Chapter 42

COMPUTER SYSTEMS

MONITORS

The widespread introduction of video display terminals (e.g., desktops, laptops, tablets, smartphones) into offices and homes has raised concerns regarding the health effects of the old VDTs (video display terminals), including ocular hazards (e.g., dry eyes, visual fatigue),[1] musculoskeletal complaints, stress, facial dermatitis, and adverse pregnancy outcomes.[2] Radiation-related effects resulting from VDT emissions are highly unlikely because radiation levels are far below current standards of exposure.[3] Although chronic sequelae (cataracts, reduced visual acuity) are unlikely, VDT operators frequently report an increase in symptoms of eyestrain (pain, burning, irritation, blurring, diplopia), along with musculoskeletal complaints of stiffness and discomfort. Poorly designed workstations probably contribute significantly to the level of discomfort.[4,5] The facial rash associated with the electrostatic fields surrounding the VDT usually responds to adjustments in humidity and ventilation.[6] Public concern regarding VDT and reproduction developed in response to reports of small clusters of miscarriages and malformations among VDT operators; however, later case-control studies and the lack of teratogenic effects in animals did not support a causal association between VDT and adverse pregnancy outcomes.[7] In the early 1990s, researchers developed large-area active matrix arrays of electronic components that allowed the use of flat panel displays for laptop computers, desktop PCs, and televisions, replacing older video display terminals. Recent design improvements use a thin layer of silicon in an amorphous form rather than the crystalline form used in conventional microchips. The plasma-enhanced deposition of silane gas (SiH_4) produces an amorphous layer of silicon on glass.

EXPOSURE

Quantity

VDTs produce low radiation levels in the non-ionizing range, primarily between 50–100 Hz (ELF or extremely low-frequency range), 15–60 kHz (VLF, RF, or radiofrequency range), and 300–600 nm (ultraviolet and visible).[8] Horizontal deflection coils and the output lead of the flyback transformers (220 V AC power supplies) produce magnetic fields in the radiofrequency range, whereas vertical deflection circuitry produces magnetic fields in the ELF range. Typical electrical field strength for operators ~0.5 m from the screen is <10 V/m (RMS), while the magnetic flux densities in the ELF range are usually <0.1 μT (RMS) with a range up to 0.6 μT.[9] A study of 67 VDT operators measured the ELF magnetic field of these operators at 0.46 m during a typical 8-hour day. The 8-hour time-weighted-average geometric mean was 0.1 μT with a range of 0.03–0.36 μT.[10] Self-reported hours of VDT usage or self-reported distance between waist and VDT were poor surrogate measures of the actual magnetic field. The corresponding densities for VLF fields usually are <0.1 μT. The typical ELF magnetic flux densities in office environments that include printers, photocopiers, modems, scanners, low-voltage desk lamps, and calculators range from 0.1–0.65 μT.[11]

TABLE 42.1. American Conference of Governmental Industrial Hygienists (ACGIH) 8-hour threshold limit values (TLV) for occupational exposure to static magnetic fields and for magnetic fields in the sub-radiofrequency ranging from 1–300 Hz.

Exposure	Ceiling (T) Static Magnetic Fields	Ceiling (mT) Sub-radiofrequency Fields (1–300 Hz)
Whole body (general workplace)[a]	2	60/*f*
Whole-body special training or controlled environment	8	60/*f*
Arms and legs	20	300/*f*
Hands and feet	20	600/*f*
Medical electronic device users	0.0005	0.1

Abbreviation: f = frequency in Hz and value in mT.
[a] For workers in a controlled workplace environment with special training (i.e., aware of transient sensory effects from rapid motion and potentially hazardous metal projectiles in static magnetic fields with flux densities exceeding 2 T).

Neon-glow tube (plasma) and light-emitting diode (LED) displays do not produce very low-frequency fields above background levels.[12]

Field Types

The physical effects of the old VDT result from 1) alternating magnetic field strengths that leak from the magnetic field bending the electron ray; and 2) the electrostatic fields generated by the positively charged, translucent film on the inside of the front glass.[13] The strongest field in terms of energy density is the electrostatic field between the charged display screen and surrounding objects. The strength of this field depends primarily on humidity, the charge surrounding objects, and the duration of exposure.[14] The ELF magnetic field is the next strongest field.

Field Forms

The complex field wave forms are periodic, but not sinusoidal; therefore, the root-mean-square (rms) is the best description of the amplitude of the field. For a series of VDT, the maximum magnetic flux density in rms values at 30 cm from the screen was 0.74 μT in the ELF range and 0.14 μT in the RF range.[15] The glass screen absorbs most of the X-rays emitted by the cathode ray tube in the VDT, so the level of exposure to X-rays is low.[16]

DOSE-EFFECT

Measurements of radiation emissions from VDT indicate the radiation dose received by VDT workers is two orders of magnitude below standards set for ultraviolet, visible, and infrared radiation and at least one order of magnitude below standards for RF and ionizing radiation. The ACGIH guidelines for static and sub-radiofrequency magnetic fields are displayed in Table 42.1.[17] The ceiling value for static magnetic fields is 2 T, whereas workers with special training may tolerate static magnetic field densities up to 8 T. Guidelines for sub-radiofrequency fields are based on frequency. Workers wearing pacemakers should not be exposed to sub-radiofrequency fields (1–300 Hz) with densities exceeding 0.1 mT unless the manufacturer confirms that the pacemaker will tolerate higher levels without electromagnetic interference.

The radiation dose from VDTs usually is well below the currently recommended levels for ELF and RF radiation. A survey of VDT indicates the dose of X-ray radiation was $<3\times10^{-9}$ R/hour with the annual effective dose equivalent to <0.002 mrem.[18] Radiation from VDTs has not been clearly associated with adverse effects. The radiofrequency radiation emitted by VDTs is similar in intensity to that emitted by most household appliances.[19]

CLINICAL RESPONSE

Skin

Many reports of dermatitis associated with VDT use originate in Northern Europe, where relative humidity in heated rooms is low and the electrostatic fields in low humidity are relatively high.[20] The rosacea-like dermatitis begins with erythema and proceeds to small papules and mild desquamation.[21] A survey of 550 VDT operators in Sweden did not detect any rashes similar to the lesions reported in Norway; however, an excess

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

incidence of seborrheic dermatitis, acne, and rosacea appeared in this group of workers.[22] Adjustments in ventilation and humidity probably are more important causal factors than the use of electrostatic shields or the purchase of VDT models with low electrostatic emissions.[6] Later studies did not detect any significant difference in the prevalence of skin diseases between VDT operators and control groups without exposure, whereas the prevalence of subjective skin sensations increased in the VDT operators compared with unexposed controls.[23] Subsequent double-blind provocation testing of these "sensitive" workers did not indicate any reaction to electromagnetic fields.[24] Although work with VDT can increase the dose of radon absorbed by the skin under certain circumstances, the actual increase in radon dose is small; therefore, the contribution of VDT use to skin diseases (e.g., actinic elastosis, Civatte's poikiloderma) is negligible.[25]

Eye

The most frequent ocular complaints of VDT operators include eye fatigue, eye irritation, and blurred vision.[26,27] Symptoms of eyestrain frequently occur after extended, intense use of >4 hours/daily, particularly in poorly lit work areas and in persons over 40 years of age.[28,29] In a case series of 76 young Nepalese adults (mean = 25.8 ± 5 years) from a variety of occupations, the most common ocular complaints were tired eyes (88.2%), sore eyes (71.1%), blurred vision (64.5%), and dry/aching eyes (61.8%).[30] Headaches (85.5%) and musculoskeletal symptoms (e.g., neck pain, 67.1%) were also common. These participants used computers for a mean of 6.9 ± 2.6 hours daily. Decreased frequency of eye blinking and the subsequent increased rate of tear evaporation may contribute to dry eyes and ocular irritation.[31] The presence of glare increases eyestrain, but these effects are usually temporary and do not produce permanent sequelae.[32] The development of afterimages has been associated with the extended use of monochrome monitors.[33] Prolonged use of dark screens with green letters causes white letters on a contrasting background to appear pink (the McCullough effect). This visual aberration does not produce permanent damage; however, these aftereffects may last several weeks due to the adaptation of cortical neurons to specific combinations of form and color.[34] Antidotal case reports suggest an association between the development of cataracts and exposure to video display terminals. Subsequent studies have not confirmed this association.[35] Examination of 10 cataract cases demonstrated no clear cause-effect relationship; the ionizing radiation dose received by the VDT operators was 10,000 times below the threshold for radiation-induced cataracts.[36]

Musculoskeletal

VDT operators also frequently complain of musculoskeletal symptoms. Sharp shooting pain and stiffness of the back, neck, shoulders, and wrists are more common than discomfort of the arms, legs, and hands.[6] These effects occur most prominently in workers with conditions involving repetitive work with little variation; long, unrelenting sessions; and/or intense, visual concentration. Factors contributing to these musculoskeletal complaints include inadequately designed workstations, lack of exercise, repetitive tasks, personal traits, pace of the job, and stress. Musculoskeletal complaints are manifestations of stressors in the work atmosphere, along with illness, sleep disturbances, psychosomatic disorders, and nervous conditions.

Reproductive Abnormalities

Although data on VDT exposure and adverse outcomes other than fetal loss are limited (e.g., poor exposure data, low statistical power), current evidence does not support a strong association between VDT use and adverse pregnancy outcomes.[37,38] Several reports in the early 1980s on small clusters of miscarriages and congenital abnormalities in the offspring of VDT operators raised concern about the reproductive effects of VDT exposure; however, a dramatic decrease in the number of reported clusters of adverse pregnancy outcomes occurred after 1979–1982.[39] Several, but not most, case-control studies demonstrated slightly elevated odds ratios for spontaneous abortions among VDT operators, particularly women with more prolonged VDT use (i.e., 15–20 hour/week).[40,41] A retrospective, case-control study of clerical workers exposed to VDTs between 1975 and 1985 demonstrated an increased risk of spontaneous abortion (OR = 3.4, 95% CI 1.4–8.6) in women exposed to high levels (>0.9 μT) of extremely low-frequency magnetic fields early in pregnancy.[42] Recall bias may account for the weak effects observed in the positive studies.[43] Some of these studies used telephone interviews conducted several years after conception as a measure of exposure.[40] A retrospective case-control study of 932 infertile couples and 698 fertile couples recruited between 1991 and 1997 at university-based infertility clinics did not suggest an association between male infertility and VDT use based on self-reported

questionnaires.[44] The odds ratio was 0.30 with a 95% CI of 0.13–0.68.

Assessment of the exposure of the VDT operators to electric and magnetic fields is difficult because the strength of these fields varies with the type of VDT and the distance from the source.[45] Most systematic epidemiological studies have not confirmed the association between VDT and adverse outcomes of pregnancy, particularly studies with more detailed magnetic field measurements.[46] In a study of 882 pregnancies in 730 directory-assistance operators exposed during their first trimester, the odds ratio for a spontaneous abortion in the exposed women was 0.93 (95% CI: 0.63–1.38) compared with general telephone operators using LED or plasma displays (no very low frequency exposure above background).[12] The study did not detect an exposure-response relationship between VDT exposure and spontaneous abortion. For women exposed to VDTs for 1–25 hours/week, the OR was 1.04 (95% CI: 0.61–1.79) compared with 1.00 (95% CI: 0.61–1.64) for VDT exposure for >25 hours/week. Measurements of abdominal exposure to ELF fields (45–60 Hz) did not demonstrate a significant difference between women using VDTs and background ELF exposure (i.e., women using non-VDT displays). A survey of adverse pregnancy outcomes among 6,212 commercial and clerical workers did not detect an increased risk of medically verified spontaneous abortions in women using VDTs.[47] A UK case-control study of 150 nulliparous women with clinically diagnosed spontaneous abortion and 297 nulliparous women attending an antepartum clinic reported no increased risk of a spontaneous abortion in women using a VDT at work (OR = 0.9, 95% confidence limit 0.6–1.4).[48] A case-control study of 508 Italian women admitted for spontaneous abortions and 1,148 hospital controls did not demonstrate an association between VDT exposure and spontaneous abortion based on the self-reporting of VDT use.[49] The odds ratio for spontaneous abortion in the exposed women was 1.0 (95% CI: 0.8–1.2). The power of most of these studies was sufficient to detect modestly elevated risks of spontaneous abortions (i.e., >1.5).

A few studies demonstrated an association between VDT exposure and fetal abnormalities, but the measures of VDT exposure were indirect. Ericson and Kallen found a borderline statistically significant increased odds ratio of 1.6 (95% CI: 1.0–2.4) for any birth defect in VDT operators that increased to 2.3 (95% CI: 1.4–3.6) for women using VDT for >20 hours/week.[41] The study identified no specific congenital defect associated with VDT exposure. Goldhaber et al. found a nonstatistically significant increase in the odds ratio of 1.4 for birth defects in women working with VDT based on self-reporting of VDT use.[40] However, most epidemiological studies demonstrate no association between VDT exposure and fetal abnormalities.

A cohort study of 2,430 telephone workers and 713 live births found no excess risk of reduced birth weight (OR = 0.9, 95% CI: 0.5–2.7) or preterm birth (OR = 0.7, 95% CI: 0.4–1.1) when comparing VDT operators with nonexposed controls.[50] An Italian case-control study of 555 neonates with small-for-gestational age at birth reported no exposure-response relationship between VDT use and small-for-gestational age at delivery.[51] Estimates of exposure were based on company records and simulated studies of electromagnetic fields near representative VDT workstations. Case-control studies of women working with VDTs from Norway[52,53] and Denmark[54] also report no association between VDT use and congenital malformations. Radiation from VDTs was not mutagenic in the standard Ames Salmonella assay.[13] Currently, the weight of evidence does not support an association between VDT use and adverse outcomes of pregnancy.

HEALTH SURVEILLANCE

Although visual or musculoskeletal problems may occur following prolonged VDT use, proper equipment, unit design, technique, and work practices minimize these issues. Guidelines are available to improve workstation design, illumination, and work regimens. (https://chemistry.osu.edu/sites/chemistry.osu.edu/files/A%20Survival%20Guide%20to%20Computer%20Workstations.pdf). Static magnetic fields and non-ionizing radiation levels associated with VDT use are far below workplace guidelines and unlikely to cause serious clinical effects.

Workstation Design

Maximum flexibility is the most important aspect of workstation design.[55] VDTs should have detachable keyboards with height-adjustable tables and chairs. In addition, the backrest of the chair should accommodate the lumbar region to provide adequate back support. The viewing distance should be adjusted to the individual with average distances from the operator to the screen ranging from 45–50 cm. The viewing angle should average 10–20° with the top edge of the screen no higher than the eye level of the operator and the bottom edge of the screen no lower than 40° below eye level.[56]

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Illumination

Lighting levels should be set at ~500–700 lux, depending on the visual needs of the surrounding area. The illumination should be increased for tasks requiring the use of hard copy and decreased for tasks requiring screen-intensive work. Sources of glare should be controlled by the placement of the VDT with respect to windows and overhead lighting, proper illumination, and the use of glare control devices on the VDT screen surface. The use of hard copy material may require a supplemental light source. Recessed direct light sources and the addition of baffles to fluorescent fixtures may be necessary to reduce glare.

Work Regimens

VDT guidelines vary between countries.[57] Periodic breaks from work may be necessary depending on the demands of the job to reduce visual fatigue and musculoskeletal complaints. As a minimum, 10- to 15-minute breaks should occur after 2 hours of continuous work and sooner for repetitive tasks with high visual demand.[58] The US Department of Labor recommends 10-minute rest breaks after 2 hours of continuous VDT use for operators under moderate visual demands, whereas a 15-minute break after 1 hour of continuous VDT work is recommended when high visual demand or intense repetitive work tasks exist.[59]

Vision Testing

A comprehensive preemployment visual examination should include both near and far central visual acuity, muscle balance and eye coordination testing, depth perception, and color discrimination.[60] The need for testing during employment depends on the severity of the visual demands and individual responses to the visual demands.

LAPTOP COMPUTERS

The electrical circuits and power supplies in laptop computers produce electromagnetic fields (EMF). The physical interaction between EMF and the human body induces electric fields and circulating electric current that potentially may produce biological effects when the current density exceeds certain threshold values. The magnetic field associated with computers is impulsive (complex) rather than a sinusoidal waveform.

