n = 6$) above 2 μg/L.

The serum Mo increases in patients with renal or liver dysfunction. In a study of 60 patients with renal failure requiring hemodialysis, the mean predialysis and postdialysis serum Mo concentrations were 21 ± 19 μg/L and 14 ± 7 μg/L, respectively, as measured by flameless atomic absorption spectrometry.[58] The reported reference range for serum Mo in this study was 0.2–1.3 μg/L. The serum Mo concentration in 14 Belgian patients with acute viral hepatitis was 6-fold higher (3.1 ± 1.46 μg/L) than 50 healthy adults (0.55 ± 0.21 μg/L) as determined by neutron activation analysis.[59]

Toxicity

Molybdenum is a minor constituent of hip implants; serum Mo concentrations are not usually elevated in a patient with either metal-on-metal Birmingham hip resurfacing or metal-on-metal total hip arthroplasties.[60] In a study of 132 MoM hip replacements followed for an average of 7 years, the mean whole blood Mo concentration remained stable between 1.70 (1–3 years) and 1.46 μg/L (6–7 years) as measured by inductively coupled plasma/mass spectrometry.[61] The mean preoperative plasma Mo concentration in 59 patients receiving standard MoM hip implants (4.5–7.0% Mo) was 1.21 ± 0.74 μg/L compared with 0.97 ± 1.09 μg/L 1 year after the implant as measured by graphite furnace atomic absorption spectrometry.[62] Patch testing demonstrated no hypersensitivity to 0.5% molybdenum chloride at the 1-year follow-up. The whole blood concentration of molybdenum in exposed workers frequently exceeds the Mo concentrations present in the general population; however, signs of clinical illness do not usually appear in these workers.[63] A study of 219 subjects from a fertility clinic suggested an inverse association between whole blood Mo concentrations and measures of male fertility (serum testosterone, sperm concentration, sperm morphology) based on linear regression analysis comparing low, medium, and high categories of Mo concentrations.[64,65] The clinical significance of this study is unclear because 70% (low Mo group) of the subjects had Mo concentrations below the limit of detection (1.0 μg/L). The upper 95% of the whole group was 2.0 μg/L; these values are well within normal reference ranges for whole blood Mo concentrations in the general population without excessive exposure to molybdenum.

Urine

A study of the urine from US residents [National Health and Nutrition Examination Survey (NHANES III)) demonstrated a 95th percentile Mo concentration of 168 μg/L.[66] The maximum Mo concentration was 688 μg/L as measured by inductively coupled argon plasma mass spectrometry. The urine Mo concentrations were similar in the NHANES IV study. In a sample of 2,019 adults 20 years and older, the geometric mean urine Mo concentration was 39.6 μg/L with a 95% upper CI of 144 μg/L. The median Mo concentration was 42.0 μg/L. In a study of the Danish population using inductively coupled plasma mass spectrometric analysis with ^{95}Mo as an isotope, the mean urine molybdenum concentration in urine was 42.5 μg/L (3.89 μg/mmol creatinine) with a 95% parametric reference interval of 10–124 μg/L (0.89–11.50 μg/mmol creatinine).[67] Age did not influence the urine Mo concentration.

Abnormalities

Several cohorts exposed to high Mo concentrations had hyperuricemia and low copper concentrations;[40,68] however, the design of these studies prevents the establishment of a definite causal relationship between Mo exposure and hyperuricemia or hypocupremia.

HEALTH SURVEILLANCE

Risk Assessment

An estimated adequate and safe adult daily Mo intake based on balance studies was 150–500 µg.[69] A tolerable daily intake of 9 µg/kg was calculated from a NOAEL and LOAEL of 0.9 and 1.6 mg Mo/kg/day, respectively, based on adverse reproductive and fetal developmental effects in rats and mice, an uncertainty factor of 10 for intraspecies differences, and an uncertainty factor of 10 for interspecies differences.[70]

The NOAEL for students receiving supplemental molybdenum in their drinking water was 8 µg/kg/day.[68] A balance study of 24 girls aged 7–9 years ingesting 75 µg Mo/day demonstrated elevated urinary Mo concentrations, but the study did not identify any adverse effects.[18] Kovalskii et al. described a syndrome of hyperuricemia and arthralgias in Armenians consuming an estimated 10–15 mg Mo/day while living in an Armenian province.[40] This area contained high Mo concentrations in the soil. This cross-sectional epidemiology study compared the incidence of gout and uric acid concentrations of residents from Ankawa (average estimated daily Mo intake, 10–15 mg) with individuals in a new, adjoining settlement (average estimated daily Mo intake 1–2 mg). Of the 184 Ankawa villagers examined, 31% had clinical evidence of gout, whereas 17.9% of the 78 control villagers had similar findings. The average serum uric acid concentration of 52 Ankawa adults was 6.2 mg/dL compared with a mean of 3.8 mg/dL in five controls. Limitations of this study included inadequate statistical analysis, inconsistent methods of ascertainment, and lack of control of confounding variables (e.g., copper deficiency); therefore, the validity of the results of this study is debatable.[41] The US EPA (IRIS database) used this study to set 140 µg Mo/kg/day as the lowest observable adverse effect level (LOAEL).

Environmental Monitoring

The US OSHA PEL–TWA for soluble molybdenum compounds of 5 mg Mo/m^3, as total dust, and 10 mg/m^3 for insoluble Mo compounds as total Mo was vacated by court order. The existing US OSHA PEL–TWA for Mo and other insoluble Mo compounds is 15 mg Mo/m^3. The ACGIH TLV–TWA recommendations for poorly water-soluble Mo compounds (molybdenum disulfide, molybdenum dioxide) and metallic Mo are 10 mg/m^3 as inhalable particulate mass and 3 mg Mo/m^3 as respirable particulate mass. These recommendations are formulated to prevent local irritation and chronic respiratory effects.[71] The TLV–TWA recommendation for soluble Mo compounds (ammonium paramolybdate, ammonium molybdate, calcium molybdate, sodium molybdate, molybdenum trioxide) is 0.5 mg Mo/m^3 as a respirable particulate mass based on inflammation (chronic alveolar inflammation, squamous metaplasia of larynx, hyaline degeneration of respiratory epithelium) in rodent studies.

TREATMENT

Treatment of molybdenum toxicity is supportive. The low acute oral toxicity of Mo compounds (e.g., <100 mg Mo based on animal studies) limits the usefulness of gut decontamination (lavage, activated charcoal), particularly after the first 1–2 hours post-ingestion. The association of increased molybdenum toxicity with deficiencies of copper and sulfate suggests that diets rich in these substances may enhance recovery from the chronic ingestion of molybdenum, but no data are available to evaluate the efficacy of these supplements.

Chapter 22

NICKEL

INORGANIC NICKEL

HISTORY

Nickel (Ni) is a ubiquitous metal used since antiquity as a common alloy for weapons.[1] Several hundred years after the birth of Christ, Chinese craftsmen incorporated a nickel alloy (white copper) into household objects and art.[2] Agricola recognized the toxic effects of nickel on the lung in the 16th century. By the 17th century, an inexpensive nickel–zinc–copper alloy from China had appeared in Europe. The Swedish chemist A.F. Cronstedt recognized nickel as the 28th element of the periodic table in 1754 by separating an impure form of nickel from niccolite (NiAs). In 1820, Berthier isolated nickel as a pure metal. Full-scale commercial production of nickel began in 1865 when J.F. Wharton produced malleable nickel for a US 3-cent piece. In the early 20th century,[3] nickel sulfate was a medicinal agent for the treatment of chorea, epilepsy, migraine, and neuralgia; however, the medicinal use of nickel was abandoned in the 1930s despite studies indicating nickel was an essential element for metabolism in animals.[4] Although animal studies associated nickel deprivation with depressed growth, reduced reproductive rates, and alterations of lipids and glucose, a deficiency state in humans was never clearly defined.[5]

By the early 1930s, nickel was a recognized cause of contact dermatitis.[6] Elevated incidences of lung cancer appeared in Germany during the 1930s. In 1958, Doll reported an increased incidence of lung and nasal cancer in UK workers primarily exposed to nickel in the first part of the 20th century.[7]

PHYSIOCHEMICAL PROPERTIES

Nickel is a silver-white metal that forms the first transition series Group 10 (Group VIII) of the periodic table along with palladium and platinum. Nickel is the 24th most abundant metal constituting ~0.16% of the earth's crust.[8] There are five natural isotopes with ^{58}Ni (68.27%) and ^{60}Ni (26.10%) being the most abundant. ^{63}Ni is a β-emitter with useful properties as a tracer element (half-life of 100.1 years). The oxidation states of nickel range from 1− to 4+ with the divalent (2+) oxidation state being the most stable species in aqueous solutions and biological systems. Nickel is a common constituent of metal alloys (e.g., stainless steel, copper–nickel) that increases the corrosion resistance, hardness, and strength of the alloy. The siderophilic properties of nickel facilitate the formation of nickel–iron alloys. Nickel possesses fair thermal/electrical conductivity and ferromagnetic properties; the conductive and magnetic properties are lower than those of silver and iron, respectively. As a member of the transition metal series, nickel is resistant to corrosion by air, water, and alkali, but nickel dissolves readily in dilute oxidizing acids. Nickel salts of strong acids and organic acids are soluble in water, whereas nickel salts of weak inorganic acids are water-insoluble. In contrast to the soluble nickel salts (acetate, chloride, nitrate, sulfate), metallic nickel, nickel sulfides, and nickel oxides are poorly water-soluble. Nickel carbonates and nickel hydroxides

are moderately water-soluble. Green nickel oxide is chemically inert, whereas black nickel oxide is relatively reactive. Table 22.1 lists the identifying information and physical properties of metallic nickel and inorganic nickel compounds. When heated, nickel acetate releases irritating fumes. Other potentially toxic thermal decomposition products of nickel compounds include sulfur oxides from the heating of nickel subsulfide.

Rather than speciation, airborne nickel exposure is typically divided by sequential extraction techniques into the following four nickel fractions: 1) soluble ($NiSO_4 \cdot 6H_2O$, $NiCl_2 \cdot 6H_2O$); 2) sulfidic (NiS, NiS_2, Ni_2S_3); 3) metallic (elemental nickel, nickel alloys); and 4) oxidic [NiO, Ni_2O_3, $Ni(OH)_2$, $NiCO_3$, $Ni_3CO_3(OH)_4$, complex nickel oxides].[9] The composition of these fractions varies somewhat with the type of nickel process. Examination of fly ash from a power plant demonstrated $NiSO_4$ and lesser amounts of NiS and NiS_2; Ni_2S_3 was not detected as measured by carbon paste electrode voltammetry.[10] Analysis of coal by XANES spectroscopy demonstrated nickel oxides and sulfides, whereas the ash contained nickel sulfate and complex nickel oxides.[11] The bottom and fly ash from this Canadian power plant contained nickel sulfate, but there were no detectable amounts of potentially carcinogenic nickel sulfides.

EXPOSURE

Production Processes

In the United States, there are no commercial nickel mines. Nickel production results from the processing of by-products of copper mining or the recycling of nickel products. The major producers of nickel include Canada, the former USSR, New Caledonia, and Australia. Nickel occurs in several ores in combination with sulfur, arsenic, antimony, and hydrated silicon dioxide (silicic acid).[8] The two main types of nickel ores are oxide ores (laterites) and sulfide ores (hydrous nickel silicate, garnierite). Lateritic ores are usually mined by

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

strip mining methods, whereas most sulfide ores are found in underground mines. The main sulfide ores are chalcopyrite ($CuFeS_2$), pentlandite ($[FeNi]_9S_8$), and pyrrhotite (Fe_7S_8). Nickel arsenide ores are relatively rare. Extraction of nickel from oxide ores (laterites, nickeliferous) accounts for ~45% of the Ni production, whereas the extraction of sulfide ores accounts for the rest of the commercial nickel. These ores typically contain up to 3% nickel.

Insoluble Ni is the predominant type of nickel in Ni-producing industries. Sampling of underground miners indicates that mining operations involving nickel ores expose the miners to respirable particles (<10 μm) in the range of 5 μg Ni/m^3, whereas the time-weighted average of total nickel in the ambient air averages ~25 μg Ni/m^3.[12] Blasting, crushing, drilling, and hauling operations typically generate ambient concentrations of insoluble nickel in the range of 0.1–1 mg/m^3. Newer processes (e.g., chloride leaching, fluid-bed roasting) substantially reduce the exposure to insoluble nickel compared with the older, dusty roasting processes.[13] During the converting operation for sulfide ores, substantial amounts of sulfur dioxide are generated during the removal of sulfur from the matte (CuNiFeS).

Pyro- and hydro-metallurgical refining processes extract the nickel from the oxide ores (laterites). These processes expose workers to insoluble nickel. Refining is the final step in the production of nickel. This step usually involves exposure to soluble nickel compounds during the electrolytic treatment process or nickel carbonyl during the Mond process. Electroplating and production of chemicals also produce exposure to soluble nickel compounds (e.g., nickel chloride, nickel nitrate). Welding stainless-steel and high-nickel alloys releases nickel fumes into the work environment.

Metal-inert-gas (MIG) welding of stainless steel produces fumes with particle sizes <0.1 μm and concentrations of 3–6.5% Ni, whereas manual metal arc (MMA) welding releases fumes with lower nickel concentrations (0.4–1% Ni) and larger particle sizes (>0.1 μm).[13] However, MMA techniques generate three to four times the volume of fumes from welding stainless steel compared with MIG techniques. The inhalation of nickel also occurs in flame spraying and mold-making in glass and ceramics factories, where hollow molds are formed by the flame spraying of metallic particles containing 70–98% Ni.

Uses

Soluble nickel is the predominant type of Ni exposure in the Ni-using industries. Historically, metallic Ni exposures were higher in Ni-producing industries with mean inhalable Ni concentrations sometimes exceeding 5 mg/m^3 compared with an order of magnitude less for airborne Ni concentrations in Ni-using industries.[14] The majority of nickel production is used for the creation of stainless steel, nickel alloys, and nickel cast iron that comprise objects (e.g., coins, electrical equipment, tools, machinery, armaments, appliances, household utensils). Nickel alloys include iron–nickel alloys (0.3–5% Ni), stainless steels (8–10% up to 25–30% Ni), nickel–copper alloys (25% Ni, 75% Cu in US coins), nickel–chromium alloys, corrosion-resistant nickel–iron–chromium/nickel–molybdenum alloys, and cast irons. Figure 22.1 demonstrates the common uses of nickel. Other uses for nickel compounds include electroplating soluble forms of black oxide, carbonate, chloride, sulfate, electroforming (nickel sulfamate), nickel–cadmium alkaline batteries (hydroxide), dye mordant (ammonium chloride, acetate), catalysts

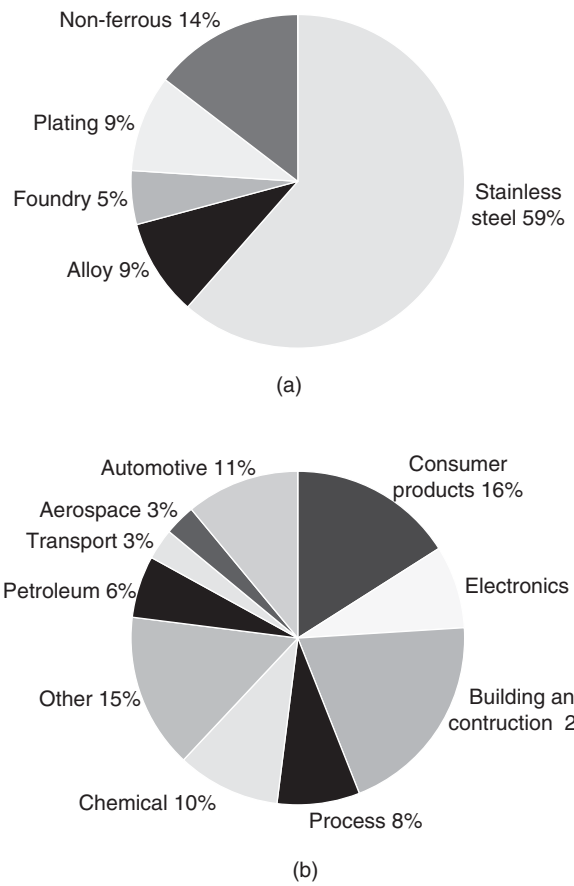

FIGURE 22.1. Common uses of nickel. (a) Nickel use by product, (b) Nickel use by industry. (Data from Morgan and Usher).[15]

(acetate, arsenate, carbonate, chloride, cyanide, formate, hydroxide, nitrate hexahydrate, sulfides), and electronic equipment (carbonates, ferrites). There is no specific commercial use for nickel subsulfide; therefore, exposure to this compound occurs during the processing of nickel ores in surface smelting–refining facilities. Nickel subsulfide does not occur naturally in ores. The widespread use of nickel alloys in jewelry and associated products causes adverse effects from contact dermatitis in a substantial segment of the population sensitive to nickel. Potential Ni sources for sensitized patients include nickel plating, stainless steel, white gold, German silver (argentan), monel (70% copper, 30% nickel), solders, nickel-plated silver, gold plating, silver-, rhodium-, or gold-plated silver, hard-gold plating, and sterling silver.[16] Uses of nickel-containing alloys include nickel plating of non-precious metals, surgical steel (0.5–30% Ni), white gold (10–15% Ni), German silver (10–15% Ni), solders, hard-gold plating, and sterling silver. Nickel coating of silver items reduces oxidation; gold plating may be combined with nickel undercoating. Additional occupational exposure to nickel results from dermal contact with cutting oils contaminated with nickel or nickel alloys.

Sources

Nickel and nickel compounds occur naturally in the earth's crust, resulting from natural (dust, volcanic eruptions, forest fires) and anthropogenic (fossil fuel combustion, waste incineration, mining, smelting, refining, production of nickel-containing alloys) sources. Nickel exposure for the general population is usually low (ambient air, food, water, tobacco smoke).

Air

Nickel exists in ambient air primarily as suspended particulate matter and rarely as an aerosol; fine particulate matter (i.e., 0.6–10 μm) contains most of the airborne nickel. Ambient air is usually a minor route of exposure for the general population, typically <0.05 μg/day.[17] The nickel concentration in ambient air is low (~<6–20 ng/m^3); however, Ni concentrations up to 150 ng/m^3 may occur in air contaminated by aerosols from anthropogenic sources including high-temperature metallurgical operations (gray-iron foundries), chemical or catalytic processes, combustion sources, or incineration of waste and sewage sludge.[18] The US EPA estimated an average ambient air nickel concentration in the United States during the middle 1990s of ~2 ng/m^3.[19] Nickel concentrations in indoor air are typically <10 ng/m^3.[20]

Combustion of fossil fuels (coal- and oil-fired boilers, coke ovens, diesel-fuel burning) produces the majority of nickel released into ambient air with nickel sulfate being the predominant form of nickel; consequently, urban ambient air contains higher Ni concentrations (5–35 ng/m^3) than rural ambient air (1–3 ng/m^3).[21] The ambient air near these sources also contains lesser amounts of nickel oxides, complex metal (iron) oxides, metallic nickel, and nickel subsulfide.[22] Other anthropogenic sources include nickel metal refining and other nickel alloy production, municipal incineration, steel production, and coal combustion.[17]

Water

Divalent nickel is the predominant form of nickel in aquatic sources, but other forms may exist depending on pH, soil use, depth of sampling, and the occurrence of organic and inorganic ligands. Most nickel compounds are water-soluble at pH <6.5.[23] Uncontaminated freshwater and seawater usually contain ~0.3 μg Ni/L. The degradation of soils and the deposition of nickel in the atmosphere release nickel into the surface-and groundwater. Local industrial discharges also contribute to the presence of nickel in these waters. The amount of total nickel in water varies widely depending on anthropogenic sources and the nickel content of pipes/containers. A survey of US surface water indicated that nickel concentrations range from 5 μg/L (Southern Nevada) to 600 μg/L (Ohio River Basin).[22] Average total nickel concentrations in drinking water ranges from 3–7 μg/L with concentrations seldom >35 μg/L.[24] Nickel concentrations increase in vessels containing corroded nickel plating. The first drawn water from hot water taps plated with nickel may contain Ni concentrations of 1–1.3 mg/L.

Soil

Nickel is the 24th most abundant element in the earth's crust, comprising about 3% of the composition of the earth, averaging ~50 ppm Ni. The molten core of the earth contains ~7% nickel, whereas the nickel content of meteorites ranges from 5–50%. The nickel concentration in soil depends on the presence of natural and anthropogenic sources with typical ranges of ~5–500 ppm up to 24,000 ppm in the soil near metal refineries and 53,000 ppm in dried sludge.[22] Farm soils contain ~3–1,000 mg Ni/kg soil.[25] In a study of soil samples from urban parks in six large European cities, mean nickel concentrations in surface samples (0–10 cm) ranged between 11–207 ppm and 10–210 ppm in subsurface samples (10–20 cm).[26]

Diet

Food is the dominant source of exposure to nickel for the general population.[27] Nickel occurs in the food chain through uptake by plants and leaching of nickel from processing equipment/utensils. The estimated daily nickel intake in the Danish diet averaged 150 μg with a range up to 900 μg,[28] whereas the average daily intake of dietary nickel in US studies ranged from ~70–160 μg.[29,30] In a study of Montreal residents, the estimated daily nickel intake from the diet was 286 μg,[31] whereas the estimated daily intake of nickel from a UK diet was 140–150 μg.[32] The leaching of nickel from kitchen utensils and water pipes may add up to 1,000 μg to the daily intake of nickel, but the use of newer stainless-steel pans adds much smaller amounts of nickel to the diet.[33] Most foods contain <0.5 mg Ni/kg wet weight. Foodstuffs with nickel concentrations exceeding 1 ppm include oatmeal, dry legumes, hazelnuts, dark chocolate, soy beans, and soys products. Cocoa usually contains the highest nickel concentrations ranging from 8.2–12 mg/kg of fresh wet weight based on a Danish study using flame atomic absorption spectrophotometry.[28] The Ni concentration in edible marine species is usually low. Typically, the Ni concentrations in freshwater fish, marine fish, and mollusks growing in uncontaminated areas range from <0.2–2.0 ppm, nondetectable–4.0 ppm, and 0.4–2.0 ppm, respectively, by wet weight.[17] Nickel is a compound generally recognized as safe (GRAS) when used as a direct ingredient in human food.

Lifestyle

Ni is a constituent of cigarette smoke with yields in mainstream smoke ranging from 0–0.51 μg/cigarette depending on growing conditions.[34] Nickel is divided approximately equally between the particulate and vapor phases. An average cigarette contains 1–3 μg Ni; smoking 1-ppd cigarettes increases the daily nickel amount inhaled by ~4 μg.[35] Most nickel in tobacco remains in the ash after smoking. About 1% of the nickel in tobacco is transferred to mainstream smoke based on studies using smoking machines; however, nickel concentrations in blood and urine from smokers and nonsmokers in nickel refineries are not significantly different.[36]

In vitro studies suggest that stainless steel prostheses (14–36% nickel) with a surface area of 200 cm^2 release 22 μg Ni/year; however, the clinical significance of this amount of nickel remains unclear.[37] A study of 13 patients with stainless-steel hip prostheses revealed that only 1 patient had an elevated serum Ni concentration (1.1 μg/L) above the reference range; he had mild renal dysfunction.[38] The amount of nickel absorbed during dialysis depends on the composition of the equipment in contact with the dialysate. The estimated Ni uptake during a typical dialysis procedure in the 1980s was 100 μg/treatment;[39] however, a meta-analysis of 128 studies on trace elements in hemodialysis patients did not identify nickel as a toxic trace metal in excess in these patients.[40]

ENVIRONMENTAL FATE

Chemical and physical forces (e.g., erosion, runoff, leaching, precipitation, and weathering) constantly distribute nickel between land, water, and air. Wet deposition accounts for about half of the removal of nickel from the air.[41]

Soil

The mobility of nickel in the soil is highly dependent on the soil type and pH.[42] Most nickel exists in soil as insoluble hydroxides at pH >6.7. The presence of sulfur and anaerobic conditions limit nickel mobility as a result of the formation of poorly soluble nickel sulfides. At pH <6.5 and aerobic conditions, most nickel compounds are relatively soluble, and divalent $Ni(H_2O)_6$ is the dominant nickel species. Consequently, acid rain increases nickel mobilization in soil by reducing the soil pH.[25] The mobility of nickel is limited in sandy aquifers unless the pH is very low (<5).[43] The addition of organic material to the soil reduces Ni mobility when compared with Ni mobility in sandy soil.[44] The large specific surface area of iron oxides (e.g., ferrihydrite, goethite, hematite) in soils provides very efficient sinks for trace metals including Ni.[45]

Water

Adsorption of nickel onto suspended particles in water is one of the primary mechanisms for nickel removal from water. Nickel is strongly adsorbed at mineral surfaces (e.g., aluminum, iron, manganese oxides) and complexing agents (humic acid, biopolymers); these reactions influence the nickel concentration in water.[17] The ultimate sink for nickel is the ocean, where deep-sea nodules contain manganese and nickel.

The bioaccumulation of nickel in aquatic and plant species is limited.[46] The range of nickel concentrations in plants averages 0.05–5 mg/kg dry weight with concentrations of >50 mg/kg dry weight being toxic for most plants.[47] Certain genera (e.g., *Alyssum*) accumulate

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nickel above 1 g/kg dry weight when grown on infertile serpentine soils rich in nickel.[48] Based on laboratory studies, nickel probably does not accumulate in fish. In a study of mussels and oysters grown in seawater containing 5 µg Ni/L for 12 weeks, analysis of tissue demonstrated average Ni concentrations of 9.62 µg/g (dry weight) and 12.96 µg/g (dry weight), respectively.[49] There is little evidence for the biomagnification of nickel in the food chain.[25]

DOSE EFFECT

Acute Toxicity

Oral

Oral nickel sulfate doses of 65–195 mg were a recommended treatment for diarrhea and epilepsy during the 1800s; however, the estimated ingestion of 325 mg nickel sulfate (73 mg Ni) produced nausea, giddiness, and decreased pulse.[50] The estimated ingestion of 0.5–2.5 g Ni from nickel sulfate and nickel chloride-contaminated drinking water was associated with nausea, vomiting, abdominal discomfort, diarrhea, giddiness, lassitude, headache, cough, and dyspnea in 32 workers; symptoms resolved within 1–2 days without sequelae.[51] A 2½-year-old girl developed stupor, nuchal rigidity, and pulmonary congestion after ingesting 10–15 g $NiSO_4$ (2.2–3.3 g Ni). She developed a cardiac arrest 8 hours after the ingestion; resuscitation was unsuccessful.[52] The ingestion of nickel may exacerbate skin lesions and produce contact dermatitis on patients sensitized to nickel.[53] Re-exposure of these lesions to nickel 1 month after the development of contact dermatitis suggests that these areas remain more reactive to nickel than non-involved areas of skin.[54] This reaction is dose-dependent with doses of 0.5–5.6 mg usually necessary to cause a cutaneous reaction.[55,56,57]

In single oral acute toxicity studies on female Sprague-Dawley rats, the LD_{50} of nickel chloride, sulfate, fluoride, and acetate salts ranged from 300–550 mg/kg compared with >11,000 mg/kg for nickel oxide, nickel subsulfide, and nickel ash.[58] The no-observed-effect-level (NOEL) for nickel acetate, chloride, fluoride, and sulfate ranged from ~150–175 mg/kg, whereas the NOEL for nickel matte (73% Ni) and nickel oxide exceeded 5,000 mg/kg.

Inhalation

A 38-year-old worker developed acute respiratory distress syndrome after spraying nickel with a metal arc process without personal protective equipment; he died 13 days after exposure.[59] The estimated nickel exposure during a simulation of the incident was 382 mg Ni/m^3 for 90 minutes (~1 g Ni), primarily metallic nickel nanoparticles (<1.4 µm). Examination of the lungs demonstrated organizing diffuse alveolar injury with alveolar hemorrhage and marked hemorrhagic consolidation. Numerous macrophages contained Ni nanoparticles (<25 µm).[60] The presence of other potential toxins in the ambient air and urine was not measured.

Chronic Toxicity

In a study of 745 nickel sinter plant workers exposed to total airborne nickel concentrations up to 100 mg/m^3 as nickel subsulfide and nickel oxides, there was no increase in small irregular opacities suggesting pulmonary inflammation or fibrosis.[61]

TOXICOKINETICS

Absorption

The absorption of nickel compounds depends on the solubility of the compounds. Generally, the absorption of nickel compounds follows this order: nickel carbonyl > soluble nickel compounds (acetate, chloride, nitrate, sulfate) > insoluble nickel compounds (metallic Ni, oxides, sulfides).

Gastrointestinal Tract

Following ingestion, the absorption of metallic nickel and sparingly soluble nickel compounds from the gastrointestinal tract is small. The absorption of soluble Ni compounds is relatively high compared with other metals, depending on dose, degree of water solubility, and the presence of food in the stomach. In a study of four volunteers ingesting the stable isotope tracer ^{62}Ni (571–879 µg), the mean Ni absorption over 5 days was 33.1 ± 4.9% with a range of 29–40%.[62] The gastrointestinal absorption of soluble nickel compounds (chloride, nitrate, sulfate) is relatively rapid with peak serum nickel concentrations occurring within ~2–3 hours after ingestion.[62,63] The presence of food in the stomach significantly reduces the bioavailability of nickel salts. In a study of volunteers ingesting 18–50 µg Ni/kg as $NiSO_4$, the mean absorption of Ni from the gastrointestinal tract over 4 days was 27 ± 17% when administered in drinking water compared with ~1% when administered in food.[64]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Inhalation

Biological monitoring of workers (e.g., stainless-steel welders) exposed to insoluble Ni suggests that some Ni absorption occurs. Although some experts suggest an average absorption rate of 20% of inhaled Ni,[65] well-designed studies have not quantified the exact value. Based on the kinetics of oral Ni compounds, water-soluble Ni salts are probably better absorbed than insoluble Ni compounds.

Skin

Dermal absorption of nickel and nickel compounds is minimal compared with absorption from inhalation and ingestion. An *in vitro* study indicated that <1% of a solution of soluble nickel salts (acetate, chloride, nitrate, sulfate, divalent nickel) penetrated cadaver skin over 96 hours.[66] Ionizable nickel compounds permeate intact skin slowly and poorly, depending on the vehicle and type of salt (e.g., nickel chloride > nickel sulfate). An *in vitro* study demonstrated a lag time of ~2 days when nickel chloride was applied to cadaver skin as an occlusive patch.[67] Percutaneous absorption is important toxicologically primarily from the development of contact dermatitis rather than diffusion through the skin (e.g., sweat releases allergenic soluble nickel salts from the corrosion of metallic nickel or nickel-bearing alloys).[68] Corrosion of nickel-containing alloys in orthopedic prostheses may release sufficient amounts of nickel to produce local or systemic allergic reactions, but the amount of nickel absorbed from the prostheses would not produce nickel toxicity.

Distribution

The estimated Ni body burden of a healthy adult with ordinary nickel exposure is ~0.5 mg (7.3 μg/kg body weight).[69] In the blood, the main nickel transport protein is albumin. Other transport proteins binding nickel include nickel-containing α_2-macroglobulin (nickeloplasmin), transferrin, and divalent metal transporter-1.[65] Nickel competes with iron for the latter two transporters; however, the amount of nickel bound to these transporters is substantially less than albumin.

The distribution of nickel in the tissues following absorption depends on the route of exposure. Animal studies indicate the highest nickel concentrations occur in the kidney after the parenteral administration of soluble nickel salts with significant nickel concentrations in the lungs, liver, and endocrine glands.[70] Relatively large amounts of nickel occur in the cartilage and connective tissue following nickel absorption.[71]

Elimination

Following absorption, the kidney is the primary route of elimination; nickel is not a cumulative toxin. The urinary excretion of nickel is rapid without evidence of dose-dependent Ni excretion. In a radiotracer study (^{62}Ni) of four adults, urinary Ni excretion accounted for 51–82% of the absorbed dose.[62] Excretion of nickel also occurs in saliva and sweat that may contribute significantly to the elimination of nickel in hot environments. Biliary excretion of nickel occurs in experimental animals, but significant biliary excretion of nickel in humans remains unclear.

Plasma half-lives of nickel typically range from ~24–36 hours, depending on the water solubility of the Ni species. The estimated plasma half-lives of nickel in four electroplaters exposed to nickel sulfate and nickel chloride ranged from 20–34 hours based on a one-compartment model.[72] In a follow-up study of a German worker accidentally overexposed to nickel while flame spraying with a wire containing 80% Ni, the elimination of Ni from blood was biphasic with half-lives of 30 and 240 days.[73]

In a study of eight volunteers ingesting 12 μg of the stable isotope ^{61}Ni/kg in drinking water, the median urinary elimination half-life ranged from ~20–27 hours.[74] Measurement of the urinary elimination of nickel in 2 welders exposed to nickel fumes revealed an elimination half-life of ~50 hours[75] compared with 17–39 hours in four welders exposed to soluble Ni ($NiCl_2$, $NiSO_4$).[72] These relatively short half-lives do not exclude the possibility of the storage of insoluble nickel deposits in the body with much longer biological half-lives. Poorly water-soluble nickel compounds may persist in the upper respiratory tract following exposure. Following inhalation, the clearance of insoluble nickel compounds from the lungs is slow, resulting in low blood Ni concentrations. The biological half-life of nickel oxide in the lung depends on particle size ranging from 11–21 months in animal studies.[76] In a study of retired nickel refinery workers exposed to nickel subsulfide and nickel oxide, the estimated half-life of nickel in the nasal mucosa following cessation of occupational exposure was 3.5 years.[77] Acute nickel toxicity developed in 23 dialysis patients when Ni leached from a nickel-plated stainless steel water heater tank and contaminated their dialysate; the urinary elimination half-life of nickel on dialysis ranged from ~20–60 hours.[78]

Maternal–Fetal Kinetics

Nickel probably crosses the placenta with nickel concentrations appearing in the cord blood of full-term

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

infants.[79] Nickel concentrations in the fetus are similar to maternal nickel concentrations. The mean nickel concentration in the milk of lactating mothers exceeds the serum Ni concentrations in these mothers. In specimens of milk obtained within 1 week postpartum, the mean Ni concentration was 17 ± 2 μg/L.[80] A study of 13 women providing breast milk samples during the first month postpartum detected a mean nickel concentration of 1.2 ± 0.4 μg/L (range, 0.5–2.0 μg/L) as measured by graphite furnace atomic absorption spectrophotometry.[81] Consequently, the average breastfed infant consumes ~5–15 μg Ni/day in the milk.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Nickel is an essential element for several animal species;[5,82] Ni-dependent processes in these animals include the synthesis of phospholipids and lipid metabolism, particularly the regulation of lipid content in tissues.[83] In studies of rats fed nickel-deficient diets (2–15 μg/kg), increased perinatal mortality occurred along with alterations in grooming behavior and liver development.[84] Although a deficiency disease for nickel in humans has not been identified and there is inadequate evidence to verify that Ni is an essential trace element for humans, some evidence suggests that Ni has some nutritional benefit.[85,86] Based on animal studies, nickel probably is involved in the action of biotin, folate,[87] and vitamin B_{12}.[88] Studies in chicks indicate that nickel deficiency impairs the absorption of iron from the intestine; thus, nickel deficiency reduces iron concentrations in these animals.[89] Nickel deficiency (13 μg Ni/kg) in rats produced disturbances in lipid metabolism and the accumulation of triacylglycerol in the liver.[90] The alterations in serum and hepatic lipids are similar to the changes developing after moderate iron deficiency. A hypothesis for the biochemical action of Ni is the CO_2-fixation of propionyl-CoA to form D-methylmalonyl-CoA.[91] Nickel-containing enzymes include carbon monoxide dehydrogenase, methyl coenzyme M reductase, hydrogenase, and urease.[5] The minimal daily dietary intake of nickel necessary for human health probably is ~100–300 μg.

Mechanism of Toxicity

Acute Toxicity

In vitro and *in vivo* experiments indicate nickel compounds bind a variety of enzymes including hepatic microsomal enzymes, enzymes catalyzing carbohydrate metabolism, and enzymes transporting ions across membranes.[22] Ni^{2+} crosses cell membranes via calcium channels and competes with Ca^{2+} for specific intracellular receptors.[92] In animal studies, exposure to metallic nickel and soluble nickel compounds (e.g., $NiCl_2$) causes direct pulmonary toxicity as demonstrated by an increase in both the number and size of type II alveolar cells, increased production of surfactant, and alteration of the morphology and function of alveolar macrophages.[93] Studies of animals given large doses of soluble nickel salts (acetate, chloride, nitrate, sulfate) suggest that lipid peroxidation may cause disruption of the cellular membrane, Ca^{2+} influx, and cell death.[94,95]

Carcinogenesis

Depending on the form of nickel, exposure may produce oxidative DNA damage and disrupt DNA repair activity via inhibition of zinc finger-containing DNA repair proteins;[96] however, nickel compounds are only weakly mutagenic in most assay systems and the mechanism of toxicity is primarily epigenetic.[97,98] Divalent nickel compounds bind sulfhydryl, azo- and amino-groups on a variety of macromolecules including nucleic acids and proteins. Although divalent Ni inhibits JmjC domain-containing histone demethylase activity,[99] Ni^{2+} is not highly reactive with DNA. Ni^{2+} promotes cell proliferation and cell survival by increasing the accumulation of hypoxia-inducible factors (HIFs) and their subsequent gene expression via DND methylation and histone modifications.[100,101] Major intracellular targets of nickel include iron- and 2-oxoglutarate-dependent dioxygenases (HIF-α, HIF-prolyl hydroxylases, H3K9 demethylases).[102]

Ni modulates gene expression by the activation of transcription factors or the silencing of genes through DNA methylation.[97] High Ni concentrations increase intracellular calcium concentrations and oxidative stress; however, Ni is a weak oxidative stress inducer that depletes glutathione. Additionally, divalent Ni activates nuclear factor kappa B (NF-κB) and other oxidation-sensitive transcription factor pathways (p53, c-MYC), resulting in the promotion of cell-cycle arrest and apoptosis.[103] This tumor suppression allows tumor cells to remain dormant until suitable microenvironments for the proliferation of micrometastases exist. Besides weak oxidative stress induction, divalent Ni modulates transcription factors and histone modifiers through alteration in iron homeostasis, resulting in the early transformation of cells.

Nickel exists in several forms including metallic nickel, water-insoluble nickel compounds (e.g., subsulfide, oxide), and water-soluble nickel compounds (e.g., sulfate). Animal studies indicate that substantial variation in the carcinogenic potential of nickel compounds occurs. This variation probably results from varying effects on different mechanisms of carcinogenesis including, the following: 1) genetic and epigenetic mechanisms (nickel subsulfide); 2) threshold effect for induction of tumors (high-temperature nickel oxides); and 3) promotion of carcinogenesis (nickel sulfate).[104,105] Generally, nickel compounds with higher valences (+3, +4) are more carcinogenic in animal models than soluble divalent nickel compounds (chloride, sulfate, ammonium sulfate). Of these nickel compounds, long-term studies in rodents demonstrate that nickel subsulfide is the most carcinogenic nickel compound. Immune mechanisms appear vulnerable to the effects of nickel subsulfide with experimental studies revealing that the local instillation of Ni_3S_2 inhibits pulmonary alveolar macrophage function and increases the NK cell-mediated killing of target cells.[106] Differences in the carcinogenic potential of various nickel compounds may also result from variations in the ability of nickel ions to enter the cell and bind to critical target areas. In animal studies, the coadministration of manganese[107] and magnesium[108] antagonizes the carcinogenic effect of nickel subsulfide.

Postmortem Examination

The postmortem examination of a 2-year-old child, who died after ingesting nickel sulfate crystals, revealed acute hemorrhagic gastritis.[52] Examination of lung tissue from a long-time welder with an extensive history of welding fume exposure demonstrated grainy material (protein, fat) in the alveoli and inflammatory cell influx.[109] Alveolar macrophages contained numerous welding particle agglomerates consisting primarily of iron, chromium, and nickel with some silicates; the presence of these metals was consistent with his history of welding chrome-molybdenum steel (Cr, Fe, Mn, Mo, Ni) for most of his career. The presence of multiple metals and his 52-pack-year history of smoking complicate the interpretation of the effect of Ni on the development of his COPD, asthma, and progressive respiratory failure.

Nickel does not accumulate in tissue with the exception of the lungs. Mean postmortem concentration (μg Ni/kg dry weight) of nickel in various tissues from 10 consecutive adult autopsies was the following: lung, 173 (range, 71–371); thyroid, 141; adrenal, 132; kidney, 62; heart, 54; liver, 50; brain, 44; spleen, 37; and pancreas, 34.[110] In a study of eight adults and two infants with occupational or para-occupational exposure to Ni, the mean Ni concentration in lung tissue was 740 ± 440 μg/kg (range, 110–2,200 μg/kg) dry weight.[111] The following nickel concentrations, as expressed in μg Ni/g wet weight, were found on postmortem examination of a 2-year-old girl who died after ingesting nickel sulfate: bile, 60; urine, 47; gastric contents, 38; liver, 27; dura mater, 10.5; salivary gland, 10; blood, 7.5; bone marrow, 5.2; fat, 2.6; and muscle, 2.5.[52]

The amount of nickel in pulmonary tissue depends on age, sex, location, and occupational exposure to nickel. A German study of 110 autopsies from an area with relatively high ambient levels of nickel revealed that the nickel concentration was twice as high in lung tissue from men as women.[112] The concentration of nickel in the lungs increased at the rate of 3% per year. Although some overlap in the concentration of nickel in the lungs occurs between the general population and workers exposed to nickel compounds, the mean concentration of nickel in workers with occupational exposure to nickel is several orders of magnitude greater than pulmonary concentrations in the general population.[113] Based on limited evidence from postmortem examination of workers with exposure to a variety of Ni compounds, nickel concentrations in lung tissue do not correlate closely with the risk of developing lung cancer.[111] Autopsies of 39 nickel workers did not demonstrate statistically significant differences between the nickel concentration in workers with lung cancer and those without lung cancer;[114] however, there was no correlation between the nickel concentration at a specific pulmonary site and the development of lung cancer at that site.

CLINICAL RESPONSE

Acute Toxicity

There are few cases of acute inorganic nickel toxicity in the medical literature. The ingestion of > 10 g nickel sulfate in a 2-year-old girl produced erythema, mydriasis, tachycardia, nuchal rigidity, pulmonary congestion, coma, and cardiac arrest.[52] The leaching of nickel from nickel-plated surfaces of a water-heating tank produced elevated concentrations of nickel in patients receiving dialysis. During dialysis, these patients developed nausea, vomiting, weakness, headache, and palpitations that resolved within several hours following the cessation of dialysis.[78] Once recovery occurs, long-term sequelae following the ingestion of nickel compounds do not usually occur.

Environmental Exposure

The typical clinical lesion associated with nickel dermatitis is a pruritic, papular, or papulovesicular dermatitis with some lichenification. This presentation is characteristic of atopic dermatitis rather than eczematous dermatitis. Nickel alloy or nickel plating is a common constituent of a variety of products including identification bands, zippers, coins, metal shoelace tips, metal underwear snaps, safety pins, metal toys, magnets, doorknobs, keys, scissors, bracelets, earrings, curlers, necklaces, bra straps, thimbles, handles, and most costume jewelry. Nickel is the most common sensitizing metal with a high prevalence rate (25–29%) in studies of patients attending an allergy clinic.[115,116] Women are more frequently affected by nickel hypersensitivity than men as a result of more frequent exposure to nickel-containing consumer items such as wristwatches, metal buttons, jewelry, cell phones, and body piercings.[117] Of 368 nickel-allergic patients presenting to a contact dermatitis clinic over a 5-year period, 91% were women.[118] Occupational Ni exposure accounted for ~1/4 of the cases of nickel sensitivity. Other common Ni-associated consumer products include dental work, dimethylglyoxime-positive surgical suite materials (e.g., chairs, tables, racks, trolleys, valves),[119] clothing fasteners, laptop computers, video game controllers, and wind-up toys.[120,121] Ear piercing is an important risk factor for the development of nickel sensitization.[122] Patients with atopic dermatitis do not have an increased risk of developing nickel sensitivity;[123] however, patients with psoriasis probably have a lower incidence of nickel sensitivity than healthy adults.[124] Once sensitization occurs, hypersensitivity to nickel usually persists; however, long periods between exposures tend to diminish the hypersensitivity reaction. Pressure, sweat, moisture, and friction increase the severity of nickel hypersensitivity. 24-karat gold does not contain nickel; however, the majority of jewelry contains nickel as an alloy.

Occupational Exposure

Cardiorespiratory

Direct effects of chronic nickel inhalation include asthma, chronic hypertrophic rhinitis and sinusitis, nasal polyposis, and perforations of the nasal septum.[125] Asthma resulting from chronic exposure to nickel is rare, but occupational asthma in metal plating workers occurs with a positive inhalation challenge to nickel sulfate[126] and the presence of nickel-specific antibodies.[127] Lymphocyte transformation tests (LTTs) with nickel suggest that nickel sensitivity may contribute to the development of hard metal asthma.[128] Although benign pneumoconiosis has been reported in workers exposed to nickel dust,[129] co-exposure to other substances causing pneumoconioses limits conclusions about the causal role of nickel dust in the development of pulmonary fibrosis. The concentrations of nickel-containing dust in these workers were an order of magnitude above current workplace standards with values representing total airborne dust rather than respirable dust. Nickel is a potent coronary vasoconstrictor in animal models, and whole blood Ni concentrations may be higher in patients with multiple myocardial infarctions than healthy controls;[130] however, there is no direct evidence that exposure to nickel in the work environment increases the prevalence of cardiovascular disease.[131,132]

Kidneys

Nephrotoxicity is not a prominent feature of chronic nickel toxicity. There are few data to indicate occupational Ni exposure causes clinically significant renal impairment. In a study of stainless-steel welders with exposures resulting in urine concentrations ranging from 2–78 μg Cr/g creatinine and 1.3–19 μg Ni/g creatinine, no dose-related alterations of renal tubular function were detected.[133] However, a study of workers exposed to high ambient air Ni concentrations (mean = 0.75 mg/m^3; range, 0.04–2.86 mg/m^3) substantially exceeding recommended TLV–TWA guidelines demonstrated subclinical changes in renal tubular function.[134] Nickel was present primarily as nickel sulfate and nickel chloride. Regression analysis demonstrated dose-related increases in the urinary excretion of β_2-microglobulin in both sexes and *N*-acetyl-β-D-glucosaminidase in men. No significant abnormalities were detected in markers (albumin, transferrin) of glomerular dysfunction. The geometric mean nickel concentrations in end-of-shift urine samples collected on the fourth workday were 5.0 μg/g creatinine (range, 0.3–123 μg/g creatinine) for 13 men and 10.3 μg/g creatinine (range, 1.5–222.6 μg/g creatinine) for 11 women.

Skin

The role of occupational exposure as a source of sensitization is difficult to evaluate; occupational allergens were suspected in ~23% of 368 patients evaluated at an allergy clinic for nickel sensitivity.[118] The most common occupations were hairdresser, retail clerk, domestic cleaner, caterer, and metalworker; however, determining the source of these allergens is complicated by the frequent presence of nickel sensitivity in the general population. A review of published

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

articles on contact allergens indicated nickel was the most prevalent contact allergen with a median prevalence of 8.6% (range, 0.7–27.8%) in the general population.[135] Nickel-associated contact dermatitis typically occurs symmetrically in a pattern related to the nickel-containing object (e.g., seating, jewelry); however, the presentation may differ as a result of variations in contact with the object (e.g., school chair sign).[136]

Reproductive Abnormalities

Although nickel crosses the placental barrier, it is not a recognized cause of fetal abnormalities following maternal nickel exposure in the environment or occupational setting. In the current medical literature, the association between Ni exposure and adverse child outcomes (birth defects, autism spectrum disorder, prematurity, small for gestational age) is weak.[137] A Russian study of 22,836 births (>27 weeks of gestation) and small-for-gestational-age infants (<10% birth weight) in the Kola Birth Registry did not detect elevated risks of reproductive abnormalities in infants born to mothers occupationally exposed to water-soluble Ni at the *beginning* of their pregnancy.[138] The abnormalities tested included self-reported spontaneous abortions, congenital musculoskeletal defects, and small-for-gestational age using logistical regression of the assigned exposure categories (background, low, high exposures). The adjusted odds ratio for Ni-exposed mothers giving birth to small-for-gestational-age infants was 0.84 (95% CI: 0.75–0.93). Analysis of this cohort demonstrated no statistically significant association between Ni exposure at the beginning of pregnancy and congenital musculoskeletal birth defects (adjusted OR = 0.96, 95% CI: 0.76–1.21)[139] or self-reported spontaneous abortions (adjusted OR = 1.14, 95% CI: 0.95–1.37).[140]

Reproductive effects following Ni exposure occur in animals exposed to high concentrations of nickel salts. Although intraperitoneal administration of high doses of nickel salts ($NiCl_2$, $NiCO_3$, $NiSO_4$) to pregnant rodents during organogenesis produces fetal malformations,[141] obvious nickel toxicity occurs at these Ni concentrations. Studies in male rats reveal degenerative changes in the testis and the epididymis including abnormalities of the spermatozoa. Studies in female animals suggest that a reduction in embryo viability and successful implantations develop following exposure to high concentrations (1.2–20 mg Ni/kg).[22,142] Reduction in litter size and decreased viability of the fetus also occur in the presence of nickel deficiency.

Carcinogenicity

Humans

In 1990, the International Agency for Research on Cancer (IARC) listed nickel compounds as Group 1 carcinogens based on sufficient evidence of cancer in animals and studies of Canadian, Norwegian, and Finnish nickel workers.[143] These studies involved exposure to metallic nickel, nickel oxides, nickel subsulfide, soluble nickel compounds, and nickel carbonyl; the identity of the nickel compound or compounds causing the increased risk of cancer was not well defined. The strongest evidence of carcinogenicity of a particular nickel species was exposure to sulfidic nickel in the nickel refinery industry. In contrast to the increased risk of lung cancer in nickel refinery workers, most studies of workers in other nickel-producing industries (i.e., nickel mining and smelting facilities, hydrometallurgical refinery, nickel alloy and stainless-steel production facilities, stainless-steel welders, nickel–chromium electroplating) did not demonstrate significant increases in the risk of lung cancer from nickel exposure.[144,145]

The IARC listed metallic nickel and nickel alloys as possibly carcinogenic (Group 2B) in 1990. A subsequent IARC review of nickel carcinogenicity concluded there is sufficient evidence (Group 1) for human carcinogenicity of nickel mixtures that include nickel compounds and metallic nickel, whereas there is only sufficient evidence in experimental animals for the carcinogenicity of metallic nickel.[146] The US National Toxicology Program lists metallic nickel as reasonably anticipated to be human carcinogens and nickel compounds as known to be human carcinogens, whereas nickel alloys are not listed as suspected human carcinogens.

Carcinogenic Nickel Fractions

The available evidence from experimental and epidemiological studies indicates that crystalline nickel compounds in the sulfidic fraction of refinery dust (e.g., NiS, NiS_2, Ni_2S_3, Ni_3S_2) and to a lesser extent nickel oxide are more potent carcinogens compared with water-soluble nickel compounds (chloride, sulfate) present in nickel smelters and refineries.[147] There is evidence that exposure to soluble nickel salts (estimated range, 0.5–2.0 mg/m^3) in the complex ambient air of the electrolysis department and other refinery workers increases the risk of lung and nasal cancer, sometimes exceeding the estimated cancer risks from exposure to less soluble nickel compounds (estimated range, 0.1–0.5 mg/m^3).[148] In a cohort of Norwegian workers at the Falconbridge nickel refinery, there was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a dose-response relationship between the risk of lung cancer and cumulative exposure to water-soluble nickel with elevated SIRs for all exposure categories based on estimations of total airborne Ni concentrations.[149] The SIR for lung cancer in the highest cumulative exposure category (≥2 mg/m^3 for years) was 4.5 (95% CI: 3.6–5.5) compared with 1.3 (95% CI: 0.6–2.3) for workers without soluble nickel exposure. Examination of data from this Falconbridge nickel refinery in Norway suggested that smoking caused a multiplicative effect on the development of lung cancer with a relative risk for smokers exposed to nickel compounds and for nonexposed smokers of 5.1 and 2.9, respectively.[150] Analysis of cumulative total Ni exposure data and relative risk of lung cancer from this cohort using Poisson regression analysis adjusted for age and smoking demonstrated a positive test for linear trend for soluble nickel ($P < 0.001$) and nickel oxide ($P = 0.05$). The relative risks for the highest exposure group (≥15 mg/m^3/year) were 3.1 (95% CI: 2.1–4.8) and 1.5 (1.0–2.2), respectively. The relative risks for the cumulative exposure categories 1–14 mg/m^3/year were not statistically significant compared with the referent group (<1 mg/m^3/year).

No excess risk of lung cancer occurred in studies of electrolysis workers in the Port Colborne refinery,[151] a Canadian hydrometallurgical nickel refinery and fertilizer complex,[152] or a Finnish smelter and nickel refinery,[153] where mean exposure to soluble nickel compounds was smaller (<0.5 mg/m^3 and <0.3 mg/m^3, respectively). An update of the Finnish refinery cohort with exposure only to nickel sulfate demonstrated a statistically significant increase (SIR = 3.38, 95% CI: 1.24–7.36) for lung cancer in workers with at least 20 years of employment.[154] This SIR did not clearly increase with the duration of employment. There was a definite increase in nasal cancer (SIR = 41.1, 95% CI: 4.97–148) among this cohort; however, the wide confidence interval suggests instability in the estimate. Concomitant exposure of these workers to insoluble nickel salts (subsulfide, oxides) and possible exposure misclassification complicate definitive conclusions regarding the contribution of soluble nickel exposure to the development of lung cancer in nickel refinery workers.[155,156] The carcinogenic potency of soluble and insoluble nickel compounds probably differs.[157,158] There is little epidemiological evidence that exposure to metallic nickel or nickel alloys alone produces an increased risk of lung cancer.[104,159,160] In a mortality study of 1,999 workers employed at a nickel alloy manufacturing plant from 1958–2000, the SMR for lung cancer was 87 (95% CI: 67–111); there were no cases of nasal cancers.[145] The SMRs for all cancers were below 100, suggesting the possibility of a healthy worker effect.

Nickel Refining

Ambient air in nickel smelters and refineries contains a variety of carcinogens (asbestos, arsenic) along with several nickel fractions including metallic Ni and aerosols of soluble/insoluble nickel. The presence of these multiple factions complicates the determination of which nickel compounds are human carcinogens. Epidemiological studies indicate that exposure to more than one nickel species produces excess cancers of the upper respiratory tract in the affected workers; however, the carcinogenic potency of these nickel species varies widely along with the water solubility (i.e., absorption) of these Ni species. Early epidemiological studies document an increased prevalence of nasal and pulmonary cancers in nickel refinery workers, particularly following exposure to nickel compounds during roasting, calcining, and sintering operations prior to 1950.[161,162,163] These early studies associated occurrence of these cancers with older, dusty processes involving exposure to the impure dusts of nickel oxides and nickel sulfides.[7,164] Nickel arsenide was a contaminant in these dusts. The risk of cancer occurred primarily in workers exposed to high concentrations (>10 mg total Ni/m^3) of nickel refinery dust, nickel subsulfide, and high-temperature nickel oxide in several different geographic regions.[165] In these studies, exposure data and smoking histories were sparse; there are few data on the Ni species or the particle size of the dust involved. A study of Norwegian nickel refinery works detected an additive effect of smoking and nickel exposure in the development of respiratory cancers.[166] In a study of 812 nickel refinery workers employed from 1953–1992 for at least 5 years, the elevation of the SMR for lung cancer to 139 (95% CI: 92–201) was not statistically significant.[167] There was one death from nasal cancer compared with an expected rate based on national mortality tables of 0.1.

In epidemiological studies of refinery workers, the relative risk of nasal cancer was substantially higher than the relative risk of lung cancer.[168] The minimal latency period for lung and nasal cancer usually exceeds 10 years.[169] The mean latency period for workers granted compensation for lung and nasal cancer at the Port Colborne sinter plant was 33.4 years (range, 17–55) and 33.5 years (range, 19–46 years), respectively.[163] This plant produced nickel and nickel oxide from sulfide matte between 1918–1958. For workers receiving compensation after working from 1948–1963 in the Copper Cliff sinter plant, the mean latency for lung and nasal cancer was 22.5 years (9–30 years) and 23.7 years (range,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

12–28 years), respectively. The anterior curvature of the middle turbinate is the primary site of nasal cancer in workers exposed to nickel dust.[170] The major histological types of lung cancer are squamous cell carcinomas and undifferentiated carcinomas with a much smaller portion (<10%) of adenocarcinomas.[171] Although some studies associate nickel exposure with cancer risks (e.g., stomach) other than lung tumors,[154] current epidemiological data do not consistently demonstrate elevated cancer risks at sites other than the lungs and nasal sinuses. The association between exposure to nickel compounds and laryngeal or gastrointestinal cancers remains controversial.[146]

Nickel Use

An excess risk of cancer is smaller in industries that *use* rather than *produce* nickel. Although there are data associating exposure to soluble nickel compounds with an increased incidence of lung cancer, this increase usually occurs in complex nickel environments with soluble and insoluble nickel compounds.[15] Similar risks of lung and nasal cancer occurred in workers exposed to soluble nickel (copper sulfate extraction, electrolysis, hydrometallurgy), often in association with exposure to nickel oxide but not with exposure to nickel subsulfide.

The risks of lung and nasal cancers were not significantly elevated in a group of 1,155 workers exposed primarily to soluble nickel compounds at moderate to low concentrations (<0.3 mg/m^3).[153] Generally, the excess risks of lung and nasal cancers were associated with exposure to soluble nickel concentrations above 1 mg Ni/m^3 and to less soluble forms of nickel (oxide, subsulfide) exceeding 10 mg Ni/m^3. Several studies of nickel and chromium platers exposed from 1953–1992 to <1 mg Ni/m^3 as metallic nickel and nickel oxide detected no increase in the SMRs for nasal or lung cancer when compared with national mortality rates.[144,145,172] The principal source of exposure was a mist of nickel sulfate and nickel chloride. The relatively short exposure period, the lack of exposure data, and the modest size of the studies complicate conclusions regarding the carcinogenicity of soluble nickel compounds based on these data.

Based on previous epidemiology studies, the risk of developing lung cancer following exposure to airborne metallic Ni concentrations currently present in the workplace appears small without concurrent exposure to other soluble or insoluble Ni compounds.[173] In general, the risk of developing lung cancer from nickel-containing welding fumes is small compared with lung cancer risk from chromium present in these fumes; the exception is MIG welding operations that use pure nickel filler wire.[174]

Animals

Insoluble nickel compounds are generally stronger animal carcinogens than soluble nickel compounds.[97] Susceptibility to upper respiratory tract cancers following exposure to nickel compounds differs substantially between animal species. Hamsters and mice are much less susceptible to the carcinogenic effects of certain nickel compounds than rats. Lifetime exposure (6 hours/day, 5 days/week for 2 years) of male and female F344/N rats to nickel subsulfide (0.15 and 1 mg/m^3) and nickel oxide (1.25 and 2.5 mg/m^3) produced an exposure-related increase in the incidence of adrenal medulla and pulmonary neoplasms.[175] A similar exposure to nickel oxide and nickel subsulfide produced little evidence of an exposure-related increase in pulmonary neoplasms in mice. Furthermore, there was no increased incidence of neoplasms in rats or mice exposed to the soluble nickel compound, nickel sulfate (0.125–1.0 mg/m^3). A study of Wistar rats exposed by whole-body inhalation to 0 mg Ni/m^3 (control), 0.1 mg Ni/m^3, 0.4 mg Ni/m^3, and 1.0 mg Ni/m^3 as Ni metal powder (MMAD = 1.8 μm with GSD of 2.4 μm) for 6 hours/day, 5 days/week for up to 24 months detected no increased incidence of lung tumors.[176] Pathological examination of the exposed animals demonstrated alveolar proteinosis and histiocytosis, chronic inflammation, and bronchiolar-alveolar hyperplasia.

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.0170 μmol/L
1 mg = 17.04 μmol
1 μmol = 58.71 μg Ni
1 nmol/L = 0.0587 μg/L
1 nmol/mmol creatinine ≈ 0.5189 μg Ni/g creatinine as an approximation

Analytical Methods

Techniques

Common and sensitive methods for the determination of nickel concentrations in biological specimens include electrothermal (graphite furnace) atomic absorption spectrophotometry (EAAS), inductively coupled

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

plasma/atomic emission spectrometry (ICP/AES), and differential pulse absorption voltammetry (DPAV). Estimated nickel detection limits in biological materials using EAAS are the following: urine, 0.45 μg/L; whole blood, 0.1 μg/L; serum, 50 ng/L; and dry tissue, 10 μg/kg.[177] Using EAAS to analyze total nickel in wet digested samples of human body tissues, the limit of detection (LOD) was 0.23 μg/L and the lower limit of quantitation was 0.76 μg/L with precision (as relative standard deviation) up to 10% and accuracy of 97.1%.[178] Analysis by ICP/AES is less sensitive (LOD, 3 μg/L) than EAAS,[179] whereas DPAV is more sensitive (1 ng/L blood); however, the latter technique is more complicated and time-consuming. Reference values for nickel have decreased significantly since 1970, when improved techniques and reduced contamination improved the precision and reliability of analytical determinations of nickel.[13] Consequently, measurements of nickel published before 1980 should be interpreted cautiously.[180]

Methods for nickel determination in environmental samples include flame or graphite furnace AAS, ICP/AES, or inductively coupled plasma/mass spectrometry (ICP/MS). Sample preparation depends on the nickel concentration, presence of interfering substances, and solubility of the sample. For food or tissues, wet ashing with sulfuric acid or dry ashing by dissolution of the ash with a dilute acidic solution (sulfuric, hydrochloric) is usually sufficient. Liquid chromatography with UV/VIS spectrophotometric detection is a highly sensitive method (LOD, 8.7 ng/mL) for the detection of nickel in environmental samples.[181]

Fractionation

Instead of speciation, the analysis of nickel in environmental samples is typically reported as total nickel and classified based on analytical methods that separate total nickel into metallic, sulfidic, oxidic, and soluble nickel fractions. The usual four-step sequential extraction of nickel from filters of airborne samples involves the following phases: 1) leaching of soluble nickel compounds by ammonium citrate solution; 2) extraction of sulfidic nickel salts by ammonium citrate/hydroxyl peroxide mixture; 3) dissolution of metallic nickel by bromine in anhydrous methanol; and 4) dissolution of the remaining nickel oxides by concentrated nitric acid/perchloric acid.[182] Alternate procedures substitute EDTA, ammonium citrate/H_2O_2, $KCuCl_3$, and nitric acid, respectively, for these four phases of nickel extraction.[183]

Biomarkers

Electrothermal atomic absorption spectrophotometry with Zeeman background correction detected an average Ni concentration of 2.3 ± 0.8 μg/L in 5 postmortem bile samples from people without occupational exposure to nickel.[110]

Blood

There are few data on nickel distribution between erythrocytes and serum. In a study of 1,016 Swedish adults in their 70s, the mean whole blood/serum nickel ratio was 3.2 as measured by inductively coupled plasma/sector field mass spectrometry. The nickel concentrations were correlated to kidney function (glomerular filtration rate).[184] In a series of healthy Italians, the mean whole blood/serum Ni ratio was ~2.[185] Serum nickel concentrations reflect recent exposure (i.e., several days) to soluble nickel compounds rather than exposure to insoluble nickel salts or unabsorbed deposits of metallic nickel in the lung. The use of stainless-steel needles during venipuncture may contaminate the blood sample when nickel leaches from the needle.