The EMF decreases with the square of the distance; consequently, induced electrical currents are higher during use of the laptop computer in direct contact with the body than during use of the laptop on a desk. In a study of five popular laptop computers using the voxel phantom model of a 26-week pregnant woman, the EMF levels of the computers ranged from 1.8–6 μT compared with 0.7–29.5 μT for the power supplies.[61] Although the estimated EMF values for the laptop computers were within International Commission on Non-Ionizing Radiation Protection (ICNIRP) guidelines,[62] the estimated electric current densities in the fetus and mother from direct contact with the laptops were 2–4-fold higher than ICNIRP guidelines. This study assumed a "worst-case" scenario involving the placement of the AC power supply very close to the mother's head and the computer next to the uterus. Additionally, the spatial distribution was modeled as a uniform field in close contact with the laptop; the fields were measured in field strength mode using a weighted peak approach for a complex waveform rather than RMS amplitude for a sinusoidal waveform.[63]

WIRELESS LOCAL AREA NETWORKS (WLAN)

A WLAN uses radio technology rather than direct wiring to connect local network nodes, and includes a set of devices capable of wireless communication over a restricted geographical area (e.g., school campus, home, business, airport); the two modes of network operation include: 1) infrastructure mode – all communication passes through a controlling access point within a Basic Service Set, and 2) *ad hoc* mode – communication passes directly between individual devices. Wi-Fi is a specific type of WLAN that conforms to Institute of Electrical and Electronic Engineers (IEEE) standards, and operates in the 2.4 GHz, 5 GHz, and 6 GHz bands to connect access points to client devices. Wireless devices (i.e., wireless network adapter or client card) communicate within the Basic Service Set (access points) that may be connected to a Distribution System of multiple access points (i.e., wireless router, wireless gateway, base station) to allow access to external network infrastructures (e.g., file servers, Internet). Wi-Fi technology exists throughout the world with "hotspots" in cafes, coffee houses, homes, train stations, airports, and other heavily traveled areas. The IEEE 802.11

standards specify band width and maximum radiated powers for WLAN devices during transmission. These devices operate primarily in the unlicensed 2.4 Gigahertz (GHz) Industrial, Scientific, and Medical Band 2,400–2,483.5 MHz (United States, 2.412–2.462 GHz unlicensed spectrum) and less commonly in the 5 GHz Unlicensed National Information Infrastructure frequency band (United States, 5.725–5.825 GHz licensed spectrum) with transmission rates up to 600 Mbps. The former bandwidth typically is 24 mHz wide; this spectrum is shared with Bluetooth wireless interfaces, cordless telephones, industrial heating, medical appliances, and microwave ovens. The maximum power in the 2.4 GHz range is 100 mW in Europe, whereas the limit for 5 GHz devices is 200 mW. These devices transmit with relatively low power for a small proportion of the time (i.e., low duty factor) to avoid monopolizing the system.

EXPOSURE

The use of Wi-Fi results in exposure to radiofrequency electromagnetic fields. The total radiofrequency exposure from a WLAN is the combination of exposure from access points and the client card with the closest source (i.e., typically the computer) accounting for the major contribution. The signals consist of intermittent bursts of radiofrequency energy, depending on duty factors. The Wi-Fi signal levels are typically far below other RF signals in the same environments. In a study involving 356 measurements of 55 US and European sites (homes, commercial spaces, education institutions, healthcare facilities), all Wi-Fi signals were very far below international exposure limits (IEEE C95.1-2005, ICNIRP).[64] Measurements were collected in public spaces as close as practical to Wi-Fi access points and ~1 m from laptops downloading and uploading large files from and to the WLAN. Using a 20 MHz bandwidth signal analyzer to measure radiofrequency power densities, the spherically integrated radiated power (IRP) for 15 laptops in the 2.45 GHz band ranged from 5–17 mW compared with 1–16 mW for 8 laptops in the 5 GHz band.[65] The IRP for 12 access points at 2.4 GHz ranged from 3–28 mW, whereas the power densities for 6 access points at 5 GHz ranged from 3–29 mW. The access points typically were wall-mounted with beams directed into the rooms, and their powers were integrated over a hemisphere. In general, the power densities were higher for access points than laptops. The maximum power densities of the laptops decreased from 22 mW/m^2 at 0.5 m to 4 mW/m^2 at 1 m, whereas the value for access points decreased from 87 mW/m^2 at 0.5 m to 18 mW/m^2 at 1 m.

DOSE-EFFECT

The low operating power of client cards and access points along with the short duty cycle of transmission limit the radiofrequency fields emanating from WLAN. The factors that determine the intensity of the radiofrequency field include the power output of the client card, antenna gain, and the duty factor (cycle) of transmission. The latter factor depends on transmission speed, signal quality, the presence of other access points or client cards using the same channel, and the capacity of the hardwired network connected to the WLAN. In a study of 55 private and public sites in the United States and Europe, all measured Wi-Fi signal levels were far below ICNIRP guidelines, and most background radiofrequency signals in these primarily suburban locations were higher than WLAN signals in the 75 MHz–3 GHz bandwidth as measured by the Narda SRM-3000 selective radiation meter (Narda Safety Test Solutions, Hauppauge, NY).[64] The median values of the power densities were ~0.001 mW/m^2 at 1 m from the laptops in the absence of uploading or downloading large files; the power density increased about 10-fold during those actions. The distance from the computer reflects field intensities in the far-field close to the computer (i.e., bystanders) rather than the near-field exposure of the computer user. The duration of monitoring was 40–120 seconds rather than the 6- or 30-minute exposure limit for ICNIRP guidelines. In a study of electric fields in 27 Belgian office locations with 7 WLAN networks, the mean dose was 0.12 ± 0.60 V/m (upper 95%, 0.90 V/m) in the 80 MHz–3 GHz range.[66] Research institutions use wireless sensor testbeds (WiLab) to evaluate wireless protocols or applications. The use of WiLab in this study resulted in an average electrical field exposure of 1.9 ± 1.41 V/m (upper 95%, 4.7 V/m), with a maximal measured electrical field value of 6.7 V/m at ≥1 m from the source.

International guidelines for limiting the thermal-related effects of exposure to radio frequency fields (e.g., International Commission of Non-Ionizing Radiation, ICNIRP) average power density exposures over time. The ICNIRP uses a 6-minute averaging period; consequently, analyzing the cumulative power density of WLAN requires applying the duty factor to the power density during transmission of the intermittent Wi-Fi bursts. In a study of 6 primary and secondary English schools, the duty factors ranged from 0.02–0.91% (mean = 0.08 ± 0.10%) for 146 laptops compared with 1.0–11.7% (mean = 4.79 ± 3.76%) for access points for 7 networks.[67] Using the data above, the maximal time-averaged exposure at 0.5 m from the laptop was 22 mW/m^2 with 1% duty factor and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. 22 mW/m^2 with 12% duty factor 0.5 m from access points. These values are well below the ICNIRP reference level of 10,000 mW/m^2. Based on the torso model of a 10-year-old child and assuming a 100 mW-burst power and 20 mW maximum power, the localized SAR will scale to 0.40 mW/kg. This value is also below the ICNIRP guideline of 2 W/kg for the general public.

CLINICAL RESPONSE

There are limited data on the health effects of WLAN; however, based on estimated exposure, radiation-related health effects are unlikely.

Chapter 43

NONIONIZING MEDICAL RADIATION

The nonionizing spectrum of electromagnetic waves ranges from extremely low-frequency electromagnetic waves to the ultraviolet portion. Energy in electromagnetic radiation varies directly with frequency and inversely with wavelength. Higher frequency is associated with greater energy and shorter wavelength. Ultraviolet waves contain the highest frequencies in the nonionizing electromagnetic spectrum; consequently, UV radiation contains the highest quantum energy. Nonionizing radiation contains enough energy to move atoms inside molecules or initiate vibrations of these atoms; however, the energy is insufficient to remove electrons. Nonionizing medical radiation (e.g., magnetic resonance imaging, ultrasound) uses low frequencies and low energy levels; some lasers use radiation from the higher frequencies in the ultraviolet range.

MAGNETIC RESONANCE IMAGING

Isidor Isaac Rabi first described the nuclear magnetic resonance (NMR) phenomenon in 1937; subsequently, he developed a molecular beam method for measuring the magnetic properties of atomic nuclei that earned him the 1944 Nobel Prize in Physics.[1] In 1946, independent observations by Felix Block and Edward Purcell first demonstrated the principle of the NMR phenomenon in liquids and solids.[2,3] They shared the Nobel Prize in Physics for their achievements in 1952. Erwin L. Hahn first used a spin-echo technique to analyze molecular diffusion in liquids; in 1966, Richard R. Ernst developed Fourier transform NMR spectroscopy.[4] He received the 1991 Nobel Prize in Chemistry. The first biomedical application of NMR occurred in 1971, when Raymond Damadian used NMR spin-echo techniques to distinguish malignant tumors from normal tissue by measuring T_1 and T_2 relaxation times in rats.[5] Paul C. Lauterbur and Peter Mansfield advanced the basis of current MR imaging machines by independently describing the use of time-varying magnetic field gradients to localize NMR signals in 1973.[6,7] They shared the 2003 Nobel Prize in Physiology and Medicine. The first magnetic resonance (MR) images of the human body were produced in 1977. In that year, Mansfield and Maudsley published MR images of the human finger with particularly good detail of the soft tissues.[8] The first whole-body MR scanner entered the commercial market in 1980; General Electric and Siemens produced the commercial scanners beginning in 1983. Subsequent advances in magnetic resonance imaging (MRI) pulse sequences, hardware (higher field strengths, improved coils), and novel techniques (magnetic resonance gating, gradient and spin-echo imaging, 2-D/3-D multislice imaging, fluid-attenuated inversion recovery, echo planar imaging, contrast-enhanced MR angiography, fat suppression, diffusion-weighted imaging, blood oxygenation-level dependence) dramatically improved the images and increased medical applications, including functional MRI and whole-body MRI.[1]

Magnetic resonance imaging (old term, nuclear magnetic resonance or NMR) depends on the absorption of nonionizing radiofrequency radiation by the magnetic moments of atomic nuclei in tissues placed

within a strong magnetic field. The production of images requires the following types of electromagnetic fields: 1) moderately strong, uniform static magnetic fields to align protons; 2) small, alternating magnetic fields for spatial orientation; and 3) pulsed radiofrequency waves to vary the energy states of the protons and create the electrical signal necessary for imaging. Consequently, the MRI machine consists of a main magnetic system, magnetic gradient coil, radiofrequency coil assemblies, associated power supplies, filters, amplifiers, and signal analysis, along with electronic and communications equipment. Differentiation of structures by MRI results from the modulation of nuclei within the tissue by the following parameters: 1) strength of the longitudinal magnetic field, 2) phase and strength of the transverse magnetic field, 3) resonance frequency, 4) T_1 (spin–lattice) longitudinal recovery time, and 5) T_2 (spin–spin) transverse relaxation time.[9]

PHYSICAL PROPERTIES

The image from MRI reflects the composition (i.e., proton density), chemical composition, and physical characteristics (T_1 recovery time, T_2 relaxation time) of the tissue.[10] Atoms with an odd mass number of protons and neutrons in their nuclei possess the quantum property of "spin," creating a dipole that can align along the axis of the applied magnetic field.[11] The spin number defines the value of nuclear spin. Certain atoms (e.g., $^1H^+$, ^{13}C, ^{19}F, ^{23}Na, ^{31}P) possess spin numbers of ½, useful for practical applications involving magnetic resonance. The principal MR active nuclei are hydrogen nuclei consisting of a single hydrogen atom; these nuclei have a relatively large magnetic moment and are abundant in water and fat molecules in the body. The inherent spin tilts and rotates the protons into similar alignment during the application of a static magnetic field (B_0), as displayed in Figure 43.1. The application of radiofrequency waves creates an oscillating magnetic field at a vector 90° to the static field. This varying magnetic field induces a phenomenon called *resonance*, wherein the protons absorb the radiofrequency radiation. As a result, the protons move into a state of excitation and out of alignment with the static magnetic field. Removal of the superimposed, oscillating gradient magnetic field allows the protons to return to equilibrium and the nuclei release the stored energy primarily in the form of signal composed of radiofrequency waves. A minimal amount of heating also develops during this process. The intensity of the emitted radiofrequency (RF) waves is proportional to the proton density in the tissue; mapping the emitted RF waves through computer algorithms using

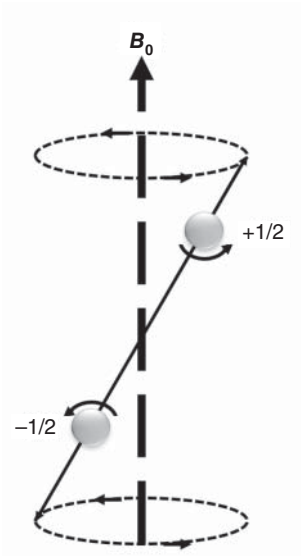

FIGURE 43.1. Precession of protons aligned with a magnetic field (B_0) applied during MR (magnetic resonance) imaging. (Tognarelli et al.).[11] Protons rotate like a spinning top about the longitudinal (vertical) axis of the magnetic field (B_0) with a precession (resonance) frequency proportional to the magnetic field strength. The magnetic vector of the spinning proton has a longitudinal component aligned with B_0 and a transverse or horizontal component related to movement about the longitudinal axis. Radiofrequency (RF) pulses of the same frequency as the resonance frequency change the energy state of protons by flipping the proton to the horizontal orientation. RF pulse strength and duration determine the flip angle. Once the RF pulse ceases, relaxation occurs with the conversion of stored energy to electrical energy, which creates a signal and subsequently a visual image.

Fourier transformation allows construction of an image of the tissue. The relationship between the emitted frequency and the field strength permits the localization of the site of the resonating nuclei.[12] The highest radiofrequency energy deposited in tissues during an MRI examination is ~6 orders of magnitude below the level required to produce ionizing radiation damage in tissue.

The T_1 (spin–lattice) recovery time represents the recapture of longitudinal magnetization parallel to the direction of the static magnetic field, whereas the T_2 (spin–spin) relaxation time characterizes the rate of signal decay after termination of the pulsed gradient radiofrequency and magnetic field. These parameters along with proton density refine the MR image of the tissue because of the diversity of the T_1/T_2 properties and the variation of proton density in different tissues. The T_1 spin–lattice or thermal recovery time represents the time for the nuclei to return to their equilibrium state in a longitudinal direction to the static magnetic field.

This value typically is 0.3–1 second. The T_2 spin–spin or transverse relaxation time represents the time required for the excited spinning nuclei to lose their alignment with other nuclei. This value usually is shorter (i.e., 0.2 seconds) than the T_1 spin–lattice time. Although T_1 and T_2 operate in all three planes, T_1 is predominantly longitudinal to the static magnetic field, whereas T_2 is mostly a transverse, collective phenomenon.[13] Differences in T_1 between tissues enhance the RF signal and improve the resolution between different tissue types.

EXPOSURE

Uses

Magnetic flux (Φ) is the flow of energy around a magnet measured in units called Webers (Wb). The amount of magnetic flux flowing through a given area around the magnet varies. To measure the flux at a specific time, the amount of flux passing through a unit area at right angles to the magnetic field lines is recorded as the flux density (B) at that point and measured in Tesla (T; $1\,T = 1\,Wb/m^2$).

Design

Cylindrical MRI scanners use superconducting magnets immersed in a bath of liquid helium at −268.93°C that surround the patient and produce static magnetic fields with magnetic flux densities typically 1.5–3 T. By the early 2010s, closed-bore (i.e., cylindrical) scanners represented the vast majority (i.e., ~90%) of MRI scanners.[14] The use of 3 T clinical MRI scanners substantially improves the signal-to-noise ratio, resulting in better image quality and reduced scan times.[15] Less common types of MRI scanner designs include open bore, horseshoe or C-shaped arms, and dipolar electromagnetic scanners with superconducting or resistive coils. A static fringe field gradient (<25 mT/m) acts as a slow, time-varying field during movement; the ever-present fringe field exists close to the bore during scanning (e.g., during interventional procedures). Active shielding reduces stray fields outside the magnet; however, these secondary coils increase the static magnetic fields near the inside end of the cylindrical bore. Thus, the static magnetic field inside the bore is nonuniform. The maximum absolute field strength in self-shielded short bore systems above the nominal field of the magnet occurs at the entrance to the bore along the inner bore edge of the magnet end. The value typically is a few percent above the specified field strength.[16] The static field magnet always remains on, resulting in the longitudinal alignment of the patient's hydrogen atoms with the static magnetic field when placed in the bore.

In addition to the superconducting magnets, three orthogonal magnetic field gradient coils produce rapidly changing spatially varying magnetic fields as they switch on and off superimposed on the static magnetic field. These complex, trapezoidal, time-varying magnetic fields facilitate spatial encoding. Radiofrequency coils produce a radiofrequency field that excites protons in the tissues to emit signals used to form MR images. The radiofrequency waves are usually 64 MHz for 1.5 T-systems and 128 MHz for 3 T-systems. MRI systems with static fields above 4 T use frequencies in the range of 200–400 MHz.

The transverse relaxation time (T_2) is the time constant for the exponential decay of magnetization in the transverse plane (transverse relation or spin–spin relaxation). After application of the RF pulse, the component of magnetization parallel with B_0 (static magnetic field) begins decaying to the equilibrium state (magnetization vector, M_0). The longitudinal relaxation time (T_1) is the time constant for the exponential decay of magnetization in the longitudinal plane (longitudinal or spin–lattice relaxation).[17] The pulsed radiofrequency fields vary between scanners with different static field strengths; various pulse sequences also use different amplitudes and waveforms of B_1 (time-varying radiofrequency magnetic field). Conventional spin-echo and fast spin-echo sequences that prolong the repetition time are required to overcome SAR (specific absorbed power) limitations associated with 3 T MR imaging; however, the increased T_1 relaxation times reduce T_1 contrast. T_1-weighted fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging techniques improve tissue resolution compared with conventional sequences.[18] The use of T_1-weighted, time-dependent (gradient) magnetic fields (dB/dt) superimposed on the static magnetic field for spatial resolution of tissue produces position-dependent variation in the absolute magnetic field strength.

Applications

The magnetic resonance (MR) examination consists of a series of individual sequences designed to display a particular orientation or be weighted to differentiate adjacent tissue types. The advantages of MRI include lack of ionizing radiation, sensitivity to flow and iron, multiplanar capabilities, and high soft tissue contrast resolution.[19] MR imaging is particularly useful for pregnant patients, patients requiring multiple scans, and pediatric patients. MR images produce high resolution for soft tissue based on the differences in the content of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

hydrogen protons in water and fat; however, the MRI signal is poor from cortical bone because the few protons in bone move minimally in the static magnetic field.[20] T_1 signals detail soft tissue anatomy better than T_2 images, whereas the latter relaxation time produces better resolution between different tissue types. The relatively slow scan time of MRI produces biological artifacts from motion, particularly respiratory movement, gastrointestinal tract peristalsis, and movement in the cardiovascular system.[21] The T_2-weighted spin echoes produce superior images of gray matter compared with similar images produced by CT scans. Ultrasound is the initial imaging modality of choice during pregnancy. MR is a nonionizing imaging alternative to ultrasound that provides a large field of view of the placenta and fetus with excellent tissue resolution of the brain, lungs, and abdomen, including images of suspected central nervous system anomalies, neck and oropharyngeal masses, diaphragmatic hernias, and fetal infections. MRI delineates abdominal and gastrointestinal tract masses inadequately examined by ultrasound.[22] Artifacts from maternal breathing and fetal movement limit the sequences available for pregnant patients. In contrast to ultrasound, obesity, oligohydramnios, fetal/maternal bone, and fetal lying do not reduce MR image quality.

MRI is very useful for imaging the central nervous and musculoskeletal systems, particularly the posterior fossa and base of the brain because bone artifacts reduce the sensitivity of CT scans. T_2-weighted MR images are sensitive studies for the detection of arteriovenous malformations and intracranial hemorrhage with the exception of acute subarachnoid hemorrhage; however, MR images are not necessarily superior to CT images for subacute or chronic hemorrhage because of the difficulty differentiating smaller acute hemorrhages from older hemosiderin deposits with MR imaging.[23] MRI is more sensitive to focal areas of cytotoxic cerebral edema than CT scans, particularly with diffusion-weighted images;[24] therefore, MRI is more effective than CT for abscesses and parenchymal brain infections (e.g., herpes simplex).[25] MRI is the most sensitive imaging technique for the detection of multiple sclerosis; however, the changes on MR images are not unique to multiple sclerosis.[26] For suspected spinal cord compression (e.g., lumbar disc herniations), MRI is the imaging technique of choice; however, CT scans more effectively delineate facet joints. MRI is an excellent imaging modality for the detection of torn menisci in the knee joint and the early detection of avascular necrosis.[27] For thoracicoabdominal diseases and the evaluation of patients with multiple traumas, MRI offers no clear advantage over CT or ultrasound.

MRI provides spatial maps and images using water signals from the tissues, whereas proton magnetic resonance spectroscopy (MRS) detects signals from tissue metabolites.[28] The difference in the magnetic resonance properties of water between normal tissues and tumors provides images that distinguish tumors from normal tissues. T_1-weighted spin-echo images provide relatively poor image contrast of brain tissue, particularly at low-field strengths. T_1-weighted fluid-attenuated inversion recovery (FLAIR) images use special sequences to improve the contrast between edematous lesions and normal parenchyma in the brain, particularly lesions in white matter and CSF.[29] Diffusion-weighted images (DWIs) measure water diffusion in normal/abnormal brain tissue and the CSF, resulting in the differentiation of normal and abnormal tissue (e.g., tumor, abscess). The DWIs of edema are hyperintense, whereas tumor tissues are hypointense. The use of the hybrid system involving PET/MR potentially allows whole-body MR screening for cancer,[30] particularly outside the brain when combined with DWI.[31] Whole-body MR imaging for lymphoma without DWI provides nonionizing radiation in contrast to the ionizing radiation of CT imaging.[32]

Magnetic Resonance Spectroscopy

Biomedical applications of nuclear magnetic resonance involve MR imaging and magnetic resonance spectroscopy. The latter is a research and whole-body clinical tool for analyzing normal and pathological biochemical processes in tissues using high-magnetic field strengths (11–14 T). The use of MR spectroscopy after MRI provides data on metabolic functions in addition to the anatomical data from the MRI; however, the sensitivity and spatial resolution of MR spectroscopy limit its use *in vivo*.[11]

Functional Magnetic Resonance Imaging

Functional magnetic resonance imaging (fMRI) is an MRI technique that correlates brain function and anatomy by detecting areas of increased blood flow during brain activity (brain mapping). This academic and medical research tool uses the blood oxygenation level dependent (BOLD) technique to detect changes in the cerebrovascular system based on different magnetic properties of oxygenated (diamagnetic) and deoxygenated (paramagnetic) blood.[33] The fMRI signal reflects the increased oxygenated blood concentration from vasodilation in areas of neural activity, particularly incoming synaptic activity rather than synaptic output from the region.[34] Hence, the BOLD signal is an indirect

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

measure of neural activity. Measuring regional blood flow limits resolution to the distribution of venules (1 mm) with whole brain scans typically exhibiting resolution of 3 mm. Additionally, random variation of the BOLD signal increases susceptibility to signal noise more than other methodologies.

Electromagnetic Fields

MRI requires three types of magnetic fields to produce three-dimensional images including: 1) a strong, constant B_0 (static magnetic field) to generate a magnetization vector (M_0) that reflects proton density; 2) transient magnetic field gradients with pulsed energy in the extremely low frequency kHz range (100–1,000 Hz) using each of three perpendicular axes (x, y, z) to localize aligned protons and allow spatial reconstruction of tissues; and 3) radiofrequency transmitter/receiver system with time-varying radiofrequency magnetic field (B_1) in the very high-frequency range (10–400 MHz) to enhance the magnetization vector for detection of the MR signal and reconstruction of the image by the scanner.[16] In the 1970s, the first research MRI machines operated at 0.4 T. By the early 1980s, 1.5 T machines had been introduced into clinical practice. The average magnitude of exposure to multiple electromagnetic fields during an MRI included: 1) static magnetic field ranging from 0.04–1 T, 2) varying magnetic field between 0.004–20 T/second, and 3) radiofrequency magnetic fields from 1–7 MHz.[35] Permanent superconducting magnets in MRI scanners generated static magnetic fields ranging from 0.2–3 T during operation in the 2000s.[36] Research applications (e.g., laboratory MR imaging instruments) now use higher static magnetic fields (i.e., up to 9.4–10 T) for whole-body patient scanning, requiring radiofrequency signals up to 400 MHz. The magnitude of the magnetic fields near the MRI scanner ranges from 1–10 mT, whereas stray static magnetic fields in the corridors near the MRI scanner extend up to 0.5 mT.[37] The ELF magnetic fields decrease much more quickly than the static magnetic fields; the ELF fields are minimal more than several meters from the magnet.[38] RF noise may be quite high within the area between the magnetic coils. The radiofrequency specific energy absorption rate (SAR) measures the heat produced in the tissue; the typical value is <0.1 W/kg as an average whole-body exposure with a peak SAR of <1 W/kg during a typical MRI scan.[35]

Static Magnetic Field

Magnetic fields are measured by magnetic flux density (magnetic field strength) in units of tesla (T). The exposure to static magnetic fields during an MRI is substantially greater than the average static magnetic field of the earth (~0.03–0.07 mT), the magnetic fields below high direct current transmission lines (0.02 mT), or older electrically powered public transit systems (0.7 mT).[39] The magnetic fields in the passenger cabins of magnetically levitated and conventional electric trains are relatively low (0.1 mT) compared with magnetic fields (several mT) at the floor level above inductors in the passenger coaches.[40] Audio headsets typically produce static magnetic fields in the range of 10 mT, whereas telephone receivers generate field strengths of 3.5 mT. The strength of the magnetic field decreases with the cube of the distance from the source. As outlined in Figure 43.2, the force applied to ferromagnetic objects is proportional to the static magnetic field strength (B), the field gradient (dB/dt), and the mass of the object. Hence, small ferromagnetic instruments, stretchers, and wheelchairs may move toward the longitudinal axis of the magnetic field. The field also applies torque to metallic objects (e.g., surgical clips, orthopedic implants) within the patient; this force depends on the strength of the field, the mass and shape of the object, the field gradient, and anatomical considerations (e.g., anatomic location, degree of attachment, type of structures surrounding the object).[41]

Gradient Magnetic Fields

Rapidly changing, lower amplitude gradient magnetic fields are superimposed on the static magnetic field to gain spatial information. The gradient magnetic field produces different resonant frequencies of aligned protons in the tissues that allow spatial localization of bidimensional MRI slices and subsequently the

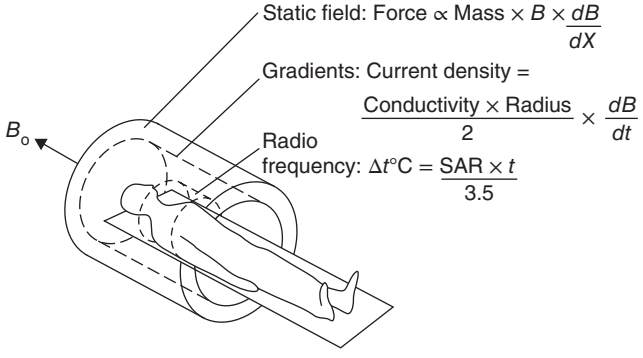

FIGURE 43.2. Three types of nonionizing radiation exposure during magnetic resonance imaging. (Budinger).[39] *Abbreviations:* B = static magnetic field strength; dB/dx = magnetic flux density; dB/dt = time-varying magnetic field gradient; SAR = specific absorbed power.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

reconstruction of three-dimensional images.[42] These gradient magnetic fields are switched on and off rapidly with varying maximum strengths depending on the particular pulse sequence and MR scanner; these imaging gradients are measured in units of milli-tesla/meter (mT/m). According to Faraday's law of induction, varying magnetic fields produce internal electrical currents in conductors (e.g., the human body) with the *potential* to stimulate nerves, muscles, and cardiac conduction. The frequencies of electric fields induced by these gradient magnetic fields (10–400 MHz) are substantially higher than the frequencies of fields created by movement in static fields (100–1,000 Hz). Modeling of the heterogeneous electric fields created by gradient magnetic fields indicates the largest electric fields occur in the periphery of the human body.[43]

Equation 43.1 describes the current density formed by time-varying gradient magnetic fields and the induced electric fields.

$$J = \rho \times r/2 \times \mathrm{dB/dt} \qquad \text{(Equation 43.1)}$$

where:

ρ = conductivity in siemens/meter,
J = current density in amperes/square meter,
r = radius of the loop in meters,
dB/dt = tesla/second.

The usual value of conductance (ρ) in the body is 0.2 siemens/meter (S/m), where the siemens is the reciprocal of an ohm. Using Equation 43.1, changes in the magnetic fields of 1 T/second induce current densities of 1 $\mu A/cm^2$ in the body. The estimated current density on the surface of the heart during a typical MRI scan is ~0.6 $\mu A/cm^2$.[44] A linear relationship exists between the rate of the varying magnetic field and the current density within a specifically shaped conducting body. Equations 43.2 and 43.3 estimate the relationship between varying magnetic field and current density in the human head and body.

$$\text{Human head: } 1\ \mathrm{T/second} \sim 0.01\ \mathrm{A/m^2} \qquad \text{(Equation 43.2)}$$

$$\text{Human body: } 1\ \mathrm{T/second} \simeq 0.015\ \mathrm{A/m^2} \qquad \text{(Equation 43.3)}$$

Radiofrequency Magnetic Fields

The radiofrequency electromagnetic radiation rotates the vector created by the static magnetic field with the time for the vector to return to equilibrium being different for each tissue. The subsequent two main imaging parameters (i.e., T_1, T_2) define image contrast created by different tissue properties. During an MRI examination, patients are typically exposed to electromagnetic radiation in the range of 8.5–340 MHz. This examination occurs in the "near-field" region; consequently, biological effects result from magnetic fields with little contribution from the electric field.[45] Exposure to RF radiation declines to insignificant levels outside the bore of the scanner. Thus, clinically significant RF exposure during MR scanning only involves the person inside the bore.

The air/surface interface reflects part of the radiofrequency (RF) radiation; the body absorbs the rest. The degree of penetration depends on the frequency of the radio waves. MRI devices operate in the range where relatively high absorption of energy occurs in the whole body (i.e., 20–300 MHz).[42] A 1 MHz wavelength penetrates 91 cm compared with 7 cm for a 100 MHz-radio wave. As a result of these properties, the skin receives the most exposure to radiofrequency radiation, whereas the subcutaneous tissue develops the greatest temperature elevation in response to currents induced by RF radiation. The primary consequence of the absorption of radiofrequency radiation is tissue heating. The specific absorption rate (SAR) is the mass normalized rate converting RF power to biological effect (local temperature elevation) defined by the total absorbed power in watts (W)/kg tissue. Thus, the SAR is the radiofrequency power absorbed per unit body mass. Equation 43.4 displays the approximate elevation in temperature/SAR.

$$\text{Change in Temp } (^\circ\mathrm{C}) = 0.29 \times (\mathrm{SAR} \times t) \qquad \text{(Equation 43.4)}$$

where:

SAR = specific absorbed power in watts (W/kg),
t = time in seconds.

All commercial MRI scanners have a display for the calculated SAR based on the patient's weight, static field strength (B_0), and scanner coil, assuming a standard RF pulse (rectangular pulse, 180° flip angle, 1 msec duration). Exceeding safety limits for SAR during an examination requires a reduction in the power deposition to the patient. Numerically simulated computer modeling of a 28-week gestation using 1.5 T and 3 T static magnetic fields indicated the mother received the highest local RF-induced heat (i.e., SAR) with the fetus receiving 40–60% of the peak SAR at 64 MHz and 50–70% at 127 MHz depending on the frequency, tissue mass used to average the local SAR, and the position of the mother relative to the magnetic coil.[46,47] The highest fetal SAR occurred in a limb; fetal movement complicates analysis of predicted maximum fetal SAR.

DOSE EFFECT

The presence of multiple electromagnetic fields complicates the quantification of clinical effects, including exposure to static magnetic fields, varying magnetic fields, and radiofrequency radiation. Potential hazards resulting from the use of MRI scans include: 1) static magnetic forces and electric currents induced by movement in these fields, 2) current induced in patients by varying magnetic fields, and 3) heating from the absorption of radiofrequency radiation.