General Population

A study of 30 healthy adults with no significant exposure to nickel demonstrated a mean whole blood Ni concentration of 0.34 ± 0.28 μg/L with a range of <0.05–1.05 μg/L.[37] In this group, the serum nickel concentrations were similar to the whole blood concentration with a mean of 0.28 ± 0.24 μg/L (range, <0.05–1.08 μg/L). The average nickel concentration in serum collected from 38 healthy adult volunteers was 0.14 ± 0.09 μg/L as measured by atomic absorption spectrometric method with Zeeman-effect background correction.[186] Plasma nickel concentrations in the general population are usually <2 μg/L. In an analysis of nickel reference values in the medical literature (TRACY Protocol), the mean Ni concentrations for the general adult population ranged from 0.14–0.63 μg/L for eight serum and plasma studies compared with <0.05–3.8 μg/L for four whole blood studies.[187] The estimated mean serum nickel concentration in 75 Danish volunteers without occupational exposure to nickel was 0.80 ± 0.04 μg/L; the calculated upper 95% was 1.53 μg/L based on a noncentral t-distribution.[188] A variety of conditions affect the Ni concentration in blood. Serum nickel concentrations increase following acute strokes, extensive burns, myocardial ischemia, and renal failure requiring hemodialysis, whereas the serum Ni concentration decreases in hepatic cirrhosis, probably as

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a result of hypoalbuminemia.[79] The mean serum nickel concentration in 27 dialysis patients was ~46 times higher (6.38 ± 3.36 μg/L) than the mean of a control group (mean = 0.14 μg/L; n = 40).[186] The serum nickel concentration in blood samples from nickel-sensitive individuals may be lower than reference concentrations because of lower environmental or occupational nickel exposure. The mean serum concentration of nickel in 35 nickel-sensitized patients was 0.24 μg/L compared with 0.425 μg/L in the control group.[189]

Toxicity

There are few data on toxicity associated with specific Ni concentrations in blood. In a group of patients with renal disease, symptoms of nickel intoxication (nausea, vomiting, headache, weakness) appeared at plasma Ni concentrations exceeding 3,000 μg/L.[78]

Urine

Following absorption, the kidneys excrete most of the absorbed Ni dose in the urine. Both the blood and a 24-hour urine sample are good measures of exposure to soluble nickel compounds over the previous 1–2 days. Urine specimens are usually preferred to blood samples for determination of recent exposure to nickel because of convenience, analytical accuracy, and sensitivity.[13] Normalization for dilute urine is important, but adjustments based on creatinine overestimate nickel excretion because renal nickel increases with urine flow, whereas the rate of creatinine excretion remains relatively stable. Hence normalization of urine dilution to a standard specific gravity rather than urine creatinine is probably more accurate.[13] At the present time, the speciation of nickel in urine is not a practical biomarker of exposure.

General Population

Urine nickel concentrations in individuals without occupational Ni exposure are typically <5 μg/L. In a EURO-TERVIHT study of 189 healthy, non-occupationally exposed Danish adults aged 40–70 years, the upper 95% Ni concentration was ~3.1 μg/L[190] compared with 10 μg/L (GM = 4.8 μg/L) in 299 healthy Finnish adults without occupational Ni exposure as measured by graphite furnace/atomic absorption spectrometry.[191] In an analysis of nickel reference values in the medical literature (TRACY Protocol), the mean urine Ni concentrations for the general adult population in four studies ranged from 0.9–3.2 μg/L.[187]

The mean urine Ni concentration in a cross-sectional study of 371 adult residents living near a Russian nickel refinery near Nikel was 4.9 μg/L (range, 0.3–61.9 μg/L) compared with 2.6 μg/L (range, 0.3–17.0 μg/L; n = 220) in the Russian city of Apatity and 4.0 μg/L (range, 1.0–17.0 μg/L; n = 20) in the Russian city of Umba.[192] The difference between the city of Nikel and the control cities was statistically significant; however, comparisons of urine nickel concentrations between 418 Russian residents (mean = 2.8 μg/L; range, 0.3–24.2 μg/L) near the nickel refinery town of Zapolyarny were not statistically different than the Russian control cities. The authors concluded that industrial nickel pollution alone did not account for the observed differences between the nickel refinery cities or between Russian and neighboring Norwegian cities. In a study of 55 Polish residents living in an industrial town with large ironworks, the mean nickel concentration in random samples was 7.8 ± 3.3 μg/L (range, 4.0–15.9 μg/L) as measured by atomic absorption spectrometry.[193] This value did not differ significantly from the mean nickel concentration (7.7 ± 4.1 μg/L) in urine samples from 76 residents of a Polish health resort. The influence of gender and smoking status on urine nickel concentrations in the general population is small.[190]

Toxicity

A 38-year-old worker died 13 days after developing acute respiratory distress syndrome following spraying nickel during a thermal arc process for coating metal surfaces; his urinary nickel concentration was 700 μg/L several days after exposure.[59]

Abnormalities

NIOSH-certified B-readers identified 47 cases of pulmonary fibrosis among 1,046 Norwegian nickel refinery workers.[194] In logistic-regression models controlling for age and smoking, there was a statistically significant (P = 0.04) increased risk of moderate pulmonary fibrosis with cumulative exposure to soluble nickel or sulfidic nickel. The dose-response trend was less clear for exposure to sulfidic nickel than soluble nickel. Comparing the highest and lowest soluble nickel exposure groups, the crude odds ratio for pulmonary fibrosis was 4.34 (95% CI: 1.75–10.77); however, the odds ratio decreased to 2.24 (95% CI: 0.82–6.16) after adjustment for age, tobacco consumption, asbestos exposure, and cumulative sulfidic nickel exposure. The odds ratio comparing the highest and lowest nickel sulfidic exposure groups also decreased after similar adjustment including soluble nickel exposure from a crude value of 5.06 (95% CI: 1.70–15.09) to an adjusted value of 2.04 (95% CI:

0.54–7.70). Workers from this plant had an elevated risk of lung cancer.

Clinical history and patch tests are the primary methods to determine Ni hypersensitivity; however, technical and interpretative limitations of patch testing resulted in the development of the *in vitro* lymphocyte transformation test (LTT).[195] However, some false-positive reactions occur in nonallergic subjects using the LTT.[196] Other *in vitro* research-oriented tests include the enzyme-linked immunospot assay (ELISpot) with interleukin-2 (IL-2) secreting cells;[197] this test depends on cytokine production at the single-cell level.[196,198]

HEALTH SURVEILLANCE

Risk Assessment

The ATSDR derived an intermediate-duration inhalation minimal risk level (MRL) of 0.2 μg Ni/m^3 for nickel based on a NOAEL of 60 μg Ni/m^3 and a LOAEL of 110 μg Ni/m^3 for the development of chronic active lung inflammation in F344/N rats exposed to nickel sulfate 6 hours/day, 5 days/week for 13 weeks.[199] The MRL included an uncertainty factor of 30 extrapolating animal data to human and human variability.

The MRL chronic-duration inhalation for Ni is 0.09 μg Ni/m^3 based on a NOAEL of 30 μg Ni/m^3 and a LOAEL of 60 μg Ni/m^3 for chronic active lung inflammation and bronchiolization of alveoli (i.e., metaplastic lesions characterized by cells resembling bronchiolar epithelium lining normal or thickened alveolar walls) in F344/N rats exposed to nickel sulfate 6 hours/day, 5 days/week for 2 years along with the same uncertainty factor.

The WHO provisional guideline value for nickel in drinking water is 20 μg/L based on an NOAEL of 5,000 μg Ni as nickel sulfate/kg/day for 2 years in a study of rats.[27] The lowest LOAEL was 7,000 μg/kg/day in a 6-month study of Wister rats exposed to nickel sulfate in drinking water based on increased kidney weights in female and male rats along with increased albumin excretion in the exposed female (but not male) rats.[200] A development study of rats suggested that the LOAEL for the second generation of a litter of rats exposed to nickel chloride was lower (1,300 μg/kg/day).[201]

Environmental Monitoring

Table 22.2 lists regulations and guidelines for exposure to metallic nickel and nickel compounds. The US OSHA PEL–TWA is 0.1 mg Ni/m^3 for soluble nickel compounds and 1 mg Ni/m^3 for metallic nickel and insoluble Ni compounds. Although some epidemiological evidence and experimental data indicate certain nickel compounds (nickel subsulfide, nickel oxide) are more potent carcinogens than soluble nickel compounds, an accurate dose-response relationship has not been established for soluble and insoluble nickel compounds. Consequently, the ACGIH lowered the TLV–TWA for exposure to nickel compounds, as inhalable nickel particulate mass, to the following: elemental nickel, 1.5 mg/m^3; soluble compounds and nickel subsulfide, 0.1 mg/m^3; and insoluble nickel compounds, 0.2 mg/m^3. These recommended limits now are based on inhalable particulates rather than particulate sampling using a 27-mm open-faced cassette. Nickel subsulfide and insoluble nickel compounds are classified as carcinogenic compounds. Extrapolation of animal and epidemiological data to these low-dose occupational nickel exposures indicates these recommended exposure limits provide adequate safety factors to manage respiratory cancer risks at acceptable occupation levels (e.g., 10^{-4}).[202] The United Kingdom and the Federal Republic of Germany allow metallic and insoluble nickel at concentrations of <0.5 mg Ni/m^3, whereas the Swedish limit for nickel subsulfide is 0.01 mg Ni/m^3.

Biological Monitoring

Biological monitoring is not a substitute for the measurement of nickel in air and other appropriate media. Because of the lack of standardized human data and well-defined toxic endpoints, biological monitoring supplements rather than replaces environmental nickel monitoring. Consequently, there are few health-based biological limit values for nickel compounds in the blood or urine. For soluble nickel compounds, suggested action levels for nickel exposure are 5–8 μg Ni/L serum and 30–50 μg Ni/L urine.[203] The latter urine Ni concentration corresponds to ~0.5 mg Ni/m^3 in ambient air.[204] A study of nickel platers indicated that exposure to 0.1 mg Ni/m^3 as a TWA corresponded to 70 μg Ni/L urine corrected to a specific gravity of 1.018.[205] Accurate biological monitoring requires that the urine sample should not be contaminated by nickel-containing dust from the air or the clothes or hands of workers.

Urine

Sparingly Soluble Nickel Compounds

Depending on the Ni fraction present in the workplace, the airborne Ni concentration does not necessarily correlate closely to urine nickel concentrations. Significant

TABLE 22.2. Regulations and guidelines for exposure to metallic nickel and nickel compounds.

Exposure Limit	Value
	OSHA
PEL–TWA (8-hour)	
Metallic nickel and insoluble nickel	1.0 mg/m^3 (as total Ni)
	NIOSH
REL–TWA (10-hour)	0.015 mg/m^3
IDLH	10 mg/m^3 (as total Ni)
	ACGIH
TLV–TWA (8-hour)	
Metallic nickel	1.5 mg/m^3 (as Ni)
Insoluble nickel salts	0.2 mg/m^3
Soluble nickel salts	0.1 mg/m^3
Nickel subsulfide	0.1 mg/m^3
	WHO
Drinking water guideline	70 µg/L
Air quality guideline nickel unit risk	3.8×10^{-5}/(µg/m^3)
	US EPA
RfD (soluble salts, chronic oral exposure)	20 µg/kg/day
Carcinogenic unit risk (daily, inhalation)	
Nickel refinery dust	2.4×10^{-4}/(µg/m^3)
Nickel subsulfide	4.8×10^{-4}/(µg/m^3)
Drinking water health advisory	
1-day (10 kg-child)	1,000 µg/L
Lifetime exposure	100 µg/L
	US FDA
Bottled water allowable limit	100 µg/L
Food	Generally recognized as safe as direct human food ingredient with no limitation other than current good manufacturing practices
	ATSDR
MRL	
Intermediate inhalation	0.2 µg/m^3
Chronic inhalation	0.09 µg/m^3

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; IDLH = immediately dangerous to life and health; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfD = reference dose; TLV = threshold limit value; TWA = time–weighted average; US EPA = US Environmental Protection Agency; US FDA = US Food and Drug Administration; WHO = World Health Organization.

amounts of sparingly soluble Ni compounds (e.g., welding fumes from stainless steel, nickel oxides) may be deposited in the lungs without rapid changes in urine Ni concentrations. Consequently, urine Ni concentrations reflect the release of poorly soluble Ni compounds from the Ni lung burden rather than recent Ni exposure.[206] These concentrations may remain elevated 3–4 years after exposure ceases.[207] As with the serum/plasma nickel, urine nickel concentrations of workers exposed to sparingly soluble compounds may increase as a result of increased nickel lung burdens; however, the absence of an increased urine Ni concentration does not exclude a risk of developing adverse health effects in workers exposed only to sparingly soluble compounds.

In a German cross-sectional study of welders (gas metal arc, flux-cored arc, tungsten inert gas, shielded metal arc), the median airborne respirable and inhalable nickel fraction in welding fumes was <3 µg/m^3 and 6 µg/m^3, respectively, compared with 4 µg/m^3 and 9 µg/m^3 for chromium.[208] These welders were not wearing personal protective equipment. An airborne nickel concentration of 10 µg/m^3 correlated to urinary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

nickel concentration of ~3 μg/L; however, there was substantial variation as a result of a significant number of welders with urine nickel concentrations below the LOQ (1 μg/L).

When workers are exposed to soluble and sparingly soluble nickel compounds, the urine nickel concentrations primarily reflect the exposure to soluble compounds because exposure to the less soluble nickel compounds produces relatively small increases in the urine nickel concentration compared with soluble nickel compounds. Biological monitoring studies suggest that nickel hydroxide yields lower urine nickel concentration than soluble nickel salts following airborne exposure; therefore, nickel hydroxide is more similar to insoluble nickel salts than soluble nickel salts.[209] The mean urine nickel concentration in 92 workers with >2 years exposure in a nickel and cadmium battery factory was 13.4 μg/L (range, 1.6–47.4 μg/L) 0.9-8.3 μg/L compared with 3.1 ± 2.3 μg/L (range, 0.9–8.3 μg/L) for 20 unexposed, nonsmoking hospital staff.[210]

Soluble Nickel Compounds

Urine Ni concentrations reflect primarily recent exposure to soluble Ni compounds (e.g., electroplating industry, nickel chloride, nickel sulfate) in the absence of significant Ni release from sparingly soluble Ni deposits in the lungs. Depending on workplace conditions and practices, the urine nickel concentration may or may not correlate well to nickel concentrations in the air because of the contribution of ingested soluble nickel compounds.[211] The mean ratio of nickel in the air (μg/m^3) to urine nickel (μg/L) for electroplaters, arc welders, and bench mechanics was 0.076, 0.95, and 4.33, respectively.[212] At relatively high ambient air Ni concentrations, the correlation is relatively good (e.g., 100 μg/m^3 ≈ 40–70 μg/L) among electroplaters,[213] whereas correlations at low ambient air Ni concentrations are worse (e.g., $r = 0.68$ at 10 μg Ni/m^3).[214] The mean urine Ni concentration in seven electroplating workers on three regular workdays ranged during the workday 34 ± 32 μg/L (pre-shift) to 64 ± 63 μg/L (mid-shift) and 46 ± 32 μg/L (end-shift). The 19 controls (hospital workers) had a mean urine Ni concentration of 2.7 ± 1.6 μg/L (pre-shift).[215] The correlation coefficient for personal air samples and urine Ni concentrations in six of these workers was 0.70 ($P \ll 0.05$). Urine nickel concentrations decreased rapidly following cessation of exposure to soluble Ni compounds. On the first day returning from a 2-week vacation, the mean urine Ni concentrations in six electroplating workers ranged from 5 ± 3 μg/L (pre-shift) to 9 ± 6 μg/L (mid-shift) and 12 ± 6 μg/L (end-shift).

The mean nickel concentrations in post-shift urine samples from 10 exposed workers at a galvanizing plant using nickel sulfate and 10 unexposed controls working in a zinc electroplating plant were 20.6 ± 18.1 μg/L (range, 2.3–54.9 μg/L) and 4.9 ± 2.2 μg/L, respectively.[216] The corresponding mean post-shift value (μg Ni/g creatinine) for the exposed workers was 14.7 ± 13.5 μg/g creatinine (range, 2.1–58.7 μg/g creatinine) compared with 3.7 ± 2.5 μg/g creatinine for controls. The post-shift urine nickel concentration of exposed workers correlated well ($r = 0.96$, $P \leq 0.001$) to ambient air Ni concentrations in the range of 2.8–116.7 μg/m^3. An ambient air Ni concentration of 100 μg/m^3 correlated to a urine Ni concentration of 50 μg/g creatinine. Increased concentrations of biomarkers of subclinical renal tubular damage (e.g., β_2-microglobulin, retinol-binding protein, *N*-acetyl-β-D-glucosaminidase) may occur in workers with nickel exposures producing urine nickel concentrations exceeding 100 μg/L.

Blood

Blood concentrations of nickel are indicators of recent exposure to soluble Ni compounds rather than measures of the risk of adverse health effects. Plasma Ni concentrations fluctuate less than urine Ni concentrations following occupational exposure to soluble nickel compounds.[217] Generally, the blood Ni concentrations are an order of magnitude higher in workers exposed to soluble nickel compounds compared with unexposed adults. Serum/plasma Ni concentrations of >8–10 μg/L indicate excessive nickel exposure, the need to review work processes, and the importance of evaluating the need for respiratory protection.[218] In nickel workers exposed only to sparingly soluble nickel compounds (e.g., Ni_3S_2, NiO), serum/plasma nickel reflects the lung burden of nickel.

Medical Monitoring

A health surveillance program includes initial and periodic medical examinations supplemented when appropriate by testing (e.g., biological monitoring, environmental sampling, chest x-rays, sputum cytology, pulmonary function tests, and patch testing).[219] Such examinations are appropriate for workers exposed to ambient nickel concentrations exceeding 50% of permissible exposure limits. Recommended screening for preplacement medical examinations includes comprehensive medical and work history with special emphasis on respiratory illness, skin conditions, allergies, asthma, and smoking because these workers may be hypersensitive to nickel exposure. The physical examination

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. should concentrate on evidence of irritation and ulceration of the mucous membranes and upper respiratory tract as well as evidence of chronic dermatitis. Preemployment testing includes a chest x-ray and screening pulmonary function tests. Determination of urine or serum/plasma nickel concentrations is a measure of exposure rather than a determination of the risk for adverse effects. Periodic medical examinations should be available for workers who develop skin or respiratory complaints. Patch testing (0.5% nickel sulfate), respiratory questionnaires, and pulmonary function testing with bronchodilators should be administered to workers with signs of dermatitis or asthma. Routine use of sputum cytology, chest x-rays, or nasal biopsy for the early detection of cancer has not been established.

TREATMENT

Little data are available to guide the treatment of ingestions of divalent nickel compounds. Generally, decontamination measures (e.g., lavage) are useful only in the first 1–2 hours post-ingestion and are often limited by the severe gastrointestinal effects of these nickel salts. Serum or urine nickel measured within 1–2 after exposure correlates to the severity of the nickel exposure. Supportive care is the mainstay of treatment. Hemodialysis is an option in cases of renal failure or life-threatening complications; however, the effectiveness of this procedure in reducing the body burden of nickel remains inadequately documented. Chelation with DDC is not recommended for divalent nickel poisoning because animal studies indicate that DDC increases nickel uptake into the brain.[220] Studies in rodents indicate that D-penicillamine is superior to DDC as a chelating agent for divalent nickel;[221] however, clinical data on the use of D-penicillamine and DMPS during divalent nickel poisoning are lacking.

NICKEL CARBONYL

HISTORY

In the 1890s, LF Mond discovered nickel carbonyl [$Ni(CO_4)$]; subsequently, he developed the Mond carbonyl process to separate nickel from nickel ores processed in nickel refineries.[222] Soon after commercial use of the Mond carbonyl process began, reports of the severe toxicity of acute exposure to nickel carbonyl appeared in the medical literature. Two fatalities following exposure to nickel carbonyl were reported in 1903.[223]

PHYSIOCHEMICAL PROPERTIES

Table 22.3 lists the identifying information and physical properties of nickel carbonyl. This highly volatile, flammable (flash point < −20°C) pale-yellow liquid vaporizes rapidly to amorphous hydrous nickel carbonate oxide with a half-life of <2 minutes. The "sooty" or "musty" odor is difficult to detect at concentrations producing mild-to-moderate toxicity depending on the familiarity of the individual with the smell; the relative vapor density of nickel carbonyl is ~6 compared with room air. Carbon monoxide is a potentially toxic thermal decomposition product from heating nickel carbonyl above 50°C.

EXPOSURE

In rotary kilns using the Mond Process for refining nickel, the nickel oxide in fine particulate form combines with carbon monoxide to form nickel carbonyl. At 200°C, the carbon monoxide dissociates from the nickel carbonyl with the deposition of relatively pure nickel. Accidental exposure to nickel carbonyl may occur at these kiln plants. Other processes that use nickel carbonyl include nickel-catalyzed coal gasification, the Reppe process for catalytic synthesis of alkyl methacrylate compounds, and the nickel vapor-plating process. Commercial uses for nickel carbonyl include the extraction of nickel (Mond process), catalyst and

TABLE 22.3. Identifying information and physical properties of nickel carbonyl.

Physical Characteristic	Nickel Carbonyl
CAS RN	13463-39-3
Synonyms	Nickel tetracarbonyl
Molecular formula	$Ni(CO)_4$
Molecular weight (g/mol)	170.73
Color	Colorless
Physical state	Volatile liquid
Odor	Musty
Melting point (°C)	−25
Boiling point (°C)	43
Water solubility (9.8°C)	0.18 g/L (poorly soluble)
Vapor pressure (mmHg)	339 (21°C)
Odor threshold air	1–3 ppm

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.

reactant in chemical synthesis (carbonylation reactions), vapor-plating nickel, gas plating, and fabrication of nickel and nickel alloys.

ENVIRONMENTAL FATE

Nickel carbonyl is unstable in air decomposing to nickel carbonate oxide. Depending on the carbon monoxide concentration, further degradation occurs to Ni and carbon monoxide. As a result of the high reactivity of nickel carbonyl, the half-life of this compound in the air is only a few minutes. Consequently, nickel carbonyl is not usually found in ambient air samples. Similarly, this compound is not usually found in drinking water because of its poor water solubility.

DOSE EFFECT

Most case reports on nickel carbonyl do not provide estimations of nickel carbonyl concentrations in ambient air at the time of exposure. Nickel carbonyl is a highly volatile liquid that produces potentially fatal concentrations following exposure to 30 ppm nickel carbonyl for 30 minutes.[224]

TOXICOKINETICS

In severe poisoning with nickel carbonyl, dermal absorption of this nickel compound may contribute to toxicity;[225] however, the amount of dermal absorption of nickel carbonyl is difficult to separate from inhalation of this highly volatile substance. Once absorbed, nickel carbonyl probably undergoes decomposition to metallic Ni, followed by oxidation to divalent Ni.[226] Following exposure to nickel carbonyl, the highest concentrations of nickel appear in the lung, brain, kidney, liver, and adrenals. Animal studies suggest ~40% of an intravenous dose of $^{63}Ni(CO)_4$ is exhaled, whereas ~30% of the dose is excreted in the urine as divalent Ni over 4 days.[227] In a Chinese study of 179 cases of acute nickel carbonyl toxicity, maximum urinary nickel excretion occurred 1–2 days after exposure with return to baseline within 1 week.[228]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Nickel carbonyl is a volatile carcinogen in rodent studies that readily diffuses across cell membranes; intracellular oxidation of this compound releases Ni^{2+} that binds to nucleic acids.[229] A 47-year-old chemical operator was exposed to nickel carbonyl during a malfunction of a chemical processing unit.[230] Analysis of the urine 24 hours after exposure was consistent with a severe nickel carbonyl exposure (535 µg Ni/L). He died of respiratory failure 4 days after exposure. The autopsy demonstrated pulmonary and cerebral edema. The kidneys and liver appeared relatively normal. In a case series of three workers dying ~2 weeks after exposure, the autopsies demonstrated diffusely consolidated lungs with congestion, edema, hemorrhage, sterile pleural inflammation, and early organizing pulmonary fibrosis along with an edematous, mildly dilated heart, cerebral edema, and mild renal parenchymal pallor and edema.[231] Microscopic changes in the lungs include interstitial edema, cellular proliferation, capillary congestion, fibrinous intra-alveolar exudates, and hypertrophy of the alveolar cells.[232]

CLINICAL RESPONSE

Almost all cases of acute nickel toxicity involve exposure to nickel carbonyl.[233] Typically, acute nickel carbonyl poisoning appears in two stages: immediate and delayed. The initial symptoms primarily involve irritation of the respiratory tract and nonspecific, flu-like symptoms.[234] The most common immediate symptoms include dizziness, frontal headache, weakness, nausea, and vomiting, followed by tightness in the chest, pleuritic chest pain, dyspnea, and a nonproductive cough. In patients with mild nickel carbonyl poisoning, these symptoms are minimal with gradual resolution within 1 day. Patients with more severe poisoning develop the onset of more intense pulmonary (pulmonary edema, acute pneumonitis, acute respiratory distress syndrome) and gastrointestinal symptoms within 12–120 hours postexposure.[228,235] Other features of severe poisoning include fever, myalgias, fatigue, profound weakness, pneumothorax, respiratory failure, delirium, and convulsions.

Fever is usually not a prominent part of the clinical picture of mild nickel carbonyl poisoning; however, body temperatures of >39°C may occur in severe poisoning.[231] Additional complications of severe nickel carbonyl poisoning involve hepatorenal dysfunction, adrenal insufficiency, and hyperglycemia. Diffuse interstitial pneumonitis and cerebral edema and/or hemorrhage are the primary causes of death in patients with severe toxicity secondary to acute nickel carbonyl exposure.[13] Patients surviving severe exposure to nickel carbonyl may develop pulmonary fibrosis;[22] however, most survivors do not develop pulmonary abnormalities as measured by pulmonary function tests.[236]

The onset of bronchial asthma has been associated with acute nickel carbonyl poisoning.[234] Exposure of pregnant animals to high doses of nickel carbonyl during organogenesis produces fetal malformations;[141] however, obvious nickel toxicity occurs at these concentrations.

DIAGNOSTIC TESTING

SI Conversion Units

1 ppm nickel carbonyl = 6.983 mg nickel carbonyl/m^3
1 mg nickel carbonyl/m^3 = 0.1432 ppm nickel carbonyl

Analytical Methods

Although gas chromatography is the best method for detecting nickel carbonyl in expired air, the rapid dissolution of nickel carbonyl in the body into carbon monoxide and divalent nickel means that atomic absorption spectrometry is the best method for measuring nickel carbonyl in biological media.

Biomarkers

Because of the rarity of nickel carbonyl toxicity, data are limited to case reports. During the first 3 days postexposure, the concentration of nickel in the urine correlates well with the severity of acute nickel carbonyl poisoning; however, later urine Ni concentrations lack correlation with clinical outcome. Eight days after exposure, the urine Ni concentration in a worker surviving exposure to nickel carbonyl was higher (78.5 μg/L) than the urine Ni concentration (23 μg/L, 43 μg/L, 71 μg/L) in three workers eventually dying from acute respiratory distress syndrome.[231] In the absence of chelation, the urine nickel concentration peaks at 24–48 hours postexposure, returning to baseline concentrations within 1–2 weeks.[236] Sunderman et al. classified the severity of acute nickel carbonyl poisoning with the following urine concentrations obtained during the initial 18 hours postexposure: mild, 60–100 μg Ni/L; moderately severe, 100–500 μg Ni/L; and severe, >500 μg Ni/L.[237] A 50-year-old industrial technician developed flu-like symptoms followed by acute pneumonitis, hypoxemia, and pulmonary infiltrates 2 days after exposure.[235] Disulfiram and prednisone were initiated within 12–24 hours after exposure. The reported urine nickel concentration 2 days after exposure was ~200 μg/L. His urine nickel concentration peaked 3 days after exposure at ~1,600 μg/L initially returning to baseline within 10 days with some later mild rebound. He recovered without sequelae.

The postmortem blood (site not reported) of three workers developing fatal nickel carbonyl toxicity contained nickel concentrations of 8.9 μg/L, 3.3 μg/L, and 8.6 μg/L; the latter patient died 14 days after exposure, whereas the former two patients died 17 days after exposure.[231] These patients received no chelation. The serum nickel concentration in the nonsmoking industrial technician 2 days after exposure was 28 μg/L.[235] The blood carboxyhemoglobin was 4%, typical of the mild elevations of blood carboxyhemoglobin associated with nickel carbonyl poisoning.

HEALTH SURVEILLANCE

The US OSHA PEL–TWA for nickel carbonyl is 0.001 ppm (0.007 mg/m^3) Ni. The TLV–TWA recommended by the ACGIH is 0.05 ppm (0.12 mg Ni/m^3) based on a level sufficient to minimize the potential for acute and chronic nickel intoxication including cancer.[224] The NIOSH REL–TLV (10-hour) is 0.001 ppm (0.007 mg/m^3), whereas the IDLH is 2 ppm (13.9 mg/m^3).

TREATMENT

First Aid

Nickel carbonyl is the only nickel compound that causes acute poisoning following inhalation; the primary target organ of acute $Ni(CO)_4$ poisoning is the respiratory tract. Patients with excessive $Ni(CO)_4$ exposure should be removed immediately from the source of exposure. Because of potential dermal absorption of $Ni(CO)_4$, contaminated clothes should be removed. Initial attention should be directed toward maintaining oxygenation by supplemental oxygen and assisted ventilation as needed. Symptomatic patients and those with heavy exposure to $Ni(CO)_4$ should be transported to an emergency department for evaluation.

Antidotes

Sodium diethyldithiocarbamate (DDC) is an investigational antidote in the United States with no manufacturer assigned to sponsor this orphan drug. Dr. F. William Sunderman, Sr, holds the Investigational

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. New Drug Application at the Institute for Clinical Science, Pennsylvania Hospital in Philadelphia (215-829-7068). Tetraethylthiuram disulfide (disulfiram, Antabuse®) is split during metabolism into two molecules of diethyldithiocarbamate (DDC). There are insufficient clinical data to judge the clinical effectiveness of disulfiram as a chelator of nickel following nickel carbonyl poisoning. In rodent models, *N*-benzyl-D-glucamine dithiocarbamate and, to a lesser extent, meso-2,3-dimercaptosuccinic acid (DMSA) are more effective nickel chelating agents than DDC.[238,239] However, there are no clinical data regarding the efficacy of these chelating agents. Patients have developed severe acute respiratory distress syndrome after nickel carbonyl and survived with intensive supportive care alone.[231]

Dithiocarb

Experimental Studies

DDC forms lipophilic chelates with divalent nickel and reduces the accumulation of nickel in the lungs of mice by redistribution;[240,241] however, the nickel-diethyldithiocarbamate complex also has an affinity for lipid-rich brain tissue. In studies of mice given low doses (0.05 μmol Ni/kg) via gavage, the simultaneous oral administration of 13 μmol DDC/kg was associated with elevated nickel concentrations in the brain compared with controls.[242] The effectiveness of DDC as a chelator of nickel in the lungs was greater when administered parenterally than orally; however, the redistribution of nickel to the brain was similar. In a rodent study, large doses (0.92 g DDC/kg) intramuscularly significantly reduced mortality from nickel carbonyl toxicity when administered within 10 minutes, but not 6 hours or 24 hours after exposure.[243] D-Penicillamine (2.52 g/kg) reduced mortality when administered intramuscularly at 10 minutes and 6 hours, but not at 24 hours after nickel carbonyl exposure.

Clinical Cases

Anecdotal experience with nickel carbonyl poisoning suggests that the affinity of nickel bisdiethyldithiocarbamate chelates for lipid tissue does not produce a clinically significant Ni uptake by the brain of patients with nickel carbonyl poisoning.[244] There were no reported deaths in a group of ~400 patients treated with DDC within 4 days of nickel carbonyl exposure;[244] however, the lack of control data and clinical details on the patients in this series limits conclusions regarding the efficacy of DDC. Vuopala et al. published a case series of 25 patients with nickel carbonyl intoxication including 15 patients with pneumonitis.[236] All patients recovered without the use of DDC; follow-up pulmonary function tests eventually normalized. The administration of DDC within 48 hours does not always prevent serious sequelae. A 47-year-old chemical operator with severe nickel carbonyl poisoning died 4 days after exposure despite receiving 4 g DDC beginning 40 hours postexposure.[230]

Indications

The decision to use DDC is a clinical judgment involving the availability of DDC, the severity of the poisoning, the amount ingested, and patient stability. Patients with moderate or severe poisoning as defined by initial 8-hour postexposure urine concentrations of >100 μg Ni/L are potential candidates for the administration of sodium DDC to reduce the nickel burden in the lungs;[245] however, there are no published clinical trials using DDC and no peer-reviewed data to confirm DDC efficacy in nickel carbonyl poisoning. Consequently, there are no definite indications for DDC use.

Administration

The protocol developed by Dr. Sunderman for an adult oral dose is 35–45 mg DDC/kg in divided doses during the first 24 hours followed by 400 mg every 8 hours until the patient is symptom-free and the urine nickel concentrations are near normal values.[246] The parenteral administration of DDC at a dose of 12.5 mg DDC/kg may be necessary for critically ill patients unable to tolerate oral medication. An Antabuse-like reaction may result from the co-ingestion of DDC and alcohol.

Disulfiram

Animal studies suggest that disulfiram (Antabuse), which the body metabolizes to two molecules of DDC, may be useful as a temporary chelating agent because of the time needed to obtain DDC. In a study of rodents, the effectiveness of disulfiram in reducing the acute toxicity of nickel carbonyl was ~70% of DDC.[247] However, animal studies suggest that disulfiram increases Ni uptake by the brain, potentially accounting for the limited efficacy of disulfiram in the treatment of acute nickel poisoning in rats.[248] Although adverse drug reactions have not been reported following the use of disulfiram in nickel intoxication, cases of hepatitis have been associated with the use of disulfiram to chelate nickel in patients with nickel allergies.[249]

A patient with severe nickel carbonyl poisoning (initial concentration, 172 μg Ni/L urine) received 750 mg

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

disulfiram orally every 8 hours for 24 hours and then 250 mg disulfiram orally every 8 hours for 1 day until the DDC arrived.[225] The patient required continuous positive airway pressure (CPAP) to maintain adequate oxygenation requiring 18 days of hospitalization. There were no abnormalities on pulmonary function testing 3 months after exposure. A 50-year-old nonsmoking industrial technician with moderately severe acute pneumonitis following acute nickel carbonyl survived without sequelae. During hospitalization, he received disulfiram 1 g 12–24 hours after exposure, 500 mg 6 hours later, and then 250 mg twice daily for 5 days along with 60 mg prednisone daily for 5 days.[235] He survived with supplemental oxygen. His only complication was a mild elevation of his serum hepatic aminotransferases that resolved without sequelae.

Supportive Care

Patients with evidence of more than minor irritation of the upper respiratory tract should be evaluated for acute chemical pneumonitis (arterial blood gases, chest x-ray, pulse oximetry) and associated carbon monoxide exposure (carboxyhemoglobin). In severe cases of $Ni(CO)_4$ poisoning, the patient should be monitored for the development of respiratory failure and cerebral edema; these patients typically develop oxygen desaturation with minimal activity. Case reports suggest pulmonary function tests usually demonstrate a restrictive defect that improves significantly within 1 week after exposure.[225] Respiratory support includes continuous positive airway pressure (CPAP) and intravenous corticosteroid therapy.

Chapter 23

PHOSPHORUS AND PHOSPHORUS COMPOUNDS

ELEMENTAL PHOSPHORUS AND BISPHOSPHONATES

HISTORY

While searching for the "Philosopher's stone" to create gold from base metals in 1669, the Hamburg physician and alchemist, Hennig Brandt, first isolated white phosphorus by precipitating the vapors from a boiling mixture of sand and human urine in water. Commercial phosphorous production began from the reduction of animal bones.[1] In 1832, the incorporation of white phosphorus into a binder of antimony sulfide and potassium chlorate produced the first "strike anywhere" (Lucifer) match.[2] The convenience of lighting a fire anywhere, despite adverse conditions, resulted in enormous demand for these matches. Friedrich Wilhelm Lorinser of Vienna first described phosphorus-induced maxillary and mandibular necrosis in 1845; in the same year, Heyfelder of Erlangen published a case series on mandibular necrosis in nine workers from a match plant in Nuremberg. During the mid- to late-1800s, an epidemic of exposed osteonecrosis of the jaw (phossy jaw) developed in match-making factory workers exposed to heated fumes from white (also known as yellow) phosphorus (P_4O_{10}). These abnormalities (i.e., painful, suppurative mandibular enlargement, debility, increased mortality) did not occur in office-based workers at these factories. Safer matches were produced in the middle 1800s after the discovery of red phosphorus by the[1] Viennese Professor Schrötter and later the use of phosphorus sesquisulfide (tetraphosphorus trisulfide, P_4S_3) replaced the more toxic white phosphorus. The recognition of the toxic effects of white phosphorus during the production of matches led to the Berne Convention of 1906 and the Match Act of 1912 that introduced a prohibitive US tax on the use of white phosphorus.[3] Although most cases of the phossy jaw (Lucifer's jaw) occurred in the match industry, sporadic cases also occurred in phosphor-bronze workers producing phosphorus-containing rat poison, and fireworks production workers during the early 20th century.[4] Increased demand for phosphorus during both World Wars resulted in increased occupational exposure to phosphorus and sporadic cases of osteonecrosis of the jaw.[5]

In the early 1900s, white phosphorus was administered as a treatment for osteomalacia, nonunion of bone fractures, and rickets.[6] Although the medicinal use of white phosphorus was associated with chronic phosphorus poisoning, osteonecrosis of the jaw was not associated with this medical use.[7] Currently, acute phosphorus toxicity results primarily from suicidal ingestion of firecrackers (totes)[8] or the accidental ingestion of white phosphorus rodenticides.

In the early 2000s, rare case reports documented the development of osteonecrosis in the jaw (bis-phossy jaw) with bisphosphonate therapy.[9] Bisphosphonate-induced osteonecrosis of the jaw was first recognized in 2003. The bone lesions and clinical course of the phossy jaw are similar to this rare complication of bisphosphonate therapy including treatment with alendronate

(Fosamax®, Merck, Whitehouse Station, NJ), ibandronate (Boniva®, Roche Laboratories, Nutley, NJ), pamidronate (Aredia®, Novartis Pharmaceuticals, East Hanover, NJ), risedronate (Actonel®, Procter and Gamble Pharmaceuticals, Cincinnati, OH), and zoledronate (Zometa®, Novartis Pharmaceuticals). The clinical presentation of these patients was similar to the 19th-century disease (phossy jaw) associated with white phosphorus exposure;[10] however, other mitigating factors (e.g., oral health, chemotherapy, immune status, bacterial infections) probably contributed to the development of bisphosphonate-associated osteonecrosis of the jaw.[11] Almost all of these patients had signs of infection with a majority of them requiring dental extractions.

PHYSIOCHEMICAL PROPERTIES

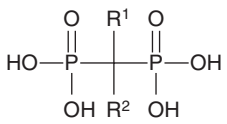
Elemental phosphorus is a metalloid in the nitrogen group that does not exist naturally in the environment. The allotropic forms of elemental phosphorus include white (or yellow) phosphorus, red phosphorus, and black phosphorus. The most important allotropic form of elemental phosphorus is white phosphorus; this relatively pure (99.9%) form has a slight yellow color resulting from the presence of traces of red phosphorus. Consequently, white phosphorus is also known as yellow phosphorus, particularly commercial grades of white phosphorus that contain more impurities than technical grades. This soft, translucent solid darkens following exposure to light. White phosphorus is a water-insoluble compound that dissolves in oils (e.g., ether, olive oil); this compound is highly fat-soluble and emits a garlic-like odor. The saturation vapor pressure is 170 mg/m^3 at 20°C; spontaneous ignition occurs on drying at 34–46°C (30°C in moist air) producing phosphorus oxides (e.g., phosphorus pentoxide, P_4O_{10}; phosphorus trioxide, P_4O_6).[12] These compounds are strong desiccants and dehydrating (corrosive) agents. The reaction of these oxides with moist air forms phosphorus-containing acids including phosphoric acid (H_3PO_4, CAS RN: 7664-38-2), pyrophosphoric acid ($H_4P_2O_7$, CAS RN: 2466-09-3), phosphorus acid (H_3PO_3, CAS RN: 13598-36-2), phosphinic acid (H_3PO_2, CAS RN: 6303-21-5), and polyphosphoric acids (CAS RN: 8017-16-1). Consequently, storage under water is necessary to prevent phosphorus ignition. Phosphine gas is a decomposition product of white phosphorus ignition in aqueous alkaline solutions at 100°C. Table 23.1 lists the identifying information and physical properties of white phosphorus. Red phosphorus is a violet–red amorphous powder that is poorly soluble in most solvents and much less reactive than white phosphorus. Black phosphorus is a solid similar to graphite.

TABLE 23.1. Identifying information and physical properties of white phosphorus.

Physical Characteristic	White Phosphorus
CAS RN	12185-10-3
Molecular formula	P_4
Molecular weight (g/mol)	123.89
Melting Point (°C)	44.15
Boiling Point (°C)	280.5
Density (g/mL)	1.82 (20°C)
Water solubility (mg/L)	3 (slight, 15°C)
Vapor pressure (mmHg)	0.025 (20°C)
Saturated vapor concentration (mg/m^3)	170 (20°C)
Partition coefficients	
Log K_{ow}	3.08
Log K_{oc}	3.05
Henry's Law constant (atm m^3/mol)	2.11×10^{-3} (20°C)

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.

Bisphosphonate compounds are analogs of pyrophosphate (P_2O_7) with the P–O–P bond replaced by P–C–P as displayed in Figure 23.1. Simple bisphosphates typically contain hydroxyl, methyl, or chloride groups in the R^1 and R^2 positions, whereas aminobisphosphonate compounds contain nitrogen and more complex carbon groups. The P–C–P and R^1 portion of the bisphosphonate molecule bind strongly to hydroxyapatite in bone minerals, whereas the R^2 portion imparts potency to inhibit osteoclast activity and induces apoptotic death of osteoclasts.



EXPOSURE

Production Processes

The production of elemental phosphorus involves refining phosphorus rock including calcium phosphate [$Ca_3(PO_4)_2$], chlorapatite [$3Ca_3(PO_4)_2CaCl_2$], hydroxyapatite [$3Ca_3(PO_4)_2Ca(OH)_2$], and fluorapatite [$3Ca_3(PO_4)_2CaF_2$]. Central Florida is the source of about 1/3 of the world's supply of elemental phosphorus. Coke or anthracite, silica chippings, and phosphate rock are heated to ~1,500°C with carbon electrodes passing an electric current through the mix in a carbon-lined furnace. The molten slag containing ferrophosphorus and calcium silicate migrates to the bottom, whereas phosphorus vapor and carbon monoxide off-gas from the furnace with the conversion of white phosphorus to phosphoric acid by aerobic hydration. The reaction of phosphate rock with sulfuric acid in the wet acid method is an alternate method of producing phosphoric acid.

The refining of phosphorus rock exposes workers to several respiratory irritants including phosphoric acid,

Drug	Relative Potency	R^1	R^2
Etidronate	1	—OH	—CH_3
Clodronate	10	—Cl	—Cl
Pamidronate	100	—OH	—CH_2-CH_2NH_2
Ibandronate	500 – 1,000	—OH	—CH_2-$CH_2N(CH_3)(C_5H_{11})$
Alendronate	1,000 – 2,000	—OH	—CH_2-CH_2-CH_2NH_2
Risedronate	2,000	—OH	—CH_2– 
Zoledronic acid	10,000	—OH	—CH_2– 

FIGURE 23.1. Chemical structures and relative potencies of bisphosphonate derivatives. (Modified from Vance).[13]

phosphorus pentoxide (volatile form of phosphoric acid), fluorides, and coal tar pitch volatiles.[14] The phosphate deposits contain significant quantities of natural radioactive material, principally ^{238}U and members of its decay series;[15] the risk of lung cancer is elevated in residents of this region compared with standardized US rates.[16] Impurities in white phosphorus at concentrations exceeding 10 ppm include aluminum, arsenic, boron, calcium, iron, and silicon. Red phosphorus is obtained by the catalytic heating of white phosphorus. The heating of white phosphorus under pressure produces black phosphorus.

Uses

Uses of white phosphorus include military applications, industrial processes, and agricultural products. Occupational exposure to phosphorus compounds includes acetyl cellulose makers, bronze alloy makers, munitions workers, smoke bomb (screens) and incendiary makers, pesticide rat poison workers, fertilizer makers, electroluminescent-coating makers, and semiconductor workers. Most white phosphorus is consumed during the production of phosphoric acid, phosphates, and, to a lesser extent, red phosphorus and phosphorus salts (trichloride, pentoxide, pentasulfide).[17] White phosphorus is a constituent of hand grenades, mortar shells, and smoke screens; combustion of white phosphorus produces a yellow flame and thick white smoke obscuring vision and weapon-tacking devices. Indications for biphosphate pharmaceuticals include osteomalacia and metastatic bone disease.

Sources

Phosphate rocks provide an abundant source of phosphorus. One of the most common methods to produce illicit methamphetamine involves the use of red phosphorus, hydrogen iodide (hydriodic acid, HI, CAS RN: 10034-85-2), and ephedrine or pseudoephedrine. The heating of red phosphorus in the presence of acids may produce phosphine gas. Consequently, law enforcement personnel potentially are exposed to phosphine gas during the investigation of clandestine methamphetamine laboratories.[18]

ENVIRONMENTAL FATE

The persistence of elemental phosphorus in the air is very short because this substance quickly oxidizes

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to phosphorus oxides and ultimately to phosphorus acids; however, the atmospheric half-time of phosphorus particles may be extended as a result of the formation of a protective layer of oxides.[17] Phosphine formed during the combustion of white phosphorus persists in the atmosphere longer than reaction products because of its slower reactivity, lower water solubility, and physical state. Phosphorus enters water primarily as phosphates with smaller amounts as elemental phosphorus; phosphate partitions primarily into the sediment. The half-life of elemental phosphorus in water is ~2–20 hours compared with ~3–7 days in soil. The disappearance half-life of elemental phosphorus from water depends on dissolved oxygen concentration, temperature, physical state (dissolved, colloidal, particle), and pH. The rate of disappearance increases with temperature, oxygen concentration, and pH.[17] The presence of anoxic conditions substantially prolongs the half-life of elemental phosphorus up to years. Volatilization of elemental phosphorus from water is the significant route of release as determined by Henry's law constant, depending on the depth of the particles and the turbulence of the water. Exposure of soil to phosphorus aerosols reduces the soil pH depending on the amount applied and the buffering capacity of the soil. In soils, rapid oxidation is the predominant route of white phosphorus degradation in <3–7 days, where the diffusion of oxygen is sufficient. The bioconcentration factor of white phosphorus in aquatic organisms is relatively low.[17]

DOSE EFFECT

White (Yellow) Phosphorus

White phosphorus is highly toxic. The acute fatal dose of white phosphorus in adults is 15–100 mg (i.e., ~1 mg/kg),[19] although survival occurred after ingestions up to 1.5 g.[20,21] In a study of 56 patients ingesting white phosphorus-containing rat poison, the fatality rate of patients ingesting >1.57 mg/kg exceeded 90%.[22] The intentional ingestion of nine firecrackers containing white phosphorus (constituents not reported) was associated with acute hepatic failure and mild encephalopathy that resolved over 2 weeks without liver transplantation, whereas the suicidal ingestion of 12 white phosphorus-containing firecrackers produced fatal hepatorenal failure.[23]

Red Phosphorus

This compound is nonvolatile, insoluble, and practically nonabsorbable. These characteristics almost always result in nontoxic ingestions. Modern matches contain no yellow phosphorus. The regular, rough surface contains red phosphorus, phosphorus sesquisulfide, potassium chlorate, and glue. The tips of safety matches contain potassium chlorate and antimony sulfide, whereas red phosphorus or sesquisulfide, sand, and glue constitute the surface. Twenty wooden matches contain 330 mg of potassium chlorate, a mucosal irritant and methemoglobin producer.

TOXICOKINETICS

The involvement of phosphorus in many cellular processes (e.g., energy transfer, carbohydrate metabolism, phospholipids, nucleotides, buffering systems) complicates the understanding of the toxicokinetics of white phosphorus and other phosphorus compounds. Consequently, there are limited data on the toxicokinetics of white phosphorus in humans.

Absorption

Although white phosphorus is poorly water-soluble, this compound is highly reactive in the presence of oxygen; the rapid conversion to oxidation products (phosphates, orthophosphates, phosphorus peroxide) potentially allows an important route of absorption. The gastrointestinal tract and respiratory tract absorb white (yellow) phosphorus based on case reports of oral toxicity and radiolabeled animal data. In rodent studies, ~80–90% of the administered dose of ^{32}P was absorbed from the gastrointestinal tract within 2–3 hours.[24] Dermal absorption of white phosphorus is not well documented. Red phosphorus is practically nonabsorbable.

Distribution

Following the oral administration of white phosphorus to rats, the highest phosphorus concentrations occur in the liver, kidney, gastrointestinal tract, and skeletal muscles.[24] After inhalation of ^{32}P, the highest ^{32}P concentration appears in the lungs, followed by bone, liver, and kidney. The concentration of ^{32}P decreases rapidly in soft tissue; however, the release of ^{32}P from bone is slow.

Elimination

Animal experiments indicate the kidney excretes white phosphorus, primarily in the form of inorganic and much smaller amounts of organic phosphates.[25] At least 96% of phosphorus excreted in the urine and feces occurs as inorganic phosphate; the remainder is organic phosphorus (e.g., phosphoproteins, nucleoproteins, nucleotides,

and phospholipids).[17] Potential inorganic oxidation products of white phosphorus include phosphates, orthophosphates, pyrophosphates, and polyphosphates; however, there are inadequate data to determine the ratio of these oxidation products following white phosphorus absorption in humans.

HISTOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Phosphorus

White phosphorus is a general protoplasmic poison that uncouples oxidative phosphorylation. The primary targets of white phosphorus include the gastrointestinal tract, liver, kidney, and bone. Death usually results from cardiovascular collapse, probably secondary to metabolic changes or a direct effect of phosphorus on the myocardium.[26] White phosphorus burns result from thermal and chemical injuries. These mechanisms of toxicity potentially include thermal damage from the heat generated by the formation of phosphorus pentoxide, the hydroscopic effect of the phosphorus pentoxide, and the corrosive effect of phosphoric acids produced during combustion.[27]

Bisphosphonates

The exact mechanism of bisphosphonate toxicity is unclear with several possibilities including direct toxicity to bone/soft tissue, avascular necrosis, altered immunity (monocyte/macrophage/γ-δ B cell function), and suppression of bone remodeling.[28] Bisphosphonate compounds concentrate in areas of active bone resorption including osteoclasts. These drugs decrease bone resorption by inhibiting osteoclast activity and increasing osteoclast apoptosis through interference with ATP-dependent enzymes (simple bisphosphonates)[29] or disrupting prenylation of regulatory proteins including guanosine triphosphatases.[30] At high concentrations, bisphosphonates alter bone mineralization by interfering with the formation of the crystalline salt of calcium (hydroxyapatite).

Pathological Changes

White Phosphorus

Pathological changes following acute exposure to white phosphorus include severe ulcerative gastritis, rarely with luminescent stools, acute yellow liver atrophy with peripheral zone necrosis and fatty degeneration, and proximal convoluted tubular and renal cortical necrosis. Liver biopsies of explanted livers from cases of acute white (yellow) phosphorus intoxication demonstrate hepatocyte necrosis with balloon degeneration.[23] Direct damage to the walls of blood vessels may develop, resulting in the exudation of fluid. Fatty degeneration of the myocardium with necrosis can occur after white phosphorus exposure. The intentional ingestion of white phosphorus by a 17-year-old girl was associated with a moderate decrease in granulocytes.[31] Bone marrow aspiration 24 hours after ingestion demonstrated interstitial edema, mild necrotic foci, and hemorrhage. She recovered within 48 hours without sequelae.

Phossy Jaw and Bisphosphonate-Induced Osteonecrosis

Chronic degenerative bone changes (phossy jaw) and osteoporosis occur after chronic phosphorus exposure exceeding 5 years, particularly in the mandible. Characteristically, pathological changes include thickening of the mandibular periosteum with distortion of architecture and a subsequent predisposition to fractures and infections. The histological abnormalities of phossy jaw and bisphosphonate-induced osteonecrosis are similar. Histological examination of patients receiving bisphosphonate therapy reveals acellular bone devoid of osteocytes, osteoclasts, or osteoblasts with signs of acute/chronic inflammation and bacterial colonization.[11]

Postmortem Examination

The most common pathological changes noted during autopsy of patients dying of acute white phosphorus poisoning are fatty degeneration of the liver and kidneys. Explanted livers from six children undergoing liver transplantation for acute white phosphorus-induced hepatic toxicity were very hard and pale; histological examination demonstrated extensive necrosis, balloon degeneration, and steatosis.[32]

CLINICAL RESPONSE

Adverse Drug Effects

Osteonecrosis of the jaw is a rare complication occurring during the treatment of osteoporosis, Paget's disease, or metastatic bone disease with bisphosphonate drugs,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

primarily aminobisphosphonate therapy. The administration of receptor activator of nuclear factor κ-B ligand inhibitors is also associated with osteonecrosis of the jaw. This complication occurs typically in the mandible and to a lesser extent in the maxilla. The occurrence of this adverse effect depends on drug potency (aminobisphosphonate ≫ simple bisphosphonates), duration of treatment, and route of exposure (intravenous ≫ oral).[33] Some patients may not respond to treatment for bisphosphonate-induced osteonecrosis.[34] In a case series of 112 patients (70% women) with osteonecrosis of the jaw, 74% had underlying malignancies; all patients had underlying jaw infections, commonly with *Actinomyces*.[11] Other risk factors include maxillary or mandibular bone surgery, poor oral hygiene, ill-fitting dentures, chronic inflammation, diabetes mellitus, and the use of glucocorticoid or antiangiogenic agents.[35]

Oral Exposure

In 1949, Rubitsky and Myerson described three stages of severe white (yellow) phosphorus toxicity after summarizing the clinical features in 16 patients almost exclusively ingesting white phosphorus in rat bait.[36] The initial stage (first day) involved gastrointestinal irritation (nausea, vomiting, hematemesis, abdominal pain) with occasional fever and garlic odor, followed by a variable quiescent period (1–3 days) characterized by transient improvement of gastrointestinal symptoms despite increasing serum aminotransferases and bilirubin. Subsequently, the final phase of multiorgan failure develops manifested by hepatorenal dysfunction, encephalopathy, coagulopathy, and shock depending on the severity of exposure. In severe cases, coma and cardiovascular collapse follow soon after the gastrointestinal phase with acute liver failure often requiring a liver transplant.[32] The most common clinical features in 85 patients admitted to 7 Ecuadorian hospitals after ingesting white phosphorus and potassium chlorate in pyrotechnics (*diablillos*) were abdominal pain, diarrhea, nausea, vomiting, jaundice, elevated serum hepatic aminotransferases, prolonged prothrombin time, and hypoglycemia.[37] Diarrhea and garlic breath are less common than vomiting and abdominal pain during the gastrointestinal stage; luminescent stools/vomitus and mucosal burns appear infrequently.[38] Case reports also associate upper abdominal pain, vomiting, lethargy, respiratory distress, hypotension, severe hepatic failure, and death with the ingestion of white phosphorus fireworks by children.[39] In a case series of 15 adult patients ingesting phosphorus-containing fireworks (14 with suicidal intention), the mortality rate was 27%.[40] Two patients had no clinical or biochemical evidence of hepatic damage, whereas four patients had a subclinical hepatic injury, five patients developed varying severity of hepatocellular necrosis, and four patients died of fulminant hepatic failure. The presence of altered consciousness and generalized myalgia indicates serious poisoning, whereas jaundice, serum aminotransferase concentrations, and abdominal pain have less prognostic significance.[21]

McCarron et al. believe acute white phosphorus toxicity has three specific forms rather than sequential stages.[41] In their retrospective review of 91 personal patients and cases culled from the medical literature, 53% of cases demonstrated the gastrointestinal form manifested by initial vomiting and abdominal pain followed by diarrhea, hepatorenal dysfunction, shock, bleeding, and central nervous system toxicity. The mortality rate was 23%. Twenty-eight percent of their reviewed cases initially displayed central nervous system toxicity. Lethargy, stupor, coma, restlessness, hypotension, and shock developed after ingestion followed by hepatorenal dysfunction, bleeding, vomiting, and diarrhea. The mortality rate was 73%. Nineteen percent of the reviewed cases demonstrated combined effects with the central nervous system and gastrointestinal toxicity occurring simultaneously followed by hepatorenal toxicity, bleeding, diarrhea, and hypotension. The mortality rate was 47%. Indicators of poor prognosis include generalized muscle tenderness and clouded sensorium. Most patients surviving for at least 6 days will recover. The degree of liver enlargement, severity of abdominal pain, intensity of jaundice, and serum hepatic aminotransferase concentrations have little prognostic value.

Dermal Exposure

White phosphorus is a yellowish to transparent combustible solid that spontaneously ignites to produce a yellow flame and dense smoke. Dermal contact with white (yellow) phosphorous produces yellowish, waxy, necrotic, full-thickness burns that penetrate deeply into underlying tissues, causing second and third burns.[42,43] After the removal of prehospital dressings, smoke may emanate from retained particles in wounds created by incendiary devices containing white phosphorus. These wounds fluoresce under ultraviolet light (e.g., Wood's lamp). Hypertrophic, tender scars may develop despite debridement of white phosphorus particles and skin grafting. Although case reports associate topical contact with white phosphorus with sudden death,[44] there are few experimental data to determine the amount of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

dermal absorption following topical exposure to white (yellow) phosphorus.

Ocular Exposure

White phosphorus is a highly reactive substance that spontaneously ignites in moist environments at room temperature; the associated explosion and white smoke cause severe eye irritation, photophobia, lacrimation, and blepharospasm. Sclerokeratitis subsequently may develop with multiple recurrences of inflammation. In contrast to the fulminant cases of recurrent inflammation of the eye following the explosive seeding of the cornea and conjunctiva with white phosphorus, multiple foreign bodies of red phosphorus produced a more benign course without late complications. A 15-year-old boy sustained bilateral conjunctival and corneal burns with multiple corneal foreign bodies after an explosion involving red phosphorus powder and potassium chlorate.[45] On examination, he had chemosis, corneal epithelial erosions with multiple red particles extending into the stroma, 1+ flare in the anterior chamber, a clear lens, normal intraocular pressures, and first-degree burns of the upper and lower eyelids. He left the hospital 10 days after admission with corrected vision of 20/60 OD and 20/100 OS. His vision improved 1½ years later to 20/30 OD, 20/40 OS, and 20/25 corrected.

Occupational Exposure

Classic phossy jaw develops after years of white phosphorus exposure, beginning with toothaches, recurrent pain, ulceration of the gum and surrounding tissue, and tooth extractions with persistent ulceration of the gums.[1] The surrounding soft tissue becomes tender, swollen, and purulent. Typically, the disease progresses slowly causing more extractions, larger ulcerations, denuded skin, and spongy alveolar bone. The destruction of soft tissue and bone may continue despite cessation of white phosphorus exposure, eventually involving large portions of the jaw that cause severe deformities. Radiographic changes may lag behind the clinical presentation. Although refining phosphorus rock exposes workers to several respiratory irritants (e.g., volatile coal tar compounds, fluorides, phosphorus oxides, phosphoric acid), a cross-sectional and 7-year follow-up study of 31 phosphorus rock refinery workers did not detect a significant reduction in pulmonary function testing attributable to their occupational exposure.[14]

Carcinogenicity

Little data exist on the carcinogenicity of phosphorus or phosphorus compounds. Neither the IARC nor the NTP lists these compounds as suspected carcinogens.

DIAGNOSTIC TESTING

SI Conversion Units

1 ppm (25°C) = 5.07 mg/m^3
1 mg/m^3 = 0.197 ppm (25°C)

Analytical Methods

Extensive pretreatment and pre-fractionation procedures required for phosphorus analysis introduce variations in the results and complicate the interpretation of the values. Sensitive methods for quantitation of phosphorus compounds in biological media include inductively coupled plasma/mass spectrometry, nuclear magnetic resonance spectroscopy, and ultra-performance liquid chromatography/mass spectrometry.[46] The use of X-ray absorption near-edge structure (XANES) spectroscopy with sequential chemical fractionation allows the characterization of dominant solid-phase species of phosphorus in soils.[47]

Biomarkers

The serum phosphate concentration in the general population is ~3.0–4.5 mg/dL. During white phosphorus poisoning, the serum phosphate concentrations do not correlate well to toxicity or prognosis.

Abnormalities

Liver failure (elevated serum aminotransferases, hypoprothrombinemia, hypoglycemia, hyperbilirubinemia), acute pancreatitis,[48,49] kidney failure (elevated BUN/creatinine, urinary casts, albumin, red blood cells, amino acids, bile pigments), and abnormal blood chemistries (hypoglycemia, leukopenia or leukocytosis, lymphocytosis, anemia or polycythemia, hypocalcemia, hypo- or hyperphosphatemia) may result from acute white phosphorus intoxication. In a series of 15 adults ingesting white phosphorus, metabolic acidosis, hypoglycemia, and severe elevation of the prothrombin time indicated a poor prognosis, whereas jaundice was not necessarily a poor prognostic sign.[40]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Large dermal burns from white phosphorus may cause systemic complications including hypocalcemia, hyperphosphatemia, and cardiac dysrhythmias. Electrocardiographic changes include T wave inversions, QT prolongation, ST-segment depression, low-voltage QRS complex, atrial fibrillation, and reduced ventricular contractility.[37,50]

HEALTH SURVEILLANCE

The Minimal Risk Level for white phosphorus derived by the ATSDR is 0.2 µg/kg/day based on a NOAEL of 0.015 mg/kg/day and a hepatic endpoint.[17] The acute inhalation MRL for acute-duration inhalation exposure to white phosphorus smoke is 20 µg/kg/day based on a minimal LOAEL of 187 mg/m^3 (throat irritation after 5-minute exposure). Table 23.2 lists the guidelines and regulations for exposure to white phosphorus.