Static Magnetic Fields

Large turning torques may occur in metallic objects with static fields at strengths below 2 T, creating mechanical hazards depending on the ferromagnetic properties of the metallic object in the static magnetic field. Thermodynamic factors suggest that changes in the conformation of enzyme structure do not occur at body temperatures below field strengths of 10 T.[48] Magnetic torque in tissues can orient diamagnetic biofluids (e.g., collagen, fibrin) and cells (osteoblasts, Schwann cells) following the application of field strengths of 8 T.[49] No mutations (sister chromatid exchanges, gross lesions) or lethal effects were observed in human cells exposed to static magnetic fields with a strength of 1 T.[50,51] A double-blind randomized crossover study of 36 volunteers exposed to a 1.0 T static magnetic field and a 2.4 T/second time-varying magnetic field from a passively shielded 7 T MR scanner did not detect statistically significant differences on a neurocognitive battery of eight tests when compared with the sham condition.[52] Subtle differences in test scores on the Rivermead Behavioral Memory Test (long-term verbal memory), Functional Acuity Contrast Test (visual acuity), and reaction time occurred when comparing volunteers exposed to the static magnetic field and the stray, time-varying magnetic field with scores on the sham exposure with head movement. However, the test scores did not comport with any focalized neurocognitive domain.

Sensory Effects

Adverse health effects from static magnetic fields below 2 T are not well documented.[53,54,55] A survey of 11 volunteers exposed to static magnetic field levels of 4 T reported vertigo, nausea (but not vomiting), metallic taste, and transient flashing light (magnetophosphene) during the course of their exposure in the previous year.[56,57] The number of self-reported experiences was significantly different than experiences reported by volunteers exposed to 1.5 T; the occurrence of headaches, hiccups, tinnitus, and numbness was not associated with exposure to static magnetic fields in this study. In an experimental study of 21 subjects performing controlled movements in the stray field of a 7-T scanner, 12 subjects detected a metallic taste during a 1.5-second episode of head shaking in the anterior/posterior direction to the magnetic field, causing a dB/dt of 2.3 ± 0.3 T/second.[58] The sensation of a metallic taste did not correlate to the presence of dental fillings.

Magnetohydrodynamic Effects

Magnetic fields (magnetohydrodynamic effect) can retard the flow of electrically conductive fluids (e.g., blood); therefore, more pressure is necessary to push the blood through the vessels. The magnetohydrodynamic slowing of blood flow is relatively small (i.e., <5% during fields <10 T); however, theoretical models predict the reduction may exceed 10% in 15 T magnetic fields.[59] An observational study of 25 healthy volunteers exposed to a 9.4 T static magnetic field at 105.92 MHz did not detect a statistically significant change in vital signs compared with baseline values, except a slight increase in blood pressure with increasing field strength.[53] An observational study of 10 human subjects exposed for 1 hour to 8 T detected no changes in body temperature, heart rate, respiratory rate, systolic/diastolic blood pressure, or ECG comparing before and after values.[60] Positive deflections occurred on T-waves with smaller, variable oscillations in amplitude during application of an 8 T-static magnetic field. Based on animal experiments, theoretical calculations indicate blood pressures within vessels are not altered at 1.5 T; however, blood pressure increases in field strengths of 6 T and 10 T by ~10% and ~28%, respectively.[39]

Cardiac and Nerve Conduction

Magnetically induced voltage changes occur during pulsatile blood flow in the aorta, resulting in increased T-wave amplitude. Animal experiments indicate the threshold for changes in the T-wave on the electrocardiogram is 0.3 T. T-wave alterations increase with increasing field strength; however, these electrocardiographic alterations are not accompanied by physiological changes (e.g., dysrhythmias, reduction in blood pressure).[61] Theoretical models predict the leakage of induced electric fields and currents for the pulsatile aortic flow in static magnetic fields may exceed maximum values of 100 mA/m^2; however, this value is ~10% of the maximum endogenous current density

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in magnetic fields of 5 T.[59] Field strengths of 10–17 mT may close the magnetic reed switch on a demand pacemaker, converting the cardiac pacemaker to the asynchronous mode. Most patients can tolerate the change to asynchronous mode for short periods of time.

Nerve conduction is more sensitive to temperature than static magnetic fields; studies in squid-axon model suggest that field strengths of 100 T are necessary to significantly disrupt nerve conduction.[62] In a study of 25 healthy volunteers, neuropsychological testing was performed before and after exposure to an experimental protocol involving a mock (0 T) and a 9.4 T scanner. The tests included working memory (Letter Number Sequencing), information processing speed (Symbol Digit Modalities), immediate/delayed memory and learning (Hopkins Verbal Learning), sustained attention (Gordon Diagnostic System), and a 9-item Brief Fatigue Inventory. The study detected no decline in the neuropsychological tests attributable to exposure to the 9.4 T MRI machine.[53] In an observational study of 10 volunteers exposed to 8 T for 1 hour, cognitive function did not change comparing tests before and after exposure as measured by literal and sematic fluency tests, the Mini-Mental Status Examination, and grooved pegboard test.[60]

Gradient Magnetic Fields

Potentially significant biological effects from the formation of induction currents in the body include the following: 1) stimulation of visual sensation (magnetophosphene), 2) nerve stimulation, and 3) induction of ventricular fibrillation. The development of visual flashes depends on the rate of magnetic field changes and the duration of the field. The threshold for the occurrence of these flashes is 2–5 T/second. Magnetophosphenes occurred in human volunteers exposed to 1.3–1.6 T/second with a 2-msec rise time and a repetition rate of 15–30/seconds;[39] the pulse duration of field changes during an MRI is usually 0.2 seconds or less. The threshold for stimulating muscles is approximately 1 million times greater than the current densities produced by MRI scans; pulsed field of 10^4 T/second is necessary to stimulate peripheral nerves.[53]

Excitation of muscle-nerve preparations does not usually occur below magnetic field fluxes of 3 T/second regardless of the pulse duration of the field.[41] Animal experiments indicate current densities near the level (3 mA/cm^2) present in nerve action potentials are required to cause seizures.[63] The threshold for the induction of ventricular fibrillation depends on a number of factors, including amplitude, time duration, waveform, and frequency. The ventricular fibrillation threshold for the human heart is ~0.3 mA/cm^2 (3 A/m^2) at the most sensitive frequencies of 10–100 Hz; this level is ~3–4 orders of magnitude above the current densities produced by a typical MRI scan.[64] Stimulation of nerves and muscles would occur *before* the induction of ventricular fibrillation based on the large current densities in these peripherally located tissues in contrast to the deep central location of the heart.[35]

Radiofrequency Magnetic Fields

The amount of temperature elevation depends partly on the ability of the body to dissipate heat. The basal metabolic rate in humans is 1.5 W/kg; the metabolic rate increases to 15 W/kg during heavy exercise. Evaporation and radiation are the primary processes for heat dissipation from the body; therefore, environmental temperature and humidity are important factors for heat dissipation. Heating from RF radiation is not necessarily uniform; hot spots may develop, especially near surfaces with large radii (chest) and areas with sharp curvatures (axilla, groin).[39]

When compared with baseline, an observational study of six healthy volunteers exposed to a whole-body-averaged specific absorption rate (SAR) of 6.0 W/kg demonstrated statistically significant ($P < 0.05$) increases in heart rate, cutaneous blood flow, tympanic membrane temperature, and skin temperature in the chest, abdomen, upper arm, hand, and thigh.[65] However, none of these changes were physiologically significant. A 70-kg man dressed in pajamas can tolerate a SAR of 8 W/kg. During a 20-minute scan at this intensity, the core temperature rose by <1°C, while skin temperature and blood flow increased substantially.[66] No elevation in the temperature of a stomach probe occurred in a healthy, 88.5 kg, 178 cm tall patient during a 2-echo, 10-slice MRI scan at 25 MHz (0.6 T) that lasted 20 minutes.[39]

HISTOLOGY AND PATHOPHYSIOLOGY

MR Imaging

Minimal magnetic susceptibility and the absence of ferromagnetic components limit the adverse effects of MR imaging in normal human tissue.[56] The short mean free paths (i.e., ~1 Å) and collision times (10^{-12} seconds) of nerve and muscle tissues also minimize the effects of magnetic fields on currents in neuromuscular tissues. Each of the three types of magnetic fields involved with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

MR examination produces different biological effects and safety hazards. Static magnetic fields potentially affect tissues by a variety of mechanisms including: 1) motion-induced currents, 2) magnetic force, 3) effect of magnetic field on moving electrical charges (Lorentz force), 4) magnetic torque, and 5) magnetic field-dependent recombination of reactive radical electron pairs.[67] Translational attraction and torque caused by the static magnetic field create movement and/or dislodgment of ferromagnetic objects in and around the human body. Low frequency (i.e., <1 Hz) static magnetic fields close to the MRI scanner induce electrical current in workers moving near the MRI scanner.[68] The induced electrical currents from movement in these nonhomogeneous, static magnetic fields are associated with transient sensory effects. Currently, there is no evidence of cumulative tissue damage following repeated use of MR imaging.[69]

Clinically significant health effects from radiofrequency radiation primarily involve heat generated during RF exposure. Adverse, nonthermal, clinical effects (e.g., blood pressure, heart rate, oxygen saturation, body temperature) from RF radiation during MR imaging are not well described in the medical literature. The amount of heat retained by the body depends on physical factors (frequency, power, repetition time, applied pulse sequence) and biological factors (specific heat of tissue, tissue sensitivity, size of current loop, conductivity, local perfusion, ability to lose heat). Spin-echo techniques typically use larger radiofrequency pulses for the 90° and 180° manipulation of tissue magnetization, resulting in higher SAR than gradient-echo sequences, particularly fast spin-echo techniques; however, certain high-speed gradient-echo sequences (e.g., time-of-flight MR angiography) also produce relatively high SAR. Altering operating procedures (e.g., ↓ flip angles, fewer slices, increased time between high and low SAR acquisitions, reduced room temperature) decreases SAR with some reduction in image quality. The currents produced by RF radiation and the SAR are negligible in areas of the body located more than several cell widths from the exposed volume of tissue.[70] Far-field approximations do not accurately characterize the SAR in a body scanned by MRI because the wavelength of RF radiation is much greater than the distance between the RF coils and the patient.

Gadolinium-Based Contrast Agents

Gadolinium (Gd)-based contrast agents (GBCAs) are nonspecific extracellular contrast agents commonly administered to enhance MR images with >300 million doses administered since their introduction in 1988; reported acute adverse reaction rates are low (0.07–2.4%).[71] GBCAs contain the MRI-active gadolinium ion (Gd^{3+}) and a carrier molecule (chelating agent) that binds gadolinium to prevent the release of free Gd^{3+} ion. The latter free ion and Ca^{2+} are similar-sized, resulting in the potential for free Gd^{3+} to replace Ca^{2+} in Ca^{2+}-binding enzymes. Intravenous administration of Gd^{3+} during an MRI shortens T_1/T_2 relaxation times and improves tissue definition. Macrocyclic and linear GBCAs can be ionic, nonionic, nonspecific extracellular, and tissue-specific, depending on the chelating agent. As defined by the retention of Gd^{3+} ion within the complex, rodent studies indicate macrocyclic chelates are thermodynamically more stable than linear chelates; ionic linear chelates are more stable than nonionic linear chelates, with the lowest tissue retention occurring following the use of nonionic, macrocyclic agents (e.g., gadoteridol).[72] The kidneys almost exclusively excrete these contrast agents. In patients with renal dysfunction, disassociation of the gadolinium complex occurs due to the extended retention of these substances in the body. In an observational, prospective pilot study of urine samples from 13 healthy subjects receiving IV gadolinium, their urine gadolinium concentrations remained above the current reference standard for >50 days based on reference standards using healthy subjects without previous gadolinium administration.[73] Although gadolinium deposition may occur in the brain (dentate nucleus, globus pallidus) and bone tissue following use of GBCAs in patients with normal renal function, the form of the gadolinium (i.e., free vs. chelated) is unclear.[74]

CLINICAL RESPONSE

Medical Exposure

Clinically significant adverse physiological effects and cognitive dysfunction are not well-established for patients undergoing MR imaging in static magnetic fields from current MRI scanners (typically 0.15–3 T), except for movements of *in vivo* metallic foreign bodies and disruption of cardiac pacemaker activity. Limited clinical data on the health effects of high static magnetic fields (i.e., >7–8 T) from MRI scanners used in research also suggest minimal adverse effects on physiological or neurocognitive function.[75] Much higher magnetic fields (i.e., 25–50 T) have the potential to cause neuromuscular stimulation and disruption of enzymatic processes. Cutaneous reactions (edema, erythema, burns) may occur when the material in contact with the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

patient conducts excessive RF-induced heat to the skin, including analgesic patches, cardiorespiratory monitors, tattoos, wires, pulse oximeters, athletic/"tech" clothing containing metallic microfibers, or inadvertent contact with the MR bore or coil.[76,77] In the absence of contact with metal, conduction of current through a closed loop formed by body parts (e.g., trunk and hand) may cause skin injuries.

Sensory Effects

Sensory effects associated with patients in MRI machines include vertigo, nausea, headaches, metallic taste, and transient flickering lights (magnetophosphenes).[78] The transitory sensations reported in these patients are dose-related with some individual sensitivity; however, these symptoms typically disappear after exposure ceases. Anxiety and suggestibility confound the interpretation of the mild, subjective effect associated with MR imaging. In a small observational study, mild vertigo, slight nausea, and metallic taste were more often reported by volunteers undergoing MR imaging in a 4 T scanner than a 1.5 T machine.[79] Responses to symptoms questionnaires by 504 individuals undergoing imaging in a 7 T MRI scanner indicated ~10% of these subjects developed transient vertigo and a sensation of spatial disorientation (e.g., leaning).[80] Reports of nausea, metallic taste, and magnetophosphenes were much less common. A meta-analysis of studies from 1992–2007 on the effect of static magnetic fields on neurocognitive function (visual processing, reaction time, eye–hand coordination, working memory), sensory perception, and vital signs demonstrated some dizziness and vertigo, primarily with movement during static magnetic field gradient exposures, and some impairment of vision (near visual contrast sensitivity).[81] Magnetic field strengths varied from 1.5–8 T. Although the results for visual impairment were consistent in the three studies, analysis of the effect sizes for homogeneity of neurocognitive effects including the visual system indicated the results were heterogeneous. The study did not detect any effects on vital signs during exposure.

Claustrophobia

A common adverse effect associated with MRI scans is the development of anxiety when the patient enters the narrow tube and the surrounding magnet; loud noises created by the switching RF fields simultaneously occur. Frequently, the patient must stay in this enclosed area for long periods of time; claustrophobia may prevent the completion of the investigation. Anxiety correlates to the constrictive dimensions of the magnet, duration of the examination, noise level, and temperature in the immediate space of the patient.[82] A detailed discussion of the procedure before initiation of the MRI open bore machines helps alleviate anxiety.

Metallic Objects

The magnetic fields created during MRI scanning exert translational forces and torque on metallic objects (e.g., surgical clips, pacemakers, joint replacements, shrapnel) present inside the body, depending on the mass, shape, and ferromagnetic properties of the object. The induced ferromagnetism depends on the composition of the metal alloys used to manufacture the metallic object including surgical clips.[83] Intracranial surgical clips may rotate depending on the composition of the clips; however, heating of surgical clips by RF radiation and varying field gradients is minimal.[84] Experimental evidence and modeling suggest the thermal effects of RF magnetic fields on orthopedic implants (e.g., osteosynthetic plates) are small.[85] High (16–35%) nickel content, cobalt, and iron demonstrate strong ferromagnetism, whereas clips composed of titanium or tantalum possess little ferromagnetism.[86] Inadvertent placement of ferromagnetic objects (e.g., wheelchairs, oxygen tanks) may result in the creation of dangerous projectiles, depending on the ferromagnetic properties and the distance from the bore entrance. Metallic leads placed on the patient may cause burns during MRI examinations.

Acoustic Noise

Loud acoustic noises (i.e., knocking, tapping, twittering sounds) occur during the rapidly changing current pulses portion of the MRI sequence; the intensity and frequency depend on MR imaging parameters and sequences; reductions in the field of view, repetition time, slice thickness, and echo time increase the noise.[87] Although previously thought to result from gradient coil design, the noise probably results from eddy current-induced vibrations of metal structures (e.g., cryostat inner bore, radiofrequency body coil) in the MRI machine.[88] The induced acoustic noise is related to the pulse sequence and dose; however, the latter value does not increase exponentially. In a study of fast pulse sequences on 14 MRI machines with static field strengths of 0.2–3 T, noise levels varied from 82.5 ± 0.1 dBA (A-weighted decibels) for a 0.23 T-system to 118.4 ± 1.3 dBA for the 3 T-system.[89] The noise level varied along the z-direction with a maximum near the bore entrance; the noise level depended more on pulse sequence parameters (field

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of view, repetition time) than field strength. Permanent acoustic trauma does not usually occur below a threshold of 140 dB in adults; these values are substantially above the noise levels produced by current MRI machines. However, safety concerns dictate the use of ear protection despite this relatively high threshold. Observational reports suggest mild temporary hearing loss manifests as a temporary threshold shift of hearing (>15 dB at 1 frequency within a few minutes after imaging ceased) following MR imaging without ear protection.[90] All threshold changes returned to baseline within 15 minutes after MRI imaging ceased. A study of 35 patients undergoing head and neck MR imaging with 3 T-machines used pure tone audiometry in a variety of different frequencies before and after imaging lasting up to ~45 minutes.[91] No threshold changes of >10 dB occurred in the group; all patients used 3M™ earplugs for the duration of the procedure.

Pacemakers

Magnetic field strengths greater than 1 mT can close the magnetic reed switch, converting demand pacemakers to the asynchronous (nonsensing) mode.[92] The threshold power density required to inhibit a pacemaker is ~15 mW/cm^2. Some pacemakers have ferromagnetic components that respond to magnetic fields by developing torque; critical electronic components may respond to magnetic fields by exhibiting nonlinear output. Both effects may disrupt pacemaker operation. Patients with pacemakers should not undergo MRI scanning unless the pacemaker is resistant to the influence of magnetic fields.[21] The induced currents with pulse widths of <3 msec are well below the values required to cause ventricular fibrillation.[93] Some MRI-safe pacemakers and intracardiac defibrillators (ICDs) are now available in the commercial US market following US Food and Drug Administration approval.

Gadolinium

Acute adverse reactions are uncommon, primarily involving mild, immediate hypersensitivity reactions (rash, lightheadedness, pruritis), and physiological reactions (nausea, vomiting, headache, paresthesia, coldness/warmth, dizziness, injection site pain). More serious allergic reactions may occur (bronchospasm, laryngeal edema, hypotension, cardiac arrest). Rarely, these patients develop widespread progressive tissue fibrosis (nephrogenic systemic fibrosis, gadolinium-induced fibrosis) involving the skin, lungs, myocardium, and/or striated muscles.[94] Changes in practice patterns (e.g., ↓ doses, screening for significant renal disease, use of low-risk gadolinium agents) have substantially reduced the incidence of this disease.[95] Even in patients with normal renal function, some storage of gadolinium occurs in the bone and brain; however, the clinically significant consequences of this deposition remain poorly documented by well-designed clinical studies.[96,97] Although an anonymous online survey associated generalized sensory symptoms with exposure to gadolinium contrast agents,[98] lack of clinical data and potential selection bias limit interpretation of the clinical significance of these reports. The patients did not report signs of movement disorders characteristic of lesions in the globus pallidus and dentate nucleus where gadolinium deposits usually occur. Nephrogenic systemic fibrosis remains the only proven disease associated with gadolinium-based contrast agents with no conclusive evidence to support a causal relationship between gadolinium-based contrast agents and specific symptoms.[99] Chelating agents are not currently recommended for patients reporting symptoms following gadolinium-based contrast agent administration because of inadequate evidence of efficacy and potential adverse effects.[96]

Occupational Exposure

Movement in low-frequency, nonhomogeneous static magnetic fields near MRI scanners may cause transient sensory symptoms including headaches, metallic taste, dizziness, nausea, vertigo, and magnetophosphenes (brief flashing lights during rapid eye movement in the magnetic field). An observational study of 361 healthcare and research staff working with MRI scanners suggests symptoms related to switching gradient fields (e.g., paresthesia, muscle contractions, vomiting) occur rarely.[100] In 633 diaries, these workers reported 2 episodes of tingling and no episodes of vomiting or muscle contractions. Epidemiological studies have not established a causal relationship between long-term occupational exposure to these electromagnetic fields and adverse long-term health effects; however, many of these studies lack appropriate controls and adequate exposure data. The workers did report some dentalgia, metallic taste, nausea, and disorientation when working with large magnets. A health questionnaire and clinical tests did not detect differences between workers with prolonged exposure to field strengths up to 0.2 T and controls.[101] Russian surveys of workers exposed to much smaller static magnetic fields revealed a number of excess nonspecific signs and symptoms (fatigue, blurred vision, dizziness, anorexia, pruritus,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

insomnia, diaphoresis, hypertension, paraesthesia); however, these surveys were poorly controlled.[35]

Reproductive Abnormalities

No adverse effects of MRI scanning on the developing embryo have been documented; however, animal research suggests that chick embryos are very sensitive to heat; human data on pregnant women exposed to electromagnetic fields are limited. Observational studies suggest neural tube and facial defects may occur in mothers experiencing prolonged high fevers (>39°C for ≥24 hours).[102] These *theoretical* concerns led to recommendations that MRI scanning not be performed in the first trimester; however, if imaging is necessary for the protection of the mother, MRI is preferable to ionizing radiation (e.g., CT scan). An analysis of 1,421 questionnaires distributed to MRI technologists in the United States did not reveal any major reproductive hazards associated with work near an MRI; there was a slight, statistically nonsignificant increase in the miscarriage rate.[103]

DOSIMETRY

Hall-effect gauss meters can measure static fringe magnetic fields with 3-axis probes that have a resolution of 0.01 mT.[78] Low-frequency EMF (e.g., static/gradient fields) analysis involves the use of impedance or finite element methods, whereas higher-frequency radiofrequency fields require analysis by finite-difference, time-domain, or finite element methods.[67] No standardized technique accurately measures the complex, nonhomogeneous, static, and time-varying electromagnetic field in a human during MR imaging. Measurement of SAR requires a phantom containing tissue-equivalent material. A few types of personal dosimeters are available to measure static and gradient fields using a magnetic field probe calibrated to simultaneously record the magnetic flux density $B(x, y, z)$ with a 3-axis Hall sensor and 3 orthogonal coils to quantify the induced voltage from movements within the magnetic fields. Experimental data indicate a 20-T Hall probe displayed relatively small measurement errors (i.e., up to ±3%) in field strengths of 0.03–3 T with decreasing sensitivity as a result of the saturation effects in the Hall elements.[104] Relatively large error (i.e., ±15%) occurred in fields of >5 T. Although induced electric field or current density are potential measures of the electromagnetic field, the complexity of these measurements limits routine daily assessments.[16] Therefore, estimation of fields in the occupational environment usually requires the use of simulated numerical models; these methods typically require complex body models and long computational times. Commercial models are available depending on the frequency of the electromagnetic field (EMF).[105]

HEALTH SURVEILLANCE

Patients

Guidelines

Magnetic Fields

MRI scanning involves patient exposure to static magnetic fields, time-varying (switched gradient) magnetic fields, radiofrequency fields, and acoustic noise. The International Commission on Nonionizing Radiation Protection (ICNIRP) recommended guidelines on the use of MR imaging based on their review of the existing scientific evidence in 2004[106] with an update in 2009.[107] The biological effects most likely to occur from MR exposures include: 1) vertigo and nausea during movement in the static magnetic field; 2) discomfort and pain from time-varying-induced electric fields and currents causing neuromuscular stimulation; 3) heating of tissue from radiofrequency fields; and 4) acoustic noise from the expansion and compression of coil mountings in response to Lorentz forces-induced interactions between static magnetic fields and electric current flowing through the gradient magnetic coils. The ICNIRP recommends the following 3-tier approach: 1) normal operating mode in routine MR examination (≤4 T whole-body static magnetic field exposure); 2) controlled operating mode for MR examination outside the normal operating rate that may cause discomfort and/or adverse effects (≤8 T for static fields); and 3) experimental operating mode for exposures outside the controlled operating range that require special ethical approval (progressively cautious approach for static fields >8 T). For time-varying gradient magnetic fields, the ICNIRP set 80% of the median perception threshold of nerve stimulation for normal operations and 100% for controlled operations. The median perception threshold was based on nerve stimulation data defined by an empirical equation as noted in Equation 43.5.[106]

$$dB/dt = 20(1+0.36/\tau)\ \text{T/seconds} \qquad \text{(Equation 43.5)}$$

where:

τ = effective stimulus duration, (msec)
= peak-to-peak variations in B/maximum time derivative of B during time period

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The basic ICNIRP restrictions for radiofrequency exposure limit the rise in core body temperature to 0.5°C for normal operating mode (head, 38°C; torso, 39°C; extremities, 40°C) compared with 1°C rise for controlled mode (head, 38°C; torso, 39°C; extremities, 40°C) and >1°C for restricted mode (head, >38°C; torso, >39°C; extremities, >40°C).

The UK Health Protection Agency Radiation Protection Division (successor of the UK National Radiological Protection Board) reviewed the ICNIRP guidance.[93] Table 43.1 displays the recommended limits of the UK Health Protection Agency (HPA) for patients receiving an MRI scan.

Acoustic Noise

Acoustic noise is a potential risk to patients undergoing MR examination at operating static magnetic levels of >0.5 T. Recommended limits are typically based on chronic occupational noise exposures rather than the relatively short-term noise produced by MRI machines. Recommended hearing protection varies with different organizations. The ICNIRP recommends offering hearing protection to patients when noise levels exceed 80 dB(A) and using hearing protection when noise levels exceed 85 dB(A).[106] The HPA, the US FDA, and the American College of Radiology encourage ear protection for all patients undergoing MRI procedures and require ear protection when the sound pressures exceed 99 dB(A).[108] Headphones usually provide superior noise protection during these procedures. The US Food and Drug Administration (FDA) considers MRI machines nonsignificant risk devices based on a safety threshold of 8 T.[109]

Safety Issues

The use of MRI scans is relatively contraindicated in patients with electrically, magnetically, or mechanically activated implants (e.g., pacemakers, ear implants, metal-containing prosthetic heart valves, neurostimulators). Issues of concern include the risk of acoustic noise, certain ferromagnetic implants, claustrophobia, and the *possibility* of adverse effects during pregnancy. Patients usually wear site-supplied gowns with no metal fasteners and all metallic objects removed, if possible, to reduce the risk of thermal burns from material conduction by RF radiation. Electrically conductive designs, silver-impregnated clothing, and metallic threads potentially may cause thermal injuries during MRI scanning. MRI examinations in patients with large metallic implants should occur only if the results of the scan are highly important to the diagnosis or treatment of the patient; MRI examinations are contraindicated in patients with ferromagnetic aneurysm clips and certain metallic implants. Objects should be checked against lists of implants and materials tested for safety and compatibility with MR systems.

Magnetic translational and rotational forces potentially may move these implants. If discomfort in the area of the prosthesis develops during the scan, the scan should be stopped immediately. The presence of metallic foreign bodies near anatomically important areas (e.g., eye, large blood vessels, nerves) requires special attention, including consideration of alternate diagnostic modalities and the use of low-strength fields. Patients with hemostatic clips should not undergo MRI scanning within the first 2 months after surgery.[110]

TABLE 43.1. The UK Health Protection Agency proposed limits for static, time-varying (switched gradient), and radiofrequency fields during MRI procedures. In general, the speed of moving patients within the bore should be limited to reduce vertigo and nausea. Controlled operating mode signifies MRI examinations done with field strengths outside the normal limits for routine examinations because special medical circumstances justify the benefit of exceeding normal limits. Experimental operating mode represents field strengths above controlled operating mode; these procedures require the approval of an ethics committee. (Modified from Centre for Radiation, Chemical, and Environmental Hazards, Health Protection Agency).[93]

Guidance	Routine Operating Mode	Controlled Operating Mode	Experimental Operating Mode
Static field (*T*)	4	8	>8
Time-varying field[a]	80	100	120
Radiofrequency fields			
Core temperature rise (°C)	0.5	1	2
Temperature limits (°C)			
Head	38	38	39
Trunk	39	39	40
Limbs	40	40	41

[a] % of median perception threshold.

Monitoring critically ill patients is difficult during MRI scanning. Most anesthetic equipment contains ferromagnetic parts. Nonferromagnetic transducers should be used to monitor cardiorespiratory functions. Distortion of the ECG from electromagnetic interactions with the ECG during MR scanning limits useful data. Current physiological monitoring devices, instruments, and pacemakers are more MR-compatible. The use of metallic leads to connect the body to external monitoring equipment during MR scanning may cause RF-induced skin burns. If resuscitation is necessary, the patient should be placed quickly on a nonmetallic stretcher and removed to an area beyond the 5 G line.[111] Electroconductive materials inside the bore require thermal insulation; as much as possible, the electrically conductive material should not directly contact the patient during imaging. The static fringe magnetic field near the magnets of the MR system may be strong enough to attract ferromagnetic objects; these metallic objects may become dangerous projectiles and should be removed from the examining room to eliminate the risk of traumatic injuries.

The American College of Radiology recommends a 4-zone model for MRI facilities including Zone I, entrance to the outpatient registration areas; Zone II, lockers, waiting room, and area for screening of previously unscreened MRI patients; Zone III, MRI control area accessible only to MRI personnel, and Zone IV, room housing the MR scanner.[112] Other than the patient undergoing MR imaging, the latter two zones are restricted to MRI personnel and required healthcare workers. All MRI patients undergoing nonemergent MR imaging should be screened twice for magnetically, electrically, and mechanically activated devices (pacemakers, cochlear implants, joint replacements), metal implants, shrapnel, tattoos, and permanently implanted eye shadow and body piercings by personnel trained to detect ferromagnetic material. Assessment of implants for magnetic field strength compatibility includes evaluation of device identification cards, medical records, manufacturer websites, online sources (www.MRIsafety.com), and handheld ferrous metal detection devices.[113]

Pregnancy

Although clinical data are limited on the reproductive outcomes of MRI examinations during pregnancy, MR imaging is an option for pregnant patients because the MRI uses nonionizing radiation and there is little clinical evidence of documents subsequent to reproductive abnormalities including after the administration of gadolinium contract media. The latter agents improve the contrast in MR images by lowering T_1 relaxation times to create better T_1-weighted signals during MR scanning.[114] In a retrospective, population-based cohort study of >1.4 million pregnancies in Ontario, Canada, the use of MRI during the first trimester of pregnancy (gestational weeks 2–14) was not associated with a statistically significant increased incidence of stillbirths and neonatal deaths, neoplasms, hearing loss, or congenital anomalies.[115] After adjustment using inverse probability weighting, the adjusted relative risk of stillbirths and neonatal deaths following maternal MRI was 1.68 (95% CI: 0.97–2.90), compared with an adjusted hazard ratio of 1.16 (95% CI: 0.96–1.40) for congenital anomalies. Pregnant patients may undergo MR scanning at any stage of pregnancy if risk–benefit analysis favors the MRI study based on the importance of the clinical information, the need to obtain the information during the pregnancy, and the inability to obtain the information by other, nonionizing techniques (e.g., ultrasound).

In contrast to ionizing diagnostic radiation, potential fetal risks from MR imaging are nonstochastic (teratogenic, acoustic-related fetal hearing loss) rather than teratogenic or carcinogenic. Clinical data are limited; a prospective cohort study of 26 pregnant women exposed to gadolinium derivatives during their first trimester did not demonstrate adverse effect on pregnancy and neonatal outcome.[116] In the large Canadian cohort study, the use of gadolinium-enhanced MRI was associated with a higher risk of stillbirth or neonatal deaths and rare adverse outcomes in offspring (i.e., broad set of rheumatological, inflammatory, or infiltrative skin conditions); however, the confidence limits were large. The adjusted relative risk for stillbirths/neonatal death was 3.70 (95% CI: 1.55–8.85), whereas the adjusted hazard ratio for the rare nephrogenic systemic fibrosis-like conditions was 1.00 (95% CI: 0.33–3.02). The incidence of congenital anomalies was not increased in the gadolinium group. Although currently there is no evidence that the electromagnetic fields associated with MRI scans adversely affect human development, *in vivo* studies and theoretical predictions suggest the *possibility* of adverse fetal effects because heat is a potential teratogen.[117] Therefore, MRI scans should be performed during the first trimester of pregnancy only when a clear medical indication exists and when alterative imaging procedures are not appropriate.