The lack of data on white phosphorus metabolites complicates the use of biomonitoring to measure the exposure of white phosphorus workers. The high serum/urine phosphate concentrations in the general population and large interindividual variability in these concentrations limit the usefulness of these measures in biomonitoring programs. In a convenience sample of five workers from a phosphorus manufacturing plant and five controls, there was no statistically significant difference in the plasma inorganic phosphorus, calcium, or magnesium concentrations between the two groups (method, *P* value, and normal ranges not reported).[1] The mean plasma inorganic phosphorus concentration in the exposed workers was 2.85 mg/dL compared with 2.9 mg/dL in controls. This paper also reported a normal serum inorganic phosphate concentration (3.5 mg/dL) in a worker with osteonecrosis of his jaw after a 4-year exposure to white phosphorus at a phosphate manufacturing plant.

TABLE 23.2. Guidelines and regulations for white phosphorus.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	0.1 mg/m^3 (0.02 ppm)
NIOSH	
REL–TWA (10-hour)	0.1 mg/m^3
IDLH	5 mg/m^3
ACGIH	
TLV–TWA (8-hour)	0.1 mg/m^3 (0.02 ppm)
REL–STEL (15-minute)	None
US FDA	
Bottled water allowable limit	None
US EPA	
RfC (chronic inhalation exposure)	None
RfD (chronic oral exposure)	None
MCL (EPA carcinogenic unit risk, daily)	None
US Federal Drinking Water Guidelines	None
ATSDR	
MRL (intermediate oral)	0.2 µg/kg/day
MRL (acute inhalation)	20 µg/kg/day (white phosphorus smoke)

TREATMENT

Decontamination

Emesis is a therapeutic option in the prehospital setting for an ingestion that presents within 1 hour unless contraindicated by alteration of consciousness or the presence of protracted vomiting; however, there is no clear evidence that this procedure improves clinical outcome. The role of activated charcoal has not been defined in this setting. Anecdotal gut decontamination measures for phosphorus poisoning include lavage with 1:5,000 potassium permanganate solution (500 mL in a child, 1–2 L in an adult), sodium bicarbonate, or oils (coconut, vegetable, liquid paraffin)[51] and the use of a mineral oil cathartic.[41] There are inadequate clinical data to recommend any of these decontamination measures. Contaminated skin should be washed copiously with water; skin with embedded phosphorus particles should be kept moist to prevent further oxidation and tissue damage before removal.[52] Health workers should wear gloves and carefully wash off all phosphorous-containing vomitus and stools. These fluids should be handled as hazardous materials and double-bagged.

Elimination Enhancement

The efficacy of exchange transfusion for white phosphorus poisoning is questionable based on current data. In a study of 15 patients with Grade IV hepatic encephalopathy from acute white phosphorus toxicity,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

2 of 5 patients died compared with 7 of 10 in the group without exchange transfusion.[8] Blood availability determined the patients receiving exchange transfusions; therefore, the groups were not randomized and conclusions regarding efficacy are limited. Hemodialysis is recommended only for the treatment of renal failure.

Antidotes

There are no antidotes for white phosphorus toxicity.

Supportive Care

1. Admit all symptomatic patients to an intensive care setting for a minimum of 72 hours of observation with careful monitoring of electrolyte balance. Patients remaining asymptomatic 6 hours after ingestion may be discharged from the ED with a close follow-up established.[53]
2. Monitor for hypoglycemia, hypomagnesemia, dysrhythmias, hypoxia, metabolic acidosis, hyperkalemia, rhabdomyolysis, and renal failure.
3. Replace fluids/electrolytes. Watch for the development of hypocalcemia, hypokalemia, hyperphosphatemia, and hypomagnesemia.
4. Follow blood chemistries (calcium, phosphorus, glucose, prothrombin time, CBC) and hepatorenal function at least daily.
5. Phosphate toxicity depends on dose and retention time. Predisposing factors in adults include co-morbidities (renal dysfunction, cardiovascular disease, extreme age) Hirschsprung's disease, and small infants in children.

Wounds

The presence of white vapor emanating from a wound with or without a garlic odor indicates the continuing formation of phosphoric acid and destruction of tissue; the presence of these vapors does not necessarily indicate spontaneous ignition.[54] Initially, white phosphorus burns should be copiously irrigated with cool saline, followed by prompt debridement of easily identifiable particles of phosphorous;[55] a Waterpik® may be necessary for mechanical debridement. The use of warm water facilitates the conversion of solid particles to liquid with a concomitant increased risk of autoignition.[56] Once removed, phosphorus particles should be kept wet with water or sterile saline to prevent reignition. Experimental evidence from rodent studies suggests copious irrigation with saline and manual debridement with forceps and scalpel may be the most effective means of decontamination.[57] The use of a Wood's lamp helps to identify retained large phosphorus particles by fluorescence of the phosphorus.[58] The burn site should be covered with saline-soaked pads after irrigation and debridement.

Irrigation with 0.5–1% copper sulfate solution and 5% sodium bicarbonate *theoretically* helps reduce phosphorus absorption while improving identification of remaining phosphorus particles in the wound by turning the particles black.[59] The development of copper toxicity depends, in part, on the extent of the burn; however, the use of copper and other solutions (e.g., 1–3% silver nitrate)[60] remains controversial as a lavage solution for phosphorus wounds because of the risk of developing copper toxicity (hemolysis, renal failure).[27,61] The wound should be kept moist until debridement eliminates all phosphorus particles to prevent spontaneous ignition of the phosphorus particles. The wound should be inspected several times daily during the first several days to identify phosphorus particles deeply embedded in the tissue.[62]

PHOSPHORIC ACID AND PHOSPHORUS SALTS

PHYSIOCHEMICAL PROPERTIES

Phosphorus trichloride (empiric formula PCl_3, molecular formula P_2O_6) is a colorless, noncombustible liquid with a high vapor pressure (100 Torr at 21°C). This compound reacts exothermically with water to form hydrochloric and phosphonic acids. Phosphorus pentachloride (empiric formula PCl_5, molecular formula P_2O_{10}) is a white to slightly yellow, noncombustible solid that sublimates without melting. This solid fumes in contact with moist air release irritating fumes containing hydrochloric acid and phosphoric acid (H_3PO_4). Phosphorus oxychloride ($POCl_3$) is a clear, colorless liquid that also spontaneously decomposes, producing a pungent odor secondary to the formation of hydrochloric and phosphoric acids. The vapor pressure is 40 Torr at 27.3°C. Phosphorus trichloride (CAS RN: 7719-12-2, PCl_3) is a colorless, noncombustible, fuming liquid with a molecular weight of 137.35; this liquid decomposes to hydrochloric acid and phosphonic acid in water or moist air.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Phosphorus pentasulfide (P_4S_{10}) is a yellow to slightly green solid with a rotten egg odor secondary to the spontaneous formation of hydrogen sulfide in moist air. The odor threshold is near 0.005 ppm. In the presence of moist air, P_4S_{10} decomposes into hydrogen sulfide and phosphoric acid.

Although phosphorus sesquisulfide (P_4S_3) is a mucous membrane, respiratory, and skin irritant, the low vapor pressure of this compound limits significant occupational exposure. Phosphorus pentachloride decomposes to hydrogen chloride and phosphoric acid following hydrolysis with water.

Phosphoric acid (H_3PO_4, orthophosphoric acid, white phosphoric acid) is a noncombustible, odorless, colorless solid or viscous liquid that is very soluble in water. Phosphoric acid mist is a mild mucous membrane and respiratory irritant. The decomposition products at temperatures above 213°C of this compound include pyrophosphoric acid ($H_4P_2O_7$). The saturation vapor concentration of phosphoric acid exceeds the recommended TLV–TWA.[63] Table 23.3 lists the identifying information and physical properties of common phosphorus compounds.

EXPOSURE

Phosphates are widely used in fertilizers, animal diets, food and beverages, industrial cleaning agents, water and waste treatments, and metal treatments. Phosphorus trichloride is an industrial catalyst and chlorinating agent also used as an intermediate in the manufacturing of surfactants, gasoline additives, plasticizers, pesticides, and dye stuff. Phosphorus oxychloride is a chlorinating agent, catalyst, and component of the manufacturing of gasoline additives, hydraulic fluids, plasticizers, and fire retardants. Phosphorus pentachloride is also a chlorinating agent and catalyst, whereas phosphorus pentasulfide is an intermediate in the synthesis of sulfur-containing organic compounds and several manufacturing processes (e.g., safety matches, lubricant additives, insecticides, igniting chemicals).

TOXICOKINETICS

Phosphate absorption occurs in the duodenum, jejunum, and, to a lesser extent, in the colon by passive diffusion and a sodium-dependent, carrier-mediated pathway with the latter demonstrating a linear relationship between phosphate absorption and intestinal phosphate concentrations. Consequently, large sodium loads (e.g., sodium phosphate enemas) enhance phosphate absorption. The kidneys excrete up to 20% of the filtered phosphate load depending on renal function and fluid status; renal impairment and volume depletion enhance phosphate retention.

TABLE 23.3. Identifying information and physical properties of common phosphorus compounds. (Based on Perez and Solderholm).[63]

Physical Characteristic	Phosphorus Trioxide	Phosphorus Pentoxide	Phosphorus Oxychloride	Phosphorus Pentachloride	Phosphorus Pentasulfide	Phosphorus Acid	Phosphoric Acid

CLINICAL RESPONSE

Phosphate toxicity occurs in children and adults following the oral or rectal administration of large doses of sodium phosphate enemas. Complications include electrolyte abnormalities (hyperphosphatemia, hypocalcemia, hypokalemia), metabolic acidosis, and dehydration. Clinical manifestations of hyperphosphatemia are vomiting, diarrhea, lethargy, fever, tetany, seizures, coma, shock, and cardiac arrest.[64] Risk factors include young age (e.g., <2 years), predisposing intestinal conditions (e.g., Hirschsprung's disease, anorectal malformations), renal dysfunction, and fluid loss. In severe cases, cardiac arrest and death may occur in children[65] and adults.[66]

Most of the commercial phosphorus compounds (PH_3, PCl_3, P_2S_5, $POCl_3$) are severe respiratory and mucous membrane irritants in rodents[67] and humans;[68,69,70] whereas phosphoric acid mist is a mild irritant of the eyes and mucous membranes. Phosphorus trichloride reacts exothermally with water to produce phosphoric acid, hydrochloric acid, phosphorus oxides, and phosphine. In a convenience sample of 17 of 450 workers and residents exposed to the decomposition products of phosphorus trichloride after a tanker accident, complaints included nausea, vomiting, lacrimation, eye irritation, and dyspnea.[71] Pulmonary function tests demonstrated some small and large airway dysfunction that cleared within 1 month in most of these patients. The sample size was too small to adjust for preexisting conditions and smoking. Other incidents associated with mixed exposure to chlorinated phosphorus compounds were associated with acute airway obstruction, mild interstitial and alveolar edema, diffusion defects, and ventilation and perfusion mismatching; the contribution of PCl_3 to these abnormalities is unclear as a result of the mixed exposure (i.e., HCl, oxalyl chloride, PCl_5, oxalic acid) and limited analysis of the exposure scenario. These abnormalities resolved rapidly.

DIAGNOSTIC TESTING

SI Conversion Units

The conversion factor for phosphorus oxychloride at 25°C is 1 ppm = 6.26 mg/m^3, whereas 1 ppm phosphorus pentachloride = 8.51 mg/m^3 and 1 ppm phosphorus trichloride = 5.60 mg/m^3.

Analytical Methods

The use of inductively coupled plasma/mass spectrometry with molecular mass spectrometric techniques and various separation techniques (liquid chromatography, gas chromatography, gel electrophoresis, capillary electrophoresis) allows the speciation of inorganic phosphorus.[72] Inductively coupled plasma/atomic emission spectrometry analyzes total and inorganic phosphorus in soils. Sediments and waters may contain substantial amounts of organic phosphorus compounds (e.g., organic condensed phosphorus species, aminophosphoric acids, sugar phosphates, phosphoamides, phosphoproteins, inositol phosphates, phospholipids, nucleic acids) as well as inorganic phosphorus compounds (orthophosphate, polyphosphate, pyrophosphate, phosphate monoesters/diesters).[73] The classical analytical method to detect dissolved organic phosphorus in soils and aquatic systems is phosphomolybdenum blue spectrophotometry; newer methods include enzymatic hydrolysis procedures, ^{31}P nuclear magnetic resonance spectroscopy, and soft X-ray fluorescence. The use of enzymatic hydrolysis techniques in natural waters and sediments is limited by the difficulty of detecting orthophosphate in the low dissolved organic phosphorus concentrations in natural waters.

Abnormalities

Electrolyte abnormalities associated with phosphate toxicity include hyperphosphatemia, hypocalcemia, hypokalemia, and metabolic acidosis.

HEALTH SURVEILLANCE

Phosphoric acid mist has an ACGIH TLV–TWA and US OSHA PEL–TWA of 1 mg/m^3. The ACGIH TLV–STEL is 3 mg/m^3, whereas the NIOSH IDLH is 1,000 mg/m^3. Table 23.4 lists the guidelines and regulations for exposure to certain phosphorus compounds.

PHOSPHIDES AND PHOSPHINE GAS

HISTORY

Aluminum and zinc phosphide are inexpensive, effective grain fumigants and rodenticides that release phosphine

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; NE = not established; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure level/limit; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average.

gas on contact with water and stomach acid. Lack of toxic residues, preservation of seed viability, and low cost encourage the use of these agents in developing countries (e.g., India, Iran, Sri Lanka, Morocco). These compounds are common suicidal agents in southeast Asia.[74,75] In a prospective study of 559 cases of acute poisoning in India, 91.4% of the cases involved suicidal intent.[76] Aluminum phosphide was an agent of choice in ~2/3 of these cases.

PHYSIOCHEMICAL PROPERTIES

The common metallic phosphides are aluminum (AlP, phostoxin, quickfor, alutal, celphide, detia gas), magnesium (trimagnesium phosphide, Mg_3P_2), and zinc (trizinc diphosphide, Zn_3P_2, detiaphos, magtoxin). These metallic phosphides are gray to gray/yellow solids that react with moisture to form phosphine gas and metallic hydroxides (i.e., nontoxic residues). Magnesium phosphide reacts with excess white phosphorus and water to form phosphine gas, whereas water directly hydrolyzes aluminum phosphide to phosphine gas and aluminum hydroxide. The formation of a protective layer of aluminum hydroxide over aluminum phosphide may reduce the production of phosphine gas from aluminum phosphide. Zinc and aluminum phosphide tablets react with acids to produce phosphine gas and chloride salts.[77] These tablets are stable under dry conditions, but they deteriorate rapidly under damp conditions. Phosphine gas blackens silver nitrate paper as a result of the formation of silver phosphate, even in trace amounts; hydrogen sulfide also turns silver nitrate paper black, but the addition of ammonium molybdate to the blackened paper will turn blue only in the presence of phosphine.[78]

Phosphine (PH_3) is a colorless, flammable gas at ambient temperature with poor odor warning properties as a pure gas. Although pure phosphine gas is not easily detectable at highly toxic concentrations (200 ppm), technical phosphine contains odoriferous impurities (methanethiol, diphosphine, substituted phosphine) that impart a fish or garlic odor detectable at a threshold of 1–5 ppm technical phosphine.[79] Phosphine readily ignites at room temperature when the ambient air phosphine concentration exceeds 1.9% (v/v), particularly in the presence of other phosphine compounds.[80] Phosphine gas causes severe corrosion of copper-containing alloys; electrical equipment that contains copper may be damaged during fumigation with phosphine gas. Phosphine gas is water-soluble; in solution, phosphine forms a neutral solution.[12] Table 23.5 lists identifying information and physical properties of phosphine gas.

EXPOSURE

Production Processes

The two major production processes for phosphine gas are the hydrolysis of magnesium-aluminum phosphide or aluminum phosphide and the electrolysis of phosphorus with nascent hydrogen. Phosphine gas is a by-product of the production of acetylene. Production of metal phosphides involves the reduction of the metal phosphate with hydrogen at 600°C, the direct reaction between amorphous phosphorus and powdered metal under heat and pressure, or the passing of phosphorus

vapor over the metal at 400°C. Uses for phosphorus compounds include chlorinating agents and catalysts (PCl_3, PCl_5), chemical intermediate for surfactants and pesticides (PCl_3, P_2S_5), and the manufacturing of plasticizers and gasoline additives ($POCl_3$, PCl_3). Phosphoric acid has a wide variety of commercial applications including rust-proofing metals, water treatment, fertilizers, detergents, foods, and beverages.

Uses

Phosphine gas is a chemical intermediate in the synthesis of organic phosphonium derivatives (flame retardants) and organophosphines (oil additive and pharmaceutical preparations). Industrial exposures occur most commonly after the use of PH_3 in the production of acetylene gas or following the use of phosphine gas as a doping agent for the manufacture of silicon crystals. The production of phosphine gas for fumigation usually involves the hydrolysis of aluminum or magnesium phosphide at the site of fumigation; this product is the only economically viable fumigant for widespread use after phasing out ozone-depleting substances in accordance with the United Nations Montreal Protocol. Satisfactory fumigation with phosphine gas requires a moisture content of ≥10%.[81] The principal use of zinc phosphide is as a rodenticide in the form of a 2.5–5% paste added to food as bait. Formulations of phosphorus-containing rodenticides include Patterson's Zinc Phosphide Rodent Bait (2%), Pearson's Rat Poison (2%), Stearn's Electric Brand Paste (3%), Rat Doom Zinc Phosphide (5%), Rough-on-Rats, 5-0 paste, and Paste Electrica. Ammonium carbamate is a common additive to commercial phosphide tablets to prevent the combustion of phosphine gas; aluminum oxide and diphosphine gas are by-products present in commercial aluminum phosphide tablets.

Sources

Phosphine gas appears rarely in nature. Transiently, the anaerobic degradation of phosphorus-containing material yields phosphine gas. Otherwise, phosphine gas in ambient air results from the use of phosphides as fumigants and rodenticides; however, the amount of phosphorus released into the air from this source is small compared with the amount of phosphate added to the environment by agricultural runoff and urban effluent.[79] The residue of phosphine in food following fumigation is usually low after aeration, except following the incomplete reaction of metal phosphides in the fumigated material.

ENVIRONMENTAL FATE

The ultimate fate of phosphine and phosphide in the environment is the formation of phosphates.[79] Phosphine and the common metal phosphides are degradable; therefore, these substances do not persist in the environment. Phosphine decomposes to several intermediates (e.g., P_2H_4) and ultimately to phosphoric acid (H_2PO_4), salts, and water.[17] Few phosphates are formed from the degradation of phosphine. Hydroxy radicals remove phosphine from the air with a half-life of <24 hours.

Phosphine is unstable in aqueous solutions, even under anaerobic conditions. Depending on the redox potential of water, the oxidation products are diphosphine (P_2H_4), phosphorus, hypophosphorous acid, phosphorus acid, and phosphoric acid.

Under moist conditions, aluminum and magnesium phosphides rapidly hydrolyze, whereas little hydrolysis of zinc phosphide occurs unless the pH is <4. Oxidation of zinc phosphide transpires in soil containing 50% water within 5 weeks.[81]

DOSE EFFECT

Aluminum phosphide grain fumigants and zinc phosphide rodenticides release phosphine gas upon contact with moisture, leading to fatalities.[82] Aluminum phosphide tablets weigh 3 g and release about 1 g phosphine gas after complete dissolution. The potentially lethal dose in an adult is 500 mg phosphine gas; hence, one

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tablet of aluminum phosphide is a potentially fatal dose. Most patients ingesting >10 g (>3 tablets of aluminum phosphide) develop cardiovascular collapse. In a series of 20 cases of poisoning from zinc phosphide, the lowest fatal dose was 4 g zinc phosphide (~80 mg/kg), whereas survival occurred after ingestion of 50 g zinc phosphide.[83] A 36-year-old schizophrenic patient presented 1–2 hours after ingestion of an estimated 400 mg zinc phosphide. He received decontamination measures (syrup of ipecac, activated charcoal); he was released asymptomatic after 4 hours of observation.[53]

Nausea, vomiting, diarrhea, dizziness, headache, cough, and tightness of the chest developed in workers exposed to an average concentration of <10 ppm phosphine gas (range up to 35 ppm phosphine).[84] Serious effects develop from exposure to phosphine gas at levels above 100 ppm (140 mg phosphine/m^3) for 0.5–1 hour; the IDLH (immediately dangerous to life or health) level is 50 ppm phosphine.[85]

TOXICOKINETICS

Absorption

The rapid onset of toxicity following exposure to phosphine gas indicates the lungs absorb phosphine gas easily. In addition to the absorption of phosphine gas following the ingestion of metal phosphides, the presence of hydrolyzable phosphide in the liver and the blood following the ingestion of aluminum phosphide indicates the stomach directly absorbs metal phosphides.[86] Dermal absorption of phosphine gas and metal phosphides is insignificant from a toxicological perspective.

Distribution

Muscles of animals poisoned by zinc phosphide do not usually contain detectable concentrations of phosphine or phosphide; however, acid-hydrolyzable phosphide was present in the kidney and liver of a patient who died from zinc phosphide poisoning.[87]

Elimination

In the body, metal phosphides are hydrolyzed to phosphine and the corresponding metal cation. Elimination of unchanged phosphine occurs primarily through the lungs with lesser amounts oxidized and excreted by the kidneys as hypophosphite and phosphite.

HISTOPATHOPHYSIOLOGY

Mechanism of Toxicity

The ingestion of aluminum and zinc phosphides results in the release of phosphine gas in the stomach, inhibition of cellular respiration, gastrointestinal irritation, and circulatory collapse. Although phosphine inhibits cytochrome C oxidase *in vitro*, phosphine gas is not a potent inhibitor of this enzyme *in vivo* compared with cyanide or hydrogen sulfide.[88] Profound shock results from inhibition of cellular respirations, fluid loss, direct myocardial toxicity, and adrenal dysfunction.[89] Although histopathological findings following phosphine poisoning suggest cellular hypoxia,[90] the exact mechanism of phosphine-induced cardiopulmonary injury is not well defined.

Additionally, phosphine is a corrosive that causes lipid peroxidation and reduction in glutathione concentrations. Indicators of oxidation stress (e.g., reduced glutathione, malonyldialdehyde) peak ~48 hours after exposure and normalize within ~5 days.[91] Severe cases of phosphine poisoning produce refractory hypotension secondary to myocardial damage, fluid loss, and peripheral vasodilation.

Postmortem Examination

In a retrospective descriptive study of fatal phosphine poisoning, the most common histological findings in the liver were fine cytoplasmic vacuolization of hepatocytes and sinusoidal congestion.[92] The vast majority (86%) of these cases were suicides. In a histological study of explanted livers from patients intentionally ingesting zinc phosphide, the major findings included microvesicular steatosis, periportal necrosis, intracellular vesiculation, reticulin collapse, and vessel wall damage.[93] Besides visceral congestion and patchy centrizonal necrosis of the liver, there are no histological changes that characterize phosphine poisoning.[94] In fatal cases of phosphine poisoning, gross examination at autopsy revealed marked pulmonary edema,[95] congestion and hemorrhage of the mucosa of the gastrointestinal tract, and petechial hemorrhages of the surface of the liver and brain.[96] Histopathological changes include centrilobular necrosis of the liver with vacuolar degeneration of the hepatocytes and dilation of central veins, desquamation of the epithelium of the bronchioles, pulmonary edema, and focal necrosis of the myocardium including contraction band necrosis, pyknosis of cardiac myocytes, and coagulation necrosis.[97,98] During postmortem examination of patients

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. dying from phosphide poisoning, an intense garlic-like odor may emanate from the body, particularly following opening of the stomach.[90]

CLINICAL RESPONSE

The signs and symptoms of phosphine poisoning are nonspecific; onset of toxicity depends on the route of exposure and the dose. Following inhalation, symptoms include immediate onset of dyspnea and airway irritation along with dizziness, weakness, headache, and ataxia. The ingestion of metal phosphides (e.g., aluminum phosphide tablets) results in the release of phosphine gas in the stomach and a slightly more delayed onset than inhalation. Exposures to phosphine gas cause severe gastrointestinal tract symptoms as well as respiratory, cardiovascular, and secondary central nervous system effects. Early symptoms of phosphine poisoning include epigastric pain, nausea, vomiting, fatigue, sweating, palpitations, cough, and headaches. These patients initially are oriented, anxious, and agitated, occasionally with the smell of garlic on their breath.[99] These symptoms may develop as soon as 5–10 minutes after the ingestion of metal phosphides. Most fatalities result from cardiovascular collapse soon after ingestion and, less often, inhalation;[100] case reports associate the intentional ingestion of aluminum phosphide with ischemia, myocardial infarction, ventricular dysrhythmias, and congestive heart failure.[101] Clinical manifestations of more serious exposure to phosphine include dyspnea, paresthesias, jaundice, ataxia, diplopia, intention tremor, dysrhythmias, and myocardial dysfunction.[102,103] In severe cases, coma, convulsions, hypotension, metabolic acidosis, tetany, hepatorenal failure, and pulmonary edema develop.[104,105] The ingestion of aluminum phosphide tablets may cause serious long-term esophageal injuries including esophageal strictures and tracheoesophageal fistulas.[106] In patients with phosphide-induced esophageal strictures, dysphagia develops within 2–8 weeks after exposure; patients unresponsive to endoscopic dilation require surgical intervention to relieve the strictures.[107] Unlike arsine gas, phosphine gas rarely produces hemolytic anemia.[99]

DIAGNOSTIC TESTING

SI Conversion Units

1 ppm (25°C) = 1.39 mg/m^3
1 mg/m^3 = 0.719 ppm

Analytical Methods

Techniques to detect and quantitate phosphine gas include headspace/gas chromatography with nitrogen phosphorous detection[86] and headspace gas chromatography/mass spectrometry.[108] The limit of quantitation for the former method is 2 μg/kg.[109] Methods to quantitate reduced phosphorus compounds (phosphite, hypophosphite, phosphine) include ion chromatography, spectrophotometric analysis in flow injection systems, and ^{31}P NMR with the former being the most selective.[110]

Biomarkers

There are no well-validated blood or urine biomarkers of phosphine poisoning. The presence of detectable amounts of phosphine following poisoning by aluminum phosphine is variable. A case series of aluminum phosphide poisoning was detected significantly higher ($P < 0.001$) blood phosphine concentrations in 30 patients with severe toxicity (i.e., shock) than the group with mild toxicity (i.e., occasional vomiting without vital sign abnormalities) as measured by colorimetry.[111] Typically, phosphine concentrations in blood and urine are not detectable, but phosphine is usually detectable in the stomach and small intestine.[108] In these cases, elevated concentrations of phosphorus and aluminum usually occur in the blood and liver, when compared with normative values.[109]

Abnormalities

Liver failure (elevated serum aminotransferases, hypoprothrombinemia, hypoglycemia, hyperbilirubinemia), acute pancreatitis,[48,49] kidney failure (elevated BUN/creatinine, urinary casts, albumin, red blood cells, amino acids, bile pigments), and abnormal blood chemistries (hypoglycemia, leukopenia or leukocytosis, lymphocytosis, anemia or polycythemia, hypocalcemia, hypo- or hyperphosphatemia) may result from phosphine intoxication. Exposure to phosphine gas does not typically cause methemoglobinemia or hemolysis.

Electrocardiographic changes associated with the intentional ingestion of aluminum phosphide are highly variable; abnormalities include ischemia (T wave inversions, ST-segment elevation/depression), conduction disturbances, and dysrhythmias.[112] In a study of 30 intensive care patients with severe aluminum phosphide poisoning, ventricular fibrillation occurred in 23.3%, symptomatic ventricular tachycardia in 40% of cases,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and atrial flutter/fibrillation cases in 20%.[113] Approximately 47% of these patients also had supraventricular tachycardias. The electrocardiogram may show changes suggestive of acute myocardial infarction, nonspecific ST–T wave changes, QT prolongation, heart block, sinus bradycardia or tachycardia, atrial fibrillation, or ventricular dysrhythmias (ventricular tachycardia, ventricular fibrillation).[114] Rare case reports associate aluminum phosphide poisoning with methemoglobinemia, particularly in severely intoxicated patients.[115] Zinc is a potentially radiopaque material; the presence of radiopaque material after the ingestion of zinc phosphide suggests serious ingestion.[116]

HEALTH SURVEILLANCE

The recommended WHO/FAO level for phosphine in food is 0.1 mg PH_3/kg for raw cereal and 0.01 mg PH_3/kg for other food products. Table 23.6 lists some guidelines and regulations for exposure to phosphine gas.

TREATMENT

Stabilization

Phosphine gas is a multisystem poison that may cause cardiopulmonary collapse soon after exposure.[117] The adequacy of oxygenation, ventilation, and circulation should be evaluated quickly. Patients should be removed from further phosphine exposure; contaminated skin should be washed thoroughly with soap and water after the removal of contaminated clothes. Health care providers may require personal protection measures (rubber gloves, full face masks) during decontamination and intubation. Symptomatic patients should have intravenous lines and fluid resuscitation along with monitoring for respiratory depression, cardiac dysrhythmias, and hypoglycemia. Patients with altered consciousness may require respiratory support (supplemental oxygen, assisted ventilation). There are no antidotes for phosphine exposure.

TABLE 23.6. Guidelines and regulations for exposure to phosphine gas.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	0.3 ppm
NIOSH	
REL–TWA (10-hour)	0.3 ppm
REL–STEL (15-minute)	1 ppm
IDLH	50 ppm
ACGIH	
TLV–TWA (8-hour)	0.05 ppm
TLV–Ceiling (15-minute)	0.15 ppm

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure level/limit; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average.

Decontamination

Emesis is not a typically recommended option because of the risk of rapid loss of consciousness, gastrointestinal irritation, and aspiration. The role of activated charcoal has not been defined in this setting. There are inadequate clinical data to recommend any decontamination measures.

Contaminated skin should be washed thoroughly; health workers should wear gloves and carefully wash off all phosphorous-containing vomitus or stools. Nausea, vomiting, and lightheadedness may occur in health workers exposed to phosphine gas released from residuals stored in the bodies of patients dying of phosphine poisoning.[118] Consequently, these fluids should be handled as hazardous materials and double-bagged.

Elimination Enhancement

Hemodialysis is recommended only if renal failure develops.

Antidotes

There are no antidotes for phosphine gas toxicity. Experimental therapy for phosphine poisoning includes the use of *N*-acetylcysteine, pralidoxime, hyperinsulinemia with hyperventilation, and trimetazidine for dysrhythmias; however, there are few clinical data to recommend any of these potential therapies.[89] A prospective, open-label pilot study of 60 patients over the age of 13 years in a north Indian tertiary care hospital suggested the addition of glucose–insulin–potassium infusions to standard supportive care for aluminum phosphide poisoning improved outcomes (↓ in-hospital case fatality, ↓ requirement for mechanical ventilation).[119] The authors opined that multicenter, double-blinded clinical trials are necessary to confirm the benefit of glucose–insulin–potassium infusions for aluminum phosphide poisoning. The presence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. cyanosis unresponsive to oxygen therapy suggests methemoglobinemia; the need for methylene blue will be determined by cooximetry and the methemoglobin concentration.

Supportive Care

1. Admit all symptomatic patients to an intensive care setting for a minimum of 72-hours of observation. Patients who remain asymptomatic 6 hours after ingestion may be discharged from the ED with a close follow-up established.[53]
2. Monitor for hypoglycemia, hypomagnesemia, dysrhythmias, hypoxia, metabolic acidosis, hyperkalemia, rhabdomyolysis, and renal failure. Poor prognostic signs include metabolic acidosis (pH <7.0), low serum bicarbonate, and ventricular dysrhythmias.[120]
3. Replace fluids/electrolytes. Watch for the development of hypocalcemia and hypomagnesemia. Although earlier studies suggested intravenous magnesium sulfate (i.e., 2 g over 30 minutes followed by 5 g over 12 hours) reduced mortality from phosphine poisoning,[121] a controlled study did not demonstrate the ability of intravenous magnesium sulfate to reduce mortality.[122] Furthermore, there was no correlation between serum magnesium concentrations and the severity of the poisoning.
4. Follow blood chemistries (calcium, phosphorus, glucose, prothrombin time, CBC, creatinine) and hepatorenal function at least daily until stabilized.
5. Before discharge, patients with dysphagia should undergo barium swallow and esophagogastroduodenoscopy to detect esophageal complications secondary to the corrosive effects of phosphine gas.
6. Extracorporeal membrane oxygenation is a potential bridge therapy for patients with intractable cardiorespiratory failure from phosphide poisoning, when this therapy is available and the patient is not responding to conventual treatment.[123] Complications include thrombocytopenia, bleeding from the cannulation site, and dysrhythmias.
7. Zinc phosphide poisoning may cause acute liver failure. In a study of 41 patients with acute liver failure primarily (93%) from ingesting zinc phosphide, the best prognostic indicators for the need for a liver transplant included a MELD (Model for End-Stage Liver Disease) score of 36 (sensitivity, 86%; specificity, 90%) and the presence of encephalopathy with INR ≥6 (sensitivity, 100%; specificity, 83%).[93]

Chapter 24

PLATINUM AND RELATED METALS

PLATINUM

PHYSIOCHEMICAL PROPERTIES

Platinum is a member of Group 10 (Group VIII) metals that include palladium and nickel. The platinum group metals include platinum, palladium, as are iridium, osmium, rhodium, and ruthenium. These metals have useful catalytic properties and high resistance to heat. Platinum occurs most commonly in the divalent (Pt^{+2}) and tetravalent (Pt^{+4}) valences combined with various halogens, sulfurs, and hydroxides. Metallic platinum (Pt^0) is the thermodynamically favored oxidation state for platinum. Mild reducing agents can convert tetravalent and divalent platinum to the metallic form; however, the conversion of Pt^0 to platinum salts requires extremely potent oxidants and acids (e.g., a mixture of nitric and hydrochloric acid, aqua regia).[1] Pentavalent and hexavalent platinum compounds (e.g., platinum hexafluoride) are rare because they are highly oxidizing agents that are unstable in air and water. The reduction of platinum in an aqueous solution produces a black powder (platinum black).

Platinum is a silvery-white, malleable, radiopaque, substance that belongs to the noble metal group characterized by high resistance to corrosion. Platinum occurs naturally in three approximately equally occurring isotopes (^{194}Pt, ^{195}Pt, ^{196}Pt). Although metallic platinum and platinum oxides are water-insoluble and *cis*-diamminedichloroplatinum (cisplatin) is only slightly water-soluble, many of the halogen and nitrogen complexes of platinum are water-soluble including most of the complex chloroplatinate salts. Table 24.1 lists some identifying information and physical properties of platinum and platinum compounds.

EXPOSURE

Uses

Valuable industrial properties of platinum include resistance to chemical corrosion over a wide range of temperatures, high tensile strength (particularly in alloys), good ductility (i.e., ability to form long, thin wires), excellent catalytic properties (i.e., along with palladium and rhodium), and high melting point. Platinum and its alloys appear in jewelry, the chemical and electrical industries, dentistry, and fiberglass production.[3] Platinum and platinum-rhodium alloys are useful for thermoelectrical applications (train gauges, thermocouples), electric contacts for relays, printed circuits, and switch gears. Complex platinum salts are catalysts in the preparation of sulfuric acid in the petroleum and pharmaceutical industries. Potassium tetrachloroplatinate is a soluble platinum salt used in developing photography paper as a toner. One of the major uses of platinum in the petroleum industry is catalytic upgrading (naphtha-reforming) to increase the octane rating of gasoline. Cisplatin (*cis*-diamminedichloroplatinum, *cis*-dichlorodiammine platinum, DDP), carboplatin, and oxaliplatin are platinum-based chemotherapeutic agents administered for the treatment of a variety of solid tumors. These indications include testicular, ovarian,

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.
[a] Decomposition; [b] Cisplatin; [c] Crystal or powder; [d] Also forms a yellow powder.

bladder, head and neck, small cell lung, prostate, and thyroid tumors that are sensitive to these drugs and do not respond to standard chemotherapy.[4] Serious adverse effects (renal failure, emesis, myelosuppression) limit the use of this chemotherapeutic agent.

Catalytic Converters

Because of the extensive use of platinum in vehicle exhaust catalysts since the mid-1970s, the automobile industry now consumes more platinum than the chemical and petroleum industries. The history of catalytic exhaust converters involves the following four main generations: 1) 1976–1979, 2-way platinum/palladium converters; 2) 1970–1986, 3-way catalysts containing platinum, palladium, and rhodium; 3) 1986–1992, 3-way converters using primarily platinum and rhodium; and 4) 1992–mid-1990s, 3-way palladium-rich converters. These catalysts convert carbon monoxide, nitrogen oxides, and hydrocarbons into carbon dioxide, nitrogen, and water, respectively. Typically, catalytic converters now contain thin layers (100–200 μm) of platinum and palladium in a ratio of ~5:2 overlying a supporting structure composed of porous, honeycombed ceramic material (aluminum, manganese oxide, silicon). This honeycomb structure contains about 400 channels/square inch covered by a washcoat consisting of Al_2O_3 and base metal oxides. The noble metals (platinum, palladium, rhodium) are impregnated on the washcoat; variations in the concentrations and combinations of these noble metals with base metals in the catalysts allow a wide range of performance characteristics necessary for specific vehicle models to meet applicable standards. Hence, the ratio of individual noble metals in catalytic converters varies between different countries. Other applications of the technology used in platinum oxidation catalysts include the reduction of trichloroethylene to ethane in water and the reduction of the emission of CO and hydrocarbons from large gas turbines.[5]

Silicone Implants

Silicone breast implants consist of silicone gel surrounded by a thin silicone elastomeric shell reinforced by hydrophobically modified amorphous silica. The shell comprises ~2–15% of the total weight of the implant.[6] Platinum (i.e., platinum-cured gel or liquid silicone rubber) is part of one of three broad categories of manufacturing processes used to produce silicone implants; the other two categories include room-temperature vulcanized rubber and heat/gum-based peroxide-cured (i.e., heat-cured). Design changes occurred over several generations of silicone breast implants to reduce the migration of the gel into breast tissue. Karstedt's catalyst is the organosoluble Pt^0 complex formed by the reduction of the tetravalent compound, chloroplatinic acid (H_2PtCl_6); this catalyst replaced Speier's catalyst [Pt^{4+}] as the most common catalyst used to cure silicone elastomers including silicone breast implants.[1] Cross-linking of the silicone elastomers results from platinum-catalyzed hydrosilylation (i.e., the addition of Si–H residues across π-bonds). The cross-linking changes the physical properties of the silicone polymers and increases their viscosity, cohesiveness, and ability to withstand degradation by solvents. After curing, almost all of the platinum catalyst is transformed into metal [Pt^0] nanoparticles. The risk of adverse effects from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the relatively low metallic platinum concentrations diffusing from silicone implants is very small.[6]

Production Processes

Platinum occurs naturally as Pt^0 in alluvial deposits in Alaska, Columbia, and Russia or in copper, iron, or nickel sulfide ores in Canada, Russia, and the Bushveld Complex in South Africa. These ores typically contain iridium, osmium, and/or palladium. The content of common platinum-containing minerals (e.g., braggite (Pt, Pd, Ni)S, cooperite (Pt, Pd)S, sperrylite ($PtAs_2$)) ranges from 1–500 mg Pt/kg.[2] Sources of platinum for refining include dredging of native placer platinum, platinum recycling, and mining of copper and nickel sulfide ores (i.e., as a byproduct). The isolation of platinum from ores occurs during the extraction of a concentrate containing the ore or the refining of the concentrate to separate platinum from other members of the platinum group. The latter process involves complex chemical techniques (e.g., precipitating crystallization, liquid–liquid extraction).[2] This purification process includes the dissolution of platinum with aqua regia (hydrochloric and nitric acids) or Cl_2/HCl and the addition of ammonium chloride to precipitate platinum as ammonium hexachloroplatinate $(NH_4)_2(PtCl_6)$. The Bushveld Complex in South Africa contains a variety of metals (gold, copper, nickel, chromium, selenium, cobalt, arsenic, zinc, vanadium pentoxide) in addition to platinum group metals and crystalline silica. Histological examination of 3,863 South African platinum miners revealed the presence of silicosis in 2.2% of the miners (n = 85), suggesting co-exposure to silica during platinum-mining processes may be sufficient to produce silicosis.[7] Recycling of platinum involves similar wet-chemical processes. The complex halogenated platinum salts are part of the manufacturing process for the valuable industrial catalyst, platinum sponge. Besides platinum refineries, occupational platinum exposures occur in recycling plants, automotive catalyst production plants, and metal-coating facilities; however, relatively high platinum exposures typically occur in only a few workers from these facilities.

Sources

Air

The primary form of platinum in air is elemental or oxidic compounds. Automobile catalytic converters are mobile emission sources that release noble metal catalysts (platinum, palladium, rhodium) into the air, mostly in the form of particulates. Data on the amount released into air are limited with current studies suggesting a wide variation (i.e., one to two orders of magnitude) in the amount of noble metals released from current catalytic converters.[8] A study of the older pellet-type catalyst revealed an emission rate of 800–1,200 ng Pt/km during simulated low-speed driving and 1,900 ng Pt/km during high-speed driving.[9] Newer cars in the United States and all cars in Europe use the newer monolithic catalysts. Limited studies on the exhaust from these catalysts indicate Pt emission from catalytic converters is several orders of magnitude below (i.e., ~10–20 ng Pt/m^3) the platinum levels released by pellet-type catalysts with the highest emissions occurring during initial use.[2] In a European study using a light-duty driving cycle, gasoline catalysts released 6–8 ng Pt/km after 30,000 km compared with 100 ng Pt/km during initial use.[10] The vast majority of platinum is released in the metallic form (0 valence); however, the amount of platinum present as soluble salts varies with the type of catalytic converter and mileage. Based on laboratory testing of emissions from catalytic converters analyzed new and after a light-duty vehicle aging cycle simulating urban driving, the soluble fraction of platinum in exhaust fumes is <10% of the total amount of platinum released.[8]

The platinum concentration in ambient air and platinum deposition on soil near roads increased with the introduction of catalytic converters depending on the most common type of noble metal catalytic converters in use, car speed, and traffic density;[11] however, the platinum concentration in air usually remains very low (few pg/m^3), even near freeways.[12] As with other platinum group elements, the distribution of platinum in fractionated airborne dust is heterogeneous with ~75% of platinum present in coarse dust (>2 μm).[13] Consequently, the total platinum concentration in air samples also depends on the sampling technique. In a German study of air samples (PM <22 μm) near a major highway, the average total airborne platinum concentration was 23 pg/m^3 (range, 2.4–55.4 pg/m^3) compared with a mean of 5.1 pg/m^3 (range, 0.4–26.6 pg/m^3) in a nonurban area.[14] In a German study during the early 1990s, the platinum concentration in small particles (0.5–8 μm) ranged from 0.02–5.1 pg/m^3 in urban air compared with 30 pg/m^3 near a highway.[15] The portion of soluble platinum in the airborne particulate matter ranged from 30–43%. The mean platinum concentrations in PM10 particles collected in Rome on a tram in moderate-high car traffic density were 14.1 ± 10.8 pg/m^3 (range, 4.07–40.1 pg/m^3).[16] The distribution of platinum in airborne particulate matter is probably not homogeneous based on the presence of higher platinum

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. concentrations in smaller particles in European studies of particulates ranging from <0.39–65.3 μm.[17]

Soil

The average platinum concentration in the earth's crust and upper mantle (lithosphere) is ~1–5 μg/kg (ppb).[18] The platinum concentration in soil is highly dependent on traffic density, wind direction, distance from the road, and the most common type of catalytic converter (e.g., pellet type releases more platinum than monolithic catalysts) with platinum concentrations typically ranging from background to several hundred ppb.[18] A study of dust near a heavily traveled freeway demonstrated platinum concentrations in dust samples of 680 μg Pt/kg dry weight (680 ppb) near the edge of the freeway, with the concentrations decreasing to ~100 ppb 34 m from the freeway edge.[19]

Water

In contrast to the relatively recent increase in the lead content in sediment, a study of platinum concentrations in the sediment of Lake Michigan indicated platinum concentrations (0.3–0.43 μg Pt/kg dry weight) have remained relatively constant over the last 50 years.[20] The platinum concentration in seawater ranges from ~100–250 pg/L.[21]

Diet

The estimated daily adult intake of platinum from the UK diet is <2.3 μg[22] based on the 2006 UK Total Diet Study compared with 1.44 μg for 21 residents of Sydney, Australia, as measured by adsorptive voltammetry.[23] Liver contains a relatively high platinum concentration compared with dairy products.[24] In the Australian study, the platinum concentration (fresh weight) was highest in liver (8.11 ppb), breakfast biscuit (4.98 ppb), beefsteak (3.67 ppb), and eggs (3.54 ppb), whereas the lowest Pt concentration occurred in whole milk (0.13 ppb), grapes (0.16 ppb), and carrots (0.27 ppb). Additionally, food-grade wrapping materials may contain platinum.

Devices

Platinum and/or platinum alloys are constituents of medical devices (e.g., pacemaker leads, vagus nerve stimulators, radiopaque markers in catheters), silicone breast implants, and dental alloys. Silicon elastomer shells contain 6–8 μg platinum/g silicone, whereas the platinum content in silicone gels is somewhat less (5 μg/g gel) as a result of lower crosslink densities.[6,25] However, the total amount of platinum in breast implants depends on the specific manufacturing process and the total size of the implant with platinum contents as low as 0.1 μg/g gel. Consequently, the total weight of platinum in a silicone implant may range from ~0.1–10 mg.[1] Studies on a few women demonstrated small amounts of platinum (ppb range) in a breast implant may diffuse through the shell into the surrounding tissues in some, but not all, women;[26,27] however, serious methodological limitations (lack of adequate control tissue, chemical matrix effects, very small sample size) and inconsistent data restrict conclusions regarding the leakage rate of platinum into the surrounding tissues. In a study of breast tissue from three women at the time of explantation (7, 8, 16 years after implant) and three women without silicone breast implants, the platinum concentration was 90 ppb (ng/g) in fatty tissue surrounding one implant with evidence of disruption of the shell, but not in muscle tissue; the platinum concentration in the fibrin layer of another implant was 25 ppb as measured by inductively coupled plasma/high-resolution isotope dilution/mass spectrometry. Platinum was not detectable (limit of detection, 2–6 ppb) in fatty or muscle tissue of a woman explanted after 8 years, whereas two of the controls without silicone breast implants had detectable platinum concentrations (i.e., 0.3 ppb, 1 ppb). Current evidence indicates that platinum in silicone breast implants is present as metallic platinum (Pt^0). Although some authors claim platinum occurs in higher oxidation states,[28] inadequate experimental detail and methodological limitations (lack of standards, separation artifacts) cause substantial uncertainty about the validity of these studies. The transformation of clinically significant amounts of metallic platinum in silicone breast implants to soluble platinum salts is unlikely.[6]

ENVIRONMENTAL FATE

Platinum is a rare metal; most commercial operations avoid significant losses of this precious metal. Furthermore, the release of platinum into the environment is limited by the fact that metallic platinum and platinum oxides are practically insoluble, resistant to most chemical reactions, and volatilize poorly. However, analysis of recent snow and ancient ice in central Greenland suggests that noble metals in catalytic converter exhausts may spread substantial distances from urban sources via the troposphere of the Northern Hemisphere.[29] Prior to the use of catalytic converters in the mid-1970s, the platinum concentration in the central Greenland snow was 6-fold (~0.06 pg/g) higher than the platinum

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

concentrations in ancient ice from 7 millennia ago. By the mid-1990s, the platinum concentration in recent snow had increased to 40-fold greater than in ancient ice. The platinum/rhodium mass ratio in recent snow was similar to the mass ratio of these two metals in newer catalytic converters.

Increasing platinum concentrations in water ecosystems including sediments also suggest that platinum is mobile in the environment to some degree as a result of the release of platinum as finely dispersed particles in the nanometer range.[30] Although initially released from catalytic converters as insoluble metallic platinum or platinum oxides, at least a part of the emitted particles are probably soluble as a result of contact with various compounds in the environment.[18] The mobility of platinum in water and soil depends on pH, redox potential, chloride concentration, and type of primary rock.[2] In general, platinum is mobile primarily in highly acidic environments containing high chloride concentrations.[31] Plants may absorb platinum from the environment, but the bioavailability of platinum depends on the solubility of the platinum compound.[32]

DOSE EFFECT

The intentional ingestion of 600 mg potassium tetrachloroplatinate (K_2PtCl_6) by a 31-year-old man was associated with acute oliguric renal failure, metabolic acidosis, fever, muscle cramps, rhabdomyolysis, gastroenteritis, and mild hepatitis.[33] Signs and symptoms of toxicity resolved within 6 days. The ingestion of 6 grains (389 mg) of K_2PtCl_6 by an infant in an 1896 case report attributed gastroenteritis, dehydration, cardiovascular collapse, and death to the ingestion.[34]

The usual dosage of cisplatin is 50–100 mg cisplatin (0.65 mg Pt)/m^2 body surface area daily. Immediate hydration ameliorates the toxicity of cisplatin. The infusion of 200 mg cisplatin/m^2 over 8 hours with hydration was associated with emesis, acute renal failure, and myelosuppression that resolved.[35] Severe emesis, renal failure, deafness, myelosuppression, seizures, hallucinations, and loss of vision developed in a 68-year-old patient after receiving a single dose of 280 mg cisplatin/m^2 without hydration.[36] After a kidney transplant, the patient survived with some residual hearing loss. The infusion of 480 mg cisplatin/m^2 over 4 days without hydration produced irreversible renal failure along with hearing loss, dysarthria, and peripheral neuropathy.[37] The creatinine clearance 18 months after the incident was 26 mL/minute.

TOXICOKINETICS

Little human data are available on the kinetics of platinum. The estimated gastrointestinal absorption of platinum from the diet during an Australian study of 21 healthy adults was 42–60% based on the ratio of dietary intake/urine Pt excretion; the actual absorption was not directly measured. These values are substantially higher than the calculated Pt absorption in rodents. Animal studies indicate little absorption of metallic platinum (^{191}Pt) or simple platinum salts ($^{191}Pt(SO_4)_2$, $^{191}PtO_2$, $^{191}PtCl_4$) in the lungs or gastrointestinal tract. The gastrointestinal tract absorbs only minute amounts of platinum oxide despite the administration of large amounts (4.3 g Pt/4-week period) to rats.[38] The principal sites of distribution are the kidney, liver, spleen, and adrenals. The highest level of ^{191}Pt appears in the kidney, where excretion of the absorbed platinum occurs. For both simple platinum salts and cisplatin complexes, an initial rapid clearance phase ($t_{1/2}$ = 24 hours) precedes a slower secondary elimination phase ($t_{1/2}$ = 8–12 days).[39,40] The uptake of platinum by erythrocytes is rapid following cisplatin infusion; these studies indicate that cisplatin may reduce the life of erythrocytes, resulting in prolonged excretion of platinum. Two male volunteers with urine platinum concentrations near control values for the general population handled platinum salts (dry $(NH_4)PtCl_6$) powder for 4 hours.[41] The mean air platinum concentrations in personal air samples were 0.15 and 1.7 μg/m^3. Based on urine samples obtained daily for 4 days and weekly samples for 6 months, the initial platinum elimination half-life was ~50 hours (95% CI: 36–66 hours) as measured by UV photolysis followed by absorptive voltammetry. The urinary excretion pattern suggested a longer terminal half-life (e.g., 24 days). The diffusion of platinum across the placenta in rats is limited.[42]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Hypersensitivity

Adverse reactions in platinum refinery workers result primarily from the potent sensitizing properties of chlorinated platinum salts including ammonium tetrachloroplatinate [$(NH_4)_2PtCl_4$], ammonium hexachloroplatinate [$(NH_4)_2PtCl_6$], and hexachloroplatinic acid ($H_2(PtCl_6)$.[43] These low-molecular-weight platinum compounds induce type I immediate hypersensitivity reactions, particularly following exposure to complex

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

platinum salts with high chloride content.[44] Platinum salts with relatively low molecular mass are haptens that bind to serum proteins forming complete antigens, whereas complex platinum salts are complete antigens without any binding. The allergic response usually increases with increasing numbers of chlorine atoms.[2]

Cohort studies indicate smoking and intensity of exposure to platinum salts are risk factors for conversion to positive platinum skin prick tests. In a 5-year prospective cohort study of 159 catalyst production workers, the relative risk of skin prick conversion was 3.9 (95% CI: 1.6–9.7).[45] Atopy and bronchial hyperresponsiveness were not risk factors in this study. The incidence rate of skin prick test conversion was 5.9/100 person-years in new employees compared with 2.1/100 person-years in workers employed at the time of the initial survey. In general, this incidence rate is lower in catalyst production plants than in precious-metal refineries, probably as a result of lower platinum exposure in catalyst production plants.[46] Metallic platinum and platinum oxides are relatively nonreactive with very low sensitization potential. The term platinosis is an old term applied to the spectrum of allergic reactions (asthma, rhinorrhea, dermatitis) associated with dermal or pulmonary exposure to soluble, halogenated platinum salts;[47,48] however, the term is inappropriate because the condition is neither fibrotic nor chronic like other pneumoconioses.

Cisplatin Toxicity

Cisplatin probably produces cytotoxicity by the formation of intracellular, intra-strand cross-links (DNA adducts) that cause cell-cycle arrest and apoptosis.[49] Cisplatin toxicity produces gastrointestinal upset, nephrotoxicity, myelosuppression, ototoxicity, peripheral neuropathy, allergic reactions, hypomagnesemia, and rarely cardiotoxicity. Cisplatin can mobilize body lead stores and increase renal lead accumulation that theoretically enhances cisplatin nephrotoxicity.[50]

CLINICAL RESPONSE

Acute Toxicity

The acute toxicity of platinum salts depends on solubility. Insoluble compounds (e.g., metallic platinum, $PtCl_2$, PtO_2) possess extremely low toxicity. Toxicity secondary to exposure to soluble platinum salts is also rare, but may be serious. The intentional ingestion of a photographic toning solution containing potassium tetrachloroplatinate (CAS RN: 10025-99-7, potassium chloroplatinite) by a 31-year-old man caused gastroenteritis, dehydration, acute oliguric renal failure, fever, and myalgias that resolved over 6 days.[33]

Environmental Exposure

Metallic platinum is biologically inert and nonallergenic.[2] Because platinum emitted from catalytic converters is released mostly in the form of metallic platinum rather than halogenated compounds, the risk of sensitization in the general population is probably very low; there is no clear evidence at the present time that environmental exposure to platinum or other members of the platinum group metals causes asthma or other hypersensitivity reactions in the general population.[51] Smoking and intense platinum exposures are potential predisposing factors for the development of platinum hypersensitivity,[52] whereas nonspecific airway hyperreactivity and atopy are not clearly related to an increased risk of platinum hypersensitivity.[53]

Occupational Exposure

Exposure to potential platinum sensitizers depends on the industry type, solubility of the metal salts in workplace air, and tasks/location of the exposure.[54] The most important medical effect of platinum exposure in the workplace is an IgE-mediated, type I allergic reaction to respiratory sensitization with hexachloroplatinate and tetrachloroplatinate salts being the most potent sensitizers, particularly in smoking workers with atopy and recent platinum exposure.[55] Following sensitization, wheezing, tearing, eczematous and urticarial skin lesions, inflammation of the mucous membranes, tightness of the chest, dyspnea, and cough may develop following occupational exposure to complex platinum salts.[56] Symptoms usually abate soon after terminating exposure unless sensitized workers remain exposed to platinum salts. Platinum skin sensitivity and airway hyperresponsiveness may persist for years after the termination of exposure to platinum salts.[57] In a nested case-control study of 14 workers at a catalyst production plant converting positive skin prick tests to platinum salts during the 5-year study, symptoms of occasional dyspnea or wheezing persisted in four subjects following cessation of platinum exposure.[58] Symptoms were not accompanied by changes in FEV_1 or bronchial responsiveness to histamine. Nasal and conjunctival irritation, sore throat, and rhinitis may also occur. Signs of platinum dermatitis include erythema, urticaria, vesiculation, and fissures. In a laboratory refining platinum

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

during the 1940s, the latency period for the development of asthma ranged from a few months to 6 years.[59,60] Particle concentrations in the ambient air in these work environments ranged up to 1,700 μg/m^3. The risk of developing hypersensitivity to platinum salts correlates with the severity of exposure because the highest rates of sensitization occur in workers with the greatest exposure to platinum salts. Cross-sectional studies of workers exposed to platinum indicate that platinum salts' sensitization is associated with cigarette smoking but not with atopic tendencies as defined by sensitivity to common aeroallergens.[61]

In a case series of six catalyst production operators exposed to high concentrations of platinum salts, three workers developed hypersensitivity to platinum salts over a period of 5 years.[62]

Cisplatin Toxicity

Adverse reactions to the use of cisplatin include nausea and vomiting in almost all patients, but diarrhea, metallic taste, and mucositis are less common. Protracted vomiting may begin within the first 24 hours and persist for 2 weeks. Nephrotoxicity develops in 2/3 of patients, manifested by acute tubular necrosis of the distal convoluted tubules;[63] the onset of acute oliguric or nonoliguric renal dysfunction occurs within 2–6 days after a cisplatin overdose.[64] Large single doses with vigorous prehydration and the use of osmotic diuretics help reduce, but do not eliminate, renal toxicity. Ototoxicity often is nonreversible, characterized by tinnitus and hearing loss in the high ranges. Peripheral neuropathies, memory loss, and intention tremor may occur. Other complications reported following cisplatin overdose include seizures, hallucinations, visual loss, severe emesis, and mild hepatic dysfunction. Rare case reports associate allergic reactions, dermatitis and anaphylaxis, with the therapeutic use of cisplatin.[65] Cardiomyopathy is a rare complication of cisplatin toxicity.

CARCINOGENICITY

Little data exist on the carcinogenicity of metallic platinum or platinum salt. Neither the IARC nor the US NTP lists these compounds as suspected carcinogens. The IARC does list cisplatin as a probable human carcinogen (Group 2A) with sufficient evidence in animals and inadequate data in humans.[66] Although cisplatin is a potent carcinogen in experimental animal studies, the issue of whether patients treated with cisplatin develop secondary cancers remains unresolved. A review of the literature indicated that most of the secondary cancers in these patients are acute nonlymphocytic leukemias or myelodysplasia; however, most of these cases do not directly implicate cisplatin alone or suggest that the combination of chemotherapeutic drugs is leukemogenic in humans.[67]

DIAGNOSTIC TESTING

SI Conversion Units

1 ppm = 7.979 mg/m^3
1 ng/mL = 5.126 nmol/L

Analytical Methods

The use of electrothermal atomic absorption spectrometry (ETAAS, single-element mode), absorptive voltammetry, and neutron activation analysis allows the detection of platinum and palladium with sufficient sensitivity in biological samples,[68] whereas X-ray fluorescence spectrometry and flameless atomic absorption spectrometry lack sufficient sensitivity in the sub-ppm range.[69] For quantitation in the ppb range necessary for environmental samples, the preferred multielement instrumental techniques include inductively coupled plasma/optical emission spectrometry (ICP/OES; LOD, 10 μg/L) and inductively coupled plasma/mass spectrometry (ICP/MS; LOD, <1 μg/L). The lower limit of quantitation for platinum in plasma using high-pressure decomposition and absorptive voltammetry was 6 pg/g compared with ~35 μg/g for flameless atomic absorption spectrophotometry.[70]

Quantitation of platinum group metals in air and blood is complicated by the low sensitivity (ng/L) required and the presence of interfering matrix constituents. Although inductively coupled plasma/mass spectrometry has sufficient sensitivity, sufficiently high spectral resolution, matrix separation, or mathematical correction is necessary to avoid spectral interference from other metals (e.g., copper, strontium, yttrium, zinc, zirconium).[71] Other sensitive methods for analyzing platinum in air samples include absorptive striping voltammetry following acid digestion in a high-pressure asher (HPA, Kuner, Rosenheim, Germany).[14] The redistribution of platinum from serum into the clotted cell mass may cause erroneously low platinum concentrations in plasma samples that are not immediately separated.[72]

Biomarkers

Blood

The median platinum concentration in whole blood samples from 18 Australian volunteers without known exposure to platinum was 0.6 µg/L (range, 0.1–2.8 µg/L) as measured by adsorptive voltammetry after dry-ashing of the blood samples in a muffle furnace.[73] In a study of 21 urban residents from Sydney, Australia, the median platinum concentration in whole blood was 0.56 µg/L (range, 0.09–1.72) with similar concentrations in 3 rural residents of Lord Howe Island, as measured by adsorptive voltammetry.[23]

The initial serum platinum concentration 12 hours after an overdose of 600 mg potassium tetrachloroplatinate was 2,450 µg/L; the patient developed oliguric renal failure, metabolic acidosis, rhabdomyolysis, myalgias, gastroenteritis, and fever that resolved over 6 days.[33] In plasma samples from six patients, an intravenous dose of 100 mg cisplatin produced an approximate mean platinum concentration of 2,500 µg/L 1 hour after administration, decreasing to 1,600 µg/L at 6 hours post-administration.[74]

Urine

In samples from 178 German workers without known exposure to platinum, the median urine platinum concentration was 4.3 ng/g creatinine with a maximum value of 45 ng/g creatinine, as measured by adsorptive voltammetry (limit of detection, 1 ng/L).[75] The platinum concentration was <20 ng/g creatinine in 96% of the urine samples; all participants with urine platinum concentrations exceeding this value had gold/platinum dental alloys. Studies of urine platinum concentrations in samples from populations outside Europe demonstrated higher median platinum concentrations. The median urine platinum concentration from 21 residents of Sydney, Australia, without known occupational exposure to platinum was 230 ng/g creatinine (180 ng/L) with a range of 30–820 ng/g creatinine as determined by adsorptive voltammetry.[23] In comparison, the median urine platinum concentration in a convenience sample of 496 participants in the third US National Health and Nutrition Examination Survey (NHANES III, 1988–1994) was 900 ng/g creatinine (1,190 ng/L) with a 95% upper limit of 3,590 ng/g creatinine (4,220 ng/L), as measured by inductively coupled argon plasma/mass spectrometry (LOD, 400 ng/L).[76] Although the ages of the participants ranged from 6–88 years, the samples were not selected to represent the US population.