Animal studies indicate repeated, supra-clinical doses of gadolinium contrast agents cause skeletal and visceral abnormalities, growth retardation, and fetal loss (US FDA category C).[118] Adverse reactions to the administration of gadolinium contrast agents are uncommon; the main adverse reactions during MR examinations include nausea, urticaria, taste disturbances, anaphylactoid reactions.[119] In patients with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

renal insufficiency, nephrogenic systemic fibrosis is a serious late sequelae of gadolinium administration, and is characterized by dermal thickening, induration, subcutaneous edema, joint contractures, and limited mobility primarily in the extremities.[120] The presence of gynecological devices (e.g., intrauterine devices) is not a contraindication for women undergoing MR imaging in static fields of ≤3 T.[121]

Currently, there are no reports confirming adverse reactions in infants breastfed by mothers receiving gadolinium-based contrast agents; however, the use of these contrast agents is controversial because gadolinium is water-soluble and crosses the placenta. The European Medicines Agency suggests interrupting breastfeeding for >24 hours after receiving gadolinium-diethylenetriamine penta-acetic acid (Gd-DTPA).[122] The American College of Obstetricians and Gynecologists does not recommend interruption of breastfeeding after maternal gadolinium administration based on the small amount of gadolinium absorbed by the fetus (i.e., 0.0004% of the maternal dose) and the lack of reported adverse effects.[123] In a study of 16 radiopharmaceuticals (^{99m}Tc-DTPA, ^{99m}Tc-HMPAP-leucocytes, ^{99m}Tc-MAA, ^{99m}Tc-MAG3, ^{99m}Tc-MDP, ^{99m}Tc-MIBI, ^{99m}Tc-pertechnetate, ^{99m}Tc-*in vivo* RBC, and ^{99m}Tc-tetrofosmin; ^{14}C-GCA, ^{14}C-triolein, ^{18}F-FDG, ^{51}Cr-EDTA, ^{125}I-iodohippurate, ^{131}I-iodohippurate, ^{131}I-NaI) administered to 53 breastfeeding patients, the total fraction of administered activity excreted in breast milk varied from 0.0057% (^{99m}Tc-*in vivo* RBC) to 48% (^{131}I-NaI).[124] Based on an effective dose limit of 1 mSv for infants, cessation of breastfeeding following ^{131}I-NaI administration and interruption of breastfeeding for 12 hours after radiopharmaceutical administration were recommended for ^{125}I-iodohippurate, ^{131}I-iodohippurate, and ^{99m}Tc-pertechnetate. Interruption of breastfeeding for the remaining radiopharmaceuticals was not recommended.

Workplace

Occupational exposure during MR scanning primarily involves static magnetic fields (B_0); in addition to fringe B_0 fields within 0.5 m of the bore entrance, the possibility of exposure to switched gradient magnetic fields (dB/dt) exceeding current reference levels may occur if the worker stays close to the scanner during image acquisition.[78] Maximum dB/dt exposure occurs as the radiographer undergoes a fast translational or bending motion near the magnet bore inner edges.[125] B_0, dB/dt, and B_1 rapidly decrease with distance from the bore entrance. Guidelines for occupational exposure to electric fields frequently use values expressed as the root mean square (RMS). The RMS value of time-varying functions (e.g., dB/dt, B_1) is the square root of the mean values of the function squared [i.e., $\sqrt{(x_1)^2 + (x_2)^2 + (x_3)^2 + \cdots + (x_n)^2/n}$].

Exposure

During traditional diagnostic MR examination, the staff typically is exposed only to static magnetic fields for a short duration while positioning the patient.[126] Exposures to gradient or radiofrequency fields occur only if patient care requires the staff to remain in the MR room during scanning. The exception is interventional radiographers treating patients in the scanner room during imaging; these staff are potentially exposed to gradient fields exceeding induced current density guidelines. However, static magnetic and radiofrequency field guidelines are usually not exceeded. Wide variation in static field exposures of radiographers in clinical MR units occurs between individuals and various sessions depending on workplace activities, scanning parameters, personal characteristics (e.g., height), and field strengths. Peak and time-weighted average (TWA) exposures in a study of 324 observations of 224 workers increased by 30–76% per 1 T-increase in the static field strength near a whole-body, closed-bore scanner, varying with exposure parameters listed above.[127] In a study of 19 radiographers using a 1.5 T MRI machine over 91 days at 4 clinical units, the mean 24-hour time-averaged static field strength was 1.8 ± 1.0 mT with a range of 0.2–6.6 mT.[128] The maximum static field strength during patient setup was 554 mT. Time-varying gradient field strength potentially exceeded ICNIRP action values up to 30 cm from the bore entrance. In a study of engineers monitored with personal dosimeters during the testing and optimization of 3 MRI systems (1.5 T and 3.0 T cylindrical whole-body scanners, 1.0 T whole body open system), peak exposures ranged from 277–944 mT/second for the 1.5 T closed system with a TWA of 1.48–44.63 mT compared with 187–3,975 mT/second for the 3.0 T closed system with a TWA of 1.23–33.52 mT.[105] The 1.5 T open system had peak exposures ranging from 54–504 mT with a TWA of 1.61–36.00. Table 43.2 lists the common ranges of magnetic field properties during the operation of the MRI machine. Occupational exposure to static fringe field gradients occurs when MR workers move in the field close (i.e., 0.5 m) to the bore during scanning including MRI guided interventional procedures (e.g., biopsies), particularly in open bore machines. Usually, MRI technologists spend only approximately 10% of their work

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 43.2. Characteristic ranges of exposures to magnetic fields during MR imaging procedures. (Adapted from McRobbie).[78]

Field (Location)	Range	Frequency	Duration
Static[a]	0.2–7 T	0 Hz	Continuous
Fringe static[b]	0–25 T/m	0 Hz	Continuous. Movement within field simulates slow, time-varying field
Imaging gradients[a]	0–50 mT/m	0–>10 kHz	Intermittent multiple trapezoidal pulses lasting few msec and repeated rapidly up to 200 T/m-second. 0.1–1 msec rise time
Radiofrequency[a]	0–0.5 mT	8–300 MHz	Amplitude-modulated pulses lasting few msec with low repetition rate

[a] Inside bore, [b] Adjacent to bore.

time in the magnet room, while the rest of their time is spent in the control room or in adjacent work areas. ICNIRP reference levels are rarely exceeded outside the bore; however, movement-related exposures (e.g., monitoring general anesthesia, MRI-guided interventional procedures) may exceed ICNIRP low-frequency reference levels, particularly with motions of 1 m/second within 0.5–1 m from the magnet.[78,129]

A study of six Neonatal Intensive Care Unit (NICU) nurses using personal dosimeters demonstrated a geometric mean for the 12-hour shift-time-weighted average magnetic field exposure of 0.17 μT compared with 0.11 μT for six other neonatal nurses in the normal newborn nursery.[130] The NICU nurses had a greater portion of their shift time exposed to magnetic fields of >0.4 μT compared with nurses in the normal newborn nursery. In a study of an Italian NICU, the typical magnetic flux density (50 Hz) in the rooms of the unit was <0.2 μT, whereas higher values occurred close to medical equipment and inside the open infant warming systems.[131]

Guidelines

The limits and reference levels currently proposed by various organizations display large variations as a result of the application of different methodologies, including the values promoted by the International Commission on Nonionizing Radiation Protection (ICNIRP), the International Electrotechnical Commission (IEC), the Institute of Electrical and Electronics Engineers (IEEE), and the UK Health Protection Agency Radiation Protection Division (successor of the UK National Radiological Protection Board). The goal of the basic restrictions typically is the avoidance of short-term, acute adverse effects defined by induced electric field (E_i), using the root mean square (rms) value as the statistical measure of the magnitude of the varying electric field. Induced fields are not directly measurable in the body.

Static Magnetic Fields

In 1991, the National Radiological Protection Board (predecessor of the UK Health Protection Agency Radiation Protection Division) established a 2-tier standard based on a lower safe level and a higher level where exposure should occur only under controlled conditions by knowledgeable workers trained to recognize and minimize any health risks.[132] These recommendations were initially based on the prevention of nausea, vertigo, decreased aortic blood flow, and elevated systolic blood pressure at static magnetic field strengths above 4 T. The NRPB revised the guidelines in 2004 to recommend a whole-body, time-weighted average exposure of 0.2 T (e.g., 32 minutes for 3 T exposure, 64 minutes at 1.5 T), an instantaneous ceiling limit of 2 T for the trunk/head, and 5 T ceiling for limbs.[133] The ICNIRP recommends a 2 T ceiling, but the guidelines allow peak exposures up to 8 T in controlled situations where trained workers can avoid adverse effects by altering work practices.[134] Table 43.3 lists the ICNIRP guidelines for exposure of workers and the general public to static magnetic fields as a means to reduce adverse sensory effects from movement in the static and fringe magnetic fields. The 0.4 T limit for the general public is below the 0.5 mT limit for protection of medical devices against flying metal objects with ferromagnetic properties sufficient to produce substantial mechanical forces in static magnetic fields. Caution is also required for workers wearing implanted ferromagnetic or electronic medical devices (pacemaker/defibrillators, insulin infusion pumps, neuromuscular stimulators, operated prosthetic devices for limbs and inner ear), particularly when the static magnetic field exceeds 0.5 mT.

Static Fringe Magnetic Fields

Movement in static fringe fields induces fields within tissues that vary with speed of movement, induced electric field, and frequency. Exposure limits are designed to avoid sensory effects resulting from the induced electric fields and the subsequent induction of electric currents

TABLE 43.3. International Commission on Nonionizing Radiation Protection (ICNIRP) guidelines for exposure to static electromagnetic fields. (Adapted from International Commission on Nonionizing Radiation Protection).[134]

Exposure Limit (Location)	Type of Exposure	Value (Magnetic Flux Density, T)
Occupational – head/trunk	Spatial peak	2 T[a]
Occupational – limbs	Spatial peak	8 T[b]
General public–any part of the body	Continuous	0.4 T

[a] Exposure up to 8 T can be justified for specific work if the environment is controlled and appropriate work practices are implemented to control movement-induced effects. [b] Inadequate information is available to recommend exposure limits >8 T.

TABLE 43.4. Exposure limits for low-frequency occupational exposure from movement in static and fringe fields as expressed in peak values. (Adapted from McRobbie).[78]

Institution	Region, Induced Fields	Frequency (Hz), Induced Fields	Induced E_i, Induced Fields (V/m)	Reference Level (Equivalent dB/dt, T/Second)
NRPB[a]	Head/trunk	<1	0.56	1.8 f (range 0–1 Hz) Peak B = 280 mT
ICNIRP	Head, CNS	1–10	0.7/f	1.8/f with range 1–8 Hz Peak B = 280 mT/f
	All head/body	1–3,000	1.1	

[a] The value is converted to induced electric field from the values published as current densities by assuming CNS conductivity is 0.1 S/m and $J = 40\,\text{mA/m}^2$; f = frequency in Hz.

in the body. Table 43.4 compares the exposure limits of the NRPB and the ICNIRP for low-frequency occupational exposure to induced electric fields resulting from movement in static magnetic fields.

Time-Varying Gradient Fields <100 kHz

The guidelines are designed to prevent the stimulation of neuromuscular units by the induction of currents in the central and peripheral nervous systems (and other excitable tissues) from time-varying magnetic fields. The basis for ICNIRP values is their analysis of data from experimental visual phosphenes studies and MRI studies on peripheral nerve stimulation thresholds.[135,136] Table 43.5 compares NRCP and ICNIRP guidelines for MRI imaging gradients. The ICNIRP value of 2.6 T/second for frequency ranges of 300–3,000 is most relevant to certain fast MRI sequences; ICNIRP peak values apply to CNS tissues in the head and any tissue in controlled situations.

Radiofrequency Fields

The basic ICNIRP (and IEEE) restrictions use whole-body SAR of 0.4 W/kg as a time-weighted average for 6 minutes; this value is 10% of the suggested limit to avoid body temperature elevations exceeding 1°C from RF magnetic field-induced heating. Most accidental burns from RF radiation result from hot spots caused by conducting material close to the person; compliance with average whole-body SAR does not necessarily guarantee the absence of hot spots. Table 43.6 displays the ICNIRP occupational exposure limits to MR imaging gradients.

Pregnancy

Pregnant healthcare practitioners may work throughout all stages of their pregnancy in and around the MR environment during archiving, injecting contrast, emergency treatment, and positioning patients prior to examination. In a survey of 280 MR-exposed technologists and nurses, the relative risk ratio for spontaneous abortions in exposed workers compared with controls (employees at other jobs) was 1.27 (95% CI: 0.92–1.77).[137] The relative risk (RR) for delivery before 39 weeks was 1.19 (95% CI: 0.76–1.88), whereas the RR was 1.01 (95% CI: 0.50–2.04) for birth weight of <2.5 kg. Adjustment for maternal age, smoking, and alcohol use did not markedly change any of these values. Although allowing pregnant workers around MRI scanners is permissible, they should not usually remain in the scanning room during data acquisition or scanning.

TABLE 43.5. Occupational exposure limits for time-varying gradient fields as expressed in peak values. (Adapted from McRobbie).[78]

Institution	Region, Induced Fields	Frequency (Hz), Induced Fields	Induced E_i, Induced Fields (V/m)	Reference Level (Equivalent dB/dt, T/Second)
NRPB[a]	Head/trunk	4–1,000	0.28	0.22 (range 25–820 Hz).
				Peak $B = 35/f$ mT as peak spatial average over body
		1,000–100,000	$f/14{,}000$[b]	$0.00027f$ (range 820–65,000 Hz).
				Peak $B = 0.043$ mT as peak spatial average over body
ICNIRP	CNS head	25–400	$0.0028f$	0.0088 (range 25–300 Hz).
				Peak $B = 1.4$ mT as peak spatial average over body
		400–3,000	1.1	2.6 (range 300–3,000 Hz).
				Peak $B = 420/f$ mT as peak spatial average over body
	Everyone in controlled environment	1–3,000	1.1	—

Abbreviations: E_i = electric field strength measured by the arithmetic average as determined over a straight line segment of 0.5 cm length oriented in any direction within the tissue, ICNIRP = International Commission on Non-Ionizing Radiation Protection, NRPB = National Radiological Protection Board.

[a] The value is converted to induced electric field from the values published as current densities by assuming CNS conductivity is 0.1 S/m and $J = 40$ mA/m^2. [b] f = frequency in Hz.