For the general population without occupational exposure to platinum or platinum-containing drugs, the main source of platinum exposure is dental gold/platinum alloys. In a study of urine samples from 50 subjects with gold dental restorations, the mean urinary platinum concentration was 11.9 ± 8.5 ng/g creatinine (range, 1.9–45.8 ng/g creatinine).[77] For 42 subjects in this study without gold dental restorations, the mean urinary platinum concentration was 6.2 ± 3.2 ng/g creatinine (range, 1.9–14.4 ng/g creatinine). In a pilot study of urine samples (mostly morning collections) from 27 dental technicians, 17 road construction workers, and 17 construction students (control group), the median platinum concentration of the dental technicians was 11.4 ng/L (95% upper limit, 104.8 ng/L) compared with 0.5 ng/L (95% upper limit, 4.3 ng/L) for the road construction workers and 1.2 ng/L (95% upper limit, 2.2 ng/L) for the control group as measured by sector field/inductively coupled plasma/mass spectrometry.[78] Five of the 27 dental technicians had a total of 11 noble metal fillings based on questionnaires.

Abnormalities

Mild metabolic acidosis, eosinophilia, hypophosphatemia, and leukocytosis developed following an overdose of potassium tetrachloroplatinate.[33] Skin prick tests are sensitive and specific biological markers of platinum salt sensitization, but not all cases of platinum-induced asthma will demonstrate a positive skin prick test.[44]

Abnormalities in the blood following the administration of cisplatin as an antitumor agent include metabolic acidosis, hypomagnesemia, hypocalcemia, hypophosphatemia, hypokalemia, and hyponatremia, particularly in the presence of renal tubular dysfunction. Leukopenia and thrombocytopenia (onset 6–26 days after administration) also may occur. Normocytic anemia appears in 9–40% of patients. Myelosuppression and renal failure are serious complications of a cisplatin overdose; mild liver dysfunction may also develop. Platinum is radiopaque.

HEALTH SURVEILLANCE

Environmental Monitoring

The American Conference of Governmental and Industrial Hygienists (ACGIH) TLV–TWA for platinum dust is 1 mg Pt/m^3, whereas the TLV–TWA for soluble salts of platinum is 0.002 mg Pt/m^3 measured as total platinum. The lower values for exposure to soluble platinum salts are recommended to minimize the risk of developing respiratory irritation, asthma, and skin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

sensitization.[79] There is no recommended TLV–STEL. The OSHA PEL–TWA for platinum metal dust of 1 mg Pt/m^3 was vacated by the 11th Circuit Court of Appeals 1992 decision in AFL-CIO vs. OSHA; however, the OSHA TLV–TWA and the NIOSH REL–TWA for platinum salts are the same as ACGIH.

Biological Monitoring

Although the few studies of platinum-exposed workers suggest plasma and urine concentrations are elevated when compared with unexposed workers, air platinum concentrations do not correlate closely to plasma or urine Pt concentrations. Consequently, there are no validated biomonitoring methods to assess platinum-exposed workers.

Blood

Serum platinum concentrations are neither specific nor sensitive for predicting platinum salt sensitization. Potential confounders to the interpretation of serum platinum concentrations include gold/platinum dental alloys, platinum-containing medications, exposure to insoluble platinum salts/metallic platinum (non-sensitizing), the timing of the sampling in relation to exposure, and smoking.[80] In a study of blood from pharmacists preparing cisplatin and graduate/staff nurses attending patients receiving cisplatin, the mean total platinum concentrations in whole blood samples from the three groups were 0.47 ± 0.31 ng/mL, 2.2 ± 1.7 ng/mL, and 3.8 ± 4.0 ng/mL, respectively.[81] The mean values for the nurses were higher than the unexposed control group (1.2 ± 0.69 ng/mL); however, the coefficient of variation (CV) exceeded 50% for all groups. Air monitoring data demonstrated increased platinum concentrations in ambient air. In blood samples from 11 workers with platinum exposure and positive skin tests for platinum hypersensitivity, the serum platinum concentration was above the limit of detection (100 µg/L) in 8 workers with a mean of 240 ± 100 µg/L (range, 150–440 µg/L).[46]

Urine

In a study of 161 police employees, the mean urine platinum concentrations of patrol officers and office workers were 4.45 ± 2.42 ng/L (95% upper CI: 10.1 ng/L) and 4.56 ± 2.84 ng/L (95% upper CI: 8.91 ng/L), respectively, as measured by inductively coupled plasma/mass spectrometry coupled to a pneumatic nebulizer.[82] These results between office workers and traffic officers potentially exposed to airborne platinum from automobile exhaust were not statistically different. In a study of workers at a plant producing and recycling catalytic converters, the highest platinum concentration (2.39 µg/m^3, 4.83 µg/m^3) in ambient air samples occurred in the department that coated supports with acid metal solutions.[83] The most reliable biomarker of the current platinum exposure was urine collected in the morning of the last day of the work week. The mean urine platinum concentration in workers from the coating department was 1,860 ± 1,120 ng/L compared with 5 ± 0.1 ng/L for unexposed controls. The urine platinum concentration in platinum refinery and catalyst production workers may substantially exceed (e.g., 6,000 ng/g creatinine) that of unexposed workers.[41]

Medical Surveillance

Preemployment screening includes questionnaires (respiratory disease, smoking, allergies, employment exposures) and a complete physical examination with pulmonary function tests. The use of skin prick tests and tests of bronchial reactivity is an option for workers with suspected sensitivity to platinum. The development of allergic hypersensitivity to platinum salts usually precludes continuing occupational exposure to platinum salts.

TREATMENT

Platinum Salts

The treatment of acute toxicity secondary to soluble platinum salts is supportive.

Cisplatin Toxicity

The treatment of cisplatin toxicity is primarily supportive (e.g., hydration, ondansetron, dexamethasone, lorazepam) with no specific antidotes available. Hydration within several hours following an overdose of cisplatin probably reduces the severity of the renal toxicity. Amifostine is approved by the US FDA as a protective agent in the prevention of cisplatin-induced nephrotoxicity; however, the efficacy of amifostine in reversing neurotoxicity is unproven.[84] Animal studies suggest that the administration of thio-reducing agents (*N*-acetylcysteine,[85,86] diethyldithiocarbamate,[87,88] sodium thiosulfate) may reduce the toxicity of cisplatin when administered within 1–2 hours after the overdose; clinical data to confirm experimental data are limited with some evidence for the efficacy of sodium thiosulfate.[89] The initial protective effects may not persist.[90]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Consequently, the use of these agents remains investigational including the administration of amifostine, fosfomycin, and colestipol.[89]

Hemodialysis is probably not effective for overdoses of cisplatin because cisplatin rapidly distributes to tissue receptors and binds to proteins.[35] A case report associated a reduction in the cisplatin concentration and clinical improvement following plasmapheresis, but three treatments with plasmapheresis removed only ~6 mg cisplatin compared with the initial infusion of 480 mg cisplatin.[36] This patient also received granulocyte-macrophage colony-stimulating factor (GM-CSF) to stimulate platelet production and reduce myelosuppression. A case report associated complete recovery from a cisplatin overdose of 400 mg/m^2 over 4 days with the use of 9 cycles of plasma exchanges beginning on the first day after the discovery of the overdose.[91] Complete blood count with differential, serum electrolytes, and serum creatinine/BUN should be monitored daily during acute intoxication. Baseline laboratory tests include serum hepatic aminotransferases, magnesium, calcium, phosphate, and uric acid; these tests should be repeated when abnormal.

PALLADIUM

PHYSIOCHEMICAL PROPERTIES

Palladium is a rare, steel-white, ductile metal that commonly exists in nature with other members of the Group 10 (Group VIII) platinum metal group (iridium, osmium, platinum, rhodium, ruthenium). Palladium exists in the following three oxidation states: Pd^0 (metallic), Pd^{2+}, and Pd^{4+}. This corrosion-resistant metal occurs most commonly in the divalent state (e.g., *cis*-diamminedichloropalladium, tetraamminepalladium, palladium chloride, palladium oxide, palladium acetate, palladium nitrate, hydrogen tetrachloropalladate). Tetravalent palladium is less common and more unstable than divalent palladium.[92] The water-insoluble metal forms a number of coordination and organic complexes. Palladium is soluble in aqua regia and nitric acid. Table 24.2 lists the identifying information and physical properties of elemental palladium. High surface energy and high surface area/volume ratio of palladium nanoparticles favor the use of these nanoparticles in catalyst materials.[93]

TABLE 24.2. Identifying information and physical properties of metallic palladium. (Based on Narayanan and El-Sayed).[93]

Physical Characteristic	Data
CAS RN	7440-05-3
Atomic symbol	Pd
Atomic Mass (g/mol)	106.42
Melting point (°C)	1554
Boiling point (°C)	2940
Density (g/mL)	12.02 (20°C)
Water solubility	Insoluble (25°C)
Odor threshold	Odorless

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.

EXPOSURE

Uses

The main uses of palladium are automobile catalytic converters, dental materials, and electrical equipment (e.g., diodes, integrated circuits, memory, transistors). Palladium is one of several constituents of 3-way catalytic converters for reduction of carbon monoxide, hydrocarbons, and nitrogen oxides in vehicle exhausts; the typical composition of noble metals in these converters includes 0.04% palladium, 0.08% platinum, and 0.005–0.07% rhodium.[18] In this application, palladium is less costly and more resistant to contamination by lead, phosphorus, zinc, and sulfur. Palladium is also a constituent of electrical equipment (Ag–Pd alloys for relays, switching systems, contacts), jewelry (ruthenium/platinum alloys), and dental restorations (Ag–Cu–Au alloys). Many divalent palladium compounds (e.g., chloride, nitrate, oxide salts) are catalysts in metallic palladium refining, chemical synthesis (vinyl acetate, methanol, acetaldehyde), high-antiknock-gasoline refining, photography, and electroplating. Commercial applications for palladium nanoparticles include electrocatalysis, hydrogen storage, electrochemical reactions in fuel cells, chemical sensors, production of electrical equipment, and glucose biosensors.[94]

Production Processes

Commercial palladium is mostly a by-product of nickel, platinum, or other base-metal refining. Melting of the sulfide pulp formed by the froth floatation of the crude ore produces a matte containing copper, nickel, and iron sulfides along with palladium. Acid leaching separates the nickel and copper. Selective dissolution

and precipitation or a solvent extraction process forms ammonium-chloro-complexes (e.g., chloropalladosamine, CAS RN: 14323-43-4) that decompose under heat to produce impure palladium sponge.

Sources

Air

Similar to platinum, catalytic converters are the primary source of palladium in the environment as a result of physical stress (sintering, thermal degeneration) on the washcoat part of the equipment.[95] The rate of emission depends on driving speed, type of catalyst, age of catalyst, and engine type. The palladium concentration in ambient air is usually in the low pg/m^3 range even near freeways, depending on the sampling techniques.[12] As with other platinum group elements, the distribution of palladium in fractionated airborne dust is heterogeneous; however, the fraction of palladium in fine dust (<2 μm) is relatively greater than that of platinum or rhodium. In a German study of air samples (PM <22 μm) near a major highway, the average total airborne palladium concentration was 14.7 pg/m^3 (range, <0.6–44.3 pg/m^3) compared with a mean of 2.8 pg/m^3 (range, <0.5–11.2 pg/m^3) in a nonurban area.[13] In samples of suburban air in Berlin, the palladium concentration ranged from 0.2–14.6 pg/m^3 as measured by graphite furnace atomic absorption spectrometry (GFAAS) and laser absorption fluorescence spectrometry (LAFS).[96] The mean concentration of palladium in PM_{10} particles collected on a tram in moderately high car traffic density in Rome was 58.0 ± 46.8 pg/m^3 (range, 16.8–168 pg/m^3).[16] In a study of heavy traffic sites in Goteborg, Sweden, the mean concentration of palladium in PM_{10} particles ($n = 7$) was 4.9 ± 3.1 pg/m^3 (range, 1.3–9.7 pg/m^3) compared with 14.1 pg/m^3 (range, 7.6–19.2 pg/m^3) for platinum.[97] The palladium concentration in air samples from low-traffic density urban areas was ~4–5-fold lower than samples from the high-traffic density urban areas. Based on laboratory testing of emissions from catalytic converters analyzed new and after a light-duty vehicle aging cycle simulating urban driving, the soluble palladium fraction in exhaust fumes is substantially higher than the soluble platinum fraction.[8]

Soil

The average palladium concentration in the earth's crust and upper mantle (lithosphere) is <1 μg/kg (ppb).[92] The maximum concentration of palladium in roadside dust from two major British highways during a 12-month study was <70 ppb compared with maximum values >500 ppb for platinum.[98] As the use of palladium-rich catalytic converters increases, the palladium concentration in soils near highways increases. In a study of a German highway, the mean palladium concentration (83 ppb; range, 20–191 ppb) in 23 samples of adjacent topsoil from the downwind side of the highway increased 15-fold between 1994–2004 compared with a 2-fold increase in platinum concentrations.[11] During this time interval, the rhodium concentration in topsoil samples increased by 1.6-fold.

Water

The intake of palladium from food and drinking water is small with an estimated daily dietary intake of <2 μg.[99] Surface waters typically contain palladium concentrations in the low ppb (ng/L) range. In a study of Canadian lakes and groundwater near sites with known palladium production, the palladium concentration averaged <5 ppt (ng/L) as measured by inductively coupled plasma/mass spectrometry (LOD, ~1 ppt).[100] Spring water samples in Nevada contained ~3 ppb Pd.[101]

Diet

There are few data on the intake of palladium in the diet. The estimated daily adult intake of palladium in the United Kingdom is 0.7 μg based on the 2006 UK Total Diet Study.[22] In this study, beverages, bread, miscellaneous cereals, and potatoes accounted for the largest portion of palladium in the diet, whereas the palladium content in eggs, fresh fruit, and offal was nondetectable (LOD, 0.03–0.2 μg/kg).

ENVIRONMENTAL FATE

The physiochemical properties including the thermodynamics of palladium and aqueous species suggest that palladium is mobile in air and water as hydroxide, chloride, and bisulfide complexes depending on pH, oxygen fugacity, ligand concentration, and temperature.[92] Palladium is more mobile in the environment than platinum and rhodium.[99] Analysis of recent snow and ancient ice in central Greenland suggests that palladium in catalytic converter exhausts may spread substantial distances from urban sources via the troposphere of the Northern Hemisphere.[29] Prior to the use of catalytic converters in the mid-1970s, the palladium concentration in the central Greenland snow was 15-fold (0.15 pg/g) higher than concentrations in ancient ice from 7 millennia ago. By the mid-1990s, the palladium concentration in recent snow had increased to 80-fold higher than in ancient ice.

DOSE EFFECT

There are limited data on dose-related palladium toxicity. The adverse effects of palladium are usually attributed to the presence or release of palladium ions rather than metallic palladium. In general, the acute toxicity of palladium and related compounds is very low to moderate after ingestion, depending on solubility.[2] Several palladium salts may cause severe primary skin and eye irritation along with skin sensitization.

TOXICOKINETICS

There are few data on the absorption of palladium in humans. In general, insoluble compounds (e.g., metallic palladium) are poorly absorbed from the gastrointestinal tract. In most animal experiments using divalent palladium chloride or sodium tetrachloropalladate, feces and urine are the main routes of excretion. In a subchronic study of rats receiving tetravalent potassium hexachloropalladate for up to 90 days in drinking water, palladium excretion was rapid, primarily via feces.[102]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Allergic reactions are the most common cause of adverse reactions to platinum group salts including palladium; however, palladium salts are relatively poor skin sensitizers that rarely cause a type IV hypersensitivity reaction.[103] Allergic reactions to these salts are typically associated with contact dermatitis rather than asthma or urticaria.[104] Although *in vitro* studies suggest that Pd nanoparticles may produce cytotoxic and proinflammatory effects, inadequate data are available to determine if these effects significantly affect ecosystems or human health.[94]

CLINICAL RESPONSE

Sensitization may occur to low palladium doses, particularly in patients with nickel allergies,[99,105] Pd-containing dental restorations,[106] or multiple body piercings;[107] however, the sensitivity of the general population to palladium is low.[92] In a study of 910 patients presenting to a dermatology clinic, 12.1% ($n = 110$) had a positive result for a 2% palladium patch test.[108] The diagnoses given to these positive patients were as follows: hand and body dermatitis, 29.2%; stomatitis, 27.4%; lichen planus-like eruptions, 15.1%; and burning mouth, 13.2%. In contrast to platinum, allergic reactions to pallidum are primarily limited to contact dermatitis based on case reports of patients exposed to palladium-rich dental restorative alloys.[109] Metallic palladium is a relatively less sensitizing agent than palladium chloride.[2] Case reports also associate palladium-containing dental restorations with bronchial asthma and chronic urticaria;[110,111] however, the contribution of palladium in the development of these effects is unclear because of the many metals used in these restorations including platinum.[112] Rarely, case reports associate dental alloys with stomatitis and asthma in patients with patch test sensitivity to palladium but not to nickel or platinum.[113] Immediate hypersensitivity reactions in refinery workers exposed to palladium usually occur in workers with sensitization to platinum salts; however, the prevalence of cross-reactivity between both metals in these workers is relatively low.[114] Rhinoconjunctivitis and asthma developed in a previously healthy worker exposed to fumes from an electroplating bath containing palladium chloride but no platinum.[115] The skin prick test and bronchial provocation test for divalent tetramminepalladium chloride were positive, whereas the skin prick test for the platinum salt was negative. There are few data on the carcinogenicity or reproductive abnormalities associated with palladium. Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program (NTP) lists palladium as a suspected carcinogen or reproductive toxin.

DIAGNOSTIC TESTING

SI Conversion Units

1 ppm = 4.353 mg/m^3
1 ng/mL = 9.340 nmol/L

Analytical Methods

Techniques for analyzing palladium in biological and environmental samples typically report total palladium concentrations without speciation. The methods for the quantitation of palladium include total reflection X-ray fluorescence after mercury coprecipitation,[14] neutron activation analysis, graphite furnace/atomic absorption spectrometry, inductively coupled plasma/mass spectrometry, and isotope dilution/inductively coupled plasma/quadrupole mass spectrometry (limit of detection in air samples, 0.01 pg Pd/m^3).[71] The limits of detection for palladium in blood and urine after acidification with nitric acid were 3 ng/L and 10 ng/L, respectively, as measured by flameless atomic absorption spectrophotometry.[116] Analytical methods for quantitation of palladium in blood usually require

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

destructive methods (e.g., ashing) to remove organic material, followed by the addition of strong acids (e.g., nitric acid) that restricts quantitation to total palladium without speciation. Similarly, urine samples require pretreatment with UV photolysis, freeze-drying, or a wet-ashing procedure with subsequent reduction of urine volume before analysis by inductively coupled plasma/mass spectrometry. Palladium is a chemical modifier used in analytical laboratories to reduce interferences associated with the determination of various trace elements in biological samples; consequently, contamination may complicate the analysis of palladium in laboratories using this chemical modifier.

Biomarkers

There are few data on the concentration of palladium in the general population without occupational exposure to palladium. Typically, the palladium concentration in blood samples is <0.1 μg/L.[92] The mean palladium concentration in whole blood from seven volunteers was 0.05 μg/L (range, 0.03–0.08 μg/L) as measured by sector field inductively coupled plasma/mass spectrometry (LOD, 0.00017 μg/L).[78] The palladium concentration in urine samples from the general population is usually <1–2 μg/L.[117] In a pilot study of urine samples (mostly morning collections) from 27 dental technicians, 17 road construction workers, and 17 construction students (control group), the median palladium concentration of the dental technicians was 97.1 ng/L (95% upper limit, 323.5 ng/L) compared with 44.7 ng/L (95% upper limit, 127.9 ng/L) for the road construction workers and 26.7 ng/L (95% upper limit, 48.3 ng/L) for the control group as measured by sector field inductively coupled plasma/mass spectrometry.[78] Five of the 27 dental technicians had a total of 11 noble metal fillings based on questionnaires.

HEALTH SURVEILLANCE

Currently, no validated methods for the biological monitoring of workers exposed to palladium exist. In a study of 84 palladium-exposed workers from the Production of Catalysts and Refining Departments, 17 occasionally exposed employees, 21 controls (administrative offices), and 25 unexposed volunteers (external controls), airborne Pd concentrations as measured by personal devices correlated with urine palladium concentrations ($r^2 = 0.684$; $P \leq 0.01$).[118] The highest mean airborne palladium concentration in personal samplers occurred in the Production of Catalysts Department (mean = 1.44 μg/m^3) and the Refining Service (mean = 5.75 μg/m^3); the corresponding mean urine Pd concentration in those departments was 1.71 μg/L (range, 0.84–3.02 μg/L) and 1.20 μg/L (range, 0.65–2.25 μg/L), respectively.

Preemployment screening should include a questionnaire for skin disease specifically for allergy to metals (nickel, cobalt, and palladium); however, routine patch tests with nickel and palladium compounds are not recommended unless applied to determine the cause of occupational dermatitis. Workers with a known nickel allergy should be cautioned about developing palladium sensitization while working with palladium salts. In general, workers with palladium allergies should avoid contact with palladium or palladium salts. During employment, regular screening for skin and respiratory health through questionnaires and examinations should be done as needed.

TREATMENT

The primary treatment for palladium sensitization is prevention of exposure to palladium compounds. Otherwise, the treatment of adverse effects from palladium exposure is supportive.

RHODIUM

PHYSIOCHEMICAL PROPERTIES

Rhodium is a rare, soft, silvery-white member of Group 9 (Group VIII) that forms alloys with other platinum group metals; this metal also occurs in gold ores. The typical oxidation state in the environment is trivalent;[103] Rh is the only stable isotope. The tendency to form soluble complexes suggests that the mobility of rhodium in the environment and bioavailability are greater than those of platinum.[119] Rhodium is insoluble in acids and aqua regia.

EXPOSURE

The most common uses of rhodium include a platinum/rhodium alloy for high-temperature thermocouples, catalytic converters, and electroplating of metals. There are few data on the intake of rhodium in the diet. The estimated daily adult intake of rhodium in the United Kingdom is <2.3 μg based on the 2006 UK Total Diet Study.[22] In this study, beverages, bread, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. miscellaneous cereals accounted for the largest portion of rhodium in the diet, whereas the rhodium content in nuts and offal was nondetectable (LOD, 0.5–3 μg/kg).

As with other platinum group elements, the distribution of rhodium in fractionated airborne dust is heterogeneous with ~95% of rhodium present as coarse dust (>2 μm).[13] Consequently, the total rhodium concentration in air samples depends on the sampling technique. In a German study of air samples (PM <22 μm) near a major highway, the average total airborne rhodium concentration was 3.9 pg/m^3 (range, <0.5–11.6 pg/m^3) compared with a mean of 0.5 pg/m^3 (range, <0.1–2.8 pg/m^3) in a nonurban area.[14] The platinum/rhodium and palladium/rhodium ratios in this study demonstrated wide variations (i.e., 2.4–10.1 and 1.7–23.3, respectively, in urban air samples). Based on laboratory testing of emissions from catalytic converters analyzed new and after a light-duty vehicle aging cycle simulating urban driving, the soluble fraction of rhodium in exhaust fumes is substantially higher than the soluble platinum fraction.[8]

Analysis of recent snow and ancient ice in central Greenland suggests that rhodium in catalytic converter exhausts may spread substantial distances from urban sources via the troposphere in the Northern Hemisphere.[29] Prior to the use of catalytic converters in the mid-1970s, the rhodium concentration in the central Greenland snow was 45-fold (0.031 pg/g) higher than the rhodium concentration in ancient ice from 7 millennia ago. By the mid-1990s, the rhodium concentration in recent snow had increased to 120-fold higher than in ancient ice. The platinum/rhodium mass ratio in recent snow was similar to the mass ratio of these two metals in newer catalytic converters.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The sensitizing potential of rhodium salts is relatively low, and most cases associating rhodium salts with allergic reactions involve sensitivity to multiple agents including other platinum group salts\ (e.g., platinum, palladium).[120] In a study of 720 eczematous patients, 2 patients had positive patch tests for rhodium chloride.[121] These two patients also had positive patch tests for cobalt and nickel. Sensitivity to metallic rhodium does not usually occur.

CLINICAL RESPONSE

Contact dermatitis associated with rhodium salts typically involves multiple platinum group allergens, primarily in jewelry workers using acidic electroplating solutions containing rhodium sulfate.[122] A 47-year-old goldsmith developed dermatitis of his hands while working with an electrogalvanic bath containing hexa-chlororhodiate solution.[123] His patch test for this solution was 3+ compared with 1+ for cobalt chloride. A 45-year-old self-employed jeweler developed a pruritic, scaly rash on her fingertips, eyelids, wrists, and legs while working in a poorly ventilated area with rhodium solutions, cyanide, and ammonia.[124] She had a prior history of allergic rhinoconjunctivitis along with the recent onset of asthma. She had a positive skin patch test for rhodium chloride and cobalt chloride; skin prick and bronchoprovocation tests for precious metal salts were not performed. A 27-year-old atopic electroplating plant operator developed work-related dyspnea and rhinitis 3 years after beginning work around electrolysis baths containing rhodium salts. He had positive skin prick tests and bronchial challenges to chloride salts of both rhodium and platinum, but the response to rhodium was 256-fold and 16-fold higher than platinum, respectively. Rarely, case reports associate the development of contact dermatitis with the use of rhodium sulfate-containing electroplating solutions by workers with positive patch tests to only 2% rhodium sulfate.[125]

TABLE 24.3. Guidelines and regulations for exposure to rhodium and rhodium compounds.

Exposure Limit	Value
	OSHA
PEL–TWA (8-hour)	0.1 mg/m^3 (metal/insoluble)[a]
	0.001 mg/m^3 (soluble compounds)[a]
	NIOSH
REL–TWA (10-hour)	0.1 mg/m^3 (metal/insoluble compounds)[a]
	0.001mg/m^3 (soluble compounds)[a]
IDLH	100 mg/m^3 (metal/insoluble compounds)[a]
	2 mg/m^3 (soluble compounds)[a]
	ACGIH
TLV–TWA (8-hour)	1.0 mg/m^3 (metal)[a]
	1.0 mg/m^3 (insoluble compounds)[a]
	0.01 mg/m^3 (soluble compounds)[a]

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time-weighted average.
[a] As total Rh.

DIAGNOSTIC TESTING

Methods for analyzing rhodium in air samples include absorptive striping voltammetry following acid digestion in a high-pressure asher (HPA, Kuner, Rosenheim, Germany),[14] graphite furnace atomic absorption spectrometry, inductively coupled plasma/atomic emission spectrometry,[126] and quadrupole inductively coupled plasma/mass spectrometry.[127] Using the latter method and online sample cleanup/pre-concentration steps in a sequential injection analysis system incorporating a column filled with chelating resin, the limit of detection for rhodium in biological samples is 0.4 ng/L.

Rhodium salts produce positive skin prick, which results in platinum salt allergic workers in catalyst production and precious metals refineries. Three of the 153 workers in a catalyst manufacturing and recycling plant had positive skin prick tests for platinum, rhodium, and iridium salts, whereas 22 (14.4%) had positive skin prick reactions to platinum salts.[128] In a study of 306 South African platinum refinery workers, 6 of 38 workers with positive RAST tests for platinum salts also had antibody responses to rhodium salts.[104]

HEALTH SURVEILLANCE

There are few data on human toxicity from rhodium exposures. The standards set for rhodium exposures are usually based on the similarity of rhodium to platinum and the minimization of the risk of sensitization. Table 24.3 displays exposure levels for rhodium.

TREATMENT

Treatment is supportive.

Chapter 25

POTASSIUM

HISTORY

The English chemist, Humphry Davy, first isolated elemental potassium in 1807 via electrolysis by decomposing molten potassium hydroxide (caustic lye) with a voltaic battery. Potassium was named after potash; the latter word is a combination of "pot" and "ash" reflecting the discovery of potassium in the water-soluble fraction of wood ash. Since antiquity, potash has been part of manufacturing processes for ceramics, glass, and soap. Leaching of the water-soluble fraction in wood ashes from the burning of broad-leaved trees in Europe, Russia, and North America was the dominant production process for potash compounds until the 1860s.[1] Extraction of lye (potassium hydroxide) from hardwood ash provided material for soap and the production of potash after boiling. During the latter 1800s, inorganic compounds and mineral potassium sources became more common sources than the old method of ash lixiviation.

Germany became the world leader in transforming the ash market for glass and soap production into a global mining operation with agriculture being the primary market.[2] The economic disruptions of World War I required the development of alternate potassium sources (Nebraska brines, California kelp) to German potassium sources. The mining of newly discovered potassium deposits in the Northern Hemisphere ultimately became a stable source of potassium. Glucose–insulin–potassium solution was suggested as a repolarizing solution to prevent dysrhythmias in patients with acute myocardial infarction; however, the benefit of this solution was never proven.[3] In the 1980s, potassium intoxication occurred after the use of potassium as a salt substitute, a nonprescription agent to alkalinize the urine, and a nutritional protein calorie supplement.[4]

Potassium chloride has a long history of use for suicides, homicides, and lethal procedures for state-sanctioned punishment.[5] Dr. Jack Kevorkian euthanized 69 people in Oakland County, Michigan, in 1990–1998 before he was incarcerated for forging the will of his last victim.[6] He used licit drugs (e.g., barbiturates) with KCl as the main fast-acting agent. He committed suicide in 2004 while in custody.

PHYSIOCHEMICAL PROPERTIES

Potassium (CAS RN: 7440-09-7) is one of the Group 1 (Group Ia) metals with lithium, sodium, rubidium, cesium, and francium; these alkaline metals are strong bases and easily form hydroxides with moisture. Potassium is a soft, waxy, and highly reactive metal that does not exist in the natural environment as elemental potassium. Potassium hydroxide (KOH, caustic potash) is a white material that dissolves easily in water. KOH (CAS RN: 1310-58-3; atomic weight (g/mol): 56.11; specific gravity: 2.044; melting point: 360°C) is a strong alkali; a 1% aqueous solution of KOH possesses the same alkaline pH as a 0.77% aqueous solution of NaOH. The relatively innocuous taste of strong alkali allows ingestion of greater volume than the sour taste of acidic substances.[7]

Metallic potassium and sodium react vigorously with water to produce heat, hydrogen gas, and hydroxide ions. The heat generated by this reaction is sufficient to ignite the evolved hydrogen gas and cause thermal burns.

Consequently, storage of elemental potassium requires submersion in mineral oil to reduce the risk of explosion.

EXPOSURE

Production Processes

Mining and manufacturing processes produce potash. Mining involves the removal of potash from an ore consisting of crystalline sodium and potassium chloride in a ratio of 3:2 along with ~5–10% clay impurities. The leading producers of potash include Canada (Saskatchewan), Russia, Belarus, Germany, Jordan, and Israel. The latter two countries use solar evaporation pans in the Dead Sea to produce carnallite (potassium chloride). The former four countries mine potash from potassium-rich salt layers formed by ancient evaporated sea beds. Sedimentary rocks are the potash source for potassium-containing fertilizers; these materials are mixtures of soluble potassium salts and elemental potassium in fertilizers, as displayed in Table 25.1. The main supply of potash occurs in the Northern Hemisphere with Canada, Russia, and Belarus producing >90% of the world's annual production.[2]

Uses

Medical

Potassium chloride is the most common potassium supplement. Other potassium salts include acetate, bicarbonate, citrate, and gluconate. The primary indication for the administration of potassium supplements is the treatment of potassium depletion in patients with inadequate potassium intake. Previous uses of potassium supplements include: 1) a salt substitute for persons on a table salt (sodium chloride)-restricted diet; 2) an aid in restoring muscular strength in some patients with myasthenia gravis in conjunction with anticholinesterase agents; and 3) an ancillary measure in the treatment of thallium poisoning. Potassium iodide is an oral medication for inflammatory dermatoses (e.g., erythema multiforme, erythema nodosum, nodular vasculitis, subacute nodular migratory panniculitis, Sweet's syndrome).[8] The use of potassium nitrate (KNO_3) as a saltpeter for the treatment of priapism resulted in hyperkalemia.[9]

TABLE 25.1. Common and chemical names of potassium-containing potash salts. Although potash technically refers to potassium carbonate, generically potash refers to several potassium salts including potassium oxide and hydroxide. (Based on Ciceri et al.).[2]

Common Name	Alternate Name	Formula	Potassium Salt
Potash fertilizer		K_2O	Oxide
Caustic potash	Potash lye	KOH	Hydroxide
Carbonate of potash	Pearlash, salts of tartar	K_2CO_3	Carbonate
Chlorate of potash		$KClO_3$	Chlorate
Muriate of potash		KCl	Chloride
Nitrate of potash	Saltpeter	KNO_3	Nitrate
Sulfate of potash		K_2SO_4	Sulfate

Industrial

Potassium fertilizers account for the vast majority of potash production (i.e., ~95%). Potassium hydroxide is a substitute for the less expensive sodium hydroxide when the greater solubility of KOH is important for industrial processes. Examples include photoengraving, lithography, electroplating, battery manufacturing, fuel cells, and the manufacture of liquid soaps and detergents. Products containing KOH include drain cleaners and paint/varnish removers. Metallic potassium is a catalyst and heat-transfer medium in the production of sodium–potassium alloys. Potassium nitrate is a constituent of match heads, fireworks, and fertilizers.

Sources

The daily intake of potassium in the US diet is ~50–150 mEq/day with 90% of the daily potassium load excreted by the kidneys.[10] Herbal medications associated with excessive potassium consumption include alfalfa, dandelion, hawthorne (berries), noni juice, and horsetail.

DOSE EFFECT

Salt Substitutes

Salt substitutes contain primarily potassium salts with the potassium content ranging from ~100–500 mg/g supplement. The calculated potassium content (mEq/teaspoon) for salt substitutes includes Morton's Lite Salt, 38; Morton's Salt Substitute, 72; No-Salt, 64; Nu-Salt, 67; and Adolph's Salt Substitute (unseasoned), 65.[11] Consumption of a large amount (26 mEq K^+/kg body weight) of Morton's salt substitute (90% KCl) resulted in a near fatal case of hyperkalemia in an 8-month-old infant.[12] This infant became unresponsive and developed difficulty in breathing. The ECG demonstrated an idioventricular rhythm with bigeminy, absent P waves, and a wide QRS interval.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Blood chemistries indicated potassium of 10.2 mEq/L, sodium of 149 mEq/L, CO_2 of 22 mEq/L, and creatinine of 0.6 mg/dL. With treatment, the serum potassium decreased to 5.4 mEq/L; the patient survived.

Potassium Supplements

Potassium chloride is available orally in capsules, powders, solutions, tablets, and parenterally for intravenous injection (0.8–3.2 mEq of K^+ and Cl^-/mL). The usual potassium maintenance requirements are 2 mEq K^+/kg/day for infants and 40–80 mEq K^+/day for adults; 40 mEq K^+ is equivalent to ~3.0 g KCl.

The ingestion of 47 slow-release KCl tablets caused the death of a 32-year-old woman (18-hour postmortem ocular fluid potassium concentration, 10.8 mEq/L).[13] A 50-year-old woman developed life-threatening arrhythmias with a peak potassium concentration of 9.7 mEq/L 13 hours after the intentional ingestion of 100 (7.5 g KCl) sustained-release K-Dur® tablets.[14] The inadvertent intravenous administration of undiluted potassium chloride instead of sodium chloride led to several deaths.[15] An intravenous bolus of 60 mg KCl can produce asystole and cardiac arrest.[16] A 2-month-old with colic was given 3 g KCl mixed with breast milk in the evening, followed by 1.5 g KCl in the morning. In a few hours, the child was listless, cyanotic, and apneic. The admission potassium concentration was 10.1 mEq/L; he died 28 hours later.

Intravenous Administration

The intravenous administration of 40 mEq of potassium chloride to a 71-year-old man with multiple medical problems (diabetes, congestive heart failure, anasarca, recent subendocardial myocardial infarction) caused a cardiac arrest within several minutes.[17] Flushing a central line with 26.4 mEq potassium phosphate produced the immediate onset of ventricular fibrillation in an 81-year-old man with atherosclerotic coronary artery disease and chronic renal failure.[17]

TOXICOKINETICS

Potassium chloride is well absorbed orally. The intracellular fluid compartment contains 98% of the body burden of potassium (150–160 mEq/L water). Total body potassium in adults averages 53–55 mEq/kg body weight; this value decreases with age and decreasing muscle mass. The kidney accounts for ~90% of the elimination of an absorbed K^+ dose, primarily by distal renal tubule secretion; however, the distal renal tubule excretes little K^+ in the presence of an *acute* potassium load. Although hyperkalemia is common in acute renal failure, elevated potassium concentrations are unusual in chronic renal failure until the serum creatinine rises above 10 mg creatinine/dL.[16] In addition, an insulin-dependent mechanism may contribute to the elimination of large potassium doses.[18] Renal potassium excretion depends on chloride ion concentration, acid-base status, and adrenal hormone secretion. Healthy patients excrete ~40–50 mEq of potassium daily in the absence of potassium supplements.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Burns

Elemental Potassium

Metallic potassium reacts exothermically with water to form hydrogen gas and potassium hydroxide. This reaction produces thermal and chemical burns including heat from the reaction and flames ignited by the release of hydrogen gas as well as the potential for explosions.

Potassium Hydroxide

KOH is a severe corrosive similar to sodium hydroxide; concentrated aqueous solutions of both substances are highly alkaline exceeding pH 13. Alkalis are proton acceptors that remove hydrogen ions from protonated amines and carboxylic groups. Strong alkali substances solubilize fat (saponification) and proteins. Once solubilized, the alkaline proteinates produce hydroxyl ions and chemical reactions (liquefaction necrosis), resulting in rapid tissue destruction and deep penetrating lesions as the KOH destroys the natural barrier of the lipid layer to water. Saponification is an exothermic reaction that produces heat and enhances tissue destruction. The amount of tissue damage depends on pH, amount ingested, physical state, and duration of exposure.

Fatal ingestions of potassium hydroxide involve burns of the upper respiratory tract, esophagus, and stomach along with hemorrhage and perforation. A 30-year-old woman died soon after ingesting a potassium hydroxide-containing drain cleaner.[19] Postmortem examination demonstrated circumoral/oropharyngeal burns, necrotic hemorrhage and edema of the tracheal and main bronchial mucosa, extensive mucosal burns of the esophagus with perforation of the cardioesophageal junction, and 100 mL clotted hemorrhage in the right pleural cavity. The greater curvature of the stomach was almost completely dissolved resulting in 600 mL of hemorrhagic material in the peritoneal cavity.

Electrolyte Imbalance

Hyperkalemia

Normal transmembrane voltage gradients and physiological function require large, stable intracellular potassium (K^+) concentrations compared with extracellular K^+ concentrations. The subsequent voltage gradients establish action potentials that allow the conduction of impulses in cardiac, skeletal/smooth muscle, and nerve cells. Like magnesium toxicity, hyperkalemia often results from reduced renal excretion in association with increased potassium loads. Aldosterone antagonist drugs may contribute to toxicity, particularly in chronic renal failure patients with low glomerular filtration rates (<15–20 mL/minute) and metabolic acidosis. Patients with normal renal function rarely develop hyperkalemia unless the poisoning is associated with severe rhabdomyolysis. Digitalis toxicity produces hyperkalemia as a result of the inhibition of Na^+/K^+ ATPase activity that normally allows potassium efflux from cells. Other mechanisms of hyperkalemia include activation of K^+ channels (e.g., fluoride toxicity) and disruption of intermediary metabolism (e.g., cyanide poisoning).

The toxic effects of hyperkalemia result from interference with normal excitation of skeletal and cardiac muscle. The Purkinje fibers are the most sensitive cardiac cells to the effects of hyperkalemia; the sinoatrial and atrioventricular nodes are more resistant. Consequently, delayed intraventricular conduction occurs before a loss of atrial conduction. Fatal potassium injections are not associated with any specific macroscopic or histological changes. A study of two fetuses terminated with KCl injections for serious medical reasons demonstrated whitish deposits on tissues and lanceolate crystals on histological examination of internal organs.[20] Two other fetuses terminated with other drugs did not demonstrate similar changes.

Hypokalemia

At least two hormonal signals maintain the normal, relatively high intracellular potassium concentration by promoting intracellular diffusion of this cation. Insulin, β-adrenergic catecholamines, and thyroid hormone reduce extracellular potassium by enhancing cell-membrane Na^+/K^+ ATPase and potassium uptake. For insulin and thyroid hormone, a negative feedback loop maintains potassium homeostasis, whereas β-agonists decrease serum potassium concentrations independent of potassium body stores. Aldosterone is the other major regulator of potassium stores by enhancing the renal elimination of potassium. Consequently, hyperinsulinemia, hyperaldosteronemia, and β-agonist ingestion are associated with hypokalemia. Other mechanisms of action include competitive blockage of the K^+ channels (chloroquine, barium), alkalosis, gastrointestinal potassium loss, increased urinary potassium excretion, and inadequate dietary potassium uptake. In contrast to hyperkalemia, hypokalemia can persist despite normal regulatory systems and renal function.[21] Hypokalemia usually results from potassium depletion secondary to abnormal potassium losses, particularly during the induction of metabolic alkalosis and excessive chloride losses from vomiting or nasogastric drainage.

The most common cause of hypokalemia is drug-induced potassium depletion, particularly diuretics. A wide range of drugs and disorders reduce serum potassium concentrations including β_2 sympathomimetic agents, xanthines, calcium-channel blockers, diuretics, mineralocorticoid/glucocorticoid agents, some antibiotics, emetics/laxatives, barium salt ingestion, hyperthyroidism, hyperinsulinemia, hypomagnesemia, and a variety of diseases (familial hypokalemic periodic paralysis, infectious diarrhea, malabsorption, Zollinger–Ellison syndrome, primary hyperaldosteronism, leukemia, type I distal renal tubular acidosis). Table 25.2 lists drugs associated with hypokalemia separated by mechanism of action. Although hydrocortisone and prednisone do not directly affect potassium secretion, the chronic administration of these drugs slightly reduces serum potassium indirectly by increasing glomerular filtration and distal sodium delivery rates.

CLINICAL RESPONSE

Burns

Dermal contact with elemental potassium exposes the skin to thermal and chemical burns. A 16-year-old boy sustained burns to his hands, groin, and thigh when he clandestinely placed elemental potassium in his pants pocket and the potassium subsequently exploded.[22] His pants caught fire; he underwent three showers clothed. One hour later in the emergency department, he had first and second-degree burns and an initial pH of 8–9 in the lavage fluid by litmus paper. He subsequently developed deep second- and three-degree burns that required split-thickness grafting (13 by 20 cm). Potassium hydroxide ingestion produces alkali burns of the esophagus and stomach similar to sodium hydroxide. Symptoms and signs of alkali ingestion are not reliable indicators of the severity of the ingestion. Grade 3 injuries typically result in esophageal scarring and gastric cicatrizations (pyloric/antral stenosis, gastric deformities, shortening/irregularity of the lesser curvature).[23]

TABLE 25.2. Drug-induced hypokalemia and associated mechanisms of action.

Class	Drug Type	Drug
	Intracellular K^+ Shift via Cell-Membrane Na^+/K^+ ATPase	
β_2-Adrenergic agonists	Epinephrine	
	Decongestant	Phenylpropanolamine, pseudoephedrine
	Bronchodilators	Albuterol, ephedrine, fenoterol, isoetharine, isoproterenol, metaproterenol, pirbuterol, terbutaline
	Tocolytic agent	Ritodrine, terbutaline
	Xanthines	Caffeine, theophylline
	Overdose	Barium salts,[a] chloroquine, insulin, verapamil
	Increased Renal K^+ Loss	
Diuretics		Acetazolamide, bumetanide, chlorthalidone, ethacrynic acid, furosemide, indapamide, metolazone, thiazides, torsemide
High-dose penicillins	Ampicillin, carbenicillin, nafcillin, penicillin	
High-dose glucocorticoids		
Magnesium depletion	Aminoglycosides, amphotericin B, cisplatin, foscarnet	
	Increased Fecal K^+ Loss	
Laxatives	Phenolphthalein	
Resin exchange	Sodium polystyrene sulfonate	

[a] Barium blocks passive potassium efflux rather than increasing efflux through the sodium–potassium pump.

Electrolyte Imbalance

Hyperkalemia

Hyperkalemia is an uncommon complication of poisoning, except in the presence of renal failure or severe rhabdomyolysis.[24] The clinical picture following a potassium overdose depends on a number of variables including the degree of serum potassium elevation, the chronicity of elevated concentrations, and the presence of underlying cardiovascular and/or renal disease. Hyperkalemia affects many organ systems (cardiac, neuromuscular) and acid–base status producing a wide spectrum of clinical features as outlined in Table 25.3. The most serious manifestation of potassium toxicity is the development of acute cardiovascular changes (bradycardia, slowed conduction, hypotension, ventricular fibrillation, asystole, death).[25] Neuromuscular symptoms include weakness, paresthesias, hyporeflexia, and ascending paralysis. Sensory and cognitive functions usually remain intact until the cardiovascular effects of hyperkalemia reduce brain perfusion. Serious cardiac abnormalities may develop without prominent early symptoms of systemic toxicity. The ingestion of slow-release preparations may delay the onset of serious cardiac effects up to 6–12 hours after ingestion.[26,27] Small-bowel ulcerations may result from the use of enteric-coated potassium chloride tablets.[28] Local pain and inflammation may occur after the intravenous administration of potassium chloride.

TABLE 25.3. Clinical features of hyperkalemia. The clinical presentation depends on the serum potassium concentration, the rate of rise of the potassium concentration, and the presence of underlying disease (cardiovascular, renal). (Based on Saxena).[16]

Organ System	Effect
Cardiovascular	Syncope, cardiac dysrhythmias, hypotension, cardiac arrest/asystole
Endocrine/ Metabolic	Weakness, metabolic acidosis, hypoaldosteronemia
Gastrointestinal	Nausea, vomiting, abdominal pain, ileus, ulceration, bowel perforation
Neuromuscular	Dysarthria, dysphagia, dysphonia, weakness, ascending paralysis, flaccidity
Renal	Oliguria, uremia

Hypokalemia

Mild hypokalemia is usually asymptomatic. Nonspecific symptoms, ileus, and generalized muscle weakness develop from hypokalemia of <2.5–3.0 mEq/L.[29] Cardiac changes include ventricular dysrhythmias (tachycardia, fibrillation), atrial tachycardia, AV disassociation, and electrocardiographic alterations (flat T waves, ST segment depression, prominent U waves).

Occupational Exposure

Although potash is an irritant that causes nasal perforation at airborne concentrations of >2,000 mg/m^3,[30] mortality studies of potash miners have not revealed increased mortality from chronic pulmonary disease.[31] Symptoms of chronic bronchitis (cough, sputum production, breathlessness) are more prevalent in potash workers that are exposed to ambient air concentrations exceeding current standards; however, statistically significant differences in pulmonary function have not been detected in these workers when compared with controls or workers exposed to lower potash concentrations in ambient air.[32]

DIAGNOSTIC TESTING

SI Conversion Units

1 mEq = 1 mmol

Biomarkers

General Population

The normal range of serum potassium is ~3.5–5.3 mEq/L when analyzed by clinical laboratories with spectrophotometry; total body potassium stores are ~50 mEq/kg. Daily fluctuations of potassium concentrations in healthy adults range up to 1.3 mEq K^+/L.[33] Vigorous exercise may increase the potassium concentrations up to 6.5 mEq K^+/L in healthy adults; however, the potassium concentration soon normalizes after exercise ceases.

Hyperkalemia

In general, mild acute hyperkalemia ranges from 5.5–6.5 mEq K^+/L with ECG changes usually absent. Moderate hyperkalemia varies from 6.5–7.5 mEq K^+/L with minor ECG changes. Severe hyperkalemia occurs at potassium concentrations of >7.5–8.0 mEq K^+/L, typically in association with significant ECG changes. Between 9 and 10 mEq K^+/L, the QRS widens significantly to join the T wave and forms a sine wave that deteriorates into ventricular fibrillation and asystole. The K^+ concentration alone does not determine the severity of the body's response to hyperkalemia, particularly following a slow rate of rise. Some accommodation to hyperkalemia occurs in end-stage renal hemodialysis patients chronically exposed to high potassium concentrations, resulting in significant attenuation of the electrocardiographic changes compared with acute hyperkalemia at similar K^+ concentrations.[34]

The primary causes of hyperkalemia include: 1) factitious elevation; 2) transmembrane shifts that increase K^+ release; and 3) reduced K^+ excretion. Factitious elevation of serum potassium may result from laboratory error, hemolysis during collection or storage, leukocytosis, or thrombocytosis. Hence, laboratory tests indicating hyperkalemia should be repeated to confirm elevated potassium concentrations. The transmembrane shift of potassium from intracellular to extracellular sites results from alterations in acid-base status or dysfunction of the Na-K-ATPase pump. Examples include acidosis or acute intoxications (digitalis, α-adrenergic, β-blocker, fluoride). In these situations, the total body potassium stores remain stable while the serum potassium increases. Reduced potassium excretion results from renal failure, Addison's disease (↓ aldosterone), medications (angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, spironolactone, succinylcholine), renal tubular disease, and impairment of distal renal tubule responsiveness to aldosterone.[35] Neuromuscular effects depend on the ratio of intracellular and extracellular potassium. Consequently, neuromuscular effects do not always closely parallel the serum potassium concentration.

The appearance of hyponatremia, hypermagnesemia, hypocalcemia, and metabolic acidosis enhances the risk of potassium toxicity at a given potassium concentration. For every 0.1 decrease in the blood pH, the plasma potassium concentration increases by ~0.6 mEq K^+/L.[36] Factitious hyperkalemia may result from the release of intracellular potassium stores (e.g., hemolyzed blood samples, prolonged tourniquet time, thrombocytosis). The serum potassium concentration is directly proportional to the platelet count; therefore, pseudo-hyperkalemia occurs commonly when the platelet count exceeds 10^{12} platelets/L. In this situation, the plasma potassium is a more accurate reflection of potassium homeostasis than the serum potassium concentration.[37]

Hypokalemia

Patients typically have no symptoms when the reduction in potassium is mild (3.0–3.5 mEq/L); however, the appearance of symptoms correlates to how quickly the serum potassium declines. Nonspecific symptoms may occur at potassium concentrations below 3.0 mEq/L including weakness, lethargy, and constipation. More serious complications occur at concentrations of <2.5 mEq/L (muscle necrosis) and <2.0 mEq/L (ascending paralysis, respiratory insufficiency). Although

dysrhythmias are uncommon in patients without cardiovascular disease, even when the serum potassium declines below 3.0 mEq/L, the likelihood of dysrhythmias increases in patients with cardiac disease (left ventricular hypertrophy, failure, ischemia) and mild/moderate hyperkalemia.

Postmortem

Blood

The potassium concentrations increase erratically in postmortem blood; therefore, elevated potassium concentrations in postmortem samples of blood or clear plasma do not necessarily indicate potassium poisoning. Furthermore, venous injection of potassium may not produce elevated potassium concentrations in postmortem blood samples.[38] The potassium concentrations in a 30-year-old suicide victim found with a potassium-containing syringe in her arm were 54 mEq/L in clear plasma from her blood and 9.2 mEq/L in vitreous humor.[39] In a 41-year-old ICU nurse found dead following an intravenous KCl injection, the cardiac and femoral postmortem blood potassium concentrations were 160.0 mEq/L and 87.3 mEq/L, respectively.[40] The median potassium concentration in postmortem femoral blood samples in 55 cases from the same institution was 35.3 mEq/L (range, 27.2–50.1 mEq/L). None of these cases involved drug overdoses.

Vitreous

Postmortem changes in the potassium concentration are more consistent in samples from the vitreous humor than blood. A variety of charts[41] and equations are published to estimate the postmortem interval (PMI) based on the vitreous humor K^+ concentration including PMI (hours) = $(4.32 \times K^+$ [μmol/L] − 18.35)[42] or = $(2.749 \times [K^+] - 11.978)$.[43] However, these equations are rough estimations of the postmortem interval with wide confidence intervals (i.e., 95% CI: 4–20 hours) depending on a variety of factors.[44] The relationship between these variables is not always linear,[45] depending on sampling methods, analytical techniques, ambient temperatures, electrolyte and fluid balance prior to death, age, length of the postmortem interval, and nitrogen retention.[46,47,48] In studies of postmortem vitreous humor samples up to 4 days after death, the potassium concentration increased rapidly, whereas the urea nitrogen concentration remained relatively stable.[49] Because of the substantial, sometimes unpredictable changes in these variables for most postmortem cases, the vitreous humor potassium concentration must be interpreted cautiously along with other factors (rigor, livor, body temperature).[50] Calculations of the postmortem interval using the vitreous potassium concentration are most accurate in adults when ambient temperature after death was <50°F, the postmortem interval was relatively short (i.e., <24–48 hours), and electrolyte concentrations were relatively normal prior to death (e.g., traumatic death in a healthy individual).[46] Other studies suggest the postmortem interval calculation is more reliable when the interval exceeds 24 hours.[51] Good sampling technique (i.e., careful withdrawal of all vitreous humor fluid without surrounding tissue) also improves the accuracy of these calculations.

Abnormalities

The sequential electrocardiographic manifestations of hyperkalemia include tall, peaked T waves, depressed S-T segments, low - amplitude R waves, P-R interval prolongation, decreased P waves, widened QRS complexes, Q-T prolongation, a sine wave appearance, and asystole. Depression of intraatrial conductions occurs when the serum potassium concentration exceeds 7 mEq/L (Figure 25.1); peaked T waves reflect resting membrane potential changes and early excitatory reaction, primarily in the precordial leads.[52] The P waves disappear as the serum potassium concentration exceeds 8.5 mEq/L (Figure 25.2). The QRS complex gradually widens with the T wave and QRS complex blending together in the range of 9–11 mEq/L to form a sinusoidal wave pattern (Figure 25.3).[52] Several factors modify the electrocardiographic response to hyperkalemia including blood pH, osmolality, and a variety of serum substances (calcium, catecholamines, insulin, sodium). Alkalemia, hypercalcemia, and hypernatremia attenuate the electrographic response to hyperkalemia. Consequently, the ECG alone is not a sensitive marker of hyperkalemia.[53] Additionally, ECG changes more commonly occur with a rapid rise in the K^+ concentration.[54] Sustained-release potassium tablets are radiopaque, but the presence of potassium capsules on x-ray examination does not necessarily indicate the presence of intact potassium capsules.

HEALTH SURVEILLANCE

The US OSHA PEL–TWA for KOH was 2 mg/m^3; the 1992 11th Circuit Court of Appeals decision in AFL-CIO vs. OSHA vacated more protective PELs set by OSHA in 1989 for 212 substances including potassium hydroxide. The NIOSH REL–TWA is 2 mg/m^3. The ACGIH recommends a TLV-Ceiling of 2 mg/m^3 to minimize the risk of eye, skin, and respiratory tract irritation.[55]

TREATMENT

Initial Stabilization

Elemental Potassium

Water is contraindicated in the initial treatment of injuries secondary to *metallic* potassium. The wounds should be covered with oil until the removal of all unreacted metal.[22] At the scene of the injury, clothing should be removed rapidly, and obvious metal particles should be extracted from the wound. In the Emergency Department, the remaining metal fragments should be debrided, and then the wound may be irrigated with water similar to other alkali burns. The extracted metallic potassium particles should be placed in tertbutyl alcohol.

Potassium Hydroxide

Contaminated clothes should be immediately removed; all particulate debris must be removed from the skin including brushing off any remaining dry chemical. The burn area should be promptly irrigated copiously with tap water or saline for 20–30 minutes.[56] The extent of an alkaline burn is frequently deeper than initial inspection suggests. Similarly, exposure of the eye to KOH also benefits from prompt irrigation of the eye with copious amounts of water or physiological saline, if available.[57]

There is no consensus on the duration of irrigation in the emergency department with some authorities recommending 1–2 hours of continuous irrigation depending on the pH of the substance and decline in the pH of the irrigation solution.[58] Alkali burns to the eye require ophthalmological consultation. Skin burns also require consultation in the emergency department depending on the extent of the burn and potential need for skin grafting.

Gut Decontamination

Gastric aspiration/lavage is an option when the stomach contains potassium capsules or the patient presents within 1 hour of ingesting potassium capsules depending on physician judgment. There are no data to indicate whether or not activated charcoal adsorbs potassium salts; however, most metals are not well absorbed by activated charcoal. The efficiency of decontamination measures should be confirmed with abdominal x-ray. A whole bowel lavage is an option for patients ingesting sustained-release potassium preparations, particularly if numerous capsules remain on the abdominal x-ray or pass into the duodenum.[59]

Hyperkalemia

Mild hyperkalemia (i.e., <6.5 mEq/L) usually responds to dietary restriction, cessation of potassium supplements, and increased intake of dietary sodium. Potassium concentrations exceeding 6.7 mEq/L indicate the need for emergent therapy. The presence of heart block, wide QRS, or ventricular dysrhythmias or serum potassium concentrations exceeding 7.5 mEq/L indicate a medical emergency requiring an intravenous line,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

drug therapy, and constant cardiac monitoring.[16] Drug therapy for hyperkalemia includes: 1) membrane stabilization to reverse cardiovascular and neuromuscular effects (calcium gluconate); 2) redistribution of serum potassium from extracellular to intracellular spaces (β-agonists, intravenous insulin, glucose as necessary) as a temporizing measure until hemodialysis; and 3) enhancement of potassium elimination (hemodialysis, loop diuretics unless the patient is hypovolemic or unable to produce urine).[60] Serious dysrhythmias may occur suddenly, despite moderate serum potassium elevations. Patients with suspected hyperkalemia should receive an electrocardiogram, serum creatinine/BUN, and serum electrolytes including calcium and magnesium concentrations.

Cardiac Membrane Stabilization

Calcium improves the transmembrane voltage gradient transiently rather than reducing the K^+ concentration; therefore, concomitant administration of other drugs is necessary to prevent clinical deterioration. The intravenous injection of 10 mL of 10% calcium gluconate in adults over 2–5 minutes antagonizes the cardiac and neuromuscular effects of hyperkalemia. This antagonistic effect occurs soon after administration. The onset of action for intravenous calcium is <5 minutes, whereas the duration of action is ~20–60 minutes.[61] Calcium salts do not increase potassium excretion from the body. The dose may be repeated in 10 minutes if needed because of an inadequate response. Calcium gluconate may be administered in a peripheral vein, whereas the use of calcium chloride usually requires a central catheter because of its irritant properties unless the patient develops a cardiac arrest. The amount of calcium is ~3 times higher in calcium chloride (13.6 mEq/10 mL) compared with calcium gluconate (4.6 mEq/10 mL). Although routinely used, the efficacy of intravenous calcium in severe hyperkalemia has not been validated in randomized clinical trials.[62]

Calcium is not traditionally recommended in patients with hyperkalemia secondary to digoxin intoxication because of concern about the induction of serious ventricular dysrhythmias; however, calcium use in this situation is controversial. A retrospective chart review of calcium use in 23 digoxin-toxic patients (mean peak potassium = 5.99 ± 0.988 mEq/L) reported no life-threatening dysrhythmias within 1 hour of intravenous calcium administration.[63] Mortality in these digoxin-toxic patients was similar for those treated with intravenous calcium (5/23, 22%) and the group not receiving intravenous calcium (27/136, 20%). The mean peak potassium concentration in the latter group was 5.30 ± 0.959 mEq/L. Hypertonic saline (3%) is usually limited to symptomatic hyperkalemic patients with hyponatremia.

Potassium Redistribution

Glucose/Insulin

Insulin alone can lower serum K^+ concentrations in a dose-dependent manner through activation of the Na^+-K^+-ATPase pump and GLUT4 receptors, resulting in increased intracellular K^+ uptake and extracellular sodium excretion. Traditionally, 25 g of glucose (1 ampule of 50 mL of $D_{50}W$) is administered with 10–20 units of regular insulin over 5 minutes in adults with serum glucose 100–200 mg/dL. Insulin with glucose increases the intracellular transport of potassium rather than increasing potassium excretion. A reduction of the serum potassium by ~0.6–1.2 mEq K^+/L occurs within 30–60 minutes and lasts ~2 hours.[64] The onset of action is <15 minutes with peak effects at 25–30 minutes.[60] Hypoglycemia is a potential adverse effect of this therapy during the first 1–3 hours after regular insulin administration. If the initial serum glucose is <100 mg/dL, the patient should receive 50 g D_{50} (100 mL) initially and the serum glucose should be monitored every 30 minutes during the first hour, then hourly for 3 hours. Serum glucose of <70 mg/dL indicates the need for supplemental dextrose as displayed in Table 25.4. The use of intravenous glucose is not necessary for patients with existing hyperglycemia (serum glucose >200 mg/dL).[65] The kidney metabolizes insulin; consequently, hypoglycemia may occur in patients with renal dysfunction or trauma from the prolonged duration of action for insulin.[66] Short-acting synthetic insulin (e.g., aspart, lispro) with shorter half-lives and more rapid absorption than regular insulin are potential alternatives in hyperkalemic patients with renal insufficiency;[67] however, clinical experience in these patients is limited.

β-agonists

Catecholamines (e.g., albuterol, salbutamol) increase potassium redistribution by enhanced Na^+-K^+-ATPase pump and Na-K-2Cl cotransporter activity. Albuterol (Ventolin®, Proventil®) is an adrenergic agonist that increases plasma insulin concentrations and enhances the intracellular shift of potassium in adult doses of 10–20 mg via nebulization (4 mL normal saline over 10 minutes) or metered-dose inhaler. The albuterol dose is higher for the treatment of hyperkalemia than for chronic obstructive airway disease. The onset of action is ~30 minutes, peak action occurs at 2 hours after administration, and the duration of action lasts ~2–6 hours.[68]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 25.4. Dextrose administration based on initial serum glucose concentrations during treatment of hyperkalemia with regular insulin. (Adapted from Long et al.).[60]

Glucose Concentration (mg/dL)	Initial Dextrose	Supplemental Dextrose	Glucose Monitoring
>200	None	25 g $D_{50}W$ if serum glucose <70 mg/dL	Hourly × 3 hours
100–200	25 g $D_{50}W$ (50 mL)	25 g $D_{50}W$ if serum glucose <70 mg/dL	Hourly × 3 hours
<100	50 g $D_{50}W$ (100 mL) or 25 g $D_{50}W$ (50 mL) in $D_{10}W$ infused at 250 mL/hr for 1 hour	25 g $D_{50}W$ if serum glucose <70 mg/dL	Every 30 minutes first hour, then hourly for 3 hours

Declines in serum potassium range from 0.4–1.2 mEq/L at 1 hour based on small studies in chronic hemodialysis patients.[69,70] The R-enantiomer (levalbuterol, 2.5 mg) and racemic albuterol (albuterol, 10 mg) administered via nebulization over 30 minutes are equipotent in reducing potassium concentrations.[71] The initial onset of action was more rapid for levalbuterol than albuterol with slightly fewer adverse effects (i.e., tachycardia, tremor, nervousness); however, the K^+ reductions in potassium concentrations were similar at 30 and 60 minutes after the nebulization treatment ended. The combination of insulin/glucose and β-agonists produces synergistic reduction in potassium concentrations.[68,72]

Sodium Bicarbonate

Bicarbonate boluses alone do not reliably reduce serum potassium concentrations within 1 hour of administration in patients with end-stage renal disease on dialysis.[72] Although sodium bicarbonate currently is not recommended for acute management of hyperkalemic patients with normal pH, hyperkalemic patients with metabolic acidosis and intact kidney function may benefit from bicarbonate use acutely.[73] In these adults, the intravenous injection of 50 mEq of bicarbonate may increase intracellular potassium movement via the sodium–hydrogen exchange system and Na^+-K^+-ATPase pump activity; however, the effect on potassium concentrations is substantially less than that of insulin or β-agonists. Cardiac and renal dysfunction limits bicarbonate use because of high sodium and fluid loads.

Enhancement of Potassium Elimination

The kidneys are the primary route of potassium excretion with euvolemia, and adequate urine output is important to maintaining satisfactory urinary potassium elimination. Hemodialysis is the most effective method to remove serum potassium. A diuresis is an initial option while awaiting hemodialysis, particularly in patient able to produce urine. Chronic anuric renal failure patients are unlikely to benefit from diuretics. Hypovolemic patients require intravenous fluids to increase potassium excretion. Loop diuretics (e.g., furosemide) are the diuretics of choice with an onset of action of ~1 hour. Other diuretics (e.g., thiazides) provide synergistic effects; however, fluid and electrolyte balance must be followed closely. Cardiac arrest secondary to hyperkalemia necessitates emergency hemodialysis with advanced cardiac life support and intravenous medications (10 mL calcium chloride 10%, epinephrine 1 mg every 3–5 minutes, short-acting insulin 10 units with 25 g dextrose) to emergently reduce serum potassium concentrations. Blood gases should be drawn early in the clinical course to determine the need for sodium bicarbonate. Medications can be administered via the hemodialysis access site if no other vascular access is available.[74]

Hemodialysis

Hemodialysis effectively removes potassium with serum K^+ concentrations declining to 1 mEq/L in the first hour and 2 mEq/L within 2–3 hours depending on blood flow rates and K^+ dialysate concentration. The release of K^+ from intracellular stores may produce a significant rebound in serum K^+ concentrations. Patients with severe renal dysfunction and moderate-to-severe hyperkalemia usually require immediate hemodialysis. Arrangements for dialysis should be initiated as soon as possible. The early use of hemodialysis is particularly useful when rapid reduction of the total body burden of potassium is necessary, particularly in patients with renal failure, poor response to other therapy, massive tissue destruction (e.g., severe rhabdomyolysis), and acute oliguric renal dysfunction (daily urine output of <400 mL).[75] Hemodialysis may be necessary for patients with persistent hyperkalemia and cardiac instability, even in the presence of normal renal function.[76]

Cation-Exchange Resin

An oral cation-exchange resin (sodium polystyrene sulfonate, Kayexalate®, Sanofi-Aventis US, Bridgewater, NJ) exchanges cations (K^+, Mg^{2+}, Ca^{2+}, ammonium) for sodium with elimination through the feces in the distal colon and lower gastrointestinal tract. The Kayexalate® resin swells with water contact; therefore, sorbitol is usually administered with the resin to prevent constipation and/or obstruction. Although uncontrolled studies with little statistical analysis from the early 1960s suggest this resin reduces potassium concentrations over 1–2 days,[77,78] no controlled human or animal experiments confirm the efficacy of this treatment for acute hyperkalemia. Potential adverse effects include constipation, gastrointestinal obstruction, colonic necrosis, and fluid overload in patients with cardiac and renal dysfunction. Because of the lack of proven efficacy within the first several hours of administration and serious potential adverse effects, Kayexalate® is not recommended for the treatment of moderate to severe acute hyperkalemia.[79]

The typical oral dose is 20–50 g Kayexalate® dissolved in 100–200 mL of 20% Sorbitol. The dose is repeated every 4 hours up to 4–5 daily doses until the potassium concentrations normalize. Rectal administration involves the suspension of 8 g of Kayexalate® and 50 g of Sorbitol in 200 mL of water; the solution is administered as a retention enema. Serum electrolytes should be monitored every 2–4 hours during therapy.

Experimental Drugs

Patiromer and sodium cyclosilicate (ZS-9) are novel cation exchangers that are potentially useful cation exchangers with less adverse effects and better efficacy than sodium polystyrene sulfonate; however, these drugs require further clinical testing to determine their exact role in treating hyperkalemia. The former is a synthetic polymer using nonabsorbable spherical beads to enhance fecal potassium excretion by exchanging distal colonic calcium for K^+. The polymer does not swell or require the use of sorbitol. The onset of action is 7–48 hours and the duration of action is 12–24 hours with a resulting ~1 mEq/L reduction in serum potassium concentration.[60] Potential adverse effects include hypomagnesemia, hypercalcemia, and increased oral drug interactions during the first 6 hours.[80,81] An open-label, randomized pilot study of 30 adult patients with end-stage renal disease and serum potassium concentrations exceeding 6.0 mEq/L were divided into 15 patients with standard care only (insulin, albuterol) and 15 patients with standard care plus a single dose of 25.2 g oral patiromer.[82] The serum potassium concentrations were lower in the patiromer group at 2 hours (mean = 5.90 mEq/L, 95% CI: 5.63–6.7 mEq/L, $P = 0.009$) than the standard of care only group (mean = 6.51 mEq/L, 95% CI: 6.25–6.78 mEq/L). The difference between the two groups was not statistically significant at 1 hour ($P = 0.075$), 4 hours ($P = 0.329$), or 6 hours ($P = 0.115$) after the initiation of treatment. No power analysis was performed *a priori* because of the small sample size.

ZS-9 is a nonabsorbable, non-polymer, selective cation exchanger that excretes K^+ throughout the gastrointestinal tract by exchanging sodium and hydrogen for potassium. The onset of action is 1–6 hours with a duration of action lasting 4–12 hours. Subgroup analysis of the HARMONIZE randomized clinical trial suggests ZS-9 may significantly reduce serum potassium

TABLE 25.5. High-potassium foods. (Adapted from Gennari).[29]

Potassium Content (K^+/g Food)	Food Class	Food
Highest (>10 mg/g)		Dried figs, molasses, seaweed
Very high (>5 mg/g)	Avocados	
	Bran cereals	
	Dried fruits	Dates, prunes
	Lima beans	
	Nuts	
	Wheat germ	
High (>2.5 mg/g)	Fruits	Bananas, cantaloupe, kiwis, mangos, oranges
	Meats	Ground beef, lamb, pork, steak, veal
	Vegetables	Beets, broccoli, carrots, cauliflower, potatoes, spinach, tomatoes, winter squash

acutely.[83] A group of 45 patients with a mean baseline serum potassium of 6.3 mEq/L (95% CI: 6.2–6.4 mEq/L; range, 6.1–7.2 mEq/L) received 10 g ZS-9 orally.[84] The mean serum K^+ concentration decreased by 0.4 mEq/L (95% CI: 0.2–0.5 mEq/L) at 1 hour after administration, 0.6 mEq/L (95% CI: 0.4–0.8 mEq/L) at 2 hours after administration, and 0.7 mEq/L (95% CI: 0.6–0.9 mEq/L) at 4 hours after administration.

Supportive Care

The safest approach to minimizing adverse effects from dietary potassium is matching potassium intake to individual patient needs. Table 25.5 lists foods with high potassium content.

Chapter 26

RARE EARTH ELEMENTS

PHYSIOCHEMICAL PROPERTIES

The rare earth elements (REEs) refer to the following Group 3 transitional metals: scandium (Sc, atomic number 21), yttrium (Y, atomic number 39), lanthanum (La, atomic number 57), and the 14 lanthanide elements (atomic numbers 58–71). Light lanthanides beside lanthanum include cerium (Ce), praseodymium (Pr), neodymium (Nd), promethium (Pm), samarium (Sm), and europium (Eu), whereas heavy lanthanides include gadolinium (Gd), terbium (Tb), dysprosium (Dy), holmium (Ho), erbium (Er), thulium (Tm), ytterbium (Yb), and lutetium (Lu). The molecular structure of the lanthanide series is similar with two electrons in the outer shell and eight to nine electrons in the next outer shell. Consequently, the physical and chemical properties of these rare elements are similar. Table 26.1 lists the identifying information and physical properties of rare earth elements.

Most of these very reactive rare earth elements are soft and malleable with a bright silver luster and high melting points; however, some of these elements (e.g., cerium, europium, lanthanum, neodymium, praseodymium) oxidize easily. Tetravalent cerium is a strong oxidant, whereas trivalent cerium is very resistant to oxidation and has an affinity for calcium in many biomolecules. These elements are not naturally part of biological processes in humans or other animals. The 4f-electrons in rare earth nanoparticles have unique magnetic and luminescent properties useful in imaging and detecting abnormal tissues.[2] In an oxygen-lean environment, CeO_2 nanoparticles act as oxygen donors to increase the combustion of hydrocarbons and soot. Lanthanides form alloys with most metals. Yttrium is a dark gray lustrous metal that is insoluble in water; however, some yttrium compounds (e.g., nitrates) are water-soluble. In general, water solubility and ionic stability increase for the heavier rare earth elements. Usually, trivalent nitrate, chloride, and sulfate salts of rare earth elements are water-soluble, whereas carbonates, phosphates, and hydroxides are water-insoluble. Most lanthanides (e.g., La) occur in the stable trivalent state, although some lanthanides exist in the divalent (e.g., Eu, Sm, Yb) and quadrivalent (e.g., Ce, Pr, Tb) states. In physiological solutions, most lanthanides are stable only in the trivalent form with the exception of Ce^{4+} and Eu^{2+}.[3] Trivalent La cations have a high affinity for oxygen door atoms (e.g., phosphate). Lanthanide ions are fluorescent or phosphorescent with emissions covering the visible and near-infrared ranges.

EXPOSURE

Production Processes

Although the concentration of most rare earth elements in the earth's crust is small, some rare earth elements are abundant; cerium, neodymium, and yttrium are more common in the earth's crust than lead or cadmium.[4] Promethium is a fission product rather than a natural element in the earth's crust. Thulium is the rarest lanthanide existing in its natural state. Most rare earth metal-containing ores (e.g., apatite, bastnaesite, euxenite, fergusonite, gadolinite, monazite, samarskite, xenotime) are mixtures of rare earth oxides rather than

pure substances. The ores containing relatively high rare earth metal content include bastnaesite (90% rare earth metal oxides) and monazite (>60% rare earth metal oxides).[5] Monazite ore may contain up to 5% thorium oxide that potentially may contribute to the pulmonary effects following the inhalation of rare earth metal dust.

Most production of rare earth elements occurs as a by-product of other mining operations (e.g., iron, lead, zinc); expensive, specialized techniques are necessary to separate individual rare earth elements because of the similar reactivity between lanthanides.

Uses

Lanthanum, cerium, and neodymium are major constituents of carbon arc lamps; heavy exposure to these compounds usually involves printers or photoengravers using these high-intensity light sources.[5] Groups of workers with exposure to rare earth elements include the following industries: arc lamps, chemical, electronic, glass, metallurgical, nuclear, and optical. Table 26.2 outlines the industrial uses of rare earth elements.

Cerium is a component of glass coloring agents, abrasives for glass polishing (mirrors, plate glass, precision optics, electronic wafers, ophthalmic lenses, television tubes), lighter flints, tracer bullets and pyrotechnics, stabilizers (fluorides) in carbon arc lamps and gas-mantle industry, control rods in nuclear reactors, color television tubes, mercury vapor and fluorescent lamps, and mischmetal (alloy of rare earth metals) as a deoxidizer for metallurgic applications (e.g., magnesium and ferrous alloys) and the production of flints for lighters. Nanoscale cerium oxide (CeO_2) is primarily a combustion catalyst used to increase fuel efficiency and reduce diesel soot emissions, potentially resulting in the release of some ultrafine (<100 nm) poorly water-soluble particles following combustion.[6,7] Other applications of these nanoparticles involve a wide variety of uses (biomedical, coatings, electronics, energy additives). Cerium sulfadiazine (2.2% cerium nitrate in 1% flamazine cream) is an antibacterial cream used to treat severe burns.[8] Historical uses of cerium include anticoagulants, antiemetic in pregnancy, and antineoplastic agents.[3] Uses of gadolinium include a neutron absorbent in the nuclear reactor control rods in marine nuclear propulsion systems, a component of the production process for manufacturing gadolinium-yttrium garnets in microwave applications, and a popular contrast agent for magnetic resonance imaging. The latter involves the sequestration of gadolinium to large organic molecules (e.g., aminopolycarboxylic acids) to form stable and biochemically inert complexes (chelates); however, de-chelation releases free Gd^{3+} ions with potential toxicity from interaction with similar-sized Ca^{2+} ions

TABLE 26.2. Uses for rare earth elements. (Adapted from Hirano and Suzuki).[4]

Element	Symbol	Uses
Cerium	Ce	Lighter flints, catalysts, glass additives (blue fluorescence, clarity, yellow coloration, resistance to UV light), ceramics, magnets, abrasives, tracer bullets, automobile catalysts
Dysprosium	Dy	Magnets, magneto-optical materials
Erbium	Er	Lasers, color glass, metallurgy, nuclear research, porcelain, fiber optic communication cables
Europium	Eu	Fluorescent materials (televisions, fluorescent lamps), imaging plates, nuclear reactor control rods
Gadolinium	Gd	Magnets, glass additives, ferrous and chromium alloys, contrast for magnetic resonance imaging
Holmium	Ho	Electric materials
Lanthanum	La	Superconductors, lighters, automobile catalysts, glass additives, ceramics, batteries, phosphate binder
Lutetium	Lu	Superconductors
Neodymium	Nd	Magnets, lighters, lasers, purple glass additives, magneto-optical material, production of promethium
Praseodymium	Pr	Magnets, lighters, alloys, intense light sources (searchlights, movie projection machines), color glass
Promethium	Pm	Luminescent dials
Samarium	Sm	Lighters, magnets, condensers, nuclear reactor control rods, dopant for lasers, color television phosphors, infrared-absorbing glass
Scandium	Sc	Cathode-ray tubes, lasers, fluorescent material
Terbium	Tb	Fluorescent lamps/televisions, magneto-optical materials, laser and solid-state dopant
Thulium	Tm	Fluorescent materials, lasers, portable radiation units
Ytterbium	Yb	Condensers, x-ray sources for portable irradiation devices, lasers, alloys
Yttrium	Y	Superconductors, fluorescent material, catalysts, ceramics, nuclear technology, ferrous, magnesium and aluminum alloys, coatings of high-temperature metals, metal deoxidizers, television screen phosphors (oxides), yttrium-aluminum-garnet (YAG) lasers

in calcium-dependent enzymes, particularly nonionic linear agents (e.g., gadodiamide).[9] The interaction of gadolinium with nearby water molecules alters the signal intensity of MR imaging, allowing the detection of pathological processes (e.g., inflammation, infection, malignancy). The stability and disassociation rates vary with the four main categories of Gd chelates (ionic, nonionic, linear, macrocyclic). Yttrium is an additive in fine ceramics and superconductors (Y–Ba–Cu oxides) and a component of yttrium-aluminum-garnet (YAG) lasers.

Sources

Air

Rare earth elements in ambient air differ between countries depending on local anthropogenic sources and natural sources of REEs. In a study of REE concentrations, the main sources of atmospheric REEs in Beijing, China, were local soils and coal fly ash compared with industry and traffic in the Netherlands.[10] The most common rare earth elements in a study of urban air in Japan were Ce, La, Nd, and Pr.[11] In coal, rare earth elements are more abundant than more toxic metals (e.g., Be, Cd, Hg, Sb, Tl). Thulium is the rarest metal in the lanthanum series. Analysis of ambient air in Ankara, Turkey, revealed the following approximate concentrations of rare earth elements: lanthanum, 2–5 ng/m^3; cerium, 2–9 ng/m^3; samarium, 0.1–0.5 ng/m^3; europium, 0.05–0.1 ng/m^3; and yttrium, 2–3 ng/m^3 as measured by neutron activation analysis.[12] In a sampling of ambient air above a university building in Tokyo, Japan, the mean concentration of Eu was 7.77 ± 0.01 pg/mL compared with 4.31 ± 0.08 for Tb; the sources were attributed to television sets (Eu, Tb) and magneto-optical disks (Tb).[13] The light REEs (La–Nd) in the airborne samples <1.1 μm were similar to automobile catalyst with mean concentrations as follows (pg/mL): La, 300 ± 23; Ce, 370 ± 10; Pr, 70.1 ± 0.1; and Nd, 269 ± 2.

Water

Runoff from the application of REE-containing fertilizers in China and industrial processes using lanthanides are anthropogenic sources of REEs in water and sediment.[14] In two areas of China with rare earth element mining facilities, the total rare earth element concentrations in drinking water averaged 1.9 and 47.0 μg/L, whereas the third region without mining activity had an average total rare earth element concentration in drinking water of 0.92 μg/L.[15] The mean total rare earth element concentration in well water near a Chinese rare earth metal mining facility was 2.87 μg/L (range, 0.59–10.26 μg/L) compared with a mean of 0.054 μg/L in drinking water from Fuzhou City, China.[16] Seawater contains extremely low REE concentrations. In a study

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of coastal seawater at Nikkawa Beach, Japan, the mean lanthanide concentration ranged from 0.25 ± 0.02 pg Eu/mL to 4.7 ± 0.3 pg La/mL as measured by ICP/MS.[17]

Soil

The approximate concentrations of rare earth elements in the earth's crust range from ≪0.1 µg Pm and 0.5 µg Tm/g to 40 µg Nd/g and 66 µg Ce/g; these elements typically exist in a variety of minerals (e.g., carbonates, fluorides, phosphates, silicates) in granites, pegmatites, and related metamorphic igneous rocks.[18] The mean total rare earth elements in soil samples collected near a rare earth metal mining facility was 242.92 ± 68.98 µg/g dw (range, 135.85–327.56 µg/g dw); the mean bioavailable portion of the total rare earth elements was ~48%.[16] Typical concentrations of Ce, La, and Nd in coal average ~10 ppm.

Lifestyle

In a study of the area surrounding a Russian phosphorus fertilizer plant, increased uptake was detected in apples, beets, carrots, and potatoes.[19] Table 26.3 compares the maximum rare earth metal concentrations in the snow near the fertilizer plant with measures of contamination (ratio of rare earth metal concentrations to snow samples 10 km from the plant) and rare earth metal concentrations in the air near the plant. Sampling of eight vegetables grown near a rare earth metal mining facility demonstrated the highest total REEs in the vegetable group occurred in water spinach (mean = 6.12 ± 6.45 µg/g dry weight, dw) and lettuce (mean = 0.73 ± 0.34 µg/g dw).[16] In general, soil acidity and higher rare earth element soil concentrations enhance REE uptake.[18] Limited data suggest REEs in environmental tobacco smoke are higher than in nonsmoking ambient air samples. In a study of 11 ambient air samples from 3 smoking households, the median concentrations were 9.6 ng Ce/m^3 and 5.9 ng La/m^3 compared with 0.4 ng Ce/m^3 and 0.2 ng La/m^3 in 28 samples from nonsmoking households.[20]

ENVIRONMENTAL FATE

The transport and biotransformation of rare earth elements (REEs) in the environment is generally low with limited mobility; consequently, increased rare earth metal concentrations occur near anthropogenic sources of these transitional elements. Soil processes in humid environments typically reduce average REEs concentrations in soil.[18] Transfer of rare earth elements from soil to plants is typically low.

DOSE EFFECT

There are few human data on the dose-response relationship of these transitional elements. Five cancer patients received single intravenous injections of ^{90}yttrium ranging from 7.4 ng/kg–1.38 mg/kg; two cancer patients received ^{177}lutecium injections of 0.04 mg/kg and 3.28 mg/kg. These patients survived ½–17 days without evidence of acute hepatic necrosis or peritoneal inflammation. Peritonitis did not develop in a cancer patient surviving for 45 days after receiving

TABLE 26.3. Maximum rare earth concentrations (C_{max}) in the snow next to a Russian phosphorus fertilizer plant using rare earth metals and a comparison of the intensity of plant pollution using the ratio (R_c) of rare earth metals near the plant with background snow concentrations 10 km from the plant source. All rare earth metals were determined by neutron activation analysis in mg/L (ppm) for snow and ng/m^3 for air 200 m from the plant. (Adapted from Volokh et al.).[19]

Rare Earth Metal	Maximum Concentration (C_{max}, ppm)	Concentration Ratio (R_c, ppm)	Mean Air Concentration 200 m from Plant (ng/m^3)
Cerium	660	7.7	10.2
Dysprosium	15.1	9.4	NR
Europium	23	8.5	0.4
Lanthanum	454	9.5	8.0
Lutetium	1.0	3.8	NR
Neodymium	126	8.4	NR
Samarium	44	6.5	0.9
Scandium	31.4	2.3	0.5
Terbium	5.6	7.0	NR
Ytterbium	5.0	5.0	NR

3.16 mg ^{177}lutecium/kg intraperitoneally, whereas 3 out of 10 cancer patients given intraperitoneal ^{90}yttrium (1.53–2.94 mg/kg) developed peritoneal inflammation. Evidence of peritoneal inflammation was not detected in seven patients receiving 1.03–3.10 mg ^{177}lutecium/kg. One patient developed acute hepatic necrosis following the administration of 1.5 mg ^{177}lutecium/kg; this intraperitoneal dose was 40 times smaller than a similar dose causing liver damage in a rodent study.[21]

In a plant using europium-activated yttrium orthovanadate during the manufacturing of color television sets, ambient air monitoring demonstrated yttrium concentrations ranging from 0.29 mg/m^3 (top of cone cleaning exhaust enclosure) to 5.64 mg/m^3 (breathing zone of puffer operator).[22] Conjunctivitis, tracheobronchitis, and contact dermatitis were attributed to vanadium pentoxide rather than yttrium. Symptoms resolved within 1 week of exposure; no systemic complaints or pneumonitis were observed.

The toxicity of rare earth elements to animals is relatively low.[4] Focal hepatic necrosis occurred in 11 of 117 rats receiving intraperitoneal doses of cerium, lanthanum, praseodymium, neodymium, or yttrium chloride in doses ranging from 25–200 mg/kg.[21] Most of the animals developed massive fibrinopurulent peritonitis with most dying within 1 month.

TOXICOKINETICS

Human data on the kinetics of rare earth elements are extremely limited. Animal experimentation provides most of the current data. In general, the gastrointestinal tract and the lungs absorb rare earth elements poorly.[23] Complexing these elements with water-soluble salts (e.g., citrates) increases absorption, but nitrate salts of rare earth elements are not well absorbed.[24] The skin does not absorb rare earth elements; the subcutaneous injection of these compounds results in granulomas underneath the skin.[25] Lanthanides with lower atomic numbers tend to deposit in the liver, whereas lanthanides with higher atomic numbers usually transfer to bone based on animal studies.[26] Some, but not all, occupational cerium exposures may result in the long-term pulmonary retention (4–30 years) of cerium.[27] Excretion of rare earth elements occurs primarily in the feces with relatively small amounts (10%) eliminated by the kidney. Lanthanum carbonate is a phosphate binder with very low oral bioavailability (~0.001%), very high protein binding, hepatobiliary excretion with little renal elimination (<2%), and low steady-state concentrations (<3 ng/L).[28] Lanthanum does not cross the blood–brain barrier or accumulate in bones.[29] An exception is gadolinium-based contrast agents. These complexes have small volumes of distribution (~0.3 L/kg body weight) similar to extracellular water, limited protein binding, no biotransformation, and almost exclusive renal elimination via glomerular filtration.[30] However, some deposition of Gd occurs in the tissues including the brain.[31] The distribution half-life is ~4 minutes with blood–brain barrier restricting diffusion of the chelated Gd (but not ionic Gd) into the brain and other tissues.[32] Fecal excretion accounts for <3% of the elimination. The terminal half-life depends on creatinine clearance. In healthy patients with normal renal function, the terminal half-life of Gd is ~1½ hours with >95% excreted within 1 day. As creatinine clearance decreases, the terminal half-life increases to ~4–8 hours (glomerular filtration rate, 30–60 mL/minute) and 18–34 hours (glomerular filtration rate, <30 mL/minute).[33]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Most experimental studies in animals indicate rare earth element oxides (e.g., gadolinium) are mild respiratory irritants that require heavy exposure over prolonged periods to produce pulmonary inflammation.[34,35] Case reports suggest at least some rare earth elements (e.g., cerium) may persist in the lungs for years when converted to insoluble compounds (e.g., cerium phosphate).[36] Multiple confounding variables (smoking, asbestos, silica, quartz) complicate the establishment of causation between rare earth exposure and fibrotic lung disease. Subacute studies of animals exposed via inhalation to a blend of rare earth oxides and fluorides demonstrated little fibrogenic activity.[37] Although the extent of pulmonary damage depends on particle characteristics, dose, and type of rare-earth complex, all these elements demonstrate minimal fibrogenic potential. The pathological potential of lanthanides to produce fibrosis is mild compared with silica and quartz.[38] Direct instillation of rare earth oxides into the lungs produced a fatal delayed chemical pneumonitis in some animals, but no chronic cellular reactions or fibrosis occurred in surviving animals.[39] Compared with rare earth metal oxides, exposure of animals to fluoride salts of rare earth elements caused a more prominent acute chemical pneumonitis that progressed with continued exposure to chronic bronchitis and bronchiolitis.[40]

Radioactive contamination of dust from rare earth elements probably does not contribute significantly to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the pulmonary effects of these transition elements.[26,41] The ionic size of lanthanides and calcium is similar; consequently, these transitional elements bind to calcium sites on biological molecules including lanthanum.

Pathological Changes

Humans

Experimental and epidemiological data suggest prolonged inhalation of high concentrations of stable lanthanides can produce pneumoconiosis and progressive pulmonary fibrosis; however, the occurrence of pulmonary damage following rare earth metal exposure is rare with frequent confounding exposures. No pathognomonic lesion is characteristic of REE exposure; concurrent radiation exposure (e.g., thorium) does not account for the fibrotic changes.[26] Nephrogenic systemic fibrosis associated with Gd chelates used in MRI scanning occurs with dermal abnormalities (nephrogenic dermal fibrosis).[42] Pathological changes include thickened, indurated skin resulting from diffuse dermal fibroplasia with spindle cells extending into subcutaneous tissues, interstitial mucin deposition, and minimal/mild inflammation. Histological features depend on the stage of the disease. Early changes include scant proliferation of spindled fibroblasts and minimal collagen production, whereas later lesions involve more numerous fibroblasts and collagen deposition in the reticular dermis and subcutis. Calcium deposits may occur in collagen as well as in other organs (kidneys, heart, lungs, muscles, testes).[43,44]

Animals

No pathological lesions distinguish the effects of rare earth elements. Following the intravenous administration of 1 mg YCl_3 to rats, the spleen and liver are the primary target organs with some elevation of plasma Ca concentrations occurring probably as a result of bone resorption.[45] The ingestion of chloride salts of rare earth elements in doses up to 1% of the diet for 12 weeks produced some minor alterations in liver histology, but no changes in growth or blood abnormalities.[46,47] Although rare earth elements do not usually damage intact skin, the application of rare earth elements to abraded skin may cause scarring and epilation. Animal studies indicate terbium is the most irritating rare earth metal for skin; however, terbium did not produce scarring in these studies when applied to intact skin.[48] Little irritation occurs following the application of lutetium chloride to intact skin, but extensive necrosis develops following the intradermal injection or the application of lutetium chloride to abraded skin.[49] Similarly, europium chloride produces transient ocular irritation without permanent scarring; the application of europium chloride to abraded skin causes scar formation in animal studies.[50]

Postmortem Examination

A 68-year-old man presented with progressive dyspnea 13 years after retiring from a 35-year career as an optical lens grinder.[51] Open lung biopsy demonstrated nonspecific interstitial fibrosis, while scanning electron microscopy with energy-dispersive x-ray analysis revealed numerous pulmonary deposits primarily consisting of cerium alone or in combination with other elements. Pathological findings included early honeycomb changes, vascular thickening, reactive alveolar pneumocytes, numerous intra-alveolar macrophages, and chronic interstitial inflammation consistent with interstitial pneumonitis. A 66-year-old projectionist with 25 years of exposure to carbon arc lamp fumes died of congestive heart failure.[52] Histological examination of lung and liver tissue demonstrated large deposits of rare earth elements in macrophages of the tracheobronchial lymph nodes and hepatic Kupffer's cells; however, he had no histological or clinical evidence of interstitial lung disease.

CLINICAL RESPONSE

Acute Toxicity

The acute toxicity of rare earth elements depends on the route of exposure; however, the rare earth element toxicity is low and increases with increasing atomic weight.[24] Case series associate nonspecific symptoms with exposure to high concentrations of rare earth element dust including nausea, headaches, and weight loss.[53,54] Acute kidney injury (i.e., >0.5 mg/dL increase in serum creatinine) may occur in chronic renal disease patients (Stage 4 or higher) receiving gadolinium-based contrast agents; the incidence of renal damage is substantially less than iodinated contrast agents. In a retrospective study of 163 patients with chronic renal disease, 5.3% of the patients receiving gadolinium developed acute kidney injury compared with 20.6% in the iodinated contrast group ($P < 0.01$).[55] Risk factors for the occurrence of acute kidney injury include poor renal function, intraarterial injections, and high Gd contrast volumes. Case series associate the use of large cumulative doses of linear

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

gadolinium-based contrast agents with the development of nephrogenic systemic fibrosis predominately in patients with Stage 5 renal disease.[56] This disease affects multiple organs including the kidneys and skin characterized by skin abnormalities (thickening/woody, edema, cobblestone texture, dimpling, hyperpigmentation) over limbs and occasionally the trunk similar to scleroderma.[57] Fibrotic changes also may occur in the heart and lungs (pleura, interstitial pulmonary fibrosis).

The onset of nephrogenic systemic fibrosis typically begins within 1–8 weeks after gadolinium-based contrast exposure with a range of up to ~3 years.[58] Nephrogenic systemic fibrosis occurs exclusively in patients with renal impairment exposed to gadolinium-based contrast agents (GBCAs), primarily with glomerular filtration rates <30 mL/minute/1.73 m^2 and receiving GBCAs with high dissociation rates.[59] The implementation of restrictions on GBCAs use in patients with known risk factors has eliminated most cases of nephrogenic systemic fibrosis.[60]

Recent data suggest gadolinium deposition from the release of free Gd^{3+} ions from less stable GBCAs with high dissolution rates (e.g., macrocyclic, linear) may occur in the presence of normal renal function.[61] Clinical studies to date indicate gadolinium deposition within brain tissues (i.e., dentate nucleus, globus pallidus) occurs in patients with neoplastic or systemic inflammatory diseases that potentially cause disruption of the blood–brain barrier.[62] The clinical consequences of potential brain tissue gadolinium deposition remain unclear in the absence of well-designed studies with established reference gadolinium levels.[61]

Occupational Exposure

Several case reports of workers in the photographic, photoengraving, and printing industries associate prolonged exposure to dust containing rare earth elements from carbon arc lamps with lung irritation and mild[63] to moderately severe[64] pulmonary fibrosis. In a 34-year-old man with an ~10-year history of handling a dry concentrate of rare earth elements, routine chest x-ray demonstrated profuse, discrete nodules throughout the lung fields, primarily in the mid-lung area.[65] He was asymptomatic with normal exercise tolerance and pulmonary function tests. A 58-year-old light smoker with a 46-year history of exposure to rare earth elements at photoengraving laboratories presented with dyspnea on exertion and a slightly productive cough for 2 years.[66] He had evidence of pulmonary hypertension on cardiac catheterization and reticulonodular changes on chest x-ray with both obstructive and restrictive abnormalities on pulmonary function testing. Lung and lymph node biopsies demonstrated elevated cerium, neodymium, lanthanum, and samarium concentrations compared with controls without occupational exposure to rare earth elements.[41]

There are no clinical data to compare rare earth metal workers with and without evidence of pulmonary fibrosis. A 66-year-old adult-onset diabetic with a history of heavy smoking, chronic alcohol abuse, and angina pectoris presented with terminal congestive heart failure.[52] His occupational history included a 25-year exposure to rare earth elements from carbon arc lamp fumes; however, he had no radiological, histological, or clinical evidence of interstitial lung disease. The contribution of confounding variables (graphite, thorium) to the development of pneumoconiosis in workers exposed to rare earth elements remains undefined.

Carcinogenesis

Rare earth elements are not recognized as animal or human carcinogens, but the neoplastic potential of isotopes of rare earth elements remains to be determined. $^{144}CeO_2$ emits beta radiation that causes an increased incidence of lung tumors in rats exposed to aerosols of $^{144}CeO_2$ based on the cumulative dose of beta radiation.[67] In these animal studies, the predominant pulmonary tumor is a squamous cell carcinoma that exhibits more malignant behavior compared with squamous cell carcinomas of the lung that result from prolonged inhalation of heavy particle loads.[68]

DIAGNOSTIC TESTING

Analytical Methods

The separation of rare earth metals is difficult because the chemical activity of the metals in this group is almost identical. Techniques for the determination of lanthanides in biological specimens include neutron activation analysis, graphite furnace atomic absorption spectrometry, inductively coupled plasma/atomic emission spectrometry, and inductively coupled plasma/mass spectrometry.[69] The latter has detection limits well above serum concentrations of rare earth elements, typically in the pg/mL (ppt) range;[70] some pretreatment of the sample is necessary to overcome matrix and spectral interferences secondary to polyatomic ions in the plasma including pre-concentration with chelating resin after acid digestion and heating.[71,72] Atomic absorption spectrometry (AAS) is the most frequent method used to quantify the concentrations of rare

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

earth elements in biological specimens. The use of a spectroscopic detection system avoids the precipitation of rare earth elements as hydroxides at neutral pH in the column.[73] Neutron activation analysis is a more sensitive method compared with AAS, but the cost is much higher. Examination of bronchoalveolar lavage fluid allows the detection and determination of rare earth elements in patients exposed to these elements by neutron activation analysis and energy-dispersive x-ray fluorescence.[74] The use of electrothermal vaporization/inductively coupled plasma/mass spectrometry allows the determination of REEs in environmental and biological samples with limits of detection in the range of 0.02–0.09 pg/mL in the former and 1–10 pg/mL in the latter.[75,76]

Biomarkers

There are few data on the concentrations of rare earth elements in samples of blood or urine; existing data indicate that the concentration of rare earth elements in biological tissues is very low. The mean lanthanide concentrations in serum from five healthy volunteers ranged from 0.66 pg Eu/mL to 235 pg Ce/mL as measured by ICP/MS.[71] Table 26.4 displays the mean lanthanide concentrations in the five healthy volunteers. In a convenience sample of blood collected from Chinese residents near a rare earth metal mining facility, the mean *total* rare earth element concentration was 689.74 ± 254.25 μg/L (range, 424.76–1,274.80 μg/L).[16] Total rare earth metals included 15 rare earth elements excluding scandium and promethium as measured by inductively coupled plasma/mass spectrometry.

TABLE 26.4. Mean rare earth element concentrations of 14 lanthanides in serum samples from 5 healthy volunteers as measured by ICP/MS. (Based on Inagari and Haraguchi).[71]

Element	Atomic Number (symbol)	Mean (μg/L, ppb)
Cerium	58 (Ce)	214 ± 22
Dysprosium	66 (Dy)	9.6 ± 1.1
Erbium	68 (Er)	9.5 ± 1.9
Europium	63 (Eu)	0.82 ± 0.19
Gadolinium	64 (Gd)	7.2 ± 1.4
Holmium	67 (Ho)	2.55 ± 0.54
Lanthanum	57 (La)	62.7 ± 7.1
Lutetium	71 (Lu)	2.46 ± 0.58
Neodymium	60 (Nd)	33.7 ± 4.2
Praseodymium	59 (Pr)	11.1 ± 1.5
Samarium	62 (Sm)	5.8 ± 1.1
Terbium	65 (Tb)	1.30 ± 0.22
Thulium	69 (Tm)	1.69 ± 0.42
Ytterbium	70 (Yb)	13.2 ± 3.2

In a study of 28 healthy French men, morning samples of plasma and urine contained concentrations of rare earth elements (Ce, Gd, La, Tb, Yb) were <0.3 μg/L, as determined by inductively coupled plasma/mass spectrometry; the single exception was a urine sample containing 1.5 μg Ce/L.[77] In a study of a convenience sample of 58 healthy Italian volunteers, the mean lanthanide concentration in urine samples ranged from ~2.5–20 pg/mL as measured by electrothermal vaporization/inductively coupled plasma/mass spectrometry.[76] Table 26.5 lists the results from this study.

TABLE 26.5. Analytical results from the study of urine samples from 58 healthy Italians without known exposure to lanthanides as measured by EVT/ICP/MS. (Based on Bettinelli et al.).[76]

Element (Atomic Symbol)	Atomic Number	Mean (pg/mL)	Median (pg/mL)	Range (pg/mL)	Samples Below Limit of Detection
Cerium (Ce)	58	15.7	14.2	>7.0–58.8	5
Dysprosium (Dy)	66	10.3	7.8	3.3–55.4	0

Abnormalities

Because of their high atomic numbers, chest x-rays of workers exposed to rare earth elements demonstrate dense infiltrates in a diffuse, nodular pattern; these patients are often asymptomatic. Characteristic radiological findings following prolonged exposure to the smoke of carbon arc lamps are small, diffuse, highly radiopaque nodules that occur primarily in the mid-lung zones.[65] Pulmonary function tests frequently are normal. Case reports associate mild-to-moderate restrictive defects in patients with the diagnosis of rare earth metal pneumoconiosis, but the presence of confounding factors (smoking, fibrogenic dust exposure) complicates the interpretation of these tests.[78] Obstructive defects are not usually present without the occurrence of confounding exposures.

HEALTH SURVEILLANCE

Currently, permissible exposure limits exist only for yttrium among the rare earth compounds. The US OSHA PEL–TWA for yttrium and yttrium compounds is 1 mg Y/m^3 as a measure to reduce the potential for pulmonary damage. NIOSH has a similar REL–TWA. The IDLH is 500 mg Y/m^3. The ACGIH TLV–TWA for yttrium and yttrium compounds is also 1 mg Y/m^3 to minimize the risk for respiratory fibrosis following large exposures. There are no biological markers established for rare earth elements.

TREATMENT

Treatment primarily is supportive. Contact with eyes or with abraded skin may require decontamination. Rare earth elements, particularly terbium and yttrium, may cause ulcerations when introduced into the dermis through abrasions or lacerations. Consequently, wounds contaminated by rare earth elements should be thoroughly cleaned and debrided. Incidental ingestion of rare earth metals is usually harmless with no decontamination measures typically necessary.

Chapter 27

SELENIUM

ELEMENTAL AND INORGANIC SELENIUM

HISTORY

Marco Polo probably recorded the first observations of selenium (Se) toxicity when he described a disease called "hoof rot" in horses in the Nan Shan and Tien Shan mountains of Turkestan, where selenium-rich soils exist.[1] In 1817, the Swedish chemist, Jöns Jacob Berzelius, isolated and identified selenium by analyzing a red deposit on the wall of a lead chamber used to produce sulfuric acid.[2] In the late 19th and early 20th centuries, livestock grazing on plants growing on highly seleniferous soils in areas of the Great Plains of the United States developed alkali disease (also known as selenosis). This disorder is caused by the chronic ingestion of grain and forage contaminated with 5–50 ppm of selenium. Signs of alkali disease in livestock include dystrophic changes in hooves, stiffness, lameness, and bilateral symmetrical alopecia (e.g., loss of the tail switch). During the first half of the 20th century, several papers associated the development of skin lesions and neuropathy in horses, sheep, and cattle grazing on plants (genera *Astragalus, Xylorhiza*, *Oonopsis*, and *Stanleya*) with high selenium concentrations in the soils of the northern Great Plains of the United States.[3,4,5,6] This subacute disease (blind staggers) occurred in livestock feeding on plants that contained up to 10,000 ppm selenium. Clinical features included anorexia, weight loss, blindness, ataxia, respiratory distress, and disorientation, resulting in the animal straying from the herd or continuously circling. The association between chronic selenosis and neurological disease in grazing animals remains controversial because the disease was not replicated in animals fed excessive selenium; alternate explanations (e.g., sulfate-related polio encephalomalacia, malignant catarrhal fever, swainsonine-induced locoism, viral infections, starvation) were not excluded.[7] Additionally, separating the effects of inorganic and organic selenium is very complex because plants contain variable amounts of both Se types depending on plant species, environmental conditions, the bioavailability of selenium species, and the type of selenium present in the environment. Pigs fed extracts from *Astragalus bisulcatus* developed more severe and disseminated neurological lesions compared with pigs fed sodium selenate or D,L-selenomethionine; however, there was no direct correlation between blood selenium concentrations and the severity of pathological changes.[8] The administration of selenocysteine did not produce any neurological lesions. Furthermore, the foraging of obligate selenium accumulators is highly unpalatable, even for grazing animals.[9]

In the early 20th century, high doses of selenium dioxide (3 mg/day) and potassium selenate (300 µg/day) briefly were advocated as a treatment for hematological malignancies.[10] This practice stopped in 1943 after an animal study reported the occurrence of low-grade

tumors (adenomas, carcinomas) in female rats that developed cirrhosis following the ingestion of high doses of ammonia potassium selenide and ammonium potassium sulfide.[11] These hepatic neoplasms occurred only after 18 months of dosing and only in rats with cirrhosis.

The first indication of the nutritional importance of selenium appeared in the 1950s, when the replacement of vitamin E in the diets of experimental animals by selenium did not produce adverse effects.[12] In the early 1970s, experiments revealed that selenium was an essential component of glutathione peroxidase, which is an important enzyme for the process that protects polyunsaturated membrane lipids from oxidative degradation.[13] The status of selenium as an essential trace element was confirmed by the discovery of a clinical condition in China called Keshan disease that resulted, at least in part, from inadequate selenium concentrations in the diet. The incidence of multifocal myocarditis and periacinar pancreatic fibrosis declined dramatically after supplementation of selenium in the Chinese diet. Selenium deficiency occurs in the geographic areas where Balkan nephropathy appears, but there is no direct evidence that selenium deficiency contributes to the development of this chronic, progressive kidney disease.[14] Selenium often is added to the feed of animals in doses up to 0.3 ppm in order to prevent selenium deficiency diseases.

Within the last several decades, research interest in selenium has increased dramatically as a result of several lines of scientific inquiry that demonstrated an *increased* risk of cancer with *low*-selenium diets.[15,16] However, there is no convincing evidence that routine use of selenium supplements reduces the risk of cancer (prostate, skin, other unspecified cancer), except possibly in areas where profoundly low selenium concentrations occur in the soil.[17,18,19]

PHYSIOCHEMICAL PROPERTIES

Selenium (Se) is a metalloid (i.e., having intermediate properties between metals and nonmetals) belonging to Group 16 (formerly Group VIA with oxygen, sulfur, polonium, tellurium) of the periodic table. The chemical properties of selenium resemble those of sulfur and, to a lesser extent, tellurium including similar atomic size, bond energies, ionization potentials, and primary oxidation states.[20] Selenium is a stable element that does not oxidize at room temperature and has a strong tendency to complex with heavy metals directly or in aqueous solutions. Selenium dioxide forms following combustion of selenium in air. The four natural oxidation states of inorganic selenium include the following: (0), elemental selenium, selenium sulfides (Se_nS_n); (2−), sodium selenide (Na_2Se), hydrogen selenide (H_2Se), mercury (II) selenide (HgSe); (4+), sodium selenite (Na_2SeO_3), selenium dioxide (SeO_2), selenious acid (H_2SeO_3); and (6+), sodium selenate (Na_2SeO_4), selenic acid (H_2SeO_4). The reduced form of selenium (i.e., selenide) is the ionized form of hydrogen selenide (H_2Se); selenide is unstable in aqueous solutions except at low oxidation–reduction potential and alkaline conditions. Elemental selenium is stable and exists in the following three allotropic forms: deep red crystals (melting point 144°C), red amorphous powder, and the black vitreous form.[21] Colloidal selenium forms a red-orange allotrope in aqueous solution that precipitates. Selenium has six stable natural isotopes divided as follows: ^{74}Se (0.89%), ^{76}Se (9.37%), ^{77}Se (7.63%), ^{78}Se (23.77%), ^{80}Se (49.61%), and ^{82}Se (8.73%). The most common artificial radioisotope is ^{75}Se, which is a gamma emitter with a half-life of ~120 days used as a diagnostic agent in medicine. The reduced heavy metal selenides (2−) and elemental selenium (0) are insoluble in water; however, the inorganic alkali selenites (4+) and the selenates (6+) are water-soluble. Therefore, these latter oxidation states possess greater bioavailability compared with selenides or elemental selenium. The salts of selenious acid (selenites) and selenic acid (selenates) are usually water-soluble, but most selenites are less soluble than the corresponding selenates. Selenium forms stable compounds with oxygen, particularly selenium dioxide. Hydrogen selenide is a colorless gas with a disagreeable odor and an odor threshold of ~0.3 ppm,[22] whereas selenium hexafluoride is a colorless gas that decomposes in water. Table 27.1 lists the identifying information and physical properties of elemental selenium and inorganic selenium compounds.

Upon contact with water, selenium dioxide (4+) forms the weak acid, selenious acid (H_2SeO_3), which has a $pK_{a1} = 2.8$ and $pK_{a2} = 8.5$. In water, selenium trioxide (6+) produces selenic acid (H_2SeO_4), which is a stronger acid than selenious acid with a $pKa_1 = -3$ and $pKa_2 = 1.7$. Selenate is the most stable oxidized form of selenium in alkaline and oxidizing solutions.

Hydrogen selenide is a highly reactive compound formed by the reaction of water or acids with metallic selenides. Alternately, H_2Se forms from the reaction of hydrogen with soluble selenium compounds. Selenious acid is a weak dibasic acid that sometimes acts as an oxidizing agent rather than a reducing agent. Hydrogen selenide (2−) is a strong reducing agent, and H_2Se is a relatively strong acid.

EXPOSURE

Uses

Elemental and inorganic selenium has many commercial uses (e.g., electronics, glass, ceramics, steel, pigment manufacturing, livestock food additives). Selenium is an essential trace element added to animal feed at concentrations of 0.1–0.3 ppm in the total diet. The principal applications of elemental and inorganic selenium include manufacture of ceramics, glass (ammonium selenite, sodium selenite, sodium selenate), photoelectric cells, pigments (cupric selenate), rectifiers, semiconductors, and steel. Other uses involve photography and pharmaceutical production (dehydrogenation-catalyst) for niacin and cortisone. Selenium dioxide is the most common industrial selenium compound. Applications include the production of photographic cells, low-voltage rectifiers, and photographic chemicals; a decolorizer for green glass; a vulcanizing agent for rubber; and an alloy with copper and steel (photocopy machines).

Selenium hexafluoride is a gaseous insulator in electric transformers. Selenite salts are red pigments for glass and enamels; selenium oxychloride is a solvent. In addition to dietary supplements, the medicinal uses of selenium include use of selenium sulfide for the treatment of seborrheic dermatitis and tinea versicolor. Gun bluing solutions contain lethal amounts of selenious acid in addition to lesser amounts of copper nitrate and nitric acid. The artificial radioactive isotope, ^{75}Se, is a gamma emitter for biochemical studies with a half-life of 120 days. The six stable isotopes of selenium do not have well-defined uses. Selenite cysteine broth is an enrichment medium for the isolation of *Salmonella* species that typically contains 4 g sodium selenite/L.

Production Processes

Although selenium is a common constituent of most rocks and soils, selenium seldom occurs naturally in its elemental form.[21] Commercial selenium is a by-product of sulfide ores (copper, gold, lead, nickel, silver) that forms during the refining of copper when selenium accumulates in electrorefining tanks. The manufacture of sulfuric acid produces small amounts of selenium. Commercial production of selenium involves either soda ash roasting or sulfuric acid roasting of copper slime. Soda ashing refining involves the roasting of a paste formed by soda ash binder and copper slime followed by the grinding and leaching to reduce hexavalent selenium to sodium selenate. Controlled heating reduces sodium selenate to sodium selenide followed by oxidation to elemental selenium by percolation of air through the leachate. Other reducing agents for hexavalent selenium in this process include hydrochloric acid and ferrous salts catalyzed by chloride ions. The sulfuric acid process involves the volatilization of selenium dioxide formed from the roasting of sulfuric acid and copper slime at 500–600°C followed by reduction to elemental selenium during scrubbing with water and sulfur dioxide.

Coal usually contains up to ~4 ppm selenium.[23] In a sample of coal from the United States, the selenium concentration ranged from 1–5 ppm Se with an average of 3.2 ppm Se.[24] Selenium also occurs in some crude oil depending on locations with selenium deposits (e.g., shale). Samples of US crude oil demonstrated Se concentrations ranging from 0.06–0.35 ppm with a mean value of 0.17 ppm. Higher Se concentrations (i.e., 0.5–0.8 ppm) occur in crude oil from seleniferous areas (e.g., San Joaquin Valley, California).

Sources

Air

Atmospheric selenium results from natural and anthropogenic sources; ambient background Se concentrations in the air are typically very low (i.e., <10 ng/m^3).[21] Combustion of fossil fuels and coal is the primary anthropogenic source of selenium in ambient air. The incineration of rubber, municipal waste, and paper adds lesser amounts of selenium to the air. Volcanic gas is the major *natural* source of selenium in ambient air; biomethylation of selenium releases small amounts of selenium into the air.[21] Although the burning of fuel produces selenium dioxide, the presence of sulfur dioxide rapidly reduces the selenium dioxide to elemental selenium.[25] Consequently, most selenium in ambient air is present in the form of elemental selenium bound to fly ash and particles. The majority of the selenium discharge from coal-fired steam plant partitions occurs via fly ash removal to nearby slag ponds rather than to air. Background Se concentrations in ambient air generally average 0.1–10 ng/m^3 with ranges up to 500 ng/m^3 near point sources.[26] In a study of seven UK sites, the selenium concentrations in the ambient atmosphere ranged from 0.1–42.3 ng/m^3 with the lowest mean (0.9 ng/m^3) in the rural area of Windermere and the highest mean (16.7 ng/m^3) in the industrial area of Walsall.[27]

Soil

The primary source of selenium in the soil is the weathering and leaching of parent bedrock materials that contain selenium in the form of selenites and selenides in association with sulfide minerals (arsenopyrite, chalcopyrite, galena, marcasite, pyrrhotite, pyrite). Selenium occurs in soil as elemental selenium, calcium selenate, basic ferric selenite, and organic selenium compounds as a result of the decay of plant and animal material; elemental selenium is rare in nature. Coal-mining operations release selenium because of the oxidation of selenium-bearing pyrite.[28] Most soils contain Se concentrations of 0.1–2 mg/kg;[29] however, the selenium content in soil varies widely between specific localities with areas of high selenium content containing up to 1,200 mg/kg. Parts of the Western and Midwestern United States contain highly seleniferous soil including parts of South and North Dakota, Wyoming, Nebraska, Kansas, Utah, Colorado, Arizona, and New Mexico. In 45 soil samples from the high-selenium areas of Enshi Prefecture of Hubei Province, China, the distribution of the total Se concentration was log normal and ranged from 2.89–87.3 μg/g (GM = 9.36 ± 18.6 μg/g).[30] Most of the selenium was bound to organic matter.

The amount of selenium in the soil is not a good indicator for the bioavailability of selenium to plants because the accumulation of selenium from soil varies between plant species. Plant genera that easily accumulate selenium as soluble selenates and selenites are *Astragalus* (several thousand ppm), *Machaeranthera* (~800 ppm), *Oonopsis* (~800 ppm), *Stanleya* (~700 ppm), and *Xylorhiza* including alfalfa (0.23 mg/kg dw), yeasts, white grains, and cruciferous species (e.g., cabbage, broccoli, cauliflower, mustard). Secondary accumulators include *Aster* (~72 ppm), *Atriplex* (~50 ppm), *Comandra*, *Grindelia*, *Gutierrezia* (~60 ppm), and *Haplopappus* (120 ppm).[12] These plants grow in soil containing 1–50 ppm selenium and accumulate Se concentrations of 100–100,000 mg/kg of plant tissue for primary accumulators and 25–100 mg/kg of plant tissue for secondary accumulators.[31] Plants that do not accumulate selenium usually contain <25 mg/kg of plant tissue.

Water

Selenium appears in water as a result of wet and dry deposition from the atmosphere and by surface and subsurface drainage. Concentrations in seawater are generally low (0.04–0.12 µg Se/L),[32,33] whereas the concentration in ground and surface water varies widely (0.06–400 µg Se/L).[34] Concentrations in public water supplies seldom exceed 10 µg Se/L.[31,35] High concentrations of selenium in surface and ground water usually occur in farm areas where irrigation water drains from soils with high selenium content. Selenium in water exists as the salts of selenic (strong) and selenious (weak) acids. The soluble selenate salts of selenic acid occur in alkaline waters with sodium selenate being one of the most mobile selenium compounds in the environment. The poor adsorption of sodium selenate to soil particles enhances the mobility of this salt in soil. Because selenious acid is a weak acid, the diselenite ion predominates in waters with pH 3.5–9. The presence of iron decreases the selenium concentration as a result of the precipitation of insoluble ferric selenite. To date, there are no published reports of selenium toxicity in humans consuming fish or fowl from selenium-contaminated areas.

Kesterson Reservoir, California

The Kesterson Reservoir near Gustine in western Merced County, California, was a series of 12 shallow, drain water-evaporation ponds fed by an 85-mile subsurface agricultural drain (San Luis Drain). This reservoir was the storage and evaporation facility for water traveling through the drain in 1978–1986. The connection between the Kesterson Reservoir and the Pacific Ocean via Suisun Bay was never built. Consequently, drain water entering the Kesterson Reservoir either percolated into groundwater or evaporated into the air. Elevated Se concentrations appeared in the Kesterson Reservoir as a result of the impounding of selenium-laden, agricultural drainage water into evaporation ponds without a natural drain.

A similar mechanism produced elevated selenium concentrations in the Tulare Basin, ~160 km south of the Kesterson Reservoir. Soluble selenium leached from the arid, saline soils, primarily in the form of selenates; the irrigation water carried the selenium into ponds or groundwater. Although selenate was the major fraction of dissolved selenium in the Kesterson Reservoir, a study of the drainage water indicated that up to ~25% of the Se species were methylated forms.[36]

Deaths and deformities (anophthalmia, microphthalmia, abnormal beaks, amelia, micromelia, ectrodactyly, hydrocephaly) in fish and resident waterfowl living in the nearby Kesterson Wildlife Refuge were associated with contamination of intake waters by high selenium concentrations that averaged ~300 µg/L[37,38] and often exceeded 1.35 mg/L.[21] Selenium concentrations in decomposing detritus in the reservoir were as high as 440 µg/g dry weight.[39] The selenium concentrations typically increased in the following order: water > sediment > plants > animals. The Se concentrations exceeded normal environmental Se concentrations at nearby reference sites by >100-fold. The average Se concentrations in Kesterson groundwater and surface water surrounding the reservoir were 31 µg/L and 22 µg/L, respectively.[36] Only 3 of the 27 evaporation basins tested in other portions of the San Joaquin Valley had total Se concentrations exceeding 0.1 mg/L.[21]

A community health survey of residents in the area surrounding the Kesterson National Wildlife Refuge did not reveal any adverse health effects in the local population, despite the presence of high selenium contamination. Examples of the extent of selenium contamination included the following: local fish (≥96 ppm Se, wet weight), aquatic birds (≥130 ppm in liver, dry weight), and waterfowl (≥5.3 ppm flesh, wet weight).[36] Selenium toxicity was not detected in any domestic animals near the Kesterson Reservoir. Biological monitoring of workers stationed at the Kesterson Reservoir and the San Luis Drain vicinity did not reveal any elevated blood or urine selenium concentrations.

Belews Lake, North Carolina

Belews Lake is a man-made reservoir that provided condenser-cooling water for a large coal-fired electric

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

power plant. At Belews Lake, contaminated effluent (100–200 µg dissolved Se/L) from a coal ash disposal basin near a newly constructed coal-fired plant produced Se concentrations (>10 µg/L) sufficient to eliminate most fish species from the reservoir.[40] The long hydrological retention time (i.e., 1,500 days) and relatively low sedimentation rate (<0.5 cm/year) in this lake contributed to Se accumulation. Discharge of selenium-containing waste into the lake stopped in 1986; the peak selenium concentration in lake water was 20 µg/L at the time discharge ceased compared with <1 µg/L in 1996.[41] Selenium concentrations in birds from Belews Lake were not high enough to produce reproductive abnormalities. Elevated selenium concentrations also occurred at other power plant cooling basins in the Hyco Reservoir, North Carolina, and the Martin Reservoir, Texas. Experimental studies in England indicate Se concentrations of >25 µg/L in freshwater ponds are sufficient to eliminate about half the resident population of perch.[42]

San Francisco Bay

Besides agricultural runoff from seleniferous soil, commercial sources of selenium in water include discharge from coal fly ash settling ponds, municipal sewage discharge (e.g., ranging up to 0.28 mg Se/L),[43] and oil refineries. The concentration of Se in crude oil depends on the source. Reported Se concentrations in crude and heavy petroleum were 0.5–0.95 g/kg and 0.5–1.65 g/kg, respectively.[44] In a study of direct discharge from oil refineries in the San Francisco Bay, the effluent contained an average of 0.067 mg/L with a range of 0.006–0.156 mg/L. The portion of selenium in the form of selenite (50–76%) was relatively high compared with natural sources.[45] This study indicated that the cycling of selenium in the San Francisco Bay was complex as a result of large temporal and spatial variation in the chemical speciation of selenium. Substantial variation in the contribution of anthropogenic sources (oil refineries, municipal sewage plants) to the total selenium depended, in part, on the variation in the discharge of water from rivers into the Bay. Despite the input of selenium from these anthropogenic sources, the highest Se concentrations present in the South Bay (i.e., near the sewage plants) and the North Reach (i.e., near the refineries) were 0.36 µg/L and 0.29 µg/L, respectively. These values were within the range measured in other estuaries.

Diet

For the general population, the primary pathway of selenium exposure is food followed by water and air.[21,46] Estimates of the daily intake of selenium in various countries include the following: United States, 60–216 µg (mean = 71–152 µg, 1–2 µg/kg/day);[21,47,48] Canada, 113–220 µg;[49] Spain, 60–106 µg;[50] and Greece, ~95–110 µg.[51] The estimated mean daily intake of selenium in eight adults living in Southern California was 127 g (range, 90–168 µg).[52] In comparison, the estimated daily selenium intake by residents of high-selenium areas in China was 2,144 µg.[30] Factors affecting the Se concentration in foods include food type, soil type, time of selenium application, time of harvest, and soil conditions. Sodium selenite is a common source of selenium in multivitamins in doses ranging from 50–100 µg/tablet.

Selenates enter the food chain through plants; the contribution of drinking water to selenium in the human diet is small. Meats, fish, poultry, grains, and cereal products are the major food sources of selenium in the diet of the general population.[49,53] In a survey of the typical US diet, selenium in beef, white bread, pork, chicken, and eggs accounted for ~50% of the total selenium consumed in the diet; dairy products account for <10%.[54] Fish and feed animal organs (liver, kidney) are the foods containing the highest Se concentrations followed by meat and eggs; however, the best Se sources in the diet are selenium-enriched yeast, wheat, and other plant material because of the greater Se bioavailability these sources have compared with animal sources.[55]

Selenium Species

Selenate and selenite are the main inorganic selenium species in the diet. Higher plants absorb selenium preferentially as selenate via the sulfur-binding enzyme, permease; however, organic selenium compounds account for the major portion of selenium in vegetables and cereals.[56] Wheat is a non-selenium accumulating plant. In a study of spring wheat grown in selenium-rich soil in India, the total selenium concentrations in two samples were ~83 µg/g and ~183 µg/g, respectively, dry weight.[57] Selenate accounted for ~2–6% of the total selenium species. Selenium in animal tissue occurs in a variety of forms including organic (e.g., selenomethionine, selenocysteine) and inorganic (e.g., selenotrisulfide, selenopersulfides, metallic selenides) selenium species.[58] Over half of the selenium in straw eluted as selenate; selenite was not detected. Inorganic selenate and selenite predominate in water.

Bioavailability

Selenium bioavailability depends on a variety of factors affecting Se content in food including Se soil content, animal feed use, Se-containing fertilizers, plant uptake/metabolism, and Se species with inorganic Se typically being less than organic Se.[59] Furthermore, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

bioavailability of inorganic selenium in plant-derived foods (e.g., wheat) is relatively high, whereas the bioavailability of selenium in animal-derived foods (e.g., fish)[60] is low to moderate.[61,62] No statistically significant differences in serum selenium were detected in 11 volunteers consuming Se-rich fish (mean = 115 ± 31 μg Se/day) compared with a control group eating a normal diet (77 ± 25 μg Se/day).[63] In the group of volunteers fed similar amounts of selenium as selenium-enriched wheat, the mean selenium concentration in the serum and the platelets increased by 17% and 30%, respectively, compared with controls. The difference was statistically significant ($P < 0.01$). Most,[64,65,66] but not all, animal studies[67] indicate that Se in seafood has relatively low (i.e., 35–60%) bioavailability compared with selenium as selenite (100%). These studies also indicate that the Se bioavailability as selenite in animal species is less than the bioavailability of selenate or selenomethionine.

The predominant Se species in drinking water is selenate depending on the pH, oxidation–reduction potential (E_h), and the presence of metals. Based on comparisons of average daily selenium intake and whole blood selenium concentrations in humans, the bioavailability of selenium is lower in water than in food.[68] The differences in bioavailability depend on a variety of factors including the criteria for an end point (e.g., platelet glutathione peroxidase activity),[69] physiochemical properties (e.g., pH, E_h), and dietary factors (selenium deficiency, lipids, metals). The formation of metal complexes with selenium reduces Se bioavailability in fish and water. Although the specific selenium compound in fish has not been identified, animal studies indicate that selenium absorption and uptake by erythrocytes in birds fed marine selenium (fish, mussel, and/or shrimp meal) differ depending on the type of selenium (e.g., selenite, selenate, selenocystine, selenomethionine).[70]

Concentration

Most agricultural crops contain <1 mg Se/kg dry weight. Fruits and vegetables typically contain <0.01 mg Se/kg, although root vegetables usually have higher Se concentrations.[71] In a Chinese study of plants from areas of high Se content and the occurrence of selenosis, corn samples contained an average Se concentration of 8.66 mg/kg (range, 0.55–44 mg/kg) and rice contained an average Se concentration of 4.0 mg/kg (range, 0.3–20.2 mg/kg).[72] Fruits and vegetables usually contain low Se concentrations (<0.01 mg/kg), whereas cereals contain intermediate Se concentrations (0.01–0.31 mg/kg fresh matter). A study of fruits and vegetables grown in saline drainage water containing 30–350 μg Se/L near the Kesterson Reservoir demonstrated statistically significant increases in Se concentrations in tomatoes (mean = 0.068 mg/kg) and cantaloupes (mean = 0.034 mg/kg), but not in honeydew melons (mean = 0.24 mg/kg) when compared with controls.[73] Based on the average consumption of these foods, the ingestion of these foods was not considered a public health concern.