TABLE 43.6. International Commission on Nonionizing Radiation Protection (ICNIRP) radiofrequency limits applicable for occupational exposure to MRI machines imaging gradients. The values are averaged over 6 minutes. (McRobbie).[78]

Exposure Limit	Value
Basic restriction	
SAR (10–400 MHz)	0.4 W/kg
	10 W/kg localized over 10 g head/trunk tissue
	20 W/kg localized over 10 g limb tissue
Reference levels	
Electric field strength (E)	61 V/m
Magnetic field strength (H)	0.16 A/m
Magnetic flux density (B)	0.2 μT
Power density	10 W/m^2

ULTRASOUND

Diagnostic ultrasound provides a pulsed wave instead of the continuous wave produced by therapeutic ultrasound (diathermy). Unlike diathermy, diagnostic ultrasound does not increase tissue temperature or alter local circulation through the transformation of the ultrasound waves into thermal energy. The ability of diagnostic ultrasound to provide low-cost imaging without ionizing radiation has profoundly impacted the practice of medicine. The introduction of real-time gray-scale ultrasound improved the anatomical imaging of the fetus and expanded the application of abdominal and pelvic ultrasound. Ultrasound is the initial imaging technique of choice for the kidney, liver, abdomen, pelvis, and fetus.[20] The coupling of gray-scale and Doppler in an imaging technique (duplex Doppler) allows the simultaneous imaging of anatomical detail and circulatory physiology; this technology is particularly useful for scanning shunts, valvular dysfunction, and deep vein thrombosis of the extremities.[138] Color coding of blood flow superimposed on real-time ultrasonic gray-scale images of the vessels and organs permits the imaging of flow, turbulence, and velocity in the vessels. Ultrasound does not produce tissue ionization; consequently, the use of ultrasound presents minimal to no risk to the fetus and mother.[139,140] Randomized controlled clinical trials of mothers scanned with ultrasound confirm that ultrasound carries little risk.[141,142]

PHYSICAL PROPERTIES

Ultrasound Waves

Ultrasound is the mechanical vibration produced by a source (transducer) and propagated through a medium (e.g., the body). The primary component of modern transducers is zirconate titanate (PZT); these devices

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

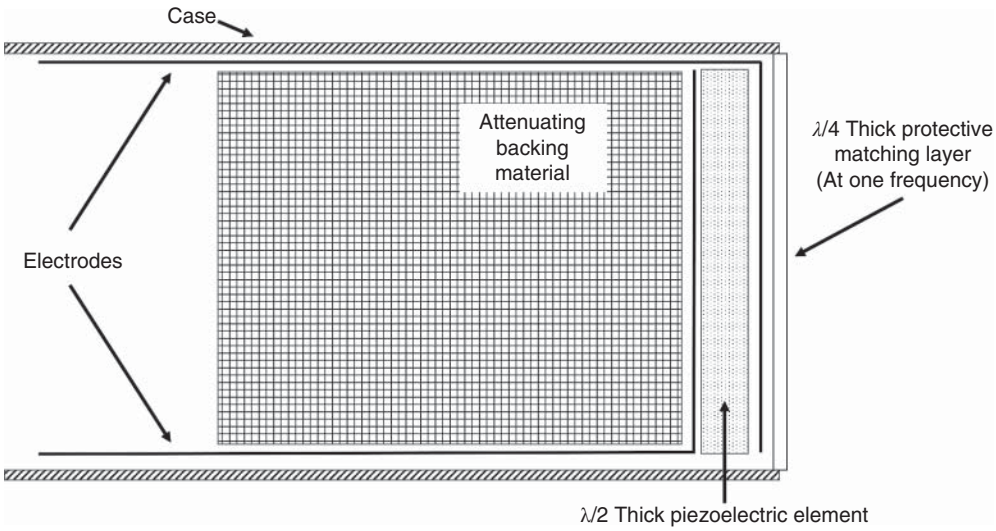

FIGURE 43.3. Ultrasound transducer construction. The transducer design incorporates a piezoelectric element thickness that resonates mechanically at the frequency (λ) of interest (i.e., $\lambda/2$). Transducers have a case for insulation from electrical interference and a wire to receive and transmit electrical inputs/outputs to the ultrasound machine. After the electrodes are attached, a case surrounds the transducer and a protective (matching) layer is attached in front of the piezoelectric crystal. Optimization of the transmission and reception of a particular frequency is maximized when the thickness of the matching layer is $\lambda/4$. The matching layer and ultrasound gel improve transmission between the patient's skin and the piezoelectric crystal by reducing the amount of reflection at this interface. The backing material shortens the spatial pulse length and improves axial resolution. Continuous-wave transducers do not require backing material. (Adapted from Chivers).[143]

convert electrical signals into ultrasonic vibrations. Figure 43.3 illustrates the design of a piezoelectric transducer. Ultrasound contains mechanical vibrations above the limit of human hearing (i.e., 0.02 MHz). Although ultrasound frequencies can be detected up to 1,000 MHz, most diagnostic ultrasound uses frequencies in the range of 2–10 MHz. In the receiving mode, ultrasound waves reflected from the body compress the surface of the crystal in the transducer; these physical alterations produce voltage changes displayed on an oscilloscope. The piezoelectric effect is the physical property describing the voltage changes resulting from the physical distortion of the crystal, as noted in Figure 43.4. The reverse piezoelectric effect occurs when the application of voltage to the crystal produces ultrasound waves. The propagation of ultrasound through the tissue depends on absorption, reflection, scattering, and refraction of the sound wave in the tissue.

Amplitude

Amplitude is the height of the sound wave; this parameter is proportional to the pressure in the tissue created by the sound wave. The voltage in the transducer reflects the amplitude of the sound wave from the piezoelectric effect within the crystal.

Intensity

Intensity (I) is the amount of energy passing per second through a specific area located perpendicular to the direction of the wave. The normal units of intensity are W/m^2 or mW/cm^2. The intensity of the ultrasound wave is a function of the square of the pressure of the wave; the intensity is a useful way to quantify the potential for damage to the tissue. Measures of intensity include temporal peak, pulsed average, and temporal average. The temporal average intensity (I_{TA}) measures many cycles, whereas the pulse average intensity (I_{PA}) averages only during the pulse, ignoring the rest of the cycle. The temporal peak intensity (I_{TP}) is the maximum instantaneous value corresponding to the peak value. The spatial average-temporal average intensity (I_{SATA}) is the intensity averaged over the time of the scan and the area of the beam. The temporal peak intensity (I_{TP}) is the maximum intensity during the pulse; the spatial peak intensity (I_{SP}) is the maximum intensity found across the beam. The symbol for the peak value over the area of the beam and the duration of the pulse is I_{SPTP}. The most common measure of the dose of ultrasound is the spatial peak-temporal average (I_{SPTA}). Figure 43.5 demonstrates the parameters used to describe the intensity of the ultrasound waves.

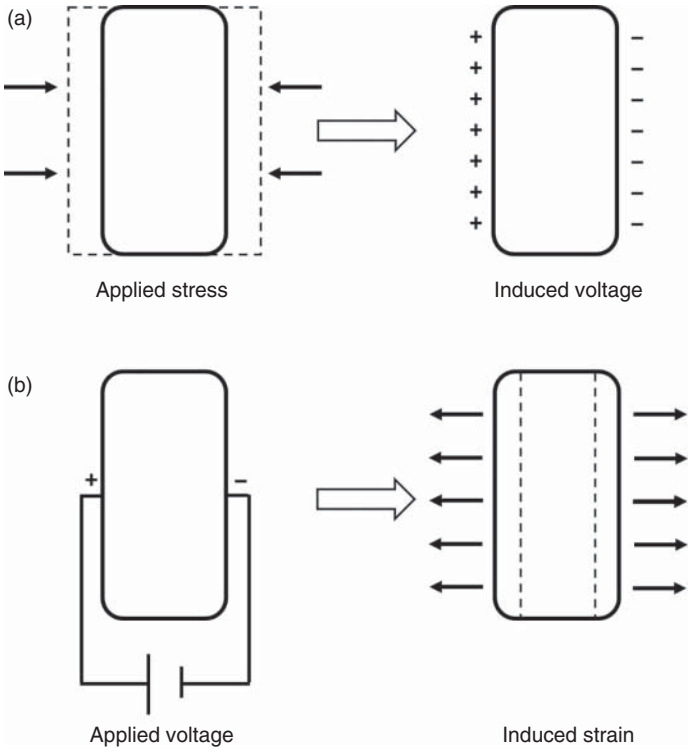

FIGURE 43.4. Schematic representation of the physical effects of applying voltage to a piezoelectric crystal. (a) piezoelectric effect resulting from applying voltage; (b) inverse piezoelectric effect when voltage ceases and crystal returns to the normal dimension. (Adapted from Lerski).[144] Mechanical stress to a piezoelectric material produces an electric field, whereas mechanical strain to a piezoelectric material causes electric displacement.

Resolution

X-ray images demonstrate better anatomical detail than ultrasound images. Axial resolution is the ability to resolve two interfaces directly in line with the ultrasound beam from the transducer. The axial or longitudinal resolution of ultrasound depends on pulse length, amplification, and frequency.[145] Axial resolution worsens as the beam penetrates the body because the tissues attenuate high-frequency portions of the pulse. The shortest resolution of a transducer is 3 wavelengths (3 λ). Higher frequencies deliver better resolution because the shortest, obtainable pulse duration is ~1 wave. Equation 43.6 describes the relationship of wavelength to velocity and frequency.

$$\text{Wavelength } (\lambda) = \text{velocity } (v)/\text{frequency } (f). \quad \text{(Equation 43.6)}$$

Consequently, a 2 MHz transducer has a wavelength of 0.77 mm; the resolution is 2.31 mm (i.e., three times the wavelength). Similarly, a 10 MHz transducer has a wavelength of 0.154 mm and a resolution of 0.462 mm. The velocity of ultrasound in most soft tissue is 1,540 m/second, whereas the velocity of ultrasound in the skull is 4,080 m/second.[145] Ultrasound waves transmit poorly in air (i.e., 330 m/second). Higher frequencies produce shorter wavelengths and greater axial resolution. Lateral resolution is the ability to detect adjacent tissues and depends on the size of the transducer aperture.[146] A larger transducer permits greater lateral resolution near the surface; however, the large transducer produces worse lateral resolution at greater depth.

EXPOSURE

Uses

Obstetrical ultrasound monitors the development and health of the fetus. During the first trimester, detection of the fetal heartbeat confirms pregnancy, whereas ultrasound during the second and third trimesters follows anatomical development. Healthy pregnant mothers typically receive two ultrasounds during the first and second trimesters of their pregnancy. The first trimester ultrasound between gestational weeks 11–14 confirms viability while screening for Down's syndrome and other serious genetic defects including severe cardiac

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 43.5. Parameters useful to describe the intensity of ultrasound power include the following: (a) Sound intensity across the beam near the tip of transducer at the position of focus shown. The intensity of the beam increases from the periphery to the center of the beam. The spatial peak intensity (I, mW/cm^2) is the highest intensity in the beam, typically on the axis at the focus. (a) The spatial average intensity (total power output/beam area) reflects the intensity spread evenly across the beam. (b) The intensity of the beam varies with time. The temporal peak intensity is the peak value, whereas the temporal average intensity reflects the average intensity over the whole cycle. Consequently, the latter value is much lower than the temporal peak intensity. (Adapted from Lerski).[144]

abnormalities.[147] Screening for fetal anomalies typically occurs at 18–20-week gestation, when the fetal anatomy is well visualized and the biparietal diameter provides an accurate measure of gestational age (i.e., within 9 days).[148]

Since the 1950s, physical therapy applications of ultrasound for therapeutic purposes have included treatment of musculoskeletal problems (e.g., tendinitis, bursitis) with low-power ultrasound in the 1-MHz range.[149] The use of high-pressure-amplitude shockwaves with the use of fluoroscopy and X-rays to focus the shock waves on the kidney stone began in the 1980s. Subsequently, the therapeutic use of ultrasound expanded to include cataract removal (phacoemulsification), ablation of uterine fibroids, transdermal drug delivery, acceleration of bone fracture/nonunion repair, and tissue cutting and hemostasis. Therapeutic ultrasound typically uses longer duration of heating with unfocused beams or higher intensities with focused beams. The latter is effective for ablation, whereas the former includes physical therapy applications to highly absorbing tissues (e.g., tendons, bones). Microbubble ultrasound contrast agents are routinely used in echocardiography for ventricular opacification and delineation of endocardial borders; the high compressibility of these microbubbles produces large impedance contrast with surrounding tissue and generation of nonlinear echoes that distinguish microbubbles containing fluid from tissue.

Equipment

Ultrasound utilizes a pulse-echo technique that uses energy **reflected** from the source to produce medical images, in contrast to CT scans that form images from the conversion of **transmitted** energy. For diagnostic ultrasound, the piezoelectric ceramic crystal produces very short, 1–5 cycle pulses characterized by a center frequency of the pulses ranging from 2–12 MHz. The ultrasound transducer operates as a transmitter and receiver of sound energy. Typically, the transducer emits sound energy for <1% of the duty cycle, while the transducer is either "listening" or "off" during the rest of the cycle. Most ultrasound machines produce a pulse repetition frequency of 500–3,000 pulses/second.[145] The application of 1–300 V over 1 microsecond (μsec) to the transducer emits a pulse of ultrasound waves that are quickly damped. The resultant pulse lasts 5–6 μsec with the remainder of the cycle recording echoes and processing data. Figure 43.6 displays the time sequence of a 1-millisecond (msec) pulse from the transducer of an ultrasound machine. The quiet period with no echoes prior to the next pulse accounts for the majority of the 1-msec pulse.

Modes of ultrasound include A (amplitude), B (brightness), M (motion), and D (Doppler). The latter Doppler mode includes duplex, continuous wave, pulsed wave, color, and power. Figure 43.7 displays the differences in the ultrasound signal from an artery using A-, B-, and M-modes. Pulsed mode ultrasound includes B-mode, M-mode, color flow Doppler, and pulsed wave (i.e., pulsed spectral) Doppler. Continuous wave Doppler, pulsed wave Doppler, and M-mode are nonscanning modes that involve a fixed ultrasound beam

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 43.6. Pulse intensity during a 1-ms duty cycle. Processing time with no echoes returning to the transducer accounts for most of the duty cycle. (Sarti).[145]

in space unless moved manually, whereas color flow Doppler and B-mode are automatic scanning modes that use a mechanical or electronically controlled ultrasound beam.

Doppler modes potentially deliver higher energies than B- or M-modes because of the higher outputs necessary to detect frequency shifts required for Doppler images. The power of ultrasound machines increased substantially over the two decades after the FDA increased the maximum spatial-peak temporal-average intensity to 720 mW/cm^2 in 1991, particularly for fetal applications. In a study of 124 regulatory submissions to the US Food and Drug Administration for transducers indicated for diagnostic fetal imaging from 1984–2010, the ultrasound power output increased approximately by one order of magnitude, while the average center frequency decreased by 4.2–3.4 MHz. Table 43.7 displays the changes in ultrasound output parameters submitted to the US FDA from this study.[150]

A(Amplitude)-Mode

The A-mode was the first type of ultrasound used for clinical purposes (e.g., evaluation of midline shifts in the brain); the amplitude mode reflects the depth of a structure below the surface of the skin, reflected as a two-dimensional waveform with variations (e.g., peaks) at the interface of two different tissues. On the oscilloscope, the *x*-axis measures depth from the surface, whereas the *y*-axis measures the signal information. In A-mode, the transducer is placed on the surface of the skin with a coupling agent (gel, oil); no scanning motion occurs. This mode is primarily of historical interest, except for some applications in ophthalmology.

B(Brightness)-Mode

B-mode provides information on depth and position by producing a two-dimensional, cross-sectional view of the examined tissue. This mode is an essential imaging modality in diagnostic ultrasound, with the amplitude of the reflected signal converted into variations in brightness of the two-dimensional gray scale from differences in organs and other tissues. Most noncardiac applications of ultrasound are in B-mode. The transducer moves across the patient on an articulated arm, generating A-mode signals in a single plane. The distance from the transducer is proportional to the time required for the reflected signal to reach the transducer. These echo signals are converted from amplitude information to brightness-modulated lines on the oscilloscope by assigning (through the computer) gray scales to the voltage amplitudes. On the oscilloscope display, the *x*-axis is the depth from the surface, whereas the z-axis is the position of the transducer, as demonstrated in Figure 43.7. Real-time ultrasound scanners replaced static B-scanners as the primary clinical ultrasound technique.

M(Motion)-Mode

For the M-mode, the ultrasound machine operates in the B-mode with the transducer stationery. Thus, the images result from the reflection of moving surfaces within the body. One axis represents the distance from the surface, whereas the other axis represents the movement of these surfaces with time. M-mode provides accurate assessments of rapid movements as a result of excellent temporal resolution (i.e., high sampling rate).