The South American nut, coco de mono (*Lecythis ollaria* Loefl., monkey's coconut), contains high Se concentrations. When grown on selenium-rich soil in South America, coco de mono nuts contain substantial amounts of selenocystathionine (7–12 g/kg dry weight).[74] Brazil nuts (*Bertholletia excelsa* Bonpl.) also contain high Se concentrations (2.54 mg/kg) because they are cultivated in the seleniferous soils of the Andes Mountains.

The Se concentration in grain and dairy products varies considerably; however, these foods typically contain lower Se concentrations than meats (i.e., ~0.3 mg Se/kg) and fish. A study of 315 *whole* fish samples from 109 stations across the United States demonstrated a geometric mean of 0.42 mg Se/kg with a maximum of 2.3 mg Se/kg (85th percentile, 0.73 mg Se/kg).[75] Fish spending their life in the open ocean away from the shoreline also contain detectable Se concentrations. The ranges of Se concentrations as wet weight in the muscle of black marlin and blue marlin were 0.4–4.3 mg/kg and 2.5–4.2 mg/kg, respectively.[76] Selenium concentrations in beef and poultry organs (e.g., liver, kidney)[77] are usually higher (~0.5 mg/kg) than muscle.[54,78] A study of Swedish fishermen consuming a mean of 800–900 g marine fish/week demonstrated a 10–15% higher plasma selenium concentration than age-matched controls consuming ~½ the amount of fish as the fisherman.[79] Although the difference was statistically significant, the overall clinical impact was limited because the mean plasma Se concentration in the high-fish consumption group was low (~0.1 mg/L). Considerable loss of volatile Se compounds from food may occur during the cooking process.

ENVIRONMENTAL FATE

The primary factor determining the fate and bioavailability of stable selenium compounds in the environment is the oxidation state; selenides (2−) and elemental selenium (0) are water-insoluble, whereas inorganic alkali selenites (4+) and selenates (6+) are water-soluble. Elemental selenium is stable in soil. The alteration of selenium bioavailability and subsequent partitioning of selenium in the environment primarily depend on several factors including pH, E_h (oxidation–reduction potential), biological activity, and the presence of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

metal oxides.[21] Selenium concentrations in water are usually low because of the precipitation of elemental selenium in sediment. Both selenite and selenate demonstrate substantial bioavailability; however, plants preferentially absorb selenates and convert them to organic compounds (selenocysteine, selenomethionine, dimethylselenide, dimethyldiselenide). Aquatic organisms (e.g., bivalves) can accumulate and magnify selenium in the food chain. The methylation of selenium, the subsequent volatilization of methylated Se species into the atmosphere and the deposition of selenite in rainwater are probably the major natural processes that recycle selenium in the environment.[21]

Air

The selenium concentration in ambient air typically is low (1–10 ng/m^3).[80] Biogeochemical cycling of selenium results from the volatilization of methylated selenides to the atmosphere from higher plants and freshwater algae; however, a net flux occurs from the atmosphere to the ocean.[81] Volatile selenium compounds include dimethylselenide, dimethyldiselenide, hydrogen selenide, and selenium dioxide. Hydrogen selenide rapidly oxidizes to water and elemental selenium.

Elemental selenium in fuel oxidizes to form selenium dioxide. Sulfur dioxide rapidly reduces airborne selenium dioxide released in emissions from combustion of fossil fuel to elemental selenium. Dry and wet deposition transports selenium from air to surface waters and soil.

Soil

Mobility

The major factors determining the transport of selenium in soils are pH and E_h. Figure 27.1 demonstrates the effect of these two parameters on selenium speciation. Elemental selenium is insoluble; thus, this form of selenium is not mobile under anaerobic conditions. Humic acids are the main Se reservoir in the soil.[82]

Selenium appears primarily as salts of selenic acids and selenious acids in the water present in soil. Insoluble heavy metal selenides and selenium sulfides predominate in acidic soils with large amounts of organic material. These forms of selenium also lack mobility.[83] Sodium and potassium selenites dominate in neutral, well-drained soil; however, aluminum and ferric oxides bind selenite in acidic or neutral soil. This interaction significantly limits the mobility of selenites under these conditions. Soluble selenate salts (6+) form in aerobic, alkaline (pH >7.5) soil. Sodium selenate is especially mobile in these environments as a result of its high water solubility and low adsorptive capacity for soil particles.[31] Most selenites (4+) are less soluble in water than the corresponding selenates as a result of their binding to iron and aluminum oxides; therefore, selenites are less mobile than the corresponding selenates.[84]

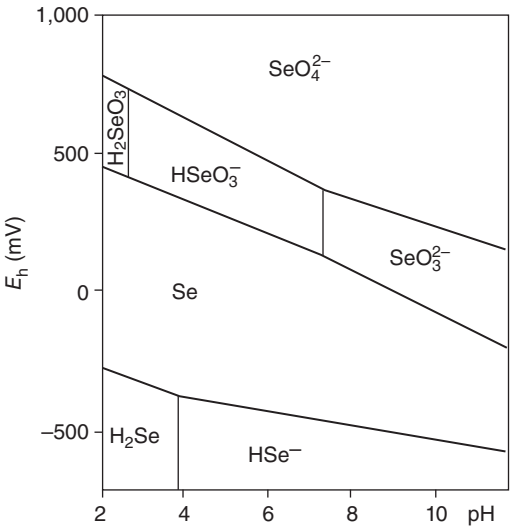

FIGURE 27.1. Effect of pH and redox potential (E_h) on selenium speciation in an aqueous system. (Adapted from Lauchli).[81]

Uptake

Metal selenides and elemental selenium (Se^0) are essentially insoluble; therefore, biological uptake is very limited. Plants preferentially accumulate selenates (i.e., principally sodium selenate) because this form is less bound to soil particles compared with selenites;[85] higher plants absorb selenium preferentially as selenate via high-affinity sulfate permease. Plants do not actively absorb selenites. Sulfate salinity inhibits the uptake of selenate by many plant species. Other factors that affect the uptake of selenium by plants include oxidation–reduction potentials (E_h), pH, soil type, the amount of organic material, and total selenium concentration.

Loss

Microorganisms methylate substantial amounts of elemental selenium and inorganic selenium compounds (e.g., sodium selenite) in soil to dimethylselenide and dimethyldiselenide. The return of selenium to the soil as selenite by rainwater completes the major natural process by which selenium recycles in the environment.

Water

Speciation

The primary forms of selenium in aqueous environments are salts of selenious and selenic acids. Selenates and selenites predominate in fresh water under aerobic and alkaline conditions rather than organic selenium, whereas selenate is the thermodynamically stable form in seawater. In groundwater and ocean, selenate is the dominant Se form.[82] In acidic conditions, mild reducing agents (SO_2, ascorbic acid) easily reduce selenite to elemental selenium; the metalloid is stable over a wide range of pH. Elemental selenium is insoluble and poorly mobile in sediment. A study of estuarine wetlands in the San Francisco Bay demonstrated that ~50% of the selenium in sediment was present as elemental selenium and ~25–30% as organic selenium.[86] In the subtropical, selenium-rich areas of the Enshi Prefecture of the Hubei Province, China, the predominant form of selenium in 48 samples of surface water was hexavalent Se; the selenium leached from rock weathering and mine tailings.[30] Rainwater in the area contained ~29% hexavalent Se. Hydrogen selenide is unstable in water, resulting in rapid Se volatilization into the atmosphere.[29]

Concentrations

Accumulation of Se in the environment depends, in part, on the Se species present in the environment. *In vitro* studies indicate that organic selenium (i.e., selenomethionine) is more readily accumulated by organisms compared with selenite and selenate.[87] Concentrations above 2–5 μg dissolved Se/L water may cause bioaccumulation in the food chain with the *potential* to cause adverse effects, whereas concentrations of >1 μg dissolved Se/L water are safe for habitation by fish.[88] The relationship between the Se concentration in water and the development of toxicity in the environment is complex and depends on site-specific processes.[89]

In a study of the Kesterson Reservoir during the period of peak contamination, mosquito fish contained up to ~170 mg Se/kg compared with average concentrations in US fish of ~0.5 mg Se/kg.[90] The relative concentrations of selenium remained stable over several years as follows: fish > benthic insects > annelids > mollusks and crustaceans > periphyton. Over 50% of the selenium present in the sediments of these ponds appeared in the organic form. The fish present in these ponds concentrated selenium in visceral tissue (25–35 mg Se/kg wet weight) to a greater degree than in skeletal tissue (6–11 mg Se/kg wet weight).[91] During the period of heavy contamination at the Kesterson Reservoir, the intake waters averaged ~0.3 mg Se/L with peak Se concentrations exceeding 1.35 mg/L.[21,38] The maximum conductance in the water at the Kesterson Reservoir was greater than that in seawater with sodium and sulfate being the predominant ions.[81] Additionally, boron and molybdenum were present in this water at relatively high concentrations.

Selenium concentrations in contaminated environments decline following reduction in the selenium input to the environment. During the subsequent 10 years after Se discharges from the coal-fired plant to Lake Belews ceased, the Se concentration in lake water decreased from a peak of 20 to <1 μg/L without remediation measures. The Se concentration in sediments decreased by 65–75%, but the Se concentrations in sediment (1–4 mg/kg) were sufficient to contaminate bottom-dwelling fish as reflected by reproductive impairment.[41] In this ecosystem, sediment-detritus pathways replaced water as the primary route of Se exposure when the Se concentration in water significantly decreased.

Bioaccumulation

Chemicals accumulate in organisms by the direct uptake from the surrounding media and ingestion of particle-bound selenium (bioconcentration or bioaccumulation) as well as the uptake of the chemical by higher trophic levels of the food chain (biomagnification). Bioconcentration is the passive uptake of the chemical directly from water or sediment across biological membranes to the aquatic organism. The bioconcentration factor (BCF) is an estimate of the extent to which an organism accumulates a chemical from the aquatic environment; this value is defined as the steady-state concentration of a chemical in the aquatic organism divided by the concentration of that chemical in water. The octanol–water partition coefficients (K_{ow}) are theoretical measures of BCFs; the BCF may be estimated by the K_{ow} or derived from experimental studies. These estimated BCFs may differ from the actual bioaccumulation of the chemical based on experimentally derived bioaccumulation factors (BAFs). These differences result from the following: degradation of the chemical in the water (e.g., hydrolysis), rapid elimination of the chemical from the organism, inadequate equilibrium time, and the presence of substances (e.g., humic acid) that alter bioavailability and solubility.[92] The general categories of the potential for bioaccumulation of a chemical based on BCFs are as follows: <30, low; 30–100, moderate; 100–1,000, high; and >1,000, very high. However, calculated BCFs do not always correlate to the actual bioaccumulation of a chemical in aquatic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. organisms because of factors listed above, particularly the rate of elimination.[93]

The bioconcentration of selenium in aquatic organisms primarily involves that the dominant waterborne Se species, selenite, and, to a much lesser extent, selenate. Experimental studies suggest the uptake of selenium by organisms varies in different trophic levels; these differences reflect alternate mechanisms for the uptake of selenate, selenite, and selenomethionine. For example, marine bacteria (*Pseudomonas marina*)[94] and marine phytoplankton[95] actively concentrate selenite, whereas little adsorption of selenate occurs. In aquatic systems, the selenate uptake is usually less than that of selenite, which more easily adsorbs and incorporates into the organic Se pool of the organism.[96]

The ratio of selenium in the organism at equilibrium to the Se concentration in water defines the bioconcentration (i.e., calculated BCFs) and bioaccumulation (i.e., experimentally derived BAFs) factors. The greatest increase in Se uptake in freshwater lakes and reservoirs occurs at the lower end of the food chain (i.e., between water and algae),[96] where the bioconcentration factor is at least several hundreds to several thousands. Certain benthic organisms (e.g., clams) accumulate Se from the intake of phytoplankton and, to a lesser extent, marine water in the sediment zone. Therefore, the estimated bioconcentration factors based on regression equations using physical properties (octanol/water partition coefficients, water solubility) may not correlate with experimentally derived bioaccumulation factors observed in the field. The bioaccumulation factors for selenium are not well defined for specific animal species because of variations in several factors including Se kinetics, Se species in the diet, Se concentration/species in aqueous environment, sample size, analytical methods (wet vs. dry weight), location (freshwater vs. saltwater), and the type of sample (skeletal muscle vs. internal organ).

Most published bioconcentration factors for selenite and selenate in freshwater fish are relatively low, ranging from 8–52.[97] Fish accumulate much more Se from the food chain than from the aquatic environment. The bioconcentration factors for an experimental study on trout were as follows: viscera (62.1), muscle (3.2), and whole trout (10.5).[21] *In vivo* studies suggest that Se bioaccumulation is slower with selenite or selenate than selenomethionine.

When the bioaccumulation of selenium results from the consumption of selenium-contaminated diets, hazards to fish and birds are more closely correlated with their tissue levels of selenium rather than the concentration of selenium in their aqueous media. The difference in the toxicity of various selenium species and the rate of biochemical transformation (i.e., formation of organic selenium in the aquatic environment) complicates the assessment of the risk from specific Se concentrations in water and animal tissue. Elevated selenium concentrations in marine waters do not result from high mercury concentrations[98] as suggested by a previous study that suggested selenium counteracted mercury toxicity.[99]

Biomagnification

Higher organisms may accumulate chemicals via biomagnification that involves the uptake of substances via the food chain. Biomagnification is highly dependent on the bioavailability and toxicokinetics of the specific chemical species.[93] In the food chain, selenium occurs both as organic selenium (e.g., selenomethionine) and as inorganic selenium (selenite, selenate). Selenium speciation in food is not well defined; however, substantial portions of the selenium in the food chain probably exist as selenomethionine rather than inorganic Se.[88] Biomagnification causes progressively higher concentrations of an element or substance in organisms at successively higher trophic levels. Selenium does accumulate in most aquatic organisms; these organisms can usually convert Se to inert and soluble forms. However, the Se concentration does not increase significantly between trophic levels once selenium enters the food chain via lower aquatic organisms. Additionally, the relatively rapid Se elimination from organisms and the wide variation of selenium in organisms limit selenium biomagnification in the higher portion of the food chain.

Although fish predators accumulate selenium from Se-contaminated food, the bioaccumulation of selenium among fish species is not necessarily related to trophic status. In a study of the San Joaquin River system, the Se concentration increased in the food chain from filamentous algae to invertebrates but not usually from invertebrates to fish.[100] This study implies that Se-enriched detritus is an important vector for Se transfer through the food chain. Fish predators from higher trophic levels accumulate less selenium than their prey that consumes higher Se concentrations in their diet. A study of Chinook salmon-fed fishmeal from high-selenium mosquito fish indicated that fish do not accumulate selenium to concentrations greater than those present in food based on whole-body samples. Additionally, there are substantial differences in Se distribution within the body. In adult fish, Se accumulates in ovaries more than muscle. Consequently, the hazard of selenium contamination to fish and wildlife may be limited to a relatively few species in a restricted area

depending on the exposure pathway (e.g., food sources) and the selenium concentration in the water.

DOSE EFFECT

Acute Toxicity

Toxicity depends on the chemical form of selenium; however, the toxicity of most forms of selenium (elemental selenium, organoselenium) is low. Human toxicity from environmental exposure to elemental selenium and selenium salts is rare; most acute toxicity results from inorganic selenium. Exposure to selenious acid or selenium dioxide can cause serious toxicity. In animal studies, selenite is slightly more toxic than selenate.

Selenite and Selenate Compounds

Consumption of 1–5 mg sodium selenite/kg by five adults caused nausea, vomiting, abdominal pain, and tremor that resolved in 24 hours. In a study of 201 patients ingesting a liquid selenium supplement containing over 200 times the labeled amount of sodium selenite, the median amount consumed was 989 mg (range, 41–5,875 mg) over 29 days (range, 1–109 days).[101] These patients complained of nausea, vomiting, diarrhea, fatigue, hair loss, joint pain, nail changes, headaches, and tingling. The symptoms gradually resolved over a few months, but some symptoms remained at 90-day follow-up. A case report associated the ingestion of an estimated 10 g sodium selenite (96% purity) with the development of vomiting, diarrhea, metabolic acidosis, and refractory hypotension.[102] The 75-year-old man died soon after admission to the intensive care unit, despite cardiopulmonary resuscitation and supportive care.

Vitamin C reduces selenite to the less toxic elemental form of selenium. Over 77 days, a 57-year-old female ingested 31 mg total Se/day along with 1,000 mg vitamin C and many other vitamins and trace metals.[103] Speciation of the selenium indicated that the tablets contained ~80% sodium selenite and ~20% elemental/organic selenium. Four days after stopping these supplements, her serum Se concentration was 0.528 μg/mL. During the time she ingested these supplements, she developed white horizontal streaks on her fingernails and a diffuse paronychia. Additionally, she had marked alopecia, nausea, vomiting, sour-milk breath, and fatigue. She recovered without sequelae. Following the daily ingestion of ~24 mg Se for 7 weeks, a 55-year-old woman developed diffuse, symmetrical hair loss, myalgias, arthralgias, fatigue, and poor concentration.[104] She recovered without sequelae following cessation of Se use. Frequent loose stools, increased serum hepatic enzymes, and transient T-wave inversions in the anterior and lateral leads developed in a young girl following the intentional ingestion of sheep drench containing 1.16 g sodium selenate (22 mg sodium selenate/kg).[105] She recovered without sequelae. The initial serum Se concentration was 3.1 μg/mL (normal range, 0.066–0.111 μg/mL).

Selenium Dioxide

Selenium dioxide is a white crystalline solid that decomposes in the aqueous environment of the gastrointestinal tract to selenic acid. A 17-year-old adolescent died after developing coma, asystole, and apnea 2 hours after ingesting an unknown amount of selenium dioxide,[106] whereas the estimated ingestion of 2 g selenium dioxide produced hematemesis and erosion of the gastrointestinal tract that resolved with supportive care.[107]

Selenious Acid

Selenious acid is the most toxic form of selenium; ingestion of this compound often causes fatalities as a result of refractory hypotension from direct myocardial depression and peripheral vasodilation. A 15 mL ingestion of gun blue (2% selenious acid) by a 2-year-old[108] and a 30–60 mL ingestion by an adult[109] resulted in death.

Chronic Toxicity

No clinical or biochemical signs of toxicity were observed in an American study of 142 volunteer farmers, who were exposed to selenium (mean daily intake of 239 μg Se/day with a range of 68–724 μg Se/day) in highly seleniferous areas of South Dakota and Wyoming.[110] Selenium doses of >900 μg Se/day are usually necessary to cause selenium toxicity with an average estimated selenium dose in Chinese residents with selenosis of ~200 μg/kg/day based on total selenium estimated from *retrospective* studies in the Wudang Mountains in Western China.[111,112] The inhabitants ingested food primarily from plants grown in this highly seleniferous area with mean Se concentrations in water of 0.54 mg/L and soil of 0.01 mg/L. The diagnostic sign of chronic selenosis was morphological changes in their fingernails. The selenium content was not speciated; hence, higher selenium concentrations may be tolerated when the selenium in the diet is less bioavailable (e.g., marine diet).

The estimated dietary Se intake was much higher (15,000–38,000 μg/day) during an epidemic of chronic selenosis (1961–1964), when a severe drought altered normal dietary habits, health, and cultural practices in that part of China.[113] Food was cooked over indoor, open pits that allowed the volatilization of large amounts of selenium from highly seleniferous coal (mean = 300–400 mg Se/kg). There was also increased consumption of high Se-containing vegetables. Consequently, the data should be extrapolated cautiously to different dietary sources (e.g., plant vs. animal) or different geographic areas, where the Se toxicity and exposure pathways are more limited. American diets contain more protein, methionine, and zinc that reduce Se toxicity from animals.[114] Additionally, vitamin E deficiency and low dietary sulfates enhance the chronic toxicity of selenium.[115]

Analysis of the Chinese studies indicates that daily Se doses up to ~1,500 μg Se can be ingested without the development of selenosis. Analysis of corn and rice grown in the Enshi area of China indicates that selenomethionine was the main Se species present in the diet of those Chinese developing chronic selenosis.[116] The ingestion of an average of 5,000 μg Se/day over a 10-year period during a severe drought in China was associated with nail deformities, alopecia, skin lesions, tooth decay, and neurological changes (paresthesias, hyperreflexia).[117] This study also reported the daily ingestion of 1,000 μg over 2 years by a 62-year-old Chinese male. He was asymptomatic, but nail changes (fragile, thickened) and a garlic odor were present. In chronic studies of rats, no apparent toxicity was observed following the administration of 4 ppm Se as sodium selenite in drinking water when compared with controls.[118]

TOXICOKINETICS

Absorption

Inhalation

Human data on the retention rate of inhaled selenium are limited. A study of workers exposed to selenium dioxide in a plant that manufactured rectifiers suggested that Se absorption occurs through inhalation based on the two to four times reduction in the urine selenium concentrations of workers after their selenium dioxide exposure was substantially decreased following the completion of engineering controls.[119] Animal studies indicate that the lungs absorb selenium compounds well, but the rate of absorption depends on the chemical form of selenium. In animals exposed to aerosols for 4 hours, the absorption of elemental selenium from the lungs was less (57%) than selenious acid (97%).[120]

Oral

The gastrointestinal tract absorbs most selenium compounds well, primarily in the duodenum and cecum by active transport via the sodium pump.[121] In volunteers receiving 1 mg Se in solution as sodium selenite or selenate, the apparent absorption (i.e., total Se dose minus fecal Se excretion) of selenate-Se was greater (94% ± 4%) than selenite-Se (62% ± 14%).[122] Data on the bioavailability of different Se species are limited. Animal studies indicate that the mechanism of absorption differs with various selenium species and Se sources.[123] Some elements decrease Se absorption including arsenic, calcium, iron, lead, and sulfur.

Whereas Se absorption as selenite occurs via passive diffusion, the absorption of selenate results from the action of sodium-mediated carrier transport shared with sulfate. The absorption of selenate-Se from the gastrointestinal tract is usually greater than selenite-Se. The absorption of selenate, but not selenite, occurs in the intestine without prior metabolism.[21] Animal studies suggest that the gastrointestinal tract also absorbs selenious acid well (i.e., ~85%), but the absorption of elemental selenium is substantially less (~50%).[120] For unknown reasons, Se bioavailability from tuna and other seafood is significantly lower than other foods.[124]

Dermal

Limited data on the dermal absorption of selenium compounds do not suggest that selenium is significantly absorbed through the skin. In a study of 15 volunteers applying 2.5% selenium disulfide to their torso and leaving the suspension on their skin overnight, the serum Se concentrations were not statistically significantly increased, when measured the following day and compared with pre-application concentrations.[125] A study using rat skin demonstrated that ~10% of a 0.1 mol solution of sodium selenite applied to the skin was absorbed within 1 hour.[126]

Distribution

In the blood, selenium binds primarily to plasma proteins (selenoprotein P, glutathione peroxidase, albumin).[127] Following an intravenous injection, selenium selenite distributes primarily to the liver and kidney.[128] The total amount of selenium in the body averages ~14 mg Se in the US general population with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a range of 3–20 mg Se depending on the intake of Se.[36] The plasma contains ~2/3 of selenium in selenoprotein P and ~1/4 in glutathione peroxidases with the remainder attached to albumin.[129] The main storage form of selenium in the tissues is selenomethionine.

Biotransformation

Methylation is the detoxification pathway for elemental selenium prior to the dose-dependent excretion of these metabolites in urine or expired air.[130] In biological systems, selenium is methylated after the reduction of selenite and selenate to hydrogen selenide, similar to the reduction of sulfites and sulfates to hydrogen sulfide; glutathione is an essential component of the reduction of selenium compounds.[131] The major reactions in selenium metabolism include: 1) reduction of selenite by cellular glutathione to selenide similar to the reduction of sulfites and sulfates to hydrogen sulfide; 2) incorporation of selenide into selenoproteins (selenoprotein P, glutathione peroxidase, type I 5′-iodothyronine deiodinase) via selenocysteine after transformation to selenocysteinyl tRNA or selenophosphate; and 3) methylation of selenide to metabolites (monomethylselenol, trimethylselenonium, dimethyldiselenide, dimethylselenide) followed by renal excretion of the methylated metabolites.[132] Formation of hydrogen selenide by stepwise reduction is the key intermediate step in the biotransformation of inorganic selenium as demonstrated in Figure 27.2. The methylated forms are generally less toxic than the non-methylated selenium compounds.[133] The conversion of selenates to dimethylselenide is more complicated than the conversion of selenide to dimethylselenide. There are a variety of potential selenium metabolites for selenium biotransformation in humans including trimethylselenonium ion, selenite, selenate, selenosugar 1, and selenosugar 2.[134]

Elimination

Humans

In humans at low selenium doses, the kidneys and intestines each excrete ~1/2 of the absorbed Se dose;[135] trimethylselenonium is a minor component (1%) of urinary excretion of selenium in diets supplemented with either selenomethionine or selenate.[136] A tri-exponential elimination phase appears after the ingestion of therapeutic selenite doses. The initial elimination phase is rapid (i.e., 1 day), whereas the second phase (8–20 days) and third phase (65–116 days) are much longer.[137] The initial elimination Se half-lives during acute intoxication by ingestion with selenious acid[138] and selenic acid[139] were 12 hours and 17.5 hours, respectively. Differences in the excretion pattern occur between selenium species. In a study of volunteers given 200 µg Se supplements as selenomethionine or selenate over 32 weeks, the mean daily selenium excretion for selenate was 57% of the daily Se dose compared with 27% for selenomethionine.[136]

Animals

Studies in animals suggest that the formation of the inactive metabolite, trimethylselenonium ion, becomes an important mechanism of detoxification following the absorption of high Se doses. At doses of 1.5 mg ^{75}Se/kg body weight, trimethylselenonium ion was the major urinary metabolite, accounting for 57–69% of the urinary metabolites.[140] The excretion of this metabolite represented 16–25% of the original ^{75}Se dose. At near-lethal Se doses, the excretion of dimethylselenide into expired air becomes an important route of Se elimination. After the injection of 0.5 μg sodium selenite/kg body weight in marine fish, the biological half-lives of selenium in the liver, gills, and skin were ~2.1 days, 2.1 days, and 5.3 days, respectively.[141] Following the inhalation of an aerosol of selenious acid, the dogs excrete ~50% of the absorbed selenium (mostly in the urine) with a biological half-life of 1.2 days.[142] The terminal half-life representing ~20% of the absorbed dose was 30–70 days.

Maternal-Fetal Kinetics

Animal[21] and human[143] studies indicate that selenium has limited potential to cross the placenta with longitudinal dietary Se supplementation studies on lactating mothers indicating Se concentrations in breast milk vary with maternal Se intake.[144] Limited data on maternal and cord blood concentrations are inconsistent. In an Indian study of 82 mothers and full-term infants, the mean plasma selenium concentration was 54.17 ± 1.34 μg/L in the neonates compared with 70.63 ± 1.62 μg/L in their mothers.[145] Maternal age, parity, and socioeconomic status did not affect the plasma selenium concentrations. However, a study of 216 mothers from three geographic regions in Northern Europe (Finland, Estonia, Russia) found higher whole blood Se concentration in full-term infants than mothers at term as measured by electrothermal atomization/atomic absorption spectrometry; these findings suggest an active transport system for fetal selenium.[146]

A study of rats suggests some transfer of selenium from the mother to the offspring occurs via breast milk.[147] A Greek study of babies breastfed up to 6 months of age demonstrated that these babies received ~5–11 μg Se/day.[51] The selenium concentration in breast milk is variable depending on maternal diet, the phase of nursing (e.g., selenium concentration declines during the first month of lactation), and the type of milk (e.g., colostrum > mature milk). In a cross-sectional study of 100 Italian breastfeeding women with 82 exclusively breastfeeding, the mean Se concentration in mature milk samples was 12 ± 3 μg/L (ng/g) with a range of 6.5–20 μg/L (ng/g) as measured by hydride generation/atomic fluorescence spectrometry.[148] The selenium concentration in milk decreases with the time since delivery. The Se concentration in 78 milk samples from 38 Austrian mothers declined during the first 10 months of lactation from 23.9 ± 12.0 μg/L in postpartum colostrum to 11.4 ± 3.0 μg/L in mature milk.[149]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Selenium is an essential trace metalloid incorporated as selenocysteine in several enzymes including thioredoxin reductase (antioxidant/intracellular control of redox potential), glutathione peroxidases (antioxidants),[150] and type I and II iodothyronine 5′-deiodinase (biotransformation of thyroxine (T_4) to triiodothyronine (T_3)).[59] There are ~25 selenoproteins involved in deactivation of thyroid hormone, antioxidant activity, T cell immunity, and modulation of inflammatory responses. The catalytic activity of all three members of the deiodinase enzyme family requires selenocysteine at the active site.[151] The selenium-containing enzyme, glutathione peroxidase, facilitates antioxidant defenses by the destruction of hydrogen peroxide and the reduction of tissue peroxide concentrations.[20] Consumption of selenium-poor diets results in deficiencies of this enzyme in animals and humans.[152] Selenium supplementation in healthy subjects with low Se concentrations increases glutathione peroxidase activities, but Se supplementation does not alter changes in the lipid peroxidation defense mechanisms. A double-blind, randomized study of 24 patients in New Zealand with asthma detected a statistically significant clinical improvement in the selenium-supplemented group despite the absence of alterations in lung function.[153] The exact role of low selenium concentrations in the pathogenesis of asthma in New Zealand remains unclear.

Animal studies suggest that Se cytotoxicity results from the prooxidant catalytic activity of the selenide (RSe^-) anions that produce superoxide anions, hydrogen peroxide, and other reactive metabolites (e.g., hydroxyl radicals).[154,155] Methylating reactions in plants and animals along with antioxidant defenses counteract the toxicity of selenium species.[154] In animals fed selenium-deficient diets, glutathione peroxidase activity and glutathione synthesis increase. These animals are more resistant to acetaminophen and aflatoxin B_1 toxicity and more sensitive to diquat toxicity than

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

controls. Nevertheless, the effectiveness of dietary selenium repletion on human diseases linked to selenium deficiency (e.g., the familial cerebral degenerative cases known as Batten's disease) remains unproven.[156]

Deficiency

Selenium is a key component of the antioxidant glutathione peroxidase enzymes, thioredoxin reductase, iodothyronine deiodinases, and sperm capsule selenoproteins present in the mid-piece region of the sperm tail. Fatal cardiomyopathy developed in patients on long-term parenteral nutrition with **low** selenium concentrations (i.e., 5–12% of normal plasma and other tissue values).[157] Myalgias along with elevated serum muscle enzymes may occur in selenium-deficient patients without cardiomyopathy.[158] Selenium deficiency may impair the activity of Se-containing type I deiodinase, particularly in older patients, therefore, inhibiting the conversion of T_4 to T_3. T_4 is the most sensitive measure of selenium deficiency and subsequent iodine repletion. In iodine-deficient patients, the Se supplementation (e.g., 2,500 μg Se over 7 days) may produce hypothyroidism.[159]

Keshan Disease

Keshan disease (KD) is a cardiovascular disease affecting primarily children and young women,[160,161] particularly in northeastern China, where the disease was first reported in 1935.[162] Selenium-containing glutathione peroxidase 1 (GPx-1 gene product) is the most prevalent glutathione peroxidase occurring in the cytosol of all cells; this selenoprotein catalyzes lipids to lipid alcohols and hydrogen peroxides to water, resulting in a reduction of oxidative stress.[163] Keshan disease results from an environment–gene interaction with the main risk factors including low GPx-1 activity (variance at codon 198 in *GPx-1* gene), family history of KD, and living in an endemic (Se-deficient) area.[164] The principal pathological findings are that multifocal pallor, necrosis, myocytolysis, and fibrosis of the myocardium manifest clinically as cardiac enlargement, congestive heart failure, cardiogenic shock, and death, respectively. Keshan disease is endemic in Se-deficiency areas of China. The incidence of acute and subacute KD in these areas diminished dramatically with selenium supplementation; however, chronic KD appeared in endemic areas of China after adequate Se supplementation. This occurrence indicates that Se deficiency is a predisposing condition rather than the primary cause of this disease.[165] The estimated number of cases of KD and chronic KD in Chinese patients is 1,675,500 (95% CI: 1,608,500–1,747,300) and 379,800 (95% CI: 346,700–412,800), respectively.

Kashin–Beck Disease

Kashin–Beck ("Big Bone") disease is an endemic, chronic osteoarthropathy of young children in China, Russia, and Korea that primarily involves the cartilage (atrophy, degeneration, necrosis). The main features of the disease are shortened stature resulting from multiple focal necroses in the growth plate of tubular bones, degenerative joint disease, and joint deformities. The Russian surveyor, I.M. Yurensky, first described bone deformities in eastern Siberian residents along the Urov River. Several years later, the Russian military physician, Nikolai Kashin, documented bony abnormalities that he associated with Urov disease.[166,167] In 1906, the Cossack Army physician, Evgeny Beck, published a monograph, *Osteoarthritis Deformans Endemica*, describing his medical observations of this degenerative disease; subsequently, the disease became known as Kashin–Beck disease.[168]

Currently, the disease occurs primarily in China where an estimated 1–3 million people are afflicted with the disease in a pattern consistent with areas of Se deficiency in the soil.[169] The etiology of this disease is probably multifactorial[170,171] with potential contributing factors including Se deficiency (and the resultant decrease in antioxidant activity), contamination of grain by fungi (*Fusarium sporotrichiella*), high organic matter concentrations (e.g., fulvic acid) in the soil, and complex genetic susceptibility involving multiple pathways affecting articular chondrocytes.[172,173] Selenium supplementation alone does not completely prevent the occurrence of Kashin–Beck disease.

Mechanism of Toxicity

Substantial variation in the toxicity of various selenium species results from differences in physiochemical properties and the natural distribution of these species. Selenium readily substitutes for sulfur in biomolecules and many biochemical reactions, potentially disrupting cellular processes and weakening support structures (e.g., keratin); however, the mechanism of toxicity is unclear. Various substances (e.g., arsenic, cysteine, heavy metals, sulfate, vitamins C and E) can alter Se toxicity. Complex interactions of selenium with metals, vitamins, and other nutrients usually reduce the toxicity of selenium.[56] Furthermore, selenium modifies the toxic effects of a variety of metals (e.g., arsenic, cadmium, copper, lead, mercury, silver, zinc).[36]

Postmortem Examination

Humans

Typical autopsy findings following fatal selenious acid ingestions include a strong garlic-like odor emanating from the body cavity along with diffuse mucosal hyperemia and focal hemorrhage of the gastric cardia and fundus.[174] The postmortem examination of a patient dying from the inhalation of *selenious acid* demonstrated myocardial and pulmonary infarctions, ascites, obstructive mucous plugs in the bronchi, interstitial pulmonary emphysema, bronchopulmonary dysplasia, barotrauma, and *Hemophilus and Legionella dumoffii* infection.[108] Other histological abnormalities associated with the absorption of toxic amounts of selenious acid include hemolysis, liver necrosis, edema of the kidneys, and red pigmentation of all viscera.

Postmortem examination of patients dying after suspected surreptitious Se administration (Se species unknown) includes pulmonary edema with pleural effusion, lymphoid infiltrates surrounding smaller bronchi and bronchioles, vascular congestion, congestion of the kidney, and necrosis of the proximal renal tubules.[175,176] The highest Se concentrations occurred in the stomach, lungs, and kidneys with the selenium concentrations declining over time. Postmortem analysis of cases with no abnormal Se sources demonstrated tissue Se concentrations in the following descending order: kidney, liver, spleen, pancreas, heart, brain, lung, bone, and skeletal muscle.[177]

Animals

Acute Se intoxication produces myocardial necrosis in sheep, pigs, and cattle.[178] Porcine poliomyelomalacia is the only form of selenium intoxication that produces obvious damage to the central nervous system. An autopsy of pigs dying after the ingestion of feed containing high (i.e., 3%) Se concentrations revealed abnormalities in the following areas: skeletal muscle (disintegration of myofibrils, hyperplasia of sarcolemma in nuclei, hyalinization, loss of striations, diffuse swelling), myocardium (vacuolation, pyknosis, eosinophilia), and spinal cord (demyelination of the ventral horns, loss of neurons, proliferation of glial cells).[179] Because keratin contains substantial Se following ingestion, keratinocyte abnormalities frequently occur during selenium intoxication. Early changes include abnormal maturation of the keratinocytes in the stratum spinosum; more advanced lesions involve ballooning degeneration and necrosis of the keratinocytes.[9] Alopecia results from atrophy of the primary hair follicles.

CLINICAL RESPONSE

Acute Toxicity

The acute ingestion of large doses of selenate and selenite produces gastrointestinal irritation manifested by nausea, vomiting, abdominal pain, loose stools, tremor, and mild hepatic inflammation. Although the toxicity of most selenium compounds is relatively low, exposure to selenious acid or selenium dioxide can cause serious human toxicity.

Selenious Acid

Acute ingestion of selenious acid is almost invariably fatal. Stupor, respiratory depression, hypotension, and death can occur several hours after ingestion.[180] Severe hypotension develops as a result of decreased myocardial contractility and reduced peripheral vascular resistance.[181] Terminal respiratory failure occurred after a selenious acid ingestion (15 mL gun bluing solution), despite the use of an extracorporeal membrane oxygenator. Red pigmentation of the nails, hair, or teeth along with a garlic odor on the breath is characteristic of selenium poisoning.[182]

Selenium Dioxide

Selenium dioxide forms the weak acid and strong oxidant, selenic acid, following contact with water. The ingestion of a product containing about 2 g selenium dioxide produced nausea, vomiting, abdominal pain, hematemesis, and gastric ulcerations that resolved with supportive care.[107] Ingestion of larger amounts of selenium dioxide caused apnea, asystole, and death.[106]

Environmental Exposure

The interpretation of reports associating excessive environmental selenium exposures with adverse effects is complicated by case series design, lack of confirmatory laboratory tests, inadequate exclusion of alternate explanations, and conflicting results. The effects of chronic selenium poisoning (selenosis) in residents of geographical areas with high selenium content characteristically involve a pruritic rash, brittle hair, and yellow, brittle, dystrophic nails with paronychia. Yellowish-white or red longitudinal streaks or transverse lines may appear on the nail surface beginning on the thumb. Loss of the fingernail occurs frequently. Skin lesions develop primarily on the limbs and scalp manifest by erythema, vesiculation, secondary infection,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. and reddish discoloration. Temporary alopecia occurred after the large consumption of the South American nut, coco de mono (*L. ollaria* Loefl., monkey's coconut), containing high Se concentrations.[183,184] Garlic odor on breath develops as a result of excessive selenium exposure because of the expiration of dimethylselenide in exhaled air.[56] In a study of 201 patients ingesting a liquid selenium supplement containing over 200 times the labeled amount of sodium selenite, the most frequent complaints were as follows: diarrhea (78%), fatigue (72%), hair loss (70), joint pain (67%), nail discoloration/brittleness (61%), nausea (57%), headache (45%), foul breath (37%), and rash (26%).[101] Less frequently reported symptoms included memory loss, mood changes, and tingling. Complete loss of scalp hair occurred in ~18% of the patients with alopecia. A follow-up questionnaire suggested that some of the symptoms persist over 90 days including nail changes, fatigue, hair loss, arthralgia, myalgias, and memory loss. In a case series of nine patients ingesting the same product, symptoms began within 1 week of starting the supplement; these patients complained of similar symptoms with the exception of three patients with tinnitus.[185]

Additional clinical effects reported in Chinese residents with chronic selenosis include dental caries, fatigue, irritability, muscle tenderness, tremor, hyperreflexia, emotional lability, depression, nervousness, nausea, vomiting, and metallic taste. However, the exact role of selenium in the causation of these symptoms remains unclear because of the concurrent effect of severe climatic conditions on the health of the Chinese populations exposed to excessive selenium.

The data linking excessive Se exposure with neurological diseases are weak. In a study of this population, abnormalities of the central nervous system occurred in only *one of five* villages with a high prevalence of selenosis. No autopsies or objective neurological testing were done to confirm the role of selenium in producing neurological abnormalities.[186] A cohort study of 5,182 Italian residents in an area with high selenium concentrations in drinking water (7–9 μg/L) demonstrated a standardized incidence ratio of 4.22 (95% CI, 1.15–10.8) for amyotrophic lateral sclerosis when compared to surrounding residents using drinking water with low selenium content (<1 μg/L).[187] A number of study limitations prevent conclusions regarding the causal role of selenium including the lack of control of confounding variables, small case numbers, and no selenium exposure data to document selenium concentrations in cases or controls. Furthermore, there was no indication that the affected patients were exposed to Se concentrations exceeding the acceptable daily intake (ADI). A retrospective case-control study of 66 patients with amyotrophic lateral sclerosis and 66 age- and sex-matched controls found no association between the disease and Se exposure based on a self-administered questionnaire.[188] This study did not confirm earlier case reports associating areas of high selenium content in South Dakota with an increased incidence of this disease.[189] Cross-sectional studies have not demonstrated a significant increase in the Se concentrations in patients with amyotrophic lateral sclerosis compared with controls.[190]

Chronic selenium poisoning in humans is not well documented in the United States. Limited data from one study suggested that chronic elemental selenium exposure can cause dental caries, but adverse effects following exposure to selenium are unusual.[191] A study of 111 rural families living in areas with high selenium content in the soil did not reveal any symptoms directly attributable to selenium poisoning.[192,193] Members of a family that consumed local well water with a concentration of 9 ppm selenium developed changes (discoloration, brittleness, loss) of their fingernails, hair loss, and lassitude. Reports from their school indicated that the child became more alert after the excessive Se exposure ceased.[194] This case study did not report any blood or urine selenium concentrations; therefore, there was no documentation of excessive Se exposure.

Occupational Exposure

Hydrogen Selenide

Hydrogen selenide is a water-soluble gas that produces irritation to the skin and mucous membranes as well as painful orange skin lesions depending on the duration of exposure and decontamination measures. The acute inhalation of high concentrations of hydrogen selenide initially causes upper respiratory tract irritation and metallic taste in the mouth followed by bronchopneumonia and pulmonary edema. The accidental inhalation of hydrogen selenide gas produced severe mucous membrane irritation, rhinitis, and wheezing followed in 18 hours by progressive dyspnea, pneumomediastinum, and markedly reduced expiratory flow rates.[195] Improvement occurred over 5 days; however, some restrictive and obstructive changes remained on pulmonary function testing 3 years later. A 21-year-old research lab student associated the development of bitter metallic taste in her mouth, garlicky breath, transverse ridges on the nails, chronic diarrhea, and abdominal pain with a weekly exposure to hydrogen selenide gas in the laboratory; however, no selenium concentrations were available to document exposure.[196]

Selenium and Selenium Dioxide

Selenium dusts produce respiratory tract irritation manifested by nasal discharge, loss of smell, epistaxis, and cough. Exposure of workers to fumes containing high Se concentrations caused acute, intense irritation of the mucous membranes and throat along with headaches; however, the workers did not develop systemic complaints.[197] Following exposure to selenium dioxide for 20 minutes during a fire, 40 workers exhibited symptoms and signs of metal fume fever characterized by headaches, chills, bronchitis, and pulmonary infiltrates.[198] There were no exposure data on airborne selenium or other metal concentrations in the ambient air. Coughing persisted for 4 days; all symptoms resolved within 1 week. Chronic exposure of workers to selenium concentrations exceeding 0.2–0.4 mg Se/m^3 was associated with garlic odor on the breath, gastrointestinal discomfort, skin lesions, metallic taste in mouth, and various psychological complaints.[119] Dermal exposure to selenium dioxide or selenium oxychloride may produce dermatitis and skin burns.[199]

Reproductive Abnormalities

Although selenium is a demonstrated teratogen (limb reductions, craniofacial, and axial skeletal malformations) in birds and crosses the human placenta, the evidence for teratogenesis in mammals is inconclusive with a lack of evidence that selenium or selenium compounds are fetotoxic to humans.[21] The teratogenic potential of selenium was suggested by case reports associating several miscarriages and minor birth defects (bilateral clubfoot) with exposure of pregnant laboratory workers to sodium selenite.[200] However, the urine selenium concentrations of these workers were comparable to controls. The presence of confounding factors indicates an alternative explanation for the reproductive abnormalities other than a direct causal connection to selenite. A study of Italian women exposed to concentrations of inorganic selenium (selenate) in drinking water ranging up to 10 µg/L did not demonstrate a statistically significant increase in adverse reproductive outcomes compared with reproductive outcomes of women from the same province without excessive selenate exposure.[201] A 41-year-old pregnant woman accidentally ingested 200 mg/day of galenic formulation of selenium from gestational week 7–12 (15th gestational week plasma selenium concentration = 29 µg/L); she developed nausea, vomiting, and hand/foot paresthesias followed by fatigue, loss of fingernails, and alopecia.[202] The child was born full term without complications (cord blood selenium = 58.1 µg/L, method not reported) or evidence of toxicity at 3 months of age (normal clinical evaluation, imaging studies, serum electrolytes/liver enzymes).

The difference in Se sensitivity between animal species may result from the accumulation of high Se concentrations (e.g., 64 ppm) in eggs compared with the mammalian fetus, which excretes excess fetal selenium and maintains lower selenium concentrations than the maternal circulation.[203] In laboratory animals, the administration of inorganic selenium compounds at concentrations that do **not** produce maternal toxicity has not caused teratogenic effects.[204] Embryonic death and congenital malformation occur in animal studies only at Se doses producing marked maternal intoxication. The primate fetus has much better protection against selenium toxicity compared with avian species.[205,206]

Carcinogenicity

Current human epidemiological and demographic studies do not suggest selenium is carcinogenic.[21] Selenium induces some genotoxic effects in animals, but other studies suggest that selenium is antimutagenic and anticarcinogenic.[207] In general, low serum selenium concentrations are not associated with an increased incidence of cancer. Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program (US NTP) lists selenium as a suspected carcinogen. Selenium and selenium compounds are classified as group 3 (not classifiable as to its carcinogenicity to humans) by the IARC.

Selenium sulfide is a separate compound rather than a salt of selenium. When administered by oral gavage to rodents, sodium sulfide produces hepatocellular carcinomas in rats (male and female) and female mice as well as alveolar or bronchiolar carcinomas and adenomas in female mice. Consequently, the US NTP lists selenium sulfide as a substance that may reasonably be anticipated to be a carcinogen based on the animal data.[208] Because selenium sulfide is not absorbed through the skin, the use of this compound as a shampoo is considered safe. In a long-term animal study, the application of 2.5% selenium sulfide (Selsun®) did not induce an increased incidence of tumors in mice or in rabbits.[209]

Despite early reports that associated Se exposure with elevated tumor rates in animals, most,[210,211,212] but not all,[213] recent studies in humans and animals have either demonstrated no relationship or an inverse relationship between cancer rates and elemental selenium exposure. In animals, high Se concentrations (5–60 times the nutritional requirement of Se) inhibit the growth of transplantable tumors[214] and the induction of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancer by chemicals/viruses.[215,216] These experimental studies suggest that selenium inhibits the initiation and promotion phases of carcinogenesis; however, reduction of the risk of cancer requires Se supplementation over the entire period of exposure to carcinogens because selenium does not appear to provide long-term protection against cancer. A randomized controlled trial of 1,312 patients followed up to 8 years (mean = 6.4 years) did not detect a difference in the incidence of basal cell or squamous cell skin cancer between patients receiving 200 μg Se/day (mean = 4.5 years) and placebo.[217] The blinded phase of the trial stopped early because of an apparent reduction (RR = 0.5, 95% CI 0.31–0.8) in total mortality from cancer. Further studies are necessary to confirm the hypothesis that selenium decreases the incidence of cancer because overall mortality was a secondary endpoint of the study.[218]

DIAGNOSTIC TESTING

SI Conversion Units

1 μg = 0.01267 μmol
1 μmol Se = 78.96 μg

Analytical Methods

Biological Samples

The low Se concentration in biological samples requires sensitive and accurate analytical techniques. Analytical methods for determining total Se concentrations in the ppb range include spectrofluorometry, neutron activation analysis (NAA), graphite furnace and hydride generation atomic absorption spectrometry (GF/AAS, HG/AAS), inductively coupled plasma/atomic emission spectrometry (ICP/AES), inductively coupled plasma/mass spectrometry (ICP/MS), gas chromatography (GC), and x-ray fluorescence analysis. Except for the latter method[219] and instrumental neutron activation analysis,[220] most analytical techniques determine total selenium in biological material rather than individual Se species or metabolites (e.g., trimethylselenonium). Neutron activation analysis is the most sensitive technique (LOD, 1–10 ng/g material), but the instrumentation is very expensive. The advantages of ICP/AES with hydride vapor generation (NIOSH method 7,300) are small sample size and high sensitivity (LOD, 0.4 μg/L).[221] This method determines total selenium concentration after the sample undergoes wet-ashing with nitric, perchloric, and sulfuric acids at high temperatures (e.g., 310 °C), resulting in Se reduction in the sample by sodium borohydride to hydrogen selenide.

Classic flame atomic absorption spectrometry is not sensitive to the low Se concentrations usually present in biological fluids. GF/AAS offers good sensitivity (LOD, 0.005 ng/g sample), but interference from the matrix may complicate analysis and requires correction (e.g., Zeeman effect) for background absorption.[222] HG/AAS produces less chemical interference, low detection limit (0.1 μg/L), and good precision (RSD = 1.0–1.5%);[223] however, this method requires a larger sample size compared with GF/AAS (e.g., 20 μL of serum). HG/AAS is specific for selenite (4+); this method allows Se speciation based on the preparation of samples with oxidative digestion and/or reduction processes prior to analysis. Oxidative digestion of organic selenide (2−) and elemental selenium (0) converts these species to selenite, whereas reduction processes convert selenate (6+) to selenite. The amount of selenium in the sample after these processes represents total selenium. HG/AAS allows the determination of the amount of selenate (6+) in the sample by measuring the difference between the sample after reduction of selenate to selenite and the amount of selenite in the original sample. Comparison of various methods for Se determination indicates that the accuracy of acid decomposition fluorometry, HGAAS, and electrochemical atomic absorption spectroscopy is similar.[224]

Environmental Samples

Determination of Se species in food sources and biological media is difficult as no method reliably extracts all selenium from food without altering the composition of selenium species.[55] Hyphenated techniques based on coupling chromatography separation with inductively coupled plasma/mass spectrometry followed by molecular mass spectrometry (ESI/MS, ESI/MS/MS, and MALDI/TOF) and isotopic dilution allow quantification of selenium species.[225] Separation of Se species by ion-pair liquid chromatography/inductively coupled plasma/mass spectrometry (LC/ICP/MS) after hot-water extraction followed by online reversed-phase liquid chromatography/electrospray ionization/tandem mass spectrometry (LC/ESI/MS/MS) allows the determination of selenium species in food samples.[226] The limit of detection for selenium species in biological fluids using capillary electrophoresis coupled with ICP/MS was 10–20 μg/L for inorganic Se species and 35–50 μg/L for organic Se species.[227] GF/AAS with selective extraction procedures and hydride-generation atomic absorption spectrometry (HGAAS) can distinguish

Se^{6+} and Se^{4+} in environmental samples because Se^{6+} does not readily form the hydride without reduction.[228]

Storage

In contrast to most trace elements, Se contamination of containers is unusual.[229] Consequently, Vacutainer® -type storage tubes are sufficient for collecting serum to analyze Se concentrations when basic principles of cleanliness are observed. Selenium compounds are usually stable under refrigerated storage conditions (4°C/39°F); however, repeated thawing and freezing may alter concentrations if protein denaturation occurs. The presence of hemolysis will increase the plasma selenium because of the relatively higher selenium content in erythrocytes than plasma or serum. Analyses of biological samples may underestimate the total Se concentration in urine as a result of the loss of volatile selenium compounds; storage of samples in polyethylene containers in the acid medium reduces these losses. The immediate freezing of biological samples following collection limits the enzymatic formation of volatile selenium compounds.

Biomarkers

Blood

The mean selenium concentration is ~30% higher in erythrocytes than whole blood,[230] whereas the plasma selenium concentration is ~65–85% of the whole blood concentration.[231,232] In a study of trace metals in a representative sample of over 400 urban, suburban, and rural northern Italian residents, the mean whole blood selenium concentration was 108 ± 6 µg/L with a range of 40–180 µg/L compared with 81 ± 1 µg/L (range, 33–121 µg/L) in plasma as measured by neutron activation analysis.[233] The plasma/erythrocyte Se ratio decreases as the whole blood concentration increases.[111] In a study on trace metal concentrations in Swedish adolescents, the median serum Se concentration was ~10% lower than whole blood.[234] Consequently, the difference between the serum and the whole blood selenium concentrations probably narrows substantially following large selenium ingestions; however, there are few clinical data to determine the precise difference during selenium intoxication. The 5-hour post-ingestion, whole blood Se concentrations were ~25% higher than plasma in a fatal case of acute selenium poisoning secondary to the ingestion of selenious acid in a gun-bluing compound.[138] In a study of New Zealand women receiving 200 µg selenium supplementation as either selenomethionine or selenate, selenium was preferentially distributed to hemoglobin with the former supplement, whereas selenium evenly distributed to hemoglobin and glutathione peroxidases following administration of selenate.[235]

At plasma Se concentrations of >0.16 mg/L, the plasma-carrying capacity becomes saturated; erythrocytes then carry an increasing amount of selenium.[236] Plasma and serum selenium concentrations reflect changes in Se intake more rapidly than Se concentrations in erythrocytes where proteins firmly bind selenium. Consequently, whole blood and, in particular, selenium content in the erythrocytes are theoretically better measures of long-term exposure to selenium than plasma or serum. However, a year-long study of 77 Wyoming and South Dakota residents of high seleniferous areas indicated that whole blood and serum were equally good sampling sites for the measurement of long-term selenium intake.[237] An exception is selenite, which produces elevated plasma selenium concentrations.[69]

General Population

Whole Blood The average whole blood selenium concentration in the general population is <100–200 µg/L;[238,239,240] however, the whole blood selenium concentrations vary widely between different localities depending on Se intake.[241] The mean whole blood selenium in 210 blood samples from residents of 19 US cities was ~210 µg/L with a range of 100–340 µg/L as measured by fluorometry.[242] In a study of random blood samples from healthy residents in three different locations, the mean whole blood selenium concentrations were as follows: 1) Oregon (n = 23), 202 ± 25 µg/L (range, 155–278 µg/L); 2) South Dakota (n = 21), 397 ± 128 µg/L (range, 221–640 µg/L); and New Zealand (n = 34), 59 ± 11 µg/L (range, 41–101 µg/L).[243] In newborns, the whole blood selenium may be as low as 30 µg/L, but the concentration increases to 100 µg/L by 1 year of age.[244] Factors affecting the blood selenium concentration other than the amount ingested include the Se species ingested (selenomethionine, selenate, selenite), vitamin E intake, the presence of serious illness,[245] ingestion of selenium-containing seafood, and exposure to inorganic mercury and cadmium.[36]

Serum/Plasma In a study of 122 Czechoslovakian volunteers, the median serum selenium concentration was ~67 µg/L with a range of 40–105 µg/L.[246] The administration of 90 µg Se as selenite over 17 weeks increased the mean plasma Se concentration in seven subjects by ~36 µg/L compared with a mean increase of ~102 µg/L following the administration of 100 µg Se as selenomethionine to four subjects.[247] There were

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

no statistical comparisons between these two groups. The addition of 150–200 g fish (~40–50 μg Se) to the diet of healthy Swedish subjects for 11 weeks was associated with a mean plasma concentration of ~96 μg Se/L.[248] This concentration represented an average 13% increase over baseline concentrations. The fish included mackerel, salmon, and herring. The estimated optimum concentration of serum selenium based on cytosolic glutathione peroxidase (i.e., indicator of selenium repletion) is 100 μg/L.[249]

Supratherapeutic

In a study of 16 subjects receiving 3,200 μg selenized yeast daily for an average of 1 year, the mean plasma selenium concentration was ~0.64 ± 0.49 mg/L.[250] A small minority of these patients complained of garlic breath, brittle nails/hair, and nausea. There was no biochemical evidence of liver, kidney, or hematological abnormalities. In a case series of nine patients ingesting a nutritional supplement containing 200 times the labeled selenium selenite dose over ~1–2 months, the median whole blood selenium concentration collected between 7 and 118 days (mean = 27.3 days; median = 14 days) after the last dose was 318 μg/L with a range of 150–732 μg/L.[185] A 36-year-old man presented with generalized alopecia, nail changes, paresthesias, fatigue, and diarrhea after ingesting excessive amounts of selenium supplements over 2 weeks. Two weeks after cessation of selenium intake, the serum contained ~0.66 mg Se/L; the Se concentration was normal when repeated 2 months later.[251]

Environmental

Whole blood concentrations exceeding 0.6 mg Se/L suggest overexposure to selenium. A study of 77 residents of South Dakota where the average daily intake was high (~0.6 mg Se) demonstrated a mean whole blood Se concentration of 0.025 mg/L with a range up to 0.521 mg/L.[252] In a study of 33 New Mexico residents exposed for at least 1 year to excessive selenium in well water (0.026–1.8 mg/L) contaminated by a uranium mill tailing pond, the mean Se whole blood concentration was 0.171 ± 0.025 mg/L with a range of 0.133–0.248 mg/L.[253] The blood selenium concentrations did not correlate to glutathione peroxidase activity; the study did not investigate any symptoms related to the whole blood selenium concentrations. In a study of a Chinese population exposed to high concentrations of environmental selenium, individuals with signs of chronic selenosis (brittle nails, hair loss, nail deformities, skin lesions) had a mean Se concentration of 3.2 mg/L blood with a range of 1.3–7.5 mg/L.[117]

Overdose

There are limited data correlating blood selenium concentrations with outcome following intentional overdose. Plasma selenium concentrations of <1 mg/L within 3–6 hours after ingestion suggest mild toxicity, whereas plasma selenium concentrations of >2 mg/L during this period suggest serious toxicity. A 75-year-old man presented to the emergency department 3.5 hours after ingesting 10 g sodium selenite; he had vomiting, diarrhea, hypotension (75/45 mm Hg), QT prolongation, and mild hypokalemia.[102] His serum selenium concentration was 5.4 mg/L. He was admitted to the ICU where he received magnesium and potassium; he remained hypotensive with worsening metabolic acidosis. Subsequently, he developed cardiac arrest and was unresponsive to resuscitation. During the cardiac resuscitation, an ABG demonstrated a serum potassium concentration of 8.8 mEq/L.

A 48-year-old schizophrenic had a serum Se concentration of 2.4 mg/L ~2 hours after the ingestion of 2 g selenium dioxide.[107] She recovered after developing gastric ulcerations and mild hepatic inflammation. A 2-year-old child accidentally ingested selenious acid; the plasma Se concentration reached 285 mg/L on the second hospital day. He developed multiple complications (esophageal burns, cardiomyopathy, hepatorenal dysfunction, acute respiratory failure).[108] Although the plasma Se concentration returned to normal limits 4 days after exposure, he died 13 days later despite aggressive treatment (e.g., extracorporeal membrane oxygenation).

Postmortem

Because of the limited number of autopsy cases with selenium concentrations, selenium concentrations should be interpreted cautiously. The postmortem whole blood selenium concentration in a peripheral blood sample from a 24-year-old, who died 4 hours after ingesting gun-bluing solution containing selenious acid, was 13 mg/L compared with 30 mg/L in serum drawn 1 hour after ingestion.[174] The postmortem bile sample also contained high Se concentrations (15 mg/L), whereas the vitreous humor contained low Se concentrations (0.031 mg/L). The postmortem blood from a 40-year-old dying 8 hours after the suicidal ingestion of 4% selenious acid contained 2.6 μg Se/g wet weight.[175]

Urine

Selenium excretion is rapid with the maximum urinary excretion occurring in the first 4 hours after absorption with renal excretion accounting for ~50% of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

absorbed dose. Urine selenium is an indication of recent (1–2 day) exposure to selenium.[254] In populations with normal Se intake without occupational Se exposure, the urine selenium level is usually <30 μg/L with most urine samples <100 μg/L.[255] In a study of trace metals in a representative sample of >400 urban, suburban, and rural northern Italian residents, the mean urine selenium concentration was 22 ± 2 μg/L with a range of 2–68 μg/L.[233] A study of 230 healthy Croatian adults found no difference in the urine selenium concentrations of groups based on age, sex, and smoking habits.[256] Using a fluorometric method, the average urine selenium concentration was 16.96 nmol Se/mmol creatinine with a SD = 5.44.

Typically, no symptoms are associated with urine selenium concentration of <100–200 μg/L,[257] whereas urine selenium concentrations of >400–700 μg/L suggest excessive recent selenium exposure.[126] Residents in areas of high seleniferous soil may ingest up to 750 μg of selenium daily without signs of selenosis.[258] In a study of 28 New Mexico residents exposed for at least 1 year to excessive selenium in drinking water (mean = 0.337 ± 549 μg/L; range, 26–1,800 μg/L) contaminated by a uranium mill tailing pond, the daily urinary excretion of selenium ranged from 14.4–337.5 μg (mean = 79.21 ± 48.12 μg).[253] No clinical symptoms were observed in ranchers in the highly seleniferous areas of South Dakota and Wyoming where livestock developed selenosis.[110] Urine samples from these ranchers contained Se concentrations up to 2,200 μg/L.

Hair/Nails

There are inadequate data to confirm the usefulness of nail or hair selenium concentrations as biomarkers of selenium exposure including supplementation.[259] The mean selenium concentration ranged from 0.54 ± 0.91 to 1.56 ± 0.58 μg/g in a review of studies on the selenium concentrations in nails, whereas the mean concentrations in hair ranged from 0.36 ± 0.17 to 3.70 ± 2.3 μg/g (ppm).[21] The mean selenium concentration in hair samples obtained from 56 adult residents of a highly seleniferous region of Glasgow, Scotland, was 18.92 ± 52.77 ppm (range, 1.27–248 ppm) as measured by neutron activation analysis.[260] In this study comparing three different regions, the mean Se concentration in 22 adults from Iran was 5.72 ± 18.7 ppm (range, 0.80–89.1 ppm) and 1.81 ± 1.32 ppm (range, 0.0037–0.2 ppm) in hair samples from 62 Icelandic adults.

Abnormalities

Electrocardiograms, liver and kidney function tests, and serum electrolytes are usually normal following chronic exposure to elemental selenium and selenium compounds. Yang et al. reported prolonged clotting times and low serum glutathione levels in Chinese patients with excessive Se exposure;[111] however, insufficient documentation of the normal values in the general Chinese population limits extrapolation of these findings. Furthermore, this abnormality did not occur in other patients with similar exposures. The administration of selenium may alter thyroid function and produce hypothyroidism in iodine-deficient patients.[159] Selenium deficiency is common in elderly patients; this deficiency may impair the activity of Se-containing type I deiodinase, resulting in a subsequent reduction in the conversion of T_4 to T_3.

Following exposure to selenious acid, laboratory abnormalities include thrombocytopenia, moderate hepatorenal dysfunction, and elevated serum creatine kinase concentrations. The electrocardiogram may demonstrate ST elevations and T wave changes characteristic of myocardial infarction. Mildly elevated serum hepatic aminotransferases and transient T-wave inversions developed after the ingestion of large amounts of selenium selenate; these changes resolved without sequelae.[105]

HEALTH SURVEILLANCE

Risk Assessment

Factors that influence the chronic Se toxicity include chemical species, bioavailability of the form of selenium in the diet, and animal species. The recommended daily allowance for selenium is 55 μg Se/day in women and men.[21] The ingestion of up to 200 μg Se/day in humans does not produce adverse effects.[261] The chronic oral reference dose (R_fD), as defined by the US EPA, is 5 μg Se/kg/day based on a no-observed-adverse-effect level (NOAEL) of 15 μg Se/kg/day and an uncertainty factor of 3 for sensitive individuals. The minimal risk level for chronic oral ingestion of selenium is also 5 μg/kg/day as determined by the Agency for Toxic Substances and Disease Registry.[21] Studies on chronic selenosis in China by Yang et al. were the basis for this calculation. Based on Chinese studies of subjects in areas containing high Se concentrations in soil (average, 10 ppm) and water (average, 54 ppb), the authors calculated the following: lowest-observed-adverse-effect level (LOAEL), 1,570 ± 653 μg Se/day; mean NOAEL

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

was 819 ± 126 μg Se/day.[72] The maximum safe dietary Se intake was 400 μg with a minimum value of 40 μg. The Joint Food and Agriculture Organization (World Health Organization) Expert Committee on Human Vitamin and Mineral Requirements recommended the intake of 6 μg/day in infants aged 0–6 months.[262]

The California Department of Health (CDH) issued a health advisory for the consumption of two species of diving ducks in Suisun Bay, near San Francisco, during 1987. These diving ducks (i.e., surf scoter, lesser and greater scaup) feed on bottom-dwelling animals (clams, mussels) that concentrate selenium from sediment and phytoplankton. In a study by the California Department of Fish and Game, the mean selenium concentrations wet weight in the muscle of ducks were 3.6 ppm in scoters and 2.2 ppm in scaups. These concentrations were up to five times higher than mean Se levels in similar species in control areas (i.e., Humboldt Bay near the border of Oregon and California). The CDH recommended limiting the consumption of scoters to 4 oz/2 weeks and scaups to 4 oz/week. Because of the known Se effects on the reproduction of birds, the CDH recommended that women of childbearing age and children less than 15 years of age not consume these ducks. The basis of this advisory is Equation 27.1.

$$\text{PI (diving ducks)} = (\text{ADI} - \text{DI}) \div \text{C} \quad \text{(Equation 27.1)}$$

where

PI = Permissible intake of duck flesh
ADI = Acceptable daily Se intake
DI = Daily Se intake of US population
C = Se concentration in duck flesh

The ADI was 210 μg Se/day based on applying a 15-fold safety factor to the lowest mean Se intake (3,200 μg Se/day) that produced toxicity.[117] Additional safety factors include the following: 1) the assumption of 100% bioavailability (e.g., the bioavailability of Se from animal sources is lower than plant sources used to set the ADI); 2) the release of volatile selenium compounds during the cooking process; 3) the beneficial interaction of dietary factors (vitamins, methionine, protein, sulfates, zinc, iron) with selenium; and 4) the use of the upper range of daily selenium ingestion (170 μg Se) for the local population.[52] Equation 27.2 outlines the CDH calculation for the permissible Se intake from the consumption of scaup flesh.

$$\begin{aligned}\text{PI (scaup)} &= (210\ \mu\text{g Se} - 170\ \mu\text{g Se}) \quad \text{(Equation 27.2)}\\ &\div 2.2\ \mu\text{g se/g flesh wet weight}\\ &= 18.18\ \text{g flesh/days}\\ &= (18.18\ \text{g} \times 7\ \text{days/week})/28.35\ \text{g/oz}\\ &= 4.5\ \text{oz/week}\end{aligned}$$

Environmental Monitoring

Table 27.2 lists the guidelines and regulations for elemental selenium and selenium compounds. The ACGIH recommends a TLV-TWA for Se and Se compounds except hydrogen selenide and selenium hexafluoride of 0.2 mg/m^3 to minimize the risk of eye/upper respiratory tract irritation and systemic complaints (rash, headache, metallic taste, garlic odor).[263] Preemployment and periodic physical examinations of selenium workers should focus on the liver, the respiratory tract, the eyes, and the skin. In particular, the nails should be examined for the red pigmentation characteristic of excessive Se exposure. The EPA Office of Drinking Water's Maximum Contaminant Level (MCL) for selenium was 50 μg/L. Recently, the EPA national water quality criterion for chronic Se exposure in freshwater was reduced to 5 μg/L. The WHO standard for drinking water is 10 μg Se/L.

Biological Monitoring

Biomarkers for selenium exposure are not well defined. Selenium concentrations in plasma/serum and urine reflect short-term exposure, whereas erythrocyte and whole blood Se concentrations reflect Se exposure over the 3-month life span of red blood cells. A study of the Greenland Intuit population suggests that plasma Se concentrations stabilize near 140 μg/L, whereas whole blood Se concentrations continue to increase with increasing Se dose.[264] The mean Se concentration in Uummannaq men was 488 μg/L in whole blood compared with 113 μg/L in plasma. The large variation in blood and urine Se concentrations complicates the interpretation of individual Se concentrations that depend on multiple factors including age, gender, smoking/drinking habits, race, environmental exposure, and supplement use.[265] Little data correlate airborne Se concentrations with blood or urine; therefore, blood and urine Se concentrations should be compared with local control concentrations and clinical manifestations of Se exposure. The suggested biological equivalent of a safe Se dose based on the EPA RfD and ATSDR MRL is 400 μg/L in whole blood, 180 μg/L in plasma, and 90 μg/L in urine.[266]

selenium, plasma selenium concentrations significantly decreased (P = 0.01) with age and current tobacco consumption; however, no correlation was found with alcohol consumption.[267] The plasma selenium concentration ranged from ~35–100 µg/L with a mean of 60.2 µg/L for workers with long-term and current exposure. The plasma Se concentration correlated with the glutathione peroxidase activity; the authors opined that decreased Se concentration reflected increased antioxidant activity in smokers and workers exposed to coal mine dust.[268] In a study of 20 workers at a Mexican rubber tire repair shop, the mean serum Se concentration was 148 ± 56 µg/L (range, 70–296 µg/L).[269] The mean selenium concentration in serum samples from 18 healthy Mexican volunteers without occupational Se exposure was 100 ± 18 µg/L (range, 70–127 µg/L). The plasma Se concentration of 20 copper refinery workers working in the selenium department ranged from 114–174 µg/L (mean = 137 ± 17 µg/L) compared with 120–187 µg/L (mean = 155 ± 19 µg/L) in the non-occupationally exposed control group as measured by fluorometry.[270] The study did not report any measures of selenium exposure in the occupational group; exposure apparently was based on job title.

URINE

In a study of Norwegian workers with no occupational selenium exposure, the mean urine level was 39 nmol Se/mmol creatinine.[271] At ambient air levels of <0.1 mg inorganic Se compounds/m^3, the urine selenium is usually <0.1 mg/L, whereas average urine Se concentration in workers exposed to air concentrations as high as 3.6 mg Se/m^3 was 0.25–0.45 mg/L.[119,272] The workers at the selenium rectifier plant were probably exposed to elemental selenium and selenium oxide (Se species was not reported). The urine selenium concentration in post urine samples from 20 copper refinery workers ranged from 34–190 µg/L (mean = 93 ± 43 µg/L) compared with 27–118 µg/L (mean = 74 ± 25 µg/L) in the non-occupationally exposed control group as measured by fluorometry.[270]

TREATMENT

First Aid

The most important first aid measure following dermal exposure to selenium compounds (selenium dioxide, selenium oxychloride, selenious acid) is copious water irrigation. These compounds are potentially absorbed through the skin. Contaminated clothes should be immediately removed. Following the inhalation of selenium compounds (hydrogen selenide, selenium oxide) with respiratory irritant effects, the patient should be removed from the contaminated area with symptomatic patients receiving oxygen as needed.

Decontamination

Although data are limited, the ingestion of elemental selenium or selenium salts usually does not require decontamination; however, selenious acid commonly present in gun-bluing solution is a potent toxin. Small amounts of this chemical are potentially lethal. All patients ingesting selenious acid require evaluation by a physician and hospitalization for observation. Gun-bluing compound containing selenious acid is corrosive and will produce esophageal burns following ingestion; however, because this acid is a serious systemic poison, the decision to use gastric aspiration and lavage judiciously is based on clinical judgment. Factors to consider in the decision to use these measures include the time since exposure (<1–2 hours), the amount of spontaneous emesis, the clinical condition of the patient, and the amount ingested.

Antidotes

There are no antidotes to selenium poisoning. In experimental animals, dimercaprol (BAL) inhibits the recovery from selenium poisoning.[273] Similarly, experiments in rats indicate that calcium disodium ethylenediaminetetraacetate ($CaNa_2EDTA$) does not improve survival rates when administered >15 minutes after an intramuscular dose of 7.5–12.5 mg sodium selenite/kg.[274] Additionally, animal studies suggest that the newer derivatives of BAL (2,3-dimercaptopropane-1-sulfonic acid or DMPS, meso–2,3-dimercaptosuccinic acid or DMSA) do not enhance Se excretion when administered 15 minutes after a subcutaneous dose of 2.24 mg sodium selenate/kg.[275]

Supplemental Care

No entirely satisfactory treatments for selenium poisoning are available. Management of acute and chronic intoxication with selenium is supportive including elimination of the selenium source. Treatment is expectant (cardiopulmonary monitoring in an intensive care setting for selenious acid ingestion) and supportive (intravenous infusion, supplemental oxygen, and ventilation as needed). Calcium gluconate jellies may be necessary for workers sustaining dermal injury from selenium hexafluoride similar to hydrogen fluoride exposure. A reductant-containing bathing solution (e.g., 10% sodium thiosulfate) may decrease pain and necrosis following dermal exposure to selenium oxides or hydrogen selenide;[36] however, the evidence is anecdotal with no clinical studies confirming efficacy.

ORGANIC SELENIUM

PHYSIOCHEMICAL PROPERTIES

Selenomethionine and selenocysteine are the main organic forms of selenium. Figure 27.3 displays the chemical structure of selenocysteine, selenomethionine, and other organic selenium compounds. The latter structure is the form of selenium present in all currently known selenium-containing enzymes (e.g., selenoprotein P, glutathione peroxidase).[277] Selenocystine is an oxidation product of selenocysteine resulting from the conversion of two –SH groups to one S–S group. The four natural oxidation states of organic selenium include (0) selenodiglutathione (dipeptide); (2−),

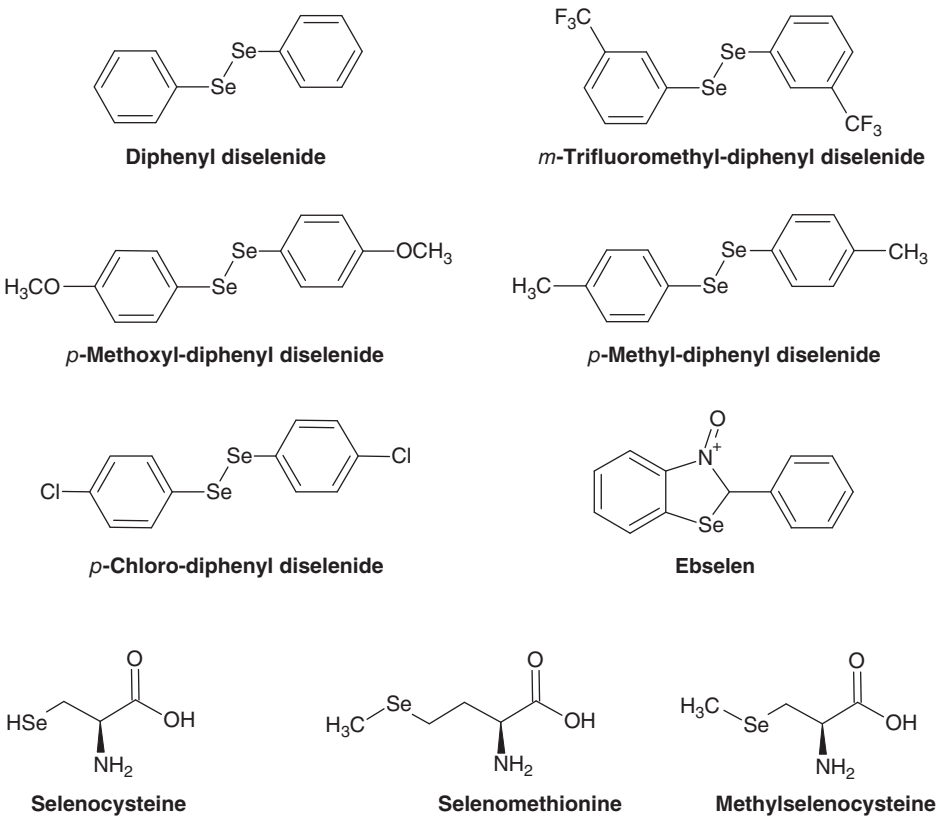

FIGURE 27.3. Chemical structure of selenocysteine, selenomethionine, and other organic selenium compounds. (Adapted from Flury et al.).[276]

dimethylselenide (C_2H_6Se); (4+); and (6+). The body metabolizes selenocystine to selenocysteine. Selenium easily replaces sulfur to form a large number of organic selenium compounds (dimethylselenide, trimethylselenium). In general, organoselenium compounds are more reactive than similar sulfur-containing compounds with selenols (i.e., R-SeH) being more acidic and more readily oxidized than thiols.

Selenomethionine in nature exists almost exclusively as the L-enantiomer.[278] Dimethylselenide is a volatile, methylated metabolite of selenium that has a strong garlic-like odor. At physiological pH, selenium occurs primarily as selenides on the side chains of selenocysteine. Table 27.3 lists identifying information and physical properties of selenocystine and selenomethionine.

TABLE 27.3. Identifying information and physical properties of selenocystine and selenomethionine.

Physical Characteristic	Selenocystine	Selenocysteine	Selenomethionine

Alkyl selenium compounds are flammable liquids that do not react with air, oxygen, or water at room temperature. The alkyl compounds are the least toxic selenium compounds; these compounds (e.g., dimethylselenide, trimethylselenonium) are the primary products of selenium detoxification in the body. Under conditions of excessive Se intake, the rate of trimethylselenonium formation exceeds the rate of methylation resulting in dimethylselenide. This compound produces a strong garlic odor in the breath during exhalation.[279]

EXPOSURE

Uses

Selenium diethyldithiocarbamate is a fungicide and rubber vulcanizing agent. Selenoproteins are common in marine organisms (fish, algae); however, there is little evidence that selenoproteins are physiologically important in higher plants and fungi.[280] Selenomethionine is a common source of selenium in multivitamins in doses ranging from 50–100 μg/tablet.

Sources

Environment

In addition to selenium dioxide, methylselenide and dimethylselenide are the most prevalent forms of selenium found in the atmosphere. Terrestrial plants can synthesize organic selenium compounds (e.g., selenomethionine and, to a lesser extent, selenocysteine).[281,282] Organic selenium species may constitute substantial portions of the selenium species in water including selenoamino acids and volatile organoselenium species (e.g., dimethylselenide, dimethyldiselenide, dimethylselenenyl sulfide). In a study of the dissolved selenium in drainage water from the Kesterson Reservoir, up to ~25% of the Se species were methylated forms (dimethylselenide, unidentified organic dimethylselenium derivatives).[36] In estuaries, biomethylation of selenium by marine microbes probably occurs rapidly; most selenium in the sea exists as organic selenium compounds.[115] Microorganisms in lake sediment can convert selenite, selenate, and organic selenium compounds to volatile methylated selenium compounds (dimethylselenide, dimethyldiselenide).[283] Determining the amount of organoselenium compounds in soil and sediment is complicated by the strong affinity of selenium for natural organic matter; current techniques probably overestimate the concentration of organoselenium compounds in solid environmental material.[284]

In vivo studies suggest that Se bioaccumulation is faster from selenomethionine than selenite or selenate. The bioconcentration factors for selenomethionine in an experimental setting are substantially higher than those for inorganic selenium.[285]

Diet

Organic selenium occurs naturally in the diet in highly variable quantities, particularly in cereals, grains, and forage crops. The predominant Se species in non-selenium accumulating plant foods are selenate and selenomethionine with less selenocysteine. The bioavailability of selenomethionine and selenocysteine in plant-derived foods is good, whereas the Se bioavailability from animal-derived foods (e.g., especially fish)[60] is low to moderate.[61,62] In a study of spring wheat grown in selenium-rich soil in India, the total selenium concentrations in 2 samples were ~83 μg/g and ~183 μg/g, respectively, dry weight.[57] Selenomethionine accounted for 72–85% of the total Se species. Se-methyl-selenocysteine was a minor constituent (0.2–0.5%). Selenium-accumulating plants (e.g., rapeseed, broccoli, cabbage, garlic, onions, leeks, wild leeks) contain primarily Se-methyl-selenocysteine and γ-glutamyl Se-methyl-selenocysteine.[286] An exception to the latter plants is Brazil nuts, which contain primarily selenomethionine and smaller amounts of selenocystine.[287] Cereal crops (e.g., barley, oats, rye, wheat) are non-accumulators. The major portion of selenium in vegetables and cereals is organic selenium compounds (e.g., selenomethionine, selenocysteine) as a result of the incorporation of these selenium species into plant proteins.[56] Organic selenium compounds (e.g., selenomethionine) constituted ~50% of the selenium in cereal.[288] Chromatographic analysis of seeds and gluten of wheat indicated that ~40% of the selenium occurred as protein-bound selenomethionine, whereas the rest of the selenium species were not identified.[289] The authors felt that the chromatographic findings of this unidentified area in the chromatograph were most consistent with selenocysteic acid and oxides of selenomethionine.

In general, foods from plant sources contain a greater portion of selenomethionine than animal sources.[55] Selenium in animal tissue exists in a variety of forms including selenomethionine and selenocysteine along with inorganic selenium.[58] The bioavailability of selenomethionine and selenocysteine in plant-derived foods is good, whereas Se bioavailability from animal-derived foods (e.g., especially fish) is low to moderate; hence, marine diets rich in selenium may be tolerated better than vegetable diets containing similar amounts

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of selenium.[60,62] Cooking may reduce the selenium content up to 50%, particularly in acidic, salty conditions.[281] Selenized yeast contains primarily selenomethionine bound in proteins as well as selenium-containing glutathione and unknown selenium species.[290]

ENVIRONMENTAL FATE

Air

Dimethylselenide and methylselenide are volatile organic compounds that partition into the atmosphere and persist in the atmosphere. The atmospheric lifetime of these volatile organoselenium species is short (5 minutes to 6 hours) as a result of rapid oxidation.[291] Other organic Se compounds released to the atmosphere as dust are removed by dry or wet deposition.

Soil

Decomposition of Se-accumulating plants is the primary source of organic selenium in the soil with Se concentrations ranging from ~0.1–0.7 mg/kg. The selenium content in tropical soils is relatively high concentrations, whereas volcanic and granite soils have low Se concentrations.[292] Iron hydroxides, clay minerals, and organic matter bind selenium in soil; therefore, the availability of organic selenium in the soil is highly variable. Figure 27.4 outlines Se depletion from soil. Microorganisms (*Aeromonas*, *Flavobacterium*, *Pseudomonas*) methylate substantial amounts of elemental selenium and inorganic selenium compounds (sodium selenite) present in soil to dimethylselenide and dimethyldiselenide. Over 100 months, ~68–88% of the selenium present in the topsoil (i.e., upper 15 cm) near the Kesterson National Wildlife Refuge dissipated with tillage and irrigation increasing selenium dissipation more than soil amendments (casein, albumin, glutin). These organic selenium compounds then volatilize in the air.[293]

After uptake of inorganic selenium, terrestrial plants metabolize selenium to selenomethionine and, to a lesser extent, to selenocysteine. Selenocysteine is readily incorporated into proteins. In contrast to non-accumulators of selenium, plants that accumulate selenium sequester selenium primarily in nonprotein selenoamino acids (methylselenocysteine, selenocystathionine).[81] The use of plant ash and lime for fertilizer in China enhanced selenium uptake; these conditions probably contributed to the development of chronic selenosis.

Water

Selenium usually exists in freshwater as selenite or selenate; however, the presence of microorganisms of algae favors the production of methylated or volatile organic Se species. As a result of the synthesis and bioaccumulation of organic selenium prior to decay, >50% of the selenium contained in sediments in the ponds and reservoir in the Kesterson National Wildlife Refuge exists as organic selenium.[21] A field study at the Kesterson Reservoir demonstrated that leaching dominated selenium depletion in the winter; volatilization dominated the environmental fate of selenium during the summer.[276]

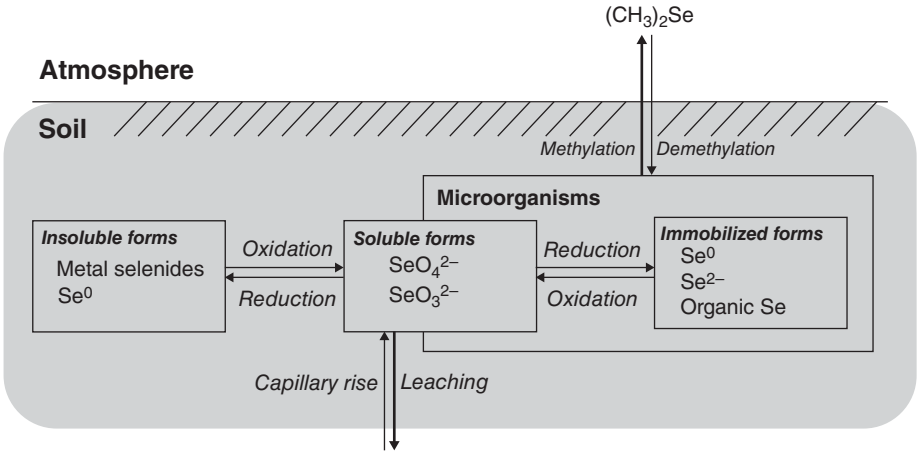

FIGURE 27.4. Schematic representation of selenium dissipation in soil. The preferred directions (bolded arrows) of these processes are methylation to dimethylselenide and leaching of soluble forms. (Modified from Nogueira and Rocha).[280]

In a study of estuarine wetlands in the San Francisco Bay, organic selenium accounted for ~25–30% of the selenium in sediment in contrast to ~50% for elemental selenium.[86] The formation of selenoamino acids by microorganisms (phytoplankton, bacteria, fungi) does *not* produce significant levels of these compounds in the environment because of the rapid catabolism of selenoamino acids by bacteria. Additionally, studies in closed-system microcosms indicate that volatilization is an important pathway for loss of selenomethionine compared with other selenium species (e.g., selenite or selenate, ~1%).[87] Following formation, methylated forms of selenium rapidly volatilize into the atmosphere. The accumulation of selenomethionine in aquatic organisms is greater than either selenate or selenite. Selenium bioaccumulates in the aquatic food chains with Se concentrations orders of magnitude higher in aquatic organisms than surrounding water; however, biomagnification factors are small (i.e., 1–2) based on examination of Se data from the San Francisco Bay.[294]

Higher plants including algae volatilize significant portions of selenium present in their structure as methylated selenides. Non-accumulators emit primarily dimethyldiselenide, whereas accumulators emit mainly dimethylselenide. At least in sewage, dimethylselenide predominates at low selenite concentrations (1–10 mg Se/kg); dimethyldiselenide and dimethylselenenyl sulfide (previously reported as dimethylselenone)[295] predominate at high concentrations (>100 mg Se/kg). These reactions are temperature dependent with a reduction in temperature from 20 to 4°C causing a 90% decrease in the formation of dimethylselenide.[283]

DOSE EFFECT

Acute Toxicity

Toxicity depends on the chemical form of selenium. The toxicity of organic selenium is low. Although selenocysteine possesses similar toxicity in animals compared with selenite, selenomethionine is somewhat less toxic.[296] Other organic selenium compounds (dimethylselenide, trimethylselenonium ion, selenoethers, selenobetaine) are much less toxic in animal studies compared with selenite.[154,297]

Chronic Toxicity

Human

Organic-bound selenium (e.g., selenomethionine) is relatively less toxic than inorganic salts, but there are limited data on the toxicity of individual compounds.[298,299] In a randomized, controlled clinical trial, 653 patients received 200 μg Se as high-selenium brewer's yeast tablet daily.[217] A total of 35 patients (21 in treatment group, 14 in control group) withdrew from the study because of adverse effects (i.e., primarily gastrointestinal complaints); there was no difference in the plasma selenium concentration between patients reporting adverse effects and the rest of the test group. The mean plasma selenium concentrations of the control and treatment groups after 9 months of selenium supplementation were 114 μg/L and 190 μg/L, respectively. In a study of 10 volunteers receiving 600 μg Se as high-selenium yeast (selenomethionine), no clinical or laboratory abnormalities were detected during the 18-month course of the study.[300] The mean whole blood Se concentration of this group was 620 μg/L. In nutritional studies, volunteers tolerate daily selenium intake from selenium supplementation (e.g., selenomethionine, high-selenium yeast, selenite) up to ~800 μg without adverse effects.[301]

Animal

Selenocysteine is the most toxic *organic* selenium compound in animal studies. In these studies, selenocystine and selenite toxicities were similar.[302] In general, methylated metabolites are less toxic than the parent compound. Methylselenocysteine (from Se-accumulator plants) produces less toxicity than selenocysteine.[154] Selenomethionine is less toxic than selenite; the L-isomer (natural) is slightly more toxic than the D-isomer (synthetic). Other organic selenium compounds (selenobetaine, trimethyselenonium ion, dimethylselenide, selenoethers) are not very toxic in comparison to selenite.[297] Substantial variation in Se toxicity in various animal species occurs with hamsters being more resistant to Se effects than rats.[303]

TOXICOKINETICS

Absorption

The absorption of selenium is greater from amino acids (i.e., selenomethionine, selenocysteine) than inorganic species (i.e., selenite, selenate);[301] however, there is substantial inter-subject variation in Se absorption in humans.[304,305] Following the ingestion of 200 μg Se by 6 volunteers, gastrointestinal absorption accounted for ~97% of the selenium dose when administered as L-selenomethionine compared with ~84% when administered as selenite.[306] In an isotope tracer study of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

fasting volunteers receiving 26.5 μg ^{74}Se, the gastrointestinal tract absorbed ~85% of the selenium when administered as L-selenomethionine.[304] In comparison, the gastrointestinal tract absorbed ~25–43% of 41.6 μg ^{76}Se as sodium selenite. The estimated mean absorption of 100 μg Se as D,L-selenomethionine over 10 weeks in this study was ~75%. The absorption of selenomethionine from the gastrointestinal tract occurs via an active transport mechanism shared with methionine. Selenocysteine may share a common active transport mechanism with basic amino acids. The absorption of selenomethionine, but not selenocysteine, occurs in the intestine without prior metabolism.[21]

Distribution

In primates receiving 600 μg selenomethionine/kg body weight orally, the highest Se concentrations in tissues occurred in the following descending order: liver, kidneys, spleen, pancreas, cardiac muscle, brain, and skeletal muscle.[307] Slightly less than ½ of the body burden of selenium resides in skeletal muscle and bone with muscular tissue accounting for the largest portion, primarily as selenomethionine.[177,306]

Metabolism

A variety of selenium compounds appear in the urine after the ingestion of selenium species including selenosugars; analytical issues complicate the determination of the chemical composition of urinary selenium metabolites in humans following ingestion of organoselenium compounds. Although earlier studies suggested that trimethylselenonium ion was a major metabolite, subsequent studies indicate that trimethylselenonium is a minor metabolite.[134] Selenosugar 2 (methyl 2-acetamido-2-deoxy-1-seleno-β-D-galactopyranoside) is probably a major metabolite with selenosugar 1 (isomer of selenosugar 2); selenosugar 3, selenite, and perhaps trimethylselenonium ion are minor metabolites.[130] Although selenosugar 2 is the primary metabolite in urine samples from most humans, substantial amounts of trimethylselenonium ions may occur in some individuals, particularly following the metabolism of selenocysteine.[308]

The metabolism of selenomethionine ultimately yields primarily monomethylated forms of selenium. The metabolism of selenomethionine to selenide and the incorporation of selenium into selenium-specific proteins occur by the following two pathways: 1) metabolism to methane selenol and selenide and 2) via selenocysteine and the transsulfuration pathway (methionine to cysteine) as demonstrated in Figure 27.2.[309] Selenocysteine β-lyase catalyzes the metabolism of selenocysteine to alanine and hydrogen selenide.[310] Pyridoxal-5-phosphate is a cofactor for this reaction. Humans metabolize the L-enantiomer of selenomethionine, whereas the kidney excretes the D-enantiomer unchanged without any significant biotransformation.[311] Biotransformation of selenobetaine and selenomethylselenocysteine involves conversion to methylselenol via β-lyase and demethylation, respectively.

Elimination

In humans ingesting low doses of selenium, the kidneys and the intestines each excrete ~1/2 of the absorbed Se dose; exhalation of selenium is a minor pathway.[135] Similar to other nonmetals, methylation of elemental selenium occurs prior to renal excretion or exhalation in air with the amount of methylation being dose-dependent.[130] Selenomethionine elimination is triphasic similar to sodium selenite; however, the terminal half-life of selenomethionine is longer than that of sodium selenite. In an isotope tracer study of four women, the average half-lives of selenomethionine for the three phases were ~0.4–2 days, 5–19 days, and 207–290 days, respectively.[312] Differences in the excretion pattern occur between selenium species. In a study of volunteers given 200 μg Se supplements as selenomethionine or selenate over 32 weeks, the mean daily Se excretion for selenomethionine was 27% of the daily dose compared with 57% for selenate.[136]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

In humans, there are at least 25 selenoproteins; these proteins all contain the amino acid, selenocysteine. The latter amino acid is structurally similar to cysteine except for the substitution of selenium for sulfur.[313] Selenocysteine is formed in the body rather than consumed in the diet as a result of the reaction of phosphoserine with monoselenophosphate. There are two classes of selenoproteins: 1) the *N*-terminal position of the function domain contains selenocysteine (e.g., glutathione peroxidases, selenoprotein P, selenoprotein W), and 2) the *C*-terminal sequence contains selenocysteine (e.g., thioredoxin reductase). Selenoamino acids (i.e., selenocysteine, selenomethionine) mediate antioxidant defense mechanisms in mammalian cells.

Glutathione peroxidase and glutathione disulfide catalyze the redox reactions that reduce various simple and lipid hydroperoxides to phospholipids. Selenomethionine has glutathione-like activity, whereas the active site of glutathione contains selenocysteine residues. Additionally, glutathione peroxidases and thioredoxin reductases are the main selenoproteins expressed by endothelial cells; these selenium-containing enzymes modulate vascular tone by several processes including maintaining the superoxide anion/nitric oxide balance and regulating inflammatory processes.[314] Thioredoxin reductase also stimulates the proliferation of normal and tumor cells as part of the repair mechanisms essential for DNA synthesis.[315]

At least 13 selenoproteins contain selenium as selenocysteine.[316] A unique stop codon UGA in mRNA encodes the endogenous synthesis of selenide and serine to selenocysteine. This reaction involves a unique tRNA, which implies that this process is under genetic control. Animals cannot synthesize selenomethionine. Other proteins that incorporate or require selenium include the following: a selenoprotein in muscle, selenoprotein P (catalytic function unknown), and the selenodeiodinases, which catalyze the deiodination reactions that convert the prohormone, thyroxine, to the active thyroid hormone, 3,5,3′-triiodothyronine.[317] The amino acid sequence of the active site of the latter enzyme requires selenocysteine for full activity. Organoselenide compounds can form selenooxides that oxidize endogenous cellular molecular targets containing thiol groups.[280]

CLINICAL RESPONSE

The toxicity of most selenium compounds is low, particularly organic selenium compounds. No statistically significant developmental abnormalities were detected in primates given toxic Se doses ranging up to 300 μg/kg as selenomethionine during organogenesis.[318] In this study, maternal toxicity included anorexia, vomiting, and decreased body weight.

DIAGNOSTIC TESTING

The identification and quantification of selenium species is challenging as a result of low selenium concentrations, oxidative degradation during sample preparation (e.g., selenomethionine), and the complexity of the matrix including the presence of polyatomic interferents (e.g., arsenic isotopes) in biological samples. Typically, hyphenated techniques that couple chromatography separation with inductively coupled plasma/mass spectrometry (ICP/MS) in combination with molecular mass spectrometry (ESI/MS, ESI/MS/MS, MALDI/TOF) and isotopic dilution allow structural characterization of selenium species.[225] High-pressure liquid chromatography/inductively coupled plasma/mass spectrometry separates and detects various selenium species including selenium isotopes. The latter distinguishes between different sources of organoselenium.[319] For the presence of organoselenium compounds in water, selective sequential hydride generation with atomic absorption spectroscopy is a common method of analysis based on selenite forming volatile hydrogen selenide after reacting with borohydride under acidic conditions.[284] Speciation of selenium in soils and sediments typically involves direct spectroscopic analysis (e.g., x-ray absorption spectroscopy) and sequential extraction procedures.

Gas chromatography is a valid separation technique for volatile selenium species (e.g., methaneselenol, dimethylselenide, dimethyldimethyldiselenide). The use of capillary electrophoresis/inductively coupled plasma/mass spectrometry allows the chiral separation of L- and D-selenomethionine previously derivatized with 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide in digested yeast samples pretreated with enzymatic hydrolysis.[225]

HEALTH SURVEILLANCE

Plasma selenium consists of selenocysteine in two selenoproteins and selenomethionine at methionine positions in all proteins along with small molecular forms (<3% of the total selenium).[320] Both animals and humans retain more selenium as selenomethionine compared with selenium as selenite or selenate, probably as a result of the uptake of selenomethionine by nonspecific cellular proteins.[321] Supplementation with selenomethionine produces higher blood Se concentrations than the same amount of inorganic Se species (selenite, selenate). During a 32-week study of 33 women receiving 200 μg Se as selenomethionine or as selenate, the whole blood Se concentration reached a plateau of ~100 μg/L following selenate supplementation.[249] The mean whole blood level of Se following selenomethionine supplementation was about 280 μg/L.

TREATMENT

The toxicity of organic selenium compounds is relatively low; treatment is supportive.

Chapter 28

SILVER

HISTORY

Silver is a nonessential trace element that demonstrates relatively low toxicity in mammals. Humans probably separated silver from lead several millennia BC with silver used for currency mentioned in the first book of the Old Testament. Lunar caustic (silver nitrate) was administered to patients with nervous disorders in the Middle Ages.[1] Silver has a long history of use as an antimicrobial agent. Crede introduced the use of silver nitrate drops into medical practice in 1884 by recommending the application of these drops to the eyes of newborns in order to prevent the development of gonococcal ophthalmia.[2] Camillo Golgi developed a histological silver stain for the study of the nervous system in 1873; later, he received the Nobel Prize in medicine for his work.[3] Several colloidal silver formulations were developed for the treatment of infectious diseases in the late 19th century including Collargol (Crede's colloidal silver antimicrobial for wounds) and Protargol (silver colloidal compound for gonorrhea).[4] By the early 1900s, a mild silver protein-stabilized solution (Argyrol) was used as an anti-infective cleansing agent for mucous membranes of the eyes and upper respiratory tract. This latter substance remains available online today (http://www.argyrol.com/agprotein.phtml).

In 1907, Dr. Paul Ehrlich recommended the parenteral administration of silver arsphenamine for the treatment of syphilis and yaws (i.e., chronic dermal, bone, and cartilage disease caused by *Treponema pallidum* subspecies *pertenue*).

Following the prolonged use of silver compounds (silver nitrate, colloidal silver preparations), a permanent bluish-gray discoloration of skin, eyes, and nails occurred during the 20th century.[5] In the late 1920s, an autopsy of the famous "blue man" of the Barnum and Bailey's Circus demonstrated large deposits of silver in his body estimated at 90–100 g.[6] This condition was called argyria; fortunately, these patients remained relatively asymptomatic. The use of silver as an antimicrobial agent declined in the 1940s with the widespread introduction of antibiotics. Medical interest in silver resurged in the 1990s with the use of silver nanoparticles in a variety of medical products. Other uses include silver nitrate for burns, prevention of gonococcal ophthalmia neonatorum, and the use of silver alloy (dental amalgam) in dentistry.

PHYSIOCHEMICAL PROPERTIES

Silver is a hard, lustrous, and malleable transitional metal that possesses the highest thermal and electrical conductivity of all metals. Copper and other metals form important alloys with silver. There are four oxidation states (0, 1+, 2+, 3+) with the metallic and monovalent forms being the most common Metallic silver, silver halides, and silver oxide are relatively insoluble in water, whereas silver nitrate and colloidal silver are water-soluble. The latter contains substantially less silver (~6%) than silver nitrate (50%).

TABLE 28.1. Identifying information and physical properties of silver and silver compounds.

Physical Characteristic	Silver	Silver Chloride	Silver Oxide	Silver Suboxide	Silver Nitrate	Silver Sulfide
CAS RN	7440-22-4	7783-90-6	20667-12-3	1301-96-8	7761-88-8	21548-73-2
Form	Lustrous white solid	White, solid	Dark brown-black	Gray-black crystals	Colorless-white crystals	Gray-black
Molecular formula	Ag	AgCl	Ag_2O	AgO	$AgNO_3$	Ag_2S
Molecular weight (g/mol)	107.87	143.32	231.8	123.87	169.87	248.81
Melting point (°C)	961.93	455			212	
Boiling point (°C)	2,212	1,550	200–300[a]	100[a]	440[a]	810[a]
Density (g/mL, 20°C)	10.5	5.56	7.14	7.48	4.35 (19)	7.36
Water solubility (mg/L, 25°C)	Insoluble	1.93	0.022	Decomposes	≥100 (16)	0.00014
Vapor pressure	100 mmHg (1,865°C)	NA	NA	NA	NA	NA
Odor threshold	Odorless	NA	Odorless	NA	Odorless	NA

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number; NA = not available.
[a] Decomposes.

Silver has two stable isotopes (^{107}Ag, ^{109}Ag); the radioisotopes of silver do not occur naturally in the environment. Table 28.1 lists the identifying information and physical properties of silver and silver compounds. Silver oxide (Ag_2O) is a strong oxidizing agent. Light is a catalyst that reduces silver compounds in the skin to metallic silver similar to the photoreduction of a photographic plate.

Historically the term colloidal refers to silver-impregnated macromolecules, often prepared from casein (milk) or serum proteins. The final product contained silver complexed to polypeptides, very small silver particles in polypeptide coating, or a mixture of the 2 Ag forms. Silver nanoparticles (<100 nm) are substantially more reactive than elemental silver with their properties dependent on size, shape, charge, stability, and impurities.

EXPOSURE

Production Processes

The production of silver primarily involves the recovery of silver during the retrieval of copper, gold, lead, and zinc ores. The main silver-containing ores are argentite (Ag_2S) and cerargyrite (Horn Silver, AgCl) with the recovery of silver by cyanide extraction, electrolytic processes, or zinc reduction. At the present time, the acquisition of silver by recycling exceeds silver production from ores. Workers in silver refineries have mixed exposures to other metallic substances including antimony, arsenic, cadmium, selenium, and tellurium.

Uses

Photographic materials and batteries (silver–lead) account for the majority of silver consumption, particularly radiographic material, along with brazing alloys and solder (silver–copper–zinc). Photographic emulsions use silver halides to produce light sensitivity. The use of silver for esthetic purposes (jewelry, sterling ware, electroplated ware) accounts for a much smaller portion of the silver produced for commercial uses. Less common uses include dental amalgam, burn treatment, cloud seeding (silver iodide), catalyst in the production of ethylene oxide and formaldehyde, and purification of water.[7] Silver nanoparticles have antimicrobial properties against bacteria and fungi; the small size and large surface area increase antibacterial potencies while reducing particle concentrations and avoiding adverse mechanical properties.[8] Medical applications include enhanced antimicrobial activity by incorporation of nanosilver in endotracheal tubes, surgical instruments, wound sutures, bone prostheses, dental/bone prostheses, and implants.[9] Other potential uses of nanosilver include site-specific delivery of cancer therapy (radiotherapy, phototherapy),[10] a biomarker, an imaging agent for signal enhancement, optical sensing, and various consumer products (toothpaste, mouthwash, pet products, pillowcases, shower filters, food containers, vacuum cleaners, washing machines, clothes, laundry detergent, shampoos, carpets).[11,12] The use of nebulized colloidal silver for the treatment of upper respiratory tract infections is a homeopathic method that may cause pulmonary infiltrates. Silver nitrate is a caustic and astringent used to cauterize bleeding surfaces.

Sources

The major source of silver in the general population is drinking water and food. Silver is a normal trace element in many organisms. In the environment, silver occurs primarily as silver sulfide (Ag_2S) or as silver sulfide associated with other metallic sulfides (e.g., copper, iron, gold, lead). Only a small portion of the total silver present in environmental samples is available as a biologically important metallic species.[13] Consequently, potential silver toxicity correlates to the concentrations of free silver ions rather than the concentration of total silver (i.e., ionic silver and silver compounds).

Air

The major forms of silver in the air are metallic silver and silver salts (carbonate, halides, sulfide, sulfate). The release of silver from natural sources includes the erosion of soil and the weathering of rocks. Important industrial sources for the release of silver into the atmosphere include cement manufacturing, cloud seeding, fossil fuel combustion, municipal waste incineration, processing of ores, and steel refining.[7] Background Ag concentrations in ambient air are typically <1 ng/m^3 with anthropogenic sources raising the ambient concentrations to 1–5 ng/m^3 based on measurements recorded with older techniques that lack the ultra-clean sampling methods currently available.[14,15] These methods also indicate that cloud seeding with silver iodide increases the silver concentration in precipitation from 0–20 ng/L to 10–4,500 ng/L;[16] associated Ag concentrations in nearby air may increase to ~0.1 ng/m^3.

Soil

Silver is the 67th most abundant element in the earth's crust with an average concentration of ~0.07 mg/kg, predominately in basalt and igneous rocks.[13] In the soil, silver exists primarily as sulfides associated with gold, iron (pyrite), lead (galena), and tellurides. The major source of elevated silver concentrations in cultivated soil is the application of silver-containing sludge as soil amendment. Biotransformation of silver in the soil probably does not occur because microorganisms are susceptible to silver toxicity. Coal-fly ash may contain Ag concentrations of 1–15 ppm (mg/kg); therefore, soil near coal-fired power plants may contain higher Ag concentrations than surrounding areas.[17,18] The US EPA Contract Laboratory Program analyzed soil samples from 2,783 Superfund hazardous sites; the 1,807 positive samples contained a geometric mean silver concentration of 4.5 ppm.[7]

Water

The major anthropogenic source of silver is effluent from photographic processes.[7] The major forms of silver in the water are monovalent ions of sulfate, bicarbonate, and sulfate salts. Complexation with chloride and sulfate ions along with adsorption of silver to particulate matter accounts for smaller amounts of silver.[19] Reducing conditions favor the formation of silver sulfide, whereas oxidizing conditions favor the formation of silver halides. Background ambient Ag concentrations in freshwater and seawater average ~0.2 μg/L and 0.25 μg/L, respectively. Surface waters leaching silver from mining operations may contain up to 100 times greater Ag concentrations than background concentrations, particularly in waters with low pH.[20] US drinking water usually contains low Ag concentrations except for waters with Ag-containing disinfecting agents. Most drinking water supplies demonstrate silver concentrations of 0.1–10 μg/L with few supplies containing Ag concentrations exceeding the current US EPA standard.[21] Typical background Ag concentrations in rivers are 0.001–0.002 μg/L.[22] Although bioconcentration of silver in fish and invertebrates occurs to a moderate degree, biomagnification in the food chain is unlikely.[7]

Lifestyle

The major sources of silver in the diet are crops grown in areas with high silver content in the soil and seafood from areas near industrial Ag sources.[7] Estimates of daily Ag intake in the diet range from ~4 μg (US men 25–30 years old)[23] to 88 ± 10 μg (single subject analyzed by older spectrometry method)[24] and 27 ± 17 μg (UK diet estimated by mass spectrometry).[25] The highest Ag concentrations in foods from the latter study occurred in milk (25–50 μg/L) and mushrooms (~100–200 μg/L). The silver concentrations in tobacco are relatively low with the high melting point limiting inhalation of silver during smoking. The release of silver from dental amalgams is extremely low; fecal excretion resulting from dental amalgams is lower for silver than mercury.[26] Food and drink are not sources of silver exposure associated with argyria or argyrosis.

ENVIRONMENTAL FATE

Coarse particles (>20 μm) of silver released from mining operations settle near the point source, whereas fine particles (<20 μm) may be transported >100 km until deposited by precipitation.[27] Factors reducing Ag mobility in soil include: 1) well-drained soil; 2)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

oxidation–reduction and pH conditions favoring the formation of iron and manganese complexes with silver; and 3) the silver adsorption to organic matter. Soil is the main deposition site for silver nanoparticles; effluent from waste treatment plants may carry nanosilver into the aquatic environment, primarily to sediment.[28] Although sediment-dwelling animals (clams, oysters, scallops) do concentrate silver, there are few data to support biomagnification of silver (i.e., the systematic increase of silver concentrations moving up the food chain).[7] Most silver entering the ecosystem is immobilized in the form of alloys, metals, or minerals.[13] Divalent (Ag^{2+}) and trivalent (Ag^{3+}) species are more effective oxidizing agents than metallic silver (Ag^0), but Ag^{2+} and Ag^{3+} are unstable in aqueous environments. In freshwater and soils under oxidizing conditions, the common silver compounds are bromides, chlorides, and iodides, whereas metallic silver and silver sulfide dominate under reducing conditions.[7] The availability of free silver in marine environments strongly depends on salinity with adsorption decreasing with increasing salt concentrations.[29]

DOSE EFFECT

The toxicity of metallic silver and silver salts is relatively low. The older medical literature indicates that the administration of ~2.3 g Ag intravenously produces argyria[30] with a range of ~1–8 g Ag. The metallic form of silver is poorly absorbed from the gastrointestinal tract; therefore, cases of argyria are unlikely except for the use of the colloidal silver preparation (Argyrol). Relatively higher doses of soluble silver salts (1–30 g) are necessary to produce argyria following ingestion compared with the intravenous route.[17] The ingestion of 60 mL 24% silver nitrate (i.e., ~62 g) by a 15-year-old boy produced spontaneous vomiting but no complaints of sore throat or dysphagia.[31] An esophagram 4 weeks later was normal. A second child developed a painless, desquamating rash where the vomitus stained the skin, but the lesion healed without sequelae.

TOXICOKINETICS

Absorption

Although studies of workers suggest the lungs absorb silver compounds,[32,33] data are inadequate to determine the extent/rate of Ag absorption. A study in dogs demonstrated absorption of ~3% of metallic silver *deposited* in the lungs.[34] Data are also limited on gastrointestinal and dermal Ag absorption. Clinical experience with a patient ingesting silver-containing anti-smoking lozenges suggests that the body absorbs ~20% of a silver acetate dose within 1 week after ingestion.[35] Absorption of silver nitrate across the oral mucosa is sufficient to produce systemic argyria following the repeat application of silver nitrate to the gums.[36] The absorption of silver compounds across the skin appears minimal, even following the application of silver nitrate on burned skin.[37] Some precipitation of silver sulfide in the stratum corneum may occur following the application of silver ions to intact skin in the presence of moisture.[38] The transdermal absorption of silver is relatively slow. The dermal flux in healthy subjects ($n = 15$) and patients with atopic dermatitis ($n = 15$) wearing a sleeve containing 3.6% (w/w) silver on their lower arms for 8 hours/day for 5 consecutive days was ~20 ng/cm^2/hour.[39] Urine Ag concentrations remained similar in the two groups during the study. Animal studies indicate that following a 5-hour application of silver compounds to the skin, <1% of the dose crosses the skin;[40] however, case reports associate prolonged, excessive application of silver sulfadiazine with elevated blood silver concentrations and Ag deposition in the tissues.[41] Experimental data suggest that the dermal absorption of Ag nanoparticles through intact and damaged skin is detectable, but very low.[42] In a study of consumer products with Ag nanoparticles, leaching of silver occurred primarily via dissolution of ions rather than particulates, particularly in liquids with high salt concentrations. The resulting silver concentrations were well below current regulatory standards.[43] Wiping these products produced silver concentrations in the wipes ranging from 0.3–23 μg/m^2.

Distribution

The liver is the primary site of deposition of silver absorbed into the body, particularly the area of the portal vein.[34] Following silver exposure, animal studies indicate Ag distributes to many tissue sites, particularly the glomerular basement membrane, the walls of the blood vessels near renal tubules, the choroid plexus in the brain, the thyroid, and the choroid layer of the eye.[44,45] Most of the silver appears in the cytosol fraction bound to high-molecular-weight proteins and the metallothionein fractions.[46] Diffusion of silver across the blood–brain barrier appears minimal.

Elimination

Following the oral administration of silver acetate, biliary excretion accounts for the vast majority of silver

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

elimination with only minor amounts excreted in the urine.[35] Rapid silver excretion occurs in the first week. The estimated Ag biological half-life in the lungs was 1 day compared with 52 days in the liver.[32] In studies on dogs, the biological half-life of silver followed a tri-exponential pattern (0.1 day, 7.6 days, 33.8 days) with an average amount of silver excreted during each period of 90%, 7%, and 3%, respectively.[47] The terminal elimination half-life of silver in a 78-year-old patient undergoing an operation using silver-containing prosthetic cement was ~6 months.

Interactions

High selenium concentrations in the diet increase deposition of insoluble silver salts in the body tissues of animals by increasing the formation of silver selenide.[48] Although there are few data available, these higher deposition rates of insoluble silver salts potentially may increase the risk of developing argyria.

Maternal–Fetal Kinetics

Silver was present in 16% of the samples of amniotic fluid with mean Ag concentrations of 25 μg/L and a maximum value of 540 μg/L.[49]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Silver has no known physiological or biochemical functions in the human body.[50] The production of silver toxicity depends on the degree of water solubility/absorption, binding to biological sites, sequestration of silver complexes, and ease of excretion. The formation of insoluble silver salts (silver chloride, silver phosphate) deposits silver in the tissue. The fate of these insoluble salts includes complexation with amino or carboxyl groups in nuclear material, reduction to metallic silver by ascorbic acid or catecholamine, or transformation of soluble silver sulfide albuminates.[51] Exposure of the skin to ultraviolet light reduces the silver chloride in the skin to metallic silver. The oxidation of metallic silver to black silver sulfide produces the characteristic blue-gray color of the skin associated with argyria.[52] There is no direct evidence to link the deposition of these silver compounds with toxic effects.[7] Silver binds to phosphate, amino, carboxyl, and imidazole groups as well as apoceruloplasmin forming silver-bound ceruloplasmin that limits copper absorption and may produce hypocupremia. Silver compounds can inactivate enzymes by forming silver sulfides that bind to sulfhydryl groups as well as reducing the activity of glutathione peroxidase and lactate dehydrogenase.[53] There is no conclusive evidence that silver crosses the blood–brain barrier or causes neurotoxicity.[54] Silver nanoparticles bind avidly to proteins and thiol groups, potentially disrupting cellular functions depending on several factors including dose, duration of exposure, temperature, and physical property (shape, size, surface coating, surface charge). Coating the surface of these particles with hydrocarbons or polysaccharides reduces cytotoxicity; however, the effectiveness of these barriers may decrease over time in physiological systems.[55] Animal models suggest silver nanoparticles have the potential to produce reactive oxygen species and oxidative stress, resulting in an inflammatory reaction as demonstrated by increased proinflammatory cytokines (e.g., IL-4, IL-6, TNF-α) and stimulation of amyloidosis.[11,56]

Pathological Changes

Typically, skin biopsies of patients with argyria demonstrate inert black-silver granules surrounding elastic fibers, eccrine glands, and walls of blood vessels primarily composed of silver sulfide and lesser amounts of silver selenide; melanocytes typically remain normal.[57,58] Histological changes in bluish macules that resulted from prolonged exposure to silver needles included the deposition of brown granules in the basement membrane of adjacent eccrine sweat glands, walls of local blood vessels, and elastic fibers.[59] Postmortem examination of a 68-year-old man with severe generalized argyria (i.e., "blue man" from the Barnum and Bailey Circus) demonstrated silver deposits primarily in connective tissues and phagocytic cells (e.g., spleen, lymph nodes, bone).[6] Compared with other organs, the silver concentrations in the brain and spinal cord were very low. X-ray microanalysis, dark-field microscopy, and electron microscopy help to confirm the diagnostic changes of argyria. Examination of biopsies from the kidney of a patient with argyria revealed electron-dense particles (30–100 nm) located in the basement membranes of the kidney.[60] The predominant component of these deposits was silver selenide.

Argyrosis produces blue-gray discoloration of the cornea, tarsal conjunctiva, and bulbar conjunctiva. Deposition of silver typically occurs in Descemet's membrane rather than the Bowman membrane.[61] Slit-lamp examination of silver workers with corneal argyrosis demonstrates diffuse, gray opacities in the deep

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

layers of the corneal stroma.[62] These highly reflective deposits are anterior to the corneal endothelium; however, these opacities do not frequently contain silver.

CLINICAL RESPONSE

Adverse Medicinal Effects

Argyria is an irreversible clinical condition characterized by blue-gray discoloration of the skin following prolonged exposure to Ag or silver compounds, particularly in sun-exposed areas (e.g., face, hands).[63] Hyperpigmentation develops when light reduces silver-containing compounds complexed with proteins in the skin to elemental silver. Silver also stimulates melanocyte tyrosinase activity and melanin production, resulting in hyperpigmentation of the nail bed, sclerae, and mucous membranes. Localized cutaneous argyria (blue-gray macules) develops from the leaching of silver from prolonged exposure to needles and jewelry that contain silver.[64] Skin abnormalities do not typically progress following cessation of Ag exposure. Little change occurred in the skin of a 72-year-old man despite the development of argyria during his early 20s when he was treated with silver nitrate for abdominal pain.[65] The differential diagnosis of blue-gray pigmentation of the skin includes drugs (chlorpromazine, antimalarials), hemochromatosis, methemoglobinemia, cyanosis, and disseminated melanoma.[66] The discoloration of the skin is permanent. Discoloration of open wounds/burns treated with silver nitrate or silver sulfadiazine may occur as a result of Ag-induced protein precipitation; however, the discoloration of the superficial layers of the epidermis sloughs as the wound heals.[67] Most cases of argyria and argyrosis result from exposure to water-soluble Ag compounds.[68] A case report associated the use of silver-containing prosthetic cement in a failed hip prosthesis with elevated serum Ag concentration of 6.3 μg/L and focal ipsilateral quadriceps femoris weakness; the latter resolved slowly.[69]

Argyrosis involves Ag deposition in the eye including pigmentation of the conjunctiva with localization to the inner canthus as an early sign; argyrosis may spread to the tarsal conjunctiva, bulbar conjunctiva, and cornea.[70] Corneal and conjunctival argyrosis can occur following chronic application of silver-containing professional eyelash tint.[71] Widespread deposition of silver in tissues may occur with continued exposure including other tissues in the body. Although several case reports associate neurological effects (seizures, myoclonus, corticobasal degeneration, coma) with the chronic ingestion of large doses of colloidal silver and elevated serum silver concentrations,[72,73] the presence of serious underlying medical diseases (diabetes, ischemic heart disease) in these cases limits conclusions regarding the causal role of silver. Argyria is not typically associated with neurological symptoms.

Occupational Exposure

Case reports associate localized and generalized silver deposition in the eye (argyrosis) with silver nitrate/oxide manufacturing,[74] silver refining,[75] and silver soldering.[62] In a study of workers exposed to silver compounds, silver deposits in the Descemet membrane of the cornea and the skin correlated with complaints of decreased night vision.[33] Electrophysiological examination of seven of the silver nitrate and oxide manufacturing workers with argyrosis and complaints of decreased night vision did not detect any visual deficits.[74] A case report associated development of argyrosis with work in a silver refinery over 7 years. After reduction of airborne silver concentrations, he remained asymptomatic and his argyrosis did not progress over 18 months of medical surveillance.[75] Although the total body burden of silver may be increased in workers exposed to insoluble silver salts as reflected in the ocular deposition of silver, toxic effects are uncommon.[76] Occupational exposure to silver dust (silver oxide, silver nitrate) may produce upper respiratory tract irritation (rhinitis, sore throat, watery eyes) as well as cough and chest tightness;[33] the corrosive effects of nitrate probably contribute substantially to the irritant effects of silver nitrate. Exposure to silver dust is not associated with the development of occupational asthma. A study of workers' exposure to silver nitrate, silver oxide, silver chloride, and silver cadmium oxide detected some marginal changes in the presence of the urinary enzyme *N*-acetyl-β-D-glucosaminidase (NAG), but co-exposure to cadmium limits the conclusions regarding the renal effects of silver dust.[77] Percutaneous exposure to powdered silver, dental amalgams, and silver compounds occasionally causes allergic contact dermatitis.[78,79]

Reproductive Abnormalities

There are few data on the reproductive effects of silver. Although data are insufficient to provide a definite conclusion regarding the reproductive effects of silver, current evidence does not suggest silver is a reproductive toxin.[7]

Carcinogenesis

Neither the IARC nor the US National Toxicology Program lists silver or silver compounds as suspected carcinogens. The weight of the evidence suggests that silver is not mutagenic, but silver may be genotoxic; however, existing animal and epidemiological studies have not provided evidence to suggest that silver or silver compounds are carcinogens.[7]

DIAGNOSTIC TESTING

SI Conversion Units

Troy ounce = 31.10 g
1 μg/L = 9.271 nmol/L
1 nmol/L = 0.1079 μg/L

Analytical Methods

Most analytical techniques measure total silver concentrations rather than silver species. Silver concentration in the range of 10^{-6}–10^{-9} g/g sample is detectable by several analytical methods including neutron activation analysis (NAA), graphite furnace (flameless) atomic absorption spectrometry (GFAAS; LOD, 0.4 μg/L),[80,81] flame atomic absorption spectroscopy (FAAS), voltammetric techniques with anodic stripping (LOD, 0.1 μg/L), high-frequency plasma torch-atomic emission spectroscopy (HFP-AES), and micro-cup atomic absorption spectroscopy (MCAAS).[7] The detection limit of atomic absorption spectroscopy is ~2 μg/L, whereas the more expensive NAA allows the detection of 2 ng Ag. Electrothermal atomic absorption spectroscopy has a detection limit of 0.1 μg/L (CV = 4.6% at 10 μg/L).[82] Accurate analysis of low silver concentrations in environmental and biological samples requires the use of ultra-clean sampling techniques with NAA, inductively coupled plasma/atomic emission spectrometry, or inductively coupled plasma/mass spectrometry that were uncommon before the late 1980s.[13]

Biomarkers

Blood

General Population

In a study of 394 healthy Italians, the mean serum Ag concentration was 0.18 μg/L (range, 0.06–0.3 μg/L), whereas the whole blood Ag concentration in 437 Italian subjects was 0.37 μg/L (range, 0.13–0.61 μg/L).[83] In a study of 15 agricultural workers without occupational Ag exposure, the mean whole blood Ag concentration was below the detection limit (0.1 μg/L) with only four samples containing detectable Ag concentrations (0.2 μg/L).[82] The plasma silver concentrations in a convenience sample of 26 Melbourne residents without known silver exposure were <2.3 μg/L, as measured by flameless atomic absorption spectrometry.[80]

Medical Therapy

After 12 weeks of using silver acetate-containing chewing gum as an antismoking aid, the mean serum silver concentration in 21 individuals was 41.7 μg/L with a maximum concentration of 117 μg/L as measured by atomic absorption spectrometry.[84] The higher silver concentrations reflect the relatively high water solubility of this Ag salt compared with water-insoluble Ag salts. No individual developed argyria; serum silver concentrations declined to a mean value of 3.2 μg/L within 14 weeks. The use of silver nitrate for cauterization of anterior epistaxis transiently may increase blood silver concentrations. In a study of nine healthy volunteers, the cauterization of the nasal mucosa with one silver nitrate applicator produced peak whole blood silver concentrations of 2.89 ± 3.12 μg/L with the peak ranging from 3 hours to 14 days.[85]

Argyrosis/Argyria

The serum silver concentration may be within the normal range in patients with localized argyria. In an asymptomatic 58-year-old man with facial changes and black-silver granules on dermal biopsy characteristic of argyria on his face, the serum Ag concentration was 11 μg/L (reference range, 0–14 μg/L).[86] A 60-year-old man with schizoaffective disorder and long history of ingesting colloidal silver presented with a generalized silvery sheen on his face and neck along with blue-gray sclera. His serum silver concentration was 11 μg/L (reference range, <5 μg/L).[63] A 27-year-old worker exposed to aerosolized silver presented with 4 months of progressive blue-gray discoloration of his facial skin; he was asymptomatic with a serum silver concentration of 154.4 μg/L (upper reference limit, 25 μg/L).[87] In an asymptomatic 51-year-old silver refiner with argyrosis and a 7-year history of Ag exposure during the electrolytic purification of silver ingots, the initial Ag concentration was 740 μg/L.[75] He remained asymptomatic during an 18-month follow-up without evidence of argyria or progression of his argyrosis. His Ag concentration at the end of this medical surveillance was 60 μg/L as measured by atomic absorption spectrometry.

URINE

The kidneys excrete small amounts of the absorbed Ag dose. In a convenience sample of 26 Melbourne residents without known silver exposure, the spot urine silver concentrations were <2 μg/L as measured by flameless atomic absorption spectrometry.[80] The mean urine Ag concentration in 472 healthy Italian volunteers was 0.46 μg/L (range, 0.04–0.88 μg/L).[83]

HEALTH SURVEILLANCE

Risk Assessment

For the general population, the US EPA reference dose (Rfd) for silver exposure is 5 μg/kg/day with an estimated critical dose of 14 μg/kg/day. The proposed Maximum Contaminant Level Goal for silver in drinking water is <0.1 mg/L.

Environmental Monitoring

Table 28.2 lists the current regulations and guidelines regarding exposure to silver and silver compounds. The ACGIH TLV–TWA for soluble silver compounds is lower than the regulations for insoluble metallic silver and insoluble silver compounds because of the greater toxicity and absorption of soluble silver compounds; however, OSHA and NIOSH do not separate the toxicity of soluble and insoluble Ag compounds. The regulations and recommendations for silver exposure are designed to minimize the risk of argyria. The risk of argyria following exposure to insoluble Ag compounds (e.g., AgCl, Ag_2S) is substantially less than that of soluble Ag compounds (e.g., silver nitrate, silver sulfadiazine, colloidal silver).

TABLE 28.2. Identifying information and physical properties of silver and silver compounds.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	0.01 mg/m^3 (as Ag)
NIOSH	
REL–TWA (10-hour)	0.01 mg/m^3 (as Ag)
IDLH	10 mg/m^3 (as Ag)
ACGIH	
TLV–TWA (8-hour)	
Metal dust and fume	0.1 mg/m^3
Soluble Ag compounds	0.01 mg/m^3 (as Ag)
US EPA	
RfD (chronic oral exposure)	0.005 mg/kg/day
US federal drinking water guidelines	0.1 mg/L

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; BEI = biological exposure indices; IDLH = immediately dangerous to life and health; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfC = reference concentration; RfD = reference dose; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency.

Biological Monitoring

BLOOD

Silver is rapidly eliminated from the body, primarily in the feces; current data are inadequate to recommend blood as a reliable biomarker of Ag exposure.[88] Analysis of whole blood from 70 silver refinery workers demonstrated a mean Ag concentration of 2.5 μg/L with a range of <0.1–16 μg/L.[82] The highest whole blood Ag concentrations in this study occurred in 19 silver reclamation workers (mean = 6.8 μg/L; range, 1.3–20 μg/L). In a study of 27 silver reclamation workers and 27 employees without occupational Ag exposure, the mean Ag concentration in whole blood from 21 workers with detectable Ag concentrations (>5 μg/L) was 10 μg/L.[76] Although 29% of the reclamation workers had ocular Ag deposits, no pulmonary, visual, or dermal dysfunctions were detected. In a workplace with exposure primarily to insoluble metallic silver dust (TWA = 0.001–0.1 mg Ag/m^3 for 80% of workers), the mean Ag whole blood concentration in 37 workers engaged in the smelting and refining of silver was 11 μg/L.[88] Two silver reclamation workers had blood Ag concentrations of 49 and 74 μg/L (sample type not reported).[89] Both workers were asymptomatic with the only physical signs being silver deposits in the skin and eyes of the latter worker. The former worker was exposed to insoluble silver compounds (halides, oxide) for 2 years, whereas the latter worker was exposed to soluble silver nitrate for 7 years.

URINE

Urine has limited utility for biological monitoring of silver because of inadequate data and minimal Ag excretion (i.e., <10%) by the kidneys. Following occupational exposure primarily to insoluble metallic silver dust (TWA = 0.001–0.1 mg Ag/m^3 for 80% of workers), the mean urine Ag concentration in spot samples from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

37 workers engaged in silver smelting and refining was below the limit of detection (0.005 μg/L) as measured by atomic absorption spectroscopy.[88]

Medical Surveillance

Medical monitoring for silver compounds should focus on the detection of argyria as well as kidney and liver dysfunction.

TREATMENT

Soluble Silver Compounds

Clinical experience with soluble silver compounds is limited. Silver oxide and silver nitrate are potential mucosal irritants. Dilution is probably an appropriate first aid measure. Symptomatic patients may require endoscopy to determine the extent of mucosal damage.

Argyria

The primary treatment for argyria is the discontinuation of Ag exposure and supportive care.[1] The dermatological changes are permanent; no specific treatment (e.g., potassium ferrocyanate, thiosulfate sodium, hydroquinone, dermabrasion, depigmenting creams) reverses the abnormal skin coloration.[65] Experimental treatment of the hyperpigmentation of argyria includes the use of the Q-switched double-frequency Nd:YAG laser.[90] Chelation with 2,3-dimercaptopropanol (BAL), D-penicillamine, or 2,3-dimercaptopropane-1-sulphonate (DMPS) removes only a small fraction of the total body burden of silver. Two 5-day courses of DMPS (0.5–2.5 g/day) removed <1% of the total amount of silver in the body of a patient with argyria.[91] Sunscreens and opaque cosmetics may conceal the skin's discoloration and prevent further darkening of the skin.

Chapter 29

TELLURIUM

PHYSIOCHEMICAL PROPERTIES

Tellurium (CAS RN: 13494-80-9; atomic mass: 127.6 g/mol) is a chalcogen metalloid that exists as a lustrous, silvery-white, crystalline solid (specific gravity, 6.25 at 20 °C) or dark gray-brown amorphous powder. As a metalloid, tellurium is an effective, one-way semiconductor that displays improved conductive properties following exposure to light. Both tellurium hexafluoride and hydrogen telluride (H_2Te) are colorless gases with offensive, garlic-like odors. Dimethyltellurium is the most common, volatile product of Te biomethylation in the environment.[1] Of the 21 known isotopes of tellurium ranging in mass numbers from 115–135, 8 occur naturally with the only unstable natural isotope being ^{127}Te.[2] Elemental tellurium is insoluble in water, whereas tellurium dioxide is sparingly soluble. Combustion of elemental tellurium (melting point 450 °C) produces a blue flame; elemental tellurium does not easily form oxides, even in the presence of heat. Most tellurite and tellurate compounds are water-soluble. Tellurium belongs to Group 16 (Group VIa, oxygen, polonium, selenium, sulfur) of the periodic table, sharing similar chemical properties with selenium and sulfur.

Tellurium exists in multiple redox states. Of the members of Group 16, tellurium is the most electropositive with valence states including −2, 0, +2, +4, and +6.[3] The tetravalent (Te^{4+}) and tellurite compounds (TeO_3^{2-}) are the most chemically stable Te compounds. The oxidation state of organotellurium compounds is usually 2+; however, the presence of a Te–Te bond results in a monovalent state. Divalent organotellurium compounds readily oxidize to the tetravalent state.[4] Dimethyltelluride is associated with the characteristic garlic-like odor following ingestion or inhalation of tellurium compounds.[5]

EXPOSURE

Production Processes

Tellurium occurs in its elemental state in nature, usually combined with other metals in the form of tellurides. Occupational exposure to Te occurs most commonly as a by-product of copper refining and, less commonly, as a by-product of silver, gold, and lead refining. Electrolytic copper refining is the major commercial source of elemental tellurium. The most common tellurium-containing ore is sylvanite [$(AgAu)Te_2$]. The anodic slime contains ~4% tellurium; recovery of Te results from the dissolution of the mud in caustic soda and the electrolysis of the solution with stainless-steel electrodes.[2] Tellurium hexafluoride is a by-product of refining the ore.

Uses

Metallurgy accounts for a majority of the production of tellurium; tellurium improves the characteristics of

a variety of alloys (bronze, copper, iron, lead, steel). During electrolytic lead refining, tellurium is emitted as an impurity, primarily as tellurium oxide.[6] Currently, the most rapidly expanding application of tellurium compounds involves the semiconductor industry; nanomaterials (e.g., quantum dots) contain Te alloys of cadmium, zinc, and other metals.[7] The latter includes experimental probes for biomedical applications (cell tracking, drug delivery, gene delivery, cancer detection, tumor therapy, *in vivo* tissue imaging).[8] Additional commercial applications that may contain Te include dopants, catalysts, rubber vulcanizers, antioxidants, explosives (blasting caps), and glazes.

Sources

Food is the main source of tellurium in the general population, particularly meats and dairy products that typically average ~4 mg Te/kg. The estimated daily Te intake from the diet is ~100–150 μg.[9,10] Ambient Te concentrations in air are low; anthropogenic sources include coal combustion and industrial plants (e.g., electrolytic copper-refining). Tellurium concentrations in surface water and drinking water are usually low (<1 ng/L),[11] whereas soil Te concentrations typically average ~10 ppb. Tellurium concentrations in ambient water are an order of magnitude lower than selenium as a result of usually low Te concentrations and a relatively higher affinity for sediment; dimethyltelluride occurs in water samples in the range of 0.01–0.1 μg/L as measured by purge-and-trap GC/ICP/MS.[12] Anthropogenic sources of organic tellurium compounds in the environment are not well documented, whereas the semiconductor industry, PVC/rubber production, municipal waste, and the use of inorganic Te during chemical synthesis are potential anthropogenic sources of inorganic Te.

ENVIRONMENTAL FATE

Organic tellurium compounds exist in the environment primarily as simple methylated tellurides (e.g., dimethyltelluride, dimethylditelluride, dimethyltellurenyl sulfide, diethyltelluride, trimethyltelluronium). Several bacteria and fungi species (*Pseudomonas* spp., *Rhodospirillum* spp., *Penicillium* spp., *Scopulariopsis* spp.) can produce organotellurium compounds (e.g., dimethyltelluride, dimethylditelluride).[12] The conversion of Te compounds to dimethyltelluride (DMTe) by mammals and the excretion of this compound in exhaled air, sweat, and urine result in detectable pungent odors.

DOSE EFFECT

The accidental instillation of 2 g sodium tellurite into the bladder of two patients with renal colic produced emesis, cyanosis (possible methemoglobinemia), hemolysis, dyspnea, coma, and death;[13] determination of the cause of death is unclear because of the lack of laboratory, clinical, and monitoring data in the 1946 case report. There are no reports of serious illness following inhalation of tellurium or tellurium compounds in industry.[14] In animal studies, inorganic and organic tellurium compounds demonstrate greater toxicity than elemental tellurium. During chronic rodent studies published in the 1930s and 1940s, administration of diets containing 25–50 ppm inorganic Te as Na_2TeO_4 for 100 days was associated with some growth retardation and hair loss;[15] slight growth retardation occurred following administration of diets containing up to 1,500 ppm elemental Te for up to 21 days.[16] The significance of these reports remains unclear because of the potential reduction in food consumption from malodorous Te-containing feed, small sample sizes, and the lack of statistical comparisons. Animal studies indicate that inhalation of TeF_6 at concentrations of 1 ppm Te for 4 hours produces pulmonary edema.[17] In rats feed tellurium compounds, oral tellurite administration is approximately twice as toxic as tellurate.[15]

TOXICOKINETICS

Absorption

Experimental data on the absorption of tellurium and tellurium compounds is limited. In a study of healthy adults, the fractional absorption of powdered elemental Te in three fasting volunteers was 10% ± 4% compared with 23% ± 9% following the ingestion of sodium tellurate (Na_2TeO_4) by four volunteers.[18] The fractional absorption of sodium telluride by a single volunteer was 21.5% as measured by atomic absorption spectrometry. No subject developed adverse effects during the study. Animal studies suggest the gastrointestinal tract absorbs ~10–20% of an oral dose of tellurites.[2] Absorption of tellurium compounds through tellurium-induced skin burns or rashes is sufficient to produce a garlic odor in the breath as a result of the formation of volatile dimethyltelluride from tellurium methylation. Organic tellurium esters may penetrate intact skin producing blue-black discoloration of the skin between the fingers.[19]

Distribution

Tellurium distributes initially from the blood to the liver, kidney, lungs, thyroid, and spleen; ~90% of the total body burden of tellurium (i.e., ~500–600 mg) exists in the bone.[9] In rodent studies, tellurium binds primarily to hemoglobin and the remainder to plasma proteins.[20]

Elimination/Metabolism

The kidney excretes most of the absorbed tellurium dose; other excretion routes include the bile and exhalation of dimethyltelluride; the latter is associated with the characteristic garlic-like, malodorous breath. In rats, the biological half-life is biexponential with a range of 9–23 days for most organs and ~2 years for bone.[21] Although inorganic tellurium (i.e., tellurite, tellurate) probably follows similar metabolic pathways as selenite and selenate in animals, few data exist on the exact metabolic pathways. These complex pathways probably produce organotellurium compounds.[22]

Maternal–Fetal Kinetics

Animal studies with radioactive tellurous acid suggest tellurium crosses the placenta.[23] In lactating rats receiving intravenous tellurium, breast milk transfers small amounts of ^{123m}Te from the mother to the suckling rat.[24]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Tellurium is a nonessential metalloid that crosses the cell membrane of Schwann cells producing segmental demyelination and peripheral neuropathy in rats characterized by weakness and/or paralysis of the hind limbs.[25,26,27] Animal studies suggest organotellurium species (e.g., dimethyltelluronium compounds) produce demyelination by the inhibition of squalene epoxidase.[28] To date, neurological changes in workers exposed to tellurium have not been described. Tellurite compounds induce alterations of the red cell membrane leading to swelling, hemolysis, and shedding of cell fragments. These membrane perturbations involve the formation of a tellurium species, possibly HTe^-, that penetrates the cell membranes.[29] Autopsies of two patients receiving intravesical injections of sodium tellurite demonstrated black tellurium deposited in the mucosa of the urinary tract along, fatty changes of the liver, and congestion of the liver, lungs, and kidneys.[13] All tissue demonstrated the strong odor of garlic.

CLINICAL RESPONSE

Acute Toxicity

Tellurium and most tellurium compounds have relatively low toxicity; however, tellurite compounds are more toxic than elemental tellurium. The accidental instillation of sodium tellurite into the bladder of two patients with renal colic was associated with vomiting, stupor, dyspnea, cyanosis (methemoglobinemia), coma, and death within 6 hours.[13] The exact cause of death is unclear because of the lack of laboratory and clinical details in the 1946 case report. A 37-year-old woman developed weight loss, fatigue, and a strong garlic odor on the breath after eating Te-contaminated meat (800–1,000 μg/kg).[30] The onset of fever occurred 2 days after ingestion with nausea and vomiting developing 3 days later. Endoscopy revealed petechial gastric bleeding in the fundus with minimal focal irritation. Hair loss developed 2 weeks after consumption of the contaminated meat. Experimental studies suggest the strong garlic odor may persist for months after exposure based on the detection of garlic odor for 237 days after the ingestion of 15 mg sodium tellurite during experimental studies from the 19th century.[31]

Two children developed vomiting, black discoloration of the oral mucosa, and a garlic odor to the breath following the ingestion of an acidic metal-oxidizing solution containing tellurium; one of the children also had corrosive injuries to the esophagus.[32] They recovered without sequelae.

Occupational Exposure

Most Te exposures occur in the workplace. Tellurium hexafluoride is a colorless, irritating gas. A 30-minute exposure during a leak of TeH_6 was associated with garlic odor in the breath and sweat, metallic taste in the mouth, anorexia, lethargy, and a bluish-black discoloration underneath the skin of the face, neck, and fingers.[19] Pulmonary symptoms did not develop; the patients recovered without sequelae. To date, serious toxicity has not been associated with exposure to tellurium and tellurium compounds in the occupational setting.[14] The most common complaint of workers exposed to tellurium is a garlic-like odor on the breath and sweat.[33] Other symptoms associated with occupational Te exposure include dry mouth, metallic sensation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in the mouth, decreased appetite, transient nausea, dry mouth, and lethargy.[30]

Reproductive Abnormalities

Epidemiological data on human reproductive abnormalities following human exposure to tellurium are limited; however, current evidence does not indicate tellurium is a human teratogen. The administration of high Te doses (500–3,000 ppm) in the diet of rats during the day 9–15 of gestation produced an increased incidence of hydrocephalus in the offspring;[34,35] however, maternal toxicity occurred at dietary Te concentrations of ≥300 ppm and no unique teratogenic abnormalities developed.[36] There are no studies demonstrating tellurium is teratogenic at doses commonly present in the workplace.

Carcinogenesis

Neither the IARC nor the US Toxicology Program lists tellurium or tellurium compounds as suspected carcinogens. Exposure of rats to sodium tellurite and sodium tellurate in drinking water (2 mg Te/L) for a lifetime (2 years) did not produce an excess incidence of tumors, despite some decrease in the longevity of female mice fed sodium tellurite.[37]

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.007837 μmol/L
1 μmol/L = 127.6 μg/L

Analytical Methods

Sensitive techniques for the determination of Te in biological and environmental samples include inductively coupled plasma/mass spectrometry (LOD, 0.01 μg/L),[38] graphite furnace/atomic absorption spectrometry (LOD, 0.3 μg/L),[39] and hydride generation/atomic absorption spectrometry (LOD, 0.03 μg/L).[40,41] Analysis of urine samples with hydride generation/atomic absorption spectrometry with derivative signal processing produces Te detection limits in the range of 1 μg/L.[42] The use of ion chromatography/inductively coupled plasma/mass spectrometry allows the speciation of inorganic Te compounds (e.g., tellurite (4+), tellurate (6+)) at detection limits of 0.01–0.08 μg/L.[43] For the identification and speciation of unknown tellurium metabolites, dual hyphenated techniques (liquid chromatography/inductively coupled plasm/mass spectrometry, liquid chromatography/electrospray ionization/tandem mass spectrometry) are recommended because sample matrix may seriously affect electrospray ionization.[22]

Biomarkers

Blood

Whole blood Te concentrations in the general population without occupational Te exposure are <1–5 μg/L.[44] The median whole blood Te concentration in a study of 99 healthy children was 0.12 μg/L (95% CI: 0.07–0.22 μg/L) compared with 0.06 μg/L (95% CI: <0.4–0.11 μg/L) in plasma samples as measured by inductively coupled plasma/mass spectrometry.[45] In a symptomatic child ingesting an acidic metal-oxidizing solution, the whole blood Te concentration was 200 μg/L.[32] A 37-year-old woman developed weight loss, fatigue, metallic taste in her mouth, a strong garlic odor, and gastrointestinal distress soon after eating Te-contaminated meat; her serum Te concentration 4 weeks after ingestion was 27.6 μg/L.[30]

Urine

The urine Te concentrations in 20 Italian subjects without occupational Te exposure were <1 μg/L.[46] In a convenience sample of 14 nonsmoking workers without occupational exposure to Te, the mean urine Te in 24-hour urine samples was 0.11 ± 0.05 (range, 0.07–0.18 μg/L).[38] Spot urine samples from two children (i.e., vomiting, garlic odor) symptomatic after ingesting a metal-oxidizing solution that contained Te concentrations of 56 μg/L and 260 μg/L.[32]

HEALTH SURVEILLANCE

Environmental Monitoring

The US OSHA PEL–TWA for tellurium and its compounds (excluding tellurium hexafluoride and bismuth telluride) is 0.1 mg Te/m^3 as a dust or fume. The recommended TLV–TWA of the American Conference of Governmental and Industrial Hygienists (ACGIH) is consistent with US OSHA standards. The ACGIH recommendation for Te and most Te compounds is formulated to reduce the likelihood of foul breath and the potential risk of central nervous effects, liver dysfunction, and cyanosis based on animal studies, whereas the TLV–TWA for TeF_6 is designed to reduce the

[a] Except tellurium hexafluoride and bismuth telluride.

risk of pulmonary irritation noted in animal studies.[14] The exact tellurium ambient air concentration at which a garlic-like odor appears in workers varies substantially as a result of individual variation and the extent of skin contamination; some workers may develop garlic-like odor in their breath at this value.[33] Table 29.1 lists the regulations and recommendations regarding exposure to tellurium and tellurium compounds.

Biological Monitoring

There are inadequate data to determine specific blood or urine Te concentrations that limit the risk of adverse long-term health effects. Case reports suggest urine Te concentrations >25 µg/L or whole blood/serum Te concentrations of >50 µg/L are levels of concern.[47] Hydrogen telluride is excluded from this TLV–TWA because of its greater toxicity compared with other tellurium compounds. The likelihood of developing garlic odor substantially decreases when the urinary tellurium concentration is <1 µmol/mol creatinine.[48] The limited data available correlating urinary Te concentrations with the development of a garlic odor suggest these odors do not develop at urine levels of <1 µg/L.[33,49] Medical surveillance of workers should include a physical examination for conditions (e.g., caries, bronchiectasis, gingivitis, exposure to selenium) that also produce an objectionable breath.

TREATMENT

Treatment is supportive. There are no known antidotes or effective chelating agents for the treatment of tellurium poisoning.

Chapter 30

THALLIUM

HISTORY

Sir William Crookes discovered thallium in 1861 while he was preparing selenium from flue dust obtained from a sulfuric acid factory. Shortly thereafter, he recognized the toxicity of thallium when he and his assistant developed signs of thallium toxicity following animal experimentation with thallium.[1] The name thallium derives from the Greek word, *thallos*; in Greek mythology, this word refers to the goddess of spring and the protector of new growth. By the end of the 19th century, thallium sulfate was a medicinal agent for the treatment of venereal disease, gout, dysentery, night sweats, and the diaphoresis associated with tuberculosis.[2] However, the prominence of gastrointestinal and neurological reactions resulted in the cessation of the medicinal use of thallium by 1912.[3] Raymond Sabouraud reported the association between thallium ingestion and cranial hair loss in 1897; subsequent clinical studies resulted in the use of thallium compounds (e.g., thallous acetate) to produce cranial alopecia as a preliminary step in the treatment of *Tinea capitis* and *Trichophyton rubrum* scalp infections.[4] Numerous cases of thallium poisoning in humans occurred following the introduction of thallium as a rodenticide and an insecticide in the 1920s.[5] In Germany, thallium acetate and thallium sulfate were reintroduced in the 1920s as a treatment for ringworm of the scalp; the latter compound was also a rodenticide. In spite of the dermatological use of thallium in reduced doses compared with earlier treatments for venereal disease, thallium poisoning continued to occur.[6] In 1930, 14 of 16 infants administered excessive thallium for the treatment of ringworm died of thallium poisoning.[7] Several case reports in the early 1930s document alopecia and lower extremities neuropathy (i.e., pain, paraesthesias) from thallium poisoning following the use of a thallium-containing depilatory (Koremlu).[8,9] Examination of a Koremlu sample by the Bureau of Investigation of the American Medical Association demonstrated that this commercial product contained 7% thallium acetate. An outbreak of thallium poisoning occurred in California during 1932 when a grain mixture containing thallium sulfate was inadvertently used to make tortillas.[10] Thirteen people died. The bait was a rodenticide used to control the ground squirrel population. By 1940, medicinal thallium use was abandoned in the United States;[11,12] however, the use of organic thallium to separate industrial diamonds from abrasives was associated with thallium toxicity in the workers during the 1950s.[13] The use of thallium as a depilatory paste continued until the 1950s in some countries.

In 1964, Hausman reported 52 cases of thallium poisoning that resulted from accidental and suicidal intentions as well as homicidal intent.[14] By 1965, federal US legislation had ended the use of thallium as a rodenticide. However, the use of thallium as a rodenticide continued in countries outside the United States, despite a World Health Organization recommendation against the use of thallium-containing rodenticides in 1973.[15] Industrial use of thallium continues along with sporadic cases of thallium poisoning. Most recent commercial uses of thallium include the manufacture of imitation jewelry, pigments, low-temperature thermometers, semiconductors, scintillation counters, and optical lenses. Thallium is a cumulative poison and

known homicidal agent used by murderers,[16] including the English serial killer, Graham Young.[17]

PHYSIOCHEMICAL PROPERTIES

Thallium is a member of Group 13 (Group IIIA including aluminum, boron, gallium, indium) of the periodic table located between lead and mercury. Metallic thallium is a soft, malleable metal with a shiny appearance and physical properties similar to lead. Upon exposure to air, this blue-white, heavy metal forms a superficial layer of brownish-black thallous oxide (Tl_2O). Elemental thallium is highly reactive, readily forming monovalent thallous (Tl^+) and trivalent thallic (Tl^{+3}) salts; elemental Tl easily oxidizes in air to form superficial layers of insoluble thallium oxide (TlO_2). The electrical charge and ionic radius of Tl^+ are similar to those of potassium (K^+). Most of these salts are colorless, odorless, and tasteless. The monovalent compounds behave like alkali metals (e.g., potassium), whereas trivalent compounds resemble less basic metals (e.g., aluminum). The trivalent (thallic) ion in inorganic thallium compounds is less stable than the monovalent thallium ion, whereas the latter ion is less stable in organic compounds. Thallium salts do not hydrolyze at pH ≥7 to form insoluble hydroxides, resulting in enhanced toxicity compared with other metal salts that form insoluble salts at physiological pH. There are 26 artificial thallium radioisotopes with masses ranging from 191–210 and physical half-lives ranging from 2.1 msec (^{201m}Tl) to 3.8 years (^{204}Ti). The natural radioisotopes are ^{205}Tl (70.48%) and ^{203}Tl (29.52%).

Table 30.1 lists the identifying information and physical properties of metallic thallium and the common thallium compounds. Most thallium salts are water-soluble, but these salts readily hydrolyze in alkaline environments (pH >7) to form insoluble hydroxides.[18] The water-soluble thallium salts include thallium acetate ($TlC_2H_3O_2$), thallium carbonate (Tl_2CO_3), thallium nitrate ($TlNO_3$), thallium oxide (Tl_2O), and thallium sulfate (Tl_2SO_4), whereas insoluble compounds include elemental thallium as well as thallous iodide (TlI), thallium sulfide (Tl_2S), and thallic oxide (Tl_2O_3). Although thallous compounds are generally much more water-soluble than thallic compounds, animal studies indicate both thallic and thallous compounds are potent toxins.[19]

Chemical properties favoring thallium use as a homicidal agent include the insidious onset of nonspecific symptoms, the lack of taste, color, and smell, and the absence of routine testing for the presence of thallium. Urine heavy metal screens do not typically detect the presence of thallium.

EXPOSURE

Production Processes

The principal mineral ores containing thallium are crookesite [Cu_7(Tl, Ag)Se_4] and lorandite ($TlAsS_2$), but the commercial production of thallium usually occurs as a by-product of cadmium production or through the recovery of thallium from the flue dust from the smelting of other metals (copper, lead, zinc). Thallium is present in the pyrites used to produce sulfuric acid; sufficient amounts of thallium are present in the waste of sulfuric acid production to recover thallium commercially. Recovery of thallium occurs primarily by electrolysis and, to a lesser extent, by precipitation or reduction. Thallium is usually present in the form of thallous sulfate.

Uses

Currently, the semiconductor industry uses most of the production of thallium (i.e., primarily as thallous salts) with the remainder used in the pharmaceutical industry for cardiac imaging and the manufacture of highly refractory optical glass.[20] Commercial uses for specific thallium compounds include the following: acetate (separation of ores by flotation using solutions with high specific gravity); carbonate (fungicide, artificial diamond production); chloride (catalyst for chlorination); chromate (pigments); nitrate (manufacture of signals at sea, photocells, fireworks, and low melting glass); oxide (production of artificial gems and highly refractive glass); selenite (semiconductors); sesquioxide (ceramics, yellow-green glass, optical fibers, semiconductors); and sulfate (chemical intermediate pharmaceutical industry, semiconductors, low range thermometers, photoelectric cells, textile fiber production, rodenticide). Uses for thallium in chemical production include oxidation of hydrocarbons and olefins, epoxidation, and polymerization. Although most industrial countries no longer permit the use of thallium as a rodenticide, its use still occurs in developing countries as an inexpensive way to control rodents. Thallium toxicity occurred following the mistaken use of thallium chloride as homeopathic medicine.[21]

Sources

Thallium is a stable, nonvolatile, heavy metal that exists in the environment mostly combined with other elements (e.g., halogens, oxygen, sulfur). Although thallium is ubiquitous in nature (e.g., sulfide ores of heavy

[a] Turns purple after exposure to sunlight; [b] Decomposes in smoke.

metals, Jurassic coal, iron/lead/zinc ores), the thallium concentration in nature is usually low (<2 mg Tl/kg).[22] Relatively high concentrations of thallium occur in granite, shale, and manganese nodules.[23] As a trace contaminant of materials, thallium enters the environment primarily from the emissions from coal-burning and ferrous/nonferrous smelting. Exposure of the general population occurs mostly through the ingestion of thallium-containing food.

Air

Emissions from cement factories, coal-burning power plants, and smelting operations are the primary source for thallium release into the air.[24] Thallium volatilizes during the combustion of coal or raw materials for cement production; then, Tl condenses as ash particles. About one-third of these particles are small enough to reach the lower respiratory tract.[25] Data on Tl concentration in ambient air are limited with thallium concentrations in unpolluted air typically <1 ng/m^3. In six US cities, the typical Tl concentration in ambient air was ~0.4 ng/m^3,[26] whereas the geometric mean thallium concentration in air around Genoa, Italy, was ~15 ng/m^3.[27] Thallium concentrations near a point source (coal-burning plant) averaged ~700 ng/m^3.[26]

Soil

Thallium typically exists as a trace mineral (<1 mg/kg) in the soil, primarily in rock formations (granite, shale) and potassium feldspar- and mica-containing soil.[28] In a study of 244 French arable soil samples, the median thallium concentration was 0.29 mg/kg with a 90th percentile concentration of 1.54 mg/kg and a range up to 55 mg/kg.[29] The highest thallium concentrations in these soil samples were not associated with anthropogenic sources, whereas silty or clay-silty soils

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

derived from limestone, marl, or granite contained relatively high thallium concentrations. In a study of soils from the industrialized Euroregion Neisse (German–Poland–Czech Republic border area), the median Tl concentration in soil was 0.5 mg/kg.[30] High thallium-containing minerals usually contain sulfur (hutchinsonite, lorandite, vrbaite) or selenium (e.g., crookesite); these minerals are rare in the earth's crust. Thallium concentrations in the soil near point sources are higher including stream sediment near a metal industry (5 mg/kg)[31] and a Michigan lake (mean = ~13 mg/kg) contaminated by air pollution.[26] Natural weathering processes and/or mining activities of thallium-rich sulfide minerals substantially increase the Tl concentration in the soil. Soil from thallium-rich pyrite processing areas near industrial sources in South China contained Tl concentrations up to 5–15 mg/kg.[32] The water-soluble fraction of thallium in these soils is small (i.e., 0.1%).[33]

Water

Typically, the thallium concentration in water samples is low. In a study of seawater samples from the Northern Atlantic Ocean, the thallium concentration ranged from 0.01–0.017 μg/L as measured by neutron activation analysis.[34] Thallium was relatively evenly distributed in seawater samples collected from the Atlantic and Pacific Oceans at depths up to 3,500 m; the range was 0.0012–0.0016 μg/L ($n = 24$).[35] In a study of 476 groundwater samples obtained from boreholes in Norwegian crystalline bedrock, the thallium concentration ranged from 0.001–0.25 μg/L as measured by inductively coupled plasma/mass spectrometry. Similar total thallium concentrations (i.e., 0.001–0.036 μg/L) occurred in water samples from the US Great Lakes.[36] The median Tl concentration in water samples from Lake Superior ($n = 26$) was 0.0012 μg/L (range, 0.0009–0.0014 μg/L) compared with 0.0094 (range, 0.0059–0.0117 μg/L) in Lake Erie ($n = 18$) and 0.0057 μg/L (range, 0.0045–0.008 μg/L) in Lake Ontario ($n = 47$). The Tl concentration did change significantly with water depth; however, the Tl concentration was substantially higher in the harbor draining St. Claire River (range, 0.023–0.036 μg/L; $n = 8$). The mean Tl concentration in 178 dissolved river water samples from a summary of 4 Japanese studies was 0.007 ± 0.152 μg/L compared with 0.025 ± 0.104 μg/L in 178 particulate samples from the same area, as measured by ICP/MS.[37] For 25 dissolved and particulate lake water samples, the mean Tl concentrations were 0.011 ± 0.020 μg/L and 0.036 ± 0.105 μg/L, respectively. The mean Tl concentrations in 31 dissolved and 24 particulate water samples from coastal seawater were 0.008 ± 0.006 μg/L and 0.003 ± 0.003 μg/L, respectively.

Substantially higher thallium concentrations exist in water samples from areas near natural and anthropogenic sources of thallium.[33] Water samples from a river surrounding a base metal sulfide mine in northeastern Canada contained thallium concentrations ranging from 2.5–80.3 μg/L.[38] A survey of tap water from over 3,000 US homes revealed an average concentration of 0.89 μg Tl/L in the 0.68% of the samples that were positive for thallium.[26] Substantially higher thallium concentrations (e.g., 17–40 μg/L) may occur in water samples from domestic wells near water sources contaminated by thallium.[39] The major sources of thallium include runoff from the following industries: mining, refining and ore processing, iron and steel manufacturing, and nonferrous metal production.

Diet

The most frequent exposure of the general population to thallium occurs following ingestion of thallium-containing food. In contaminated areas, most terrestrial food contains <1 mg Tl/kg fresh weight with typical thallium concentrations in edible plants ranging from 0.03–0.3 mg/kg.[22] Plants grown in high-thallium soils can accumulate thallium above typical Tl concentrations. Cereal grains and green cabbage grown in soil contaminated by thallium emissions from a German cement plant contained average thallium concentrations of 9.5 mg/kg and 45 mg/kg, respectively.[40] The concentration of thallium in farm animals correlates with Tl concentrations in fodder. Bioconcentration of thallium occurs in water-dwelling organisms. Experimental studies revealed thallium bioconcentration factor in muscle from juvenile Atlantic salmon ranging from 27–1,430;[38] however, biomagnification of thallium either in aquatic or terrestrial food chains is unlikely.

The average daily Tl intake from the diet of the general population is <5 μg Tl, whereas the US EPA daily reference doses are as follows: insoluble thallium, 0.07 μg/kg; thallium sulfate, 0.08 μg/kg; and thallium acetate, 0.07 μg/kg.[41] Green vegetables are usually the major source of thallium in the diet, whereas thallium concentrations in red meat range from 50–70 μg/kg.[42] Typical thallium concentrations in milk range from 10–30 μg/kg with an estimated mean total dietary Tl exposure of 0.024–0.27 mg/kg in toddlers aged 1.5–4 years; the estimated adult daily Tl dose was smaller (0.011–0.012 mg/kg).[43] Smoking may contribute to Tl intake with estimated consumption of 1.1–2.4 ng/cigarette.[44] Typically, the urinary Tl excretion is higher in smokers than nonsmokers.[26]

ENVIRONMENTAL FATE

Air

Because thallium is nonvolatile, anthropogenic sources (cement plants, coal-fired power-generating plants) release fly ash containing thallium into the air.[22] Thallium chloride is a major form of thallium in the ash from cement plants. Oxidation of thallium in the air occurs slowly. Although thallous chloride is photosensitive, photochemical reactions do not account for a significant part of Tl elimination from the atmosphere.

Soil

Elevated Tl concentrations occur primarily on the upper surfaces as a result of wet and dry deposition of thallium-contaminated fly ash. The fate of thallium in soil depends on pH (i.e., increasing water solubility in acidic conditions) and the soil type with increased retention in soils that contain large amounts of iron or magnesium oxides, organic matter, or clay. The uptake of thallium in plants increases as the soil pH decreases.

Water

In some markedly acidic soil, thallium will leach into groundwater or surface water. Most thallium in seawater and well-oxidized freshwater exists in the trivalent form, whereas the thallous ion is the predominant species in other freshwater. Hydrolysis of thallium in freshwater precipitates thallium as a hydroxide or an oxide that settles in organic-rich sediment. There is no direct evidence that thallium is transformed in the environment into other compounds.

DOSE EFFECT

Signs of acute thallium intoxication may appear at doses as low as 4 mg Tl/kg.[45] The typical adult and prepubescent children's Tl dose (i.e., depilatory dose) as thallium acetate used as a preliminary step in the treatment of fungal infections of the scalp was 8 mg Tl/kg (range, 4–10 mg Tl/kg body weight) with toxicity reported in ~5% of the patients.[4,46] Severe poisoning occurs with doses of >0.8–1 g thallium salts in adults and >8 mg thallium salts/kg in children. The average lethal adult dose is 1–2 g (10–15 mg/kg) soluble thallium salt. In a case series of three workers poisoned by surreptitious addition of thallium acetate to their beverages, the perpetrator kept careful records of the thallium doses.[47] The administration of 0.93 g thallium in two or three divided doses caused death, whereas the third victim survived the administration of 0.31 g after developing vomiting, diarrhea, weakness, paresthesias, and hair loss. The acute, surreptitious ingestion of an estimated 1.5 g thallium in drinking water by a husband and wife was associated with the acute onset of mild nausea and vomiting followed by the development of a painful neuropathy. Later, lower extremity muscle weakness, eczematous rash, alopecia, Mees lines, and diarrhea occurred.[48] Administration of Prussian blue began 3 weeks after exposure. At 1-year follow-up, hyporeflexia, lower extremity weakness, and hypoesthesias persisted. Survival occurred after the ingestion of 1.3 g thallium sulfate, whereas the intentional ingestion by adults of 3.2 g thallium sulfate[49] and of 4–8 g Tl as thallium nitrate[50] resulted in death. The ingestion of 10 g thallous malonate (8 g Tl) produced terminal cardiac failure in a 26-year-old man presenting 6 hours after ingestion, despite the use of hemodialysis and hemoperfusion.[51] In animals, the toxicity of water-insoluble thallium(III) oxide by oral and parenteral routes is somewhat lower than that of water-soluble thallous(I) compounds.[22]

TOXICOKINETICS

Absorption

Most thallium compounds are water-soluble; the gastrointestinal tract absorbs these thallium compounds rapidly.[52] Limited animal and human data suggest that Tl absorption following ingestion is almost complete.[53] Dermal absorption occurs after the application of ointments, but no data are available to accurately quantify the extent of dermal absorption of thallium salts. Percutaneous absorption of organic thallium was the suspected cause of gastrointestinal symptoms, malaise, myalgias, and alopecia in workers with reportedly no significant airborne Tl exposure.[13] The absorption of thallium following nasal insufflation of thallium sulfate-containing illicit drugs was sufficient to produce thallium toxicity (hypertension, alopecia, paresthesias).[54] Although there are little quantitative data on Tl absorption following inhalation, absorption probably would be sufficient to cause toxicity depending on the severity of exposure based on case reports of thallium toxicity in workers exposed to water-soluble thallium salts (e.g., carbonate, sulfate).[55]

Distribution

The volume of distribution of thallium is relatively large. In a study of nine patients undergoing myocardial scintigraphy with tracer amounts of ^{201}TlCl, the mean steady-state volume of distribution was 4.23 ± 0.67 L/kg.[56] Following an overdose, the distribution of thallium was similar at ~1–5 L/kg; Tl distribution occurs primarily intracellularly, where thallium mimics the movement of potassium.[52] Analysis of blood thallium concentrations following fatal ingestion of thallous malonate revealed a red blood cell/plasma ratio of 9.52. Thallous ions accumulate in tissues with high concentrations of potassium.

Thallium distributes rapidly into cells based on radionuclide studies with ^{201}TlCl; 5 minutes after the intravenous injection of 2–5 mCi ^{201}TlCl, 5–8% of the injected activity remained in the blood of 11 patients.[57] Based on data from tracer studies in animal[58] and postmortem studies in humans,[51] thallium distributes primarily to the kidney, soft tissue (muscle), scalp hair, the heart, and, to a lesser extent, the brain and liver. Case reports suggest thallium distributes more slowly to the central nervous system than blood. In a patient with severe thallium poisoning, the CSF thallium concentration increased from 1,200 µg/L on day 1 to 2,100 µg/L on the day of death (day 3), whereas the serum thallium concentration decreased from 8,700 to 7,200 µg/L.[59] Depending on the time since ingestion, large amounts of thallium may be present in the large intestine. Thallium is soluble at physiological pH; unlike lead and arsenic, thallium does not form complexes in bone. Because of its rapid accumulation in cells, whole blood Tl concentrations do not reflect the Tl concentration in tissues.[22]

Elimination

Thallium elimination follows a two-compartment model in human pharmacokinetic studies. In a study of nine patients undergoing myocardial scintigraphy with ^{201}TlCl, the mean terminal plasma half-life of thallium was 51.8 ± 14.9 hours.[56] The major portion of thallium remains in the gut following an acute overdose, probably because of enterohepatic recirculation; elimination occurs primarily via the feces.[60] However, following the ingestion of small doses of thallium, the kidney excretes most of the body burden of thallium with a daily urinary loss of about 3% of the total body burden of thallium.[53,61] During the first month after admission for severe thallium intoxication (respiratory failure, areflexic paralysis of all extremities, visual loss), the elimination half-life of thallium averaged ~2–4 days (range, 3–8 days); treatment with Prussian blue and potassium began midway through this period.[60,62] Thereafter, the elimination half-life increased considerably. Without treatment, the biological half-life of thallium is ~10–15 days based on limited data.[63,64] Compared with laboratory animals, the excretion of thallium in humans is slower, occurring primarily via the kidney and substantially less in the feces. Thallium does not accumulate in the body.

Maternal–Fetal Kinetics

Thallium does cross the placental barrier and produces alopecia and nail abnormalities in a fetus exposed in the last trimester.[65] Excretion of thallium in human milk occurs after the administration of ^{201}Tl to breastfeeding mothers.[66] In a lactating mother receiving 111 MBq (3 mCi) for evaluation of a residual brain tumor, the estimated dose to the breastfeeding infant was 0.00072–1.92 mSv depending on the age of the child.[67]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Thallium is a nonessential heavy metal. The exact mechanism of thallium toxicity remains unclear; however, animal models and *in vitro* experiments suggest that thallium causes lipoperoxidation and interferes with mitochondrial function by competing with potassium ions in essential enzymes.[68] Potential mechanisms include: 1) modification of the Na^+/K^+ ATPase pump and alteration of resting membrane potential across the active cells;[69] 2) inhibition of energy production from glucose (i.e., pyruvate kinase-catalyzed conversion of ADP to ATP);[70] and 3) inactivation of riboflavin and reduction in the activity of the Krebs cycle.[71] Like other heavy metals, thallium has an affinity for sulfhydryl groups of mitochondrial membranes; therefore, thallium inhibits sulfhydryl-containing enzymes involved in respiration and protein synthesis (e.g., keratin). Inhibition of the sulfhydryl-containing enzyme, cysteine, inhibits keratinization resulting in alopecia. Succinic dehydrogenase, protease, and monoamine oxidase are all thiol enzymes that are reduced in the corpus striatum of thallium-fed experimental animals.[72] The interaction of thallium with sulfhydryl groups produces free radicals and increases lipid peroxidation in the brain. The increased rate of lipid peroxidation depletes glutathione,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

leading to the accumulation of lipid peroxides and the formation of lipofuscin granules in the kidney, liver, and brain.

Sharing similar ionic radii, thallium displaces potassium throughout the body and interferes with oxidative phosphorylation by inhibiting Na^+/K^+ ATPase.[73] The affinity of the Na^+/K^+ ATPase enzyme is over 10 times greater for thallium than potassium.[11] Axonal mitochondria accumulate thallium, resulting in necrosis.[74] Deficiencies of riboflavin produce a clinical picture similar to thallium poisoning including dermatitis, alopecia, and neuropathy. Another potential mechanism of action for thallium toxicity is the interference of riboflavin homeostasis by the formation of insoluble complexes that sequester riboflavin intracellularly.[75]

Pathological Changes

Microscopic examination of the peripheral nerves following thallium intoxication demonstrates primarily axonal degeneration with preservation of most overlying myelin, particularly in the small sensory nerves.[76] Secondary myelin degeneration may occur. Electron microscopy demonstrates damage to small and unmyelinated fibers with denervation of the epidermis and loss of epidermal nerves.[77] Medium-sized nerves are selectively damaged; decreased density of large myelinated fibers also occurs. Examination of the brain reveals edema and necrosis of the neurons and glial cells. Electron microscopic changes are most prominent in the mitochondria with marked swelling, dilation of intermembrane spaces, distortion of the endoplasmic reticulum, and destruction of cristae and membranes.[78]

Biopsies of acneiform pustules of the face and hyperkeratotic lesions of the feet demonstrate gross follicular plugging with eosinophilic keratohyalin granules in adjacent layers of the epidermis along with the disintegration of the hair shafts, atrophy of the hair bulb, dystrophic cuticles, and cystic dilation of the follicles.[79] Polarized light microscopic examination of hair roots during the first week after thallium exposure demonstrates dark zones around the hair root as a result of the accumulation of gaseous inclusion bodies that refract light; thallium is typically not deposited in the skin as analyzed by the rhodizonate staining test.[80] The alteration of hair shaft diameter and disorganization of the cortex appear as dark zones under transmitted-light microscopy. Multiple dark zones may occur following poisoning by successive doses of thallium. Histological examination of crusted eczematous lesions from a patient with thallium poisoning demonstrated marked parakeratosis, mild epidermal atrophy and vacuolar degeneration of the basal layer, and dilated hair follicles filled with keratin and necrotic sebaceous debris.[48]

Postmortem

Autopsies of patients dying of thallium poisoning demonstrate mucosal hemorrhages of the intestine, heart, lungs, and endocrine glands, degenerative changes in the renal tubules and glomeruli, fatty infiltration of the heart and liver, and central nervous system fatty degeneration of the ganglion cells with preservation of the anterior horn cells and deterioration of the myelin sheaths and axons.[81] Nerve biopsies from patients with thallium poisoning reveal demyelination characterized by focal beading of the myelin along with an axonopathy characterized by prominent fusiform dilations and loss of axons.[82] Pathological changes of muscle fibers include central nucleation, splitting of fibers, and necrosis.[20] Case reports suggest distal peripheral degeneration of motor and sensory axons occurs following thallium poisoning with relative preservation of proximal fibers.[47] Postmortem examination of a 32-year-old man with thallium poisoning demonstrated widespread loss of peripheral nerve fibers and chromatolysis of spinal neurons, particularly long distal fibers (i.e., lumbar sensory > cervical sensory).[83]

CLINICAL RESPONSE

The differential diagnosis of thallium poisoning includes heavy metal poisoning (arsenic, lead, mercury, selenium), adverse drug reactions (isoniazid, hydralazine, phenytoin), botulism, alcoholic peripheral neuropathy, musculoskeletal pain, connective tissue diseases, Guillain–Barré syndrome, and thiamine deficiency. The presentation of chronic thallium intoxication is similar to the presentation of acute thallium poisoning. However, symptoms of chronic thallium poisoning begin insidiously with symptoms peaking within 2–3 weeks followed by gradual resolution or death.[65]

Acute Toxicity

The classic presentation of acute thallium poisoning is the initial development of mild gastroenteritis (nausea, vomiting, diarrhea, epigastric pain) followed by polyneuritis (prominent paresthesias/pain, ptosis, dysphagia, tremor, confusion, encephalopathy, cerebellar symptoms, choreiform movements) within 2–5 days and subsequently dermatological abnormalities (alopecia, loss of lateral third of eyebrow,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

acneform/eczematous lesions, scaling of palms and soles, Mees' lines) ~2–3 weeks postexposure.[84,85,86] Peak alopecia occurs ~3–4 weeks after acute ingestion with some sparing of axillary, pubic, and facial hair (e.g., eyelashes).[2,87] The absence of alopecia does not exclude the diagnosis of thallium poisoning.[88] Nonspecific autonomic effects include tachycardia, hypertension, fever, salivation, fatigue, and sweating. Hematemesis is rare; coma and death may occur following massive overdoses of thallium acetate or thallium sulfate.[2,89] In severe cases, cranial neuropathies may develop.

Central Nervous System

Although symptoms of peripheral neuropathy often dominate the clinical presentation, CNS symptoms also occur including optic neuritis, encephalopathy, extrapyramidal signs, and cerebellar dysfunction.[90] The central nervous system features of acute thallium poisoning include disorientation, irritability, poor concentration, headache, lethargy, tremor, ataxia, coma, convulsions, psychosis, thirst, insomnia, visual illusions, ophthalmoplegia, and cerebral edema with central respiratory failure. Cranial nerve abnormalities and cerebellar signs are less common than clinical features of peripheral neuropathy. Although recovery from neurological abnormalities occurs after cessation of thallium exposure, the improvement is variable; some central nervous system abnormalities may persist including psychosis,[2] ataxia, tremor, intellectual impairment (poor performance IQ, reasoning skills, memory impairment),[91,92] and visual loss.[93] The latter case report documents persistent visual loss 3 years after thallium poisoning.

Peripheral Nervous System

Within ~2–5 days after acute, severe thallium exposure, symptoms of a painful, rapidly progressive peripheral neuropathy begin; by the second to third week, these symptoms dominate the clinical picture. Neurological examination may detect a stocking-glove type of polyneuropathy involving a combined motor and sensory neuropathy that is primarily a distal axonopathy manifest in the lower extremities.[55,94] Involvement of the upper extremities occurs infrequently; cranial nerve palsies following thallium poisoning are rare. Hyperesthesia of the palms and soles may be particularly severe. Unlike Guillain–Barré syndrome, stretch reflexes are preserved until late in the course of toxicity; prominent sensory changes precede the distal motor weakness. Leg cramps may be severe. Peripheral nervous system abnormalities (e.g., motor weakness, foot drop, visual loss) usually improve, but weakness and sensory disturbances may persist for at least several years, primarily in the lower extremities.[95]

Cardiorespiratory System

Severe cases of Tl toxicity may exhibit myocardial necrosis with dysrhythmias and cardiac failure.[96] Death usually results from respiratory or cardiac failure. Intractable hypotension, elevated pulmonary wedge pressures, and bradycardia may dominate the clinical picture. Acute respiratory distress syndrome may develop within the first 48 hours of hospitalization after a large Tl ingestion based on case reports documenting normal pulmonary capillary wedge pressures with diffuse interstitial and alveolar inflammation.[97] Postmortem examination confirmed the latter with hyaline membrane formation. Variations in blood pressure occur as a result of autonomic dysfunction.

Eye

Early signs of ocular involvement include blepharitis, conjunctivitis, diplopia, ptosis, nystagmus, bilateral facial palsy, facial hyperesthesias, and hyperemia of the optic disc. The severity of visual impairment depends on dose; early ocular signs may be transient.[98] Late ocular signs of thallium poisoning include optic atrophy, visual loss, and a central scotoma. In a case report of two women with severe thallium poisoning including visual abnormalities, severe asymmetrical vision impairment persisted in both women along with central scotomata and impaired color discrimination at 2-year follow-up.[99]

Skin

Nonspecific dermal signs begin within the first week after ingestion including scaling of the palms and soles, acneform lesions and dark pigmentation of the hair roots, and black, tapered, dystrophic anagen roots.[79,100] The cortex appears disorganized and the hair shaft may display intermittent, dark transverse bands. Severe acne may develop on the nose, cheeks, and nasolabial folds manifested by necrotic lesions and follicular plugging along with blue-gray lines on the gums.[101] Other dermatological abnormalities include crusted eczematous lesions, palmar erythema, dry scaly skin with hyperkeratosis, anhydrosis, glossitis, stomatitis, and discoloration of the hair. Approximately 2–4 weeks after thallium exposure, the most characteristic dermatological sign is the development of scalp and facial hair loss, primarily in the scalp and temporal parts of the eyebrows.[75]

Pubic and axillary hair along with eyelashes are relatively spared during thallium intoxication. Crusted eczematous lesions and dry scaly skin may appear on the trunk and the distal portions of the extremities as a result of generalized anhidrosis and destruction of sebaceous glands. Impaired growth of the nails occurs along with the appearance of white stripes (Mees lines) across nails ~1 month after exposure. Alopecia and nail changes (e.g., Mees lines) usually resolve completely after cessation of thallium exposure.[102] The hair loss stops ~2–3 months after Tl exposure ceases.[103] The appearance of new hair begins ~2 months later; hair regrowth is complete within 2 months.[48]

Environmental Exposure

In a study of 1,265 residents living near a thallium-emitting cement production plant, the primary route of thallium exposure was the consumption of Tl-contaminated vegetables and fruits grown in private gardens near the plant.[104] The reference group included 31 residents of a small German city (Steinfurt) and 10 residents of a large urban area (Dusseldorf). Although an exposure-response relation existed between urinary thallium concentrations and a variety of complaints (neuralgias, sleep disorders, weakness, tiredness, headache, fatigue, neurasthenia, joint pains, paresthesias), skin alterations, and gastrointestinal dysfunction did not correlate to urine Tl concentrations.

Occupational Exposure

Although thallium is a potent toxin, industrially related thallium toxicity is relatively uncommon with most cases occurring before the 1960s. Chronic percutaneous Tl exposure was associated with the onset of abdominal pain, alopecia, fatigue, irritability, myalgias, and weight loss in 12 of 15 workers using organic thallium salts to separate industrial diamonds from abrasives.[13] A 29-year-old specialty glass worker developed alopecia, abdominal pain, diarrhea, weight loss, fatigue, myalgias, and paresthesias of the extremities following the initiation of a new glass production process requiring thallium carbonate.[55] After cessation of his exposure to Tl-containing dust, his symptoms gradually improved; however, his complaints of gastrointestinal discomfort and extremity numbness remained over 2 years after his thallium exposure ceased. A survey of workers with Tl exposure from the production of Tl–Mg–Al alloys (5% Tl) for anodes in magnesium seawater batteries; routes of exposure included fumes from furnaces, percutaneous contact with the alloys, and dust generated during brushing the alloy.[105] Examination of medical records did not detect differences between 86 Tl-exposed workers and 79 unexposed workers, despite Tl concentrations up to 236 μg/L in spot urine samples from the exposed workers as measured by colorimetric methods. Medical history and physical examination of 128 Tl-exposed German cement plant workers with urine Tl concentrations up to 6.3 μg/L did not reveal Tl-associated adverse effects as measured by statistical differences in diagnostic codes between the two groups.[106]

Reproductive Abnormalities

There are few data on the teratogenicity of thallium. Existing animal data suggest that thallium may affect fetal cartilage or bone formation, but teratogenic effects are limited compared with maternal toxicity.[107] Thallium crosses the placental barrier resulting in Tl toxicity during maternal toxicity. A review of thallium intoxication during pregnancy indicated a wide variety of fetal effects ranging from normal development to severe toxicity in infants born to mothers poisoned with thallium.[108] There were insufficient data to formulate prognostic factors for the fetal outcome of pregnant women poisoned with thallium including the severity of maternal toxicity. Relatively low birth weight and alopecia occurred in neonates born to mothers who developed thallium poisoning during pregnancy; however, other congenital abnormalities were not detected.[22] The ingestion of 750 mg thallium sulfate 60 days before delivery produced alopecia and nail abnormalities characteristic of thallium intoxication in a neonate.[109] A follow-up study of 297 children living near the Tl-emitting cement plant did not detect a causal relationship between thallium and the occurrence of congenital malformations in the children investigated based on retrospective community health surveys and comparisons with general rates of congenital malformations in control populations.[40] The authors noted the difficulty in estimating the maternal thallium exposures retrospectively. In a study of 1,106 Chinese women without occupational thallium exposure, the median thallium concentrations in the group of women with adverse pregnancy outcomes ($n = 73$) and the referent group were not statistically different as measured by inductively coupled plasma/mass spectrometry.[110] The mean Tl concentration in umbilical cord samples from the adverse outcome group was 0.40 ± 0.38 μg/L compared with 0.41 ± 0.33 μg/L in the referent group. The latter group consisted of 106 women randomly selected from the women with normal pregnancy outcomes.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Although the transplacental transfer of thallium does occur, many strains of mice and rats demonstrate either no or only slight teratogenic effects following Tl exposure. In rodents, fetal thallium concentrations are lower than maternal Tl concentrations.[111]

Carcinogenesis

Neither the IARC nor the US National Toxicology Program lists thallium or soluble thallium salts as potential carcinogens; however, little data are available regarding the carcinogenic potential of thallium and thallium salts, primarily as a result of the difficulty of conducting carcinogenic studies because of the severe toxicity of thallium.

DIAGNOSTIC TESTING

SI Conversion Units

1 mg = 4.893 μmol
1 μmol = 0.2044 mg

Analytical Method

A commonly used method to analyze blood thallium concentrations is direct aspiration atomic absorption spectrometry, whereas furnace atomic absorption analysis, inductively coupled plasma/mass spectrometry, and neutron activation analysis are sensitive methods for very low concentrations (μg/kg) of thallium in small samples.[112] Inductively coupled plasma/atomic emission analysis and isotope dilution mass spectrometry are accurate and precise methods for multi-analyte analyses in biological and environmental samples at μg/kg (ppb) concentrations.[20] Urine specimens should be collected in pre-cleaned polyethylene or polypropylene containers; blood samples are typically collected in BD Vacutainer® Plus tubes with Royal Blue Hemogard™ using Terumo® Venoject needles. These tubes contain sodium heparin and Na_2EDTA specifically for trace metal analysis.

Biomarkers

Blood

Measurement of thallium in blood reflects recent exposure (i.e., several days) because of the rapid distribution of thallium intracellularly. The Tl half-life in the blood following the ingestion of 38 mg Tl as a soluble thallous salt was ~2 days.[53] Most internal thallium resides in the red blood cell; whole blood Tl concentrations are approximately twice the serum Tl concentration.

General Population

About 80% of 320 specimens of whole blood from asymptomatic children aged 1–5 years residing in Newark, New Jersey, were below the Tl limit of detection (<5 μg Tl/L); 1.6% of the sample ranged between 21–40 μg Tl/L as measured by atomic absorption spectrophotometry.[113] The highest recorded thallium concentration in this sample was 80 μg/L. In a study of 418 Italian subjects without occupational Tl exposure, the mean Tl concentration was 0.39 ± 0.05 μg/L (range, 0.1–1.1 μg/L); for 360 serum samples, the mean Tl concentration was 0.18 ± 009 μg/L (range, <0.05–0.4 μg/L) as measured by electrothermal/atomic absorption spectroscopy and neutron activation analysis.[114] The mean whole blood Tl concentration in 47 young Taiwanese adults was 1.9 ± 1.67 μg/L with a maximum of 4.76 μg/L.[115] The authors suggested the relatively high Tl concentrations reflected environmental exposure from thallium in commercial products (incense sticks, candles, mosquito coils) and fish consumption.

Toxicity

Generally, serum Tl concentrations of >200 μg/L are associated with toxicity, whereas serum Tl concentrations of >300 μg/L indicate severe poisoning. A 10-year-old boy was admitted with scalp alopecia, abdominal pain, lower extremity paresthesias, and seizures 2 weeks after drinking a bottle containing thallium; his admission serum thallium concentration was 296 μg/L.[103] He survived without sequelae. A 7-year-old survived thallium poisoning with intensive care and a whole blood thallium concentration of 358 μg/L at admission (i.e., ~1 week after ingestion); in the same case series, a 5-year-old girl with a whole blood thallium concentration of 289 μg/L at admission died later.[84] A 39-year-old man was admitted to an intensive care unit with hair loss, nystagmus, facial/bulbar weakness, mild upper extremity weakness, and flaccid paralysis of the lower extremities with absent reflexes; his illness began 20 days before admission.[62] His admission serum thallium concentration was 2,068 μg/L. After a prolonged hospital course including 3 months on the respirator, he was discharged with visual impairment and difficulty walking more than a few steps with aid. Survival with severe neurological impairment (flaccid extremities, ataxia, intellectual impairment) occurred in a patient with an admission serum Tl concentration of 5,750 μg/L.[91]

Urine

Urine is the best fluid to measure chronic Tl exposure; large sample size also allows pre-concentration prior to analysis. Limited data correlate urine thallium concentrations with potential clinical effects.

General Population

The urine Tl concentration in the general population is typically <1–1.5 μg Tl/L or <1 μg Tl/g creatinine.[106,116] Based on a sample of 776 participants (≥40 years of age) in the 1999–2000 National Health and Nutrition Examination Survey (NHANES III), the geometric mean urine thallium concentrations were 0.165 μg/L with a maximum of 0.86 μg/L (95th percentile, 0.440 μg/L).[117] The geometric mean Tl concentrations in a representative sample of 2,848 individuals age 6 years and older from NHANES IV data were 0.144 μg/L (95% CI: 0.41 μg/L).[118] In a convenience cohort of 273 British residents without occupational Tl exposure, the 95% upper limit of urine thallium was 0.36 μg/L compared with 0.41 μg/L for 565 workers without known thallium exposure.[119] The mean Tl concentration in urine samples from 496 Italian subjects without known sources of Tl exposure was 0.42 ± 0.09 (range, 0.06–0.82).[114]

In a study of 1,265 residents living near a thallium-emitting cement production plant, the mean Tl concentration in 24-hour urine samples was 2.6 μg/L with a range up to 76 μg Tl/L; the mean Tl concentration in the two referent groups was 0.2 μg/L (urban) and 0.4 μg/L (rural).[104] Urine thallium concentrations of <5 μg/L present in the general population living near point sources of thallium are not associated with causing adverse effects, whereas clinical effects occur in patients when thallium concentrations exceed 500 μg/L.[22] There are few data on the risk of thallium exposure resulting in urine Tl concentrations of 5–500 μg/L.

Toxicity

Urinary thallium concentrations following thallium intoxication are frequently reported in the range of 2,000–4,000 μg/L with potentially fatal cases associated with urine thallium concentrations exceeding 5,000 μg/L.[97] Painful paresthesias of the lower extremities, acne, gastrointestinal distress, stomatitis, scalp alopecia, and urinary retention developed in two patients after drinking thallium-contaminated water.[77] A few weeks after presentation, the urine thallium concentration was 11,325 and 14,520 μg/L. Both patients survived with partial improvement in sensory symptoms 6 months after presentation.

Hair

Examination of scalp hair roots showed that black pigmentation was present in 95% of cases after 4 days.[11] Little quantitative data are available to use hair analysis as an indicator of Tl exposure. Thallium may be incorporated into hair; therefore, external contamination complicates the interpretation of thallium concentrations in hair. Normal concentrations of thallium in hair typically range from 5–10 ng/g.[20] Most hair samples from the scalp, and to a lesser extent, from the chest and legs are positive in cases of thallium poisoning; however, hair from the eyebrows often does not contain thallium following Tl exposure.

Bone

Typically bones from individuals without exposure to thallium contain non-detectable concentrations (<0.01–0.05 μg/g tissue) of thallium. Analysis of the skull and thigh bones from a victim of thallium poisoning 29 years after death revealed thallium concentrations of 2.63 μg/g and 1.76 μg/g, respectively, as measured by laser ablation in combination with inductively coupled plasma sector field/mass spectrometry.[120]

Abnormalities

Blood

A slightly depressed serum potassium concentration and mild hypochloremic alkalosis probably reflect thallium-induced renal tubular dysfunction.[4] Lymphopenia, neutrophilia, and thrombocytopenia were associated with a fatal case of chronic thallium poisoning.[121] Laboratory abnormalities detected in a case series of 10 family members poisoned by Tl-contaminated cake included normochromic, normocytic anemia, thrombocytopenia, hyponatremia, hypokalemia, hypomagnesemia, and hypermagnesemia; the hypokalemia was attributed to the administration of Prussian blue.[85] Unlike lead poisoning, thallium intoxication does not alter coproporphyrinogen III or protoporphyrin IX concentrations.[122]

Imaging

Thallium is radiopaque in concentrated form; the radiographic appearance of thallium in the gut following Tl exposure is inconsistent depending on the amount of thallium present.[60] A hazy abdominal opacity on X-ray may correspond to thallium in the liver; however, the absence of radiopaque material in the gastrointestinal tract does not exclude the ingestion of a fatal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Tl dose.[123] A week or more after exposure, laboratory evidence of renal, liver, or muscle dysfunction may become apparent including hypointense lesions in T1-weighted images and hyperintense lesions in T2-weighted images of the corpus striatum during brain MRI.

Electrocardiogram

Electrocardiographic abnormalities include T wave inversion, ST-segment depression or elevation, prolonged QT interval, heart block, and both atrial and ventricular dysrhythmias.

Electrophysiology