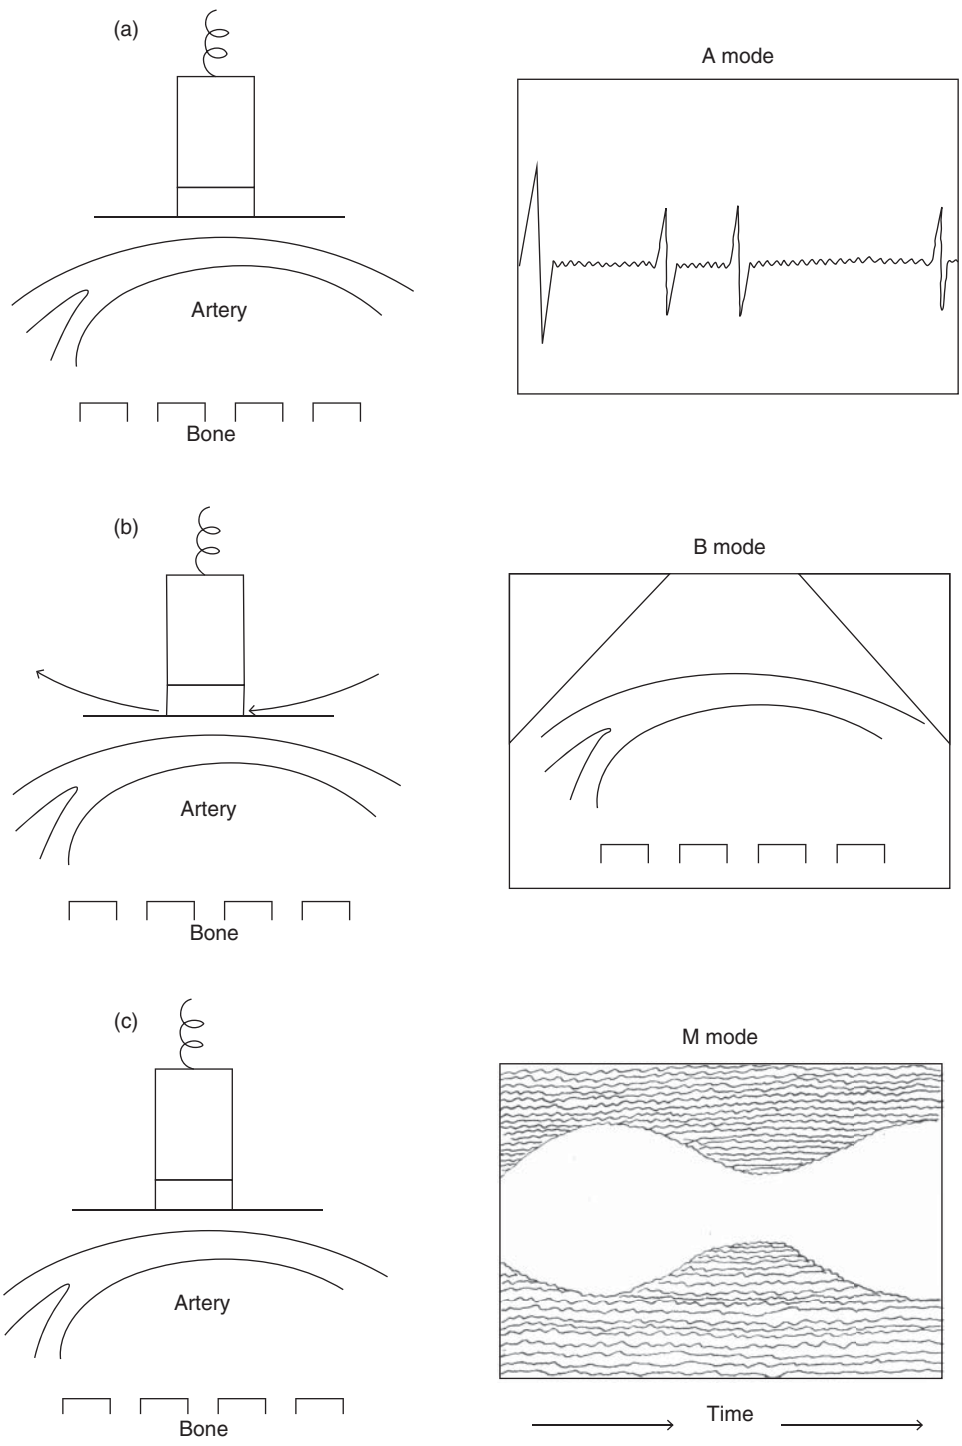

FIGURE 43.7. Differences in the image of an artery using A- (a), B- (b), and M- (c) modes during ultrasound. A-mode displays the artery as two spikes in amplitude, whereas B-mode creates a two-dimensional image through the plane of the body on the *x*–z axes as the transducer moves over the surface of the body. The x- and z-axes represent depth and amplitude, respectively. There is no y-axis in B-mode. M-mode displays a section of the artery over time and is particularly useful to image rapidly moving objects. The *y*-axis reflects pulsation of the arterial walls; the *x*-axis represents time. (Sarti).[145]

TABLE 43.7. Changes in ultrasound output parameters for submissions to the US Food and Drug Administration (USFDA) involving transducers used for fetal applications, 1984–2010. (Adapted from Cibull et al.).[150]

Parameter	1984–1989	1992–1997	2005–2010
Mean power, (range), mW	8.4 ± 13 (0.008–73)	102 ± 115 (0.5–712)	75 ± 75 (0.3–659)
Mean center frequency (MHz)	4.2	3.7	3.4
Mean bone thermal index (TIB)	0.19	1.8	2.0

D(Doppler)-Mode

The basis of this imaging mode is the change in frequency caused by the reciprocal movement of the sound generator and the observer (i.e., Doppler shift); reflections from erythrocytes provide the ultrasound signal backscatter to analyze blood flow. The combination of Doppler technology with real-time ultrasound allows the imaging of blood flow inside vessels using B- and M-modes. Doppler duplex imaging uses both continuous-wave and pulsed-wave techniques. Continuous-wave Doppler uses two piezoelectric crystals, one sending and one receiving the signal, whereas pulsed-wave Doppler uses a single piezoelectric crystal with a definite delay before receiving the reflected signal. The former measures high-velocity signals well without identifying the Doppler signal source; the latter provides blood flow direction and precise measurements of the Doppler signal source, with limited accuracy in high-velocity states.

DOSE EFFECT

The biological effects of ultrasound result primarily from heating and acoustic cavitation. The amplitude of ultrasound waves decreases with distance from the source as a result of absorption and scattering during the propagation of the wave through tissue.[151] Absorption represents the portion of ultrasonic wave converted into heat, whereas scattering is the portion that changes direction. Temperature in the tissues rises when the rate of heat production exceeds the rate of heat removal. Consequently, the amount of temperature elevation resulting from the absorption of ultrasonic radiation depends on the intensity of the ultrasound wave, the absorptive and scattering properties of the medium, and the heat capacity and thermal conductivity of the medium.[152] Intensity is a measure of the ultrasound dose and the capability of the ultrasound waves to induce thermal changes in tissue. The spatial peak temporal average (I_{SPTA}) of typical ultrasound machines ranges from 0.01–200 mW/cm^2; the instantaneous peak (ITP) is ~5–10 W/cm^2.[152] Initial temperature rises of 0.002°C occur from a several MHz ultrasound at an intensity (I_{SPTA}) of 100 mW/cm^2. A review of the *in vivo* and the *in vitro* effects of continuous wave exposure for <10 minutes did not identify an effect at I_{SPTA} levels of <100 mW/cm^2.[153]

Low-output pulsed Doppler equipment (I_{SPTA}, 112 mW/cm^2 at the dermal surface) did not produce detectable temperature elevations (i.e., 0.05°C) in fetal subcutaneous tissue during a 10-minute span.[154] Commercial pulse-echo diagnostic machine may produce ITP in the range of 100 W/cm^2. Although the average ultrasound procedure requires 10–45 minutes, the actual scan time is 5–10 minutes. Most diagnostic instruments perform at average intensities of ~15 mW/cm^2 with peak intensities of 4–7 W/cm^2. The overall average output of ultrasound Doppler instruments is 10–100 times greater than the average output of B-scanners and real-time scanners.

The threshold for stable cavitation in the range of 1–4 MHz is an intensity of 0.2–5 W/cm^2 with continuous waves (e.g., diathermy). Alternately, the same intensity with many cycles of pulsed ultrasound is necessary to produce the phenomenon of stable cavitation.[144] Although laboratory experiments suggest cavitation can occur at a frequency of 1 MHz with a duty cycle of 0.1 and a temporal average intensity of 14 W/second,[155] currently there is no definite scientific evidence that cavitation occurs at the existing intensities of diagnostic ultrasound.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Absorption of the ultrasound energy by the tissues produces heat. Increasing frequency, pulse length, and nonlinear acoustic distortion increase heating and some nonthermal mechanisms, whereas increasing power or intensity typically increases the magnitude and risk of all ultrasound-related adverse effects. Temperature elevations and subsequent adverse effects from diagnostic ultrasound are usually clinically negligible.[156] The biological effects of therapeutic or diagnostic ultrasound do not accumulate during repeat examinations.[149]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Cavitation is the production and movement of bubbles in a liquid medium (e.g., biological tissue). When the negative pressure created by the ultrasonic wave crossing the tissue exceeds the minimum molecular distance required to hold the fluid intact, voids in the tissue occur (i.e., cavitation bubbles). Gas diffuses out of solution (called rectified diffusion) during the rarefaction phase, enhanced by heat from the absorption of ultrasound energy.[157] Decreasing frequency with high-intensity ultrasound increases the risk of cavitation, including gas body activation.[158] Most ordinary liquids contain microbubbles of dissolved gases that expand and contract during the passage of different phases of a sound wave. Stable cavitation is the sustainable, periodic, nonlinear expansion and contraction of the gas bubble. Elevated vapor pressure within the bubble increases the bubble up to the resonant size. Cavitation-related mechanisms include microjets (high-speed, penetrating jets formed from inertial collapse near rigid surface), microstreaming (shear stresses from the transfer of momentum caused by energy absorption), shock waves, strain, and free radical formation.[151] Cavitation and gas body activation cause primarily local tissue injuries in the area of cavitation, including cell death and hemorrhage from damaged blood vessels. Cavitation typically does not occur at the power intensities used for ultrasound imaging.[159]

Microstreaming occurs when the sinusoidal sound wave alternately increases and decreases the resonant bubble size. This movement produces shear forces on the surrounding cells and organelles that may cause damage. As the intensity of the pressure wave increases, the cavity becomes unstable and collapses. At high energy levels, the bubble becomes lenticular in shape with the walls approaching the center at supersonic speeds. The very high temperatures (several thousand K) and pressures (several hundred atmospheres) of collapsing gas bubbles produce thermal dissociation of water vapor into hydroxyl radicals and hydrogen atoms.[160] The formation of a variety of short-lived free radicals *potentially* can produce cell damage and lysis;[161] however, there is no conclusive evidence that diagnostic ultrasound causes intracellular free radical formation or cellular dysfunction.

CLINICAL RESPONSE

Thermal Effects

Modern diagnostic ultrasound machines are unlikely to cause adverse thermal effects. A review of the research literature on tissue temperatures indicated an 18°C temperature elevation for 100 msec is necessary to produce tissue damage.[162]

Nonthermal Effects

Biological tissue does not typically contain gas bodies; consequently, cavitation is unlikely to occur during the use of ultrasound. When inertial cavitation or microstreaming occurs, the effect is typically localized to the small region of the gas body. The probability of a strategically placed gas body being able to cause a deleterious effect is highly unlikely.[163]

Carcinogenesis

An increase in sister chromatid exchanges (SCEs) often occurs in the presence of mutagenic agents; however, this short-term assay produces false positive and false negative results. Most studies of SCE induction after exposure to diagnostic ultrasound are negative;[164,165] however, two studies reported positive findings.[166] Subsequent studies did not confirm a clinically relevant increase in SCEs at exposure levels (e.g., 5 MHz linear transducer for 0.16–20 minutes) present during diagnostic studies.[167,168] The exact significance of SCEs remains unclear in relation to the assessment of teratogenic and carcinogenic agents. In a study of 10 patients with low back pain receiving 10 sessions of ultrasound therapy (intensity of 2 W/cm^2; frequency, 1 MHz; duration, 10 minutes; and 10 controls sham therapy), examination of peripheral blood for cytogenic damage as measured by micronucleus frequencies demonstrated no statistically significant difference comparing preexposure and postexposure values.[169]

Reproductive Abnormalities

Although the number of large prospective studies on the effects of ultrasound is limited, the results have generally been negative; there is no clear evidence that the use of diagnostic ultrasound during pregnancy causes significant health risks to the fetus or mother.[170] A study of 1,114 healthy pregnant women undergoing diagnostic ultrasound at various stages of pregnancy did not detect an elevated incidence of fetal abnormalities (i.e., 2.7%).[171] A 12-year follow-up of 425 children exposed to diagnostic ultrasound *in utero* did not demonstrate any abnormalities in hearing, vision, cognitive function, behavior, or other neurological effects.[172] A retrospective nested case-control study of physiotherapists

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

exposed to ultrasound during diathermy reported a 3-fold increased incidence of spontaneous abortion, but not congenital abnormalities; however, the difference was not statistically significant after controlling for confounding variables.[173] In a study of 434 pregnant physiotherapists using shortwave diathermy and adverse pregnancy outcomes, only low birth weight reached statistical significance (OR = 2.75, 95% CI: 1.07–7.04, $P = 0.03$) after controlling for potential confounding variables.[174]

Animal studies of ultrasound indicate the presence of *in vivo* reproductive effects (e.g., fetal weight reduction, elevated postpartum fetal mortality, fetal abnormalities, hind limb paralysis, behavioral alterations, blood flow stasis); however, these changes occur at high levels (intensities >0.1–1 W/cm^2) compared with the intensity of ultrasound.[175] Figure 43.8 displays an estimation of the theoretical threshold line for potential adverse thermal effects, including teratogenesis, plotted as temperature elevation (*y*-axis) against duration (*x*-axis). Typically, temperature increases of ≥4°C for 5 minutes are necessary to produce developmental abnormalities in the animals.[156] Congenital abnormalities have not been associated with the use of diagnostic ultrasound in humans. Cavitation is unlikely to occur in the fetus because of the lack of identifiable gas bodies. A review of adverse nonthermal effects and diagnostic ultrasound did not identify any causal relationship between fetal abnormalities and the use of diagnostic ultrasound; the potential for adverse effects exists for low-intensity pulsed ultrasound effects used to accelerate bone fracture repair and induce healing of nonunions in humans.[176]

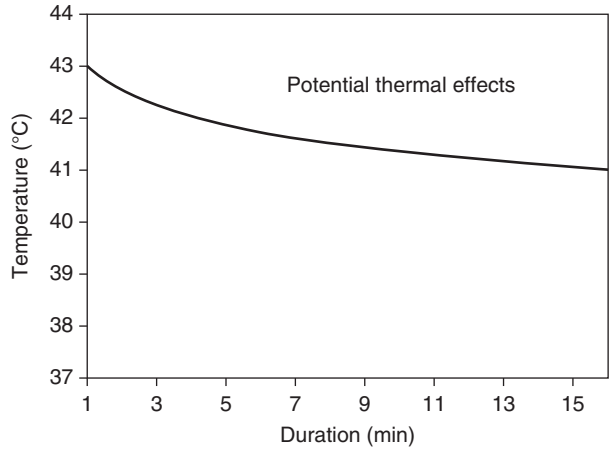

FIGURE 43.8. An estimation of the theoretical threshold line for potential adverse thermal effects including teratogenesis plotted as temperature elevation (*y*-axis) against duration (*x*-axis) based on animal studies. Although some spectral Doppler exposures may approach this line based on the thermal index display, the figure demonstrates that very long times (e.g., >4 hours for 2°C elevation above body temperature) are necessary for normal ultrasound examination duration in the fixed plane. (Adapted from Miller).[170]

DOSIMETRY

The pulsatile characteristic of ultrasound waves requires evaluation by temporal peak and temporal average exposure metrics. The energy in the pulse is typically expressed as the pulse-average intensity (power delivered/unit area, W/cm^2) at the spatial peak on the beam axis near the focus. The two primary effects of transmission of ultrasonic waves through tissues are heating from absorption of the energy by tissues and cavitation from the expansion/contraction of gases in the tissues. Heating correlates to the temporal average intensity (thermal indices), whereas cavitation correlates to temporal peak measures (mechanical indices). The screens of diagnostic ultrasound machines display these parameters as required by the Output Display Standard published by the American Institute of Ultrasound in Medicine and the National Electrical Manufacturers Association.[177]

HEALTH SURVEILLANCE

Risk

Although heating and cavitation are potential mechanisms for adverse biological effects, neither of these mechanisms has been documented under current imaging conditions for ultrasound.[162,178] Currently, there is no well-documented risk associated with the use of diagnostic ultrasound in the fetus; however, sufficiently large prospective epidemiological studies are not available to exclude subtle effects on the mother or the fetus.

Fetus

The US Food and Drug Administration 510(k) premarket approval process established an initial limit of 46 mW/cm^2 of spatial peak temporal average (SPTA) intensity for obstetrical ultrasound in 1985.[179] Following adoption of the Output Display Standard, the allowable output for obstetrical ultrasound increased to an average exposure of 720 mW/cm^2 SPTA intensity; the peak exposure was established via the Mechanical

Index. Ultrasound machines configured for obstetric use typically produce a lower temperature than machines with nonobstetric transducers and settings including color Doppler machines.

Thermal Indices

Calculating the temperature profile from an ultrasound examination is very complex. Acoustic output from diagnostic ultrasound devices can cause temperature elevation in fetal tissue with the elevation progressively greater from D-mode to color Doppler to spectral Doppler applications.[180] Temperature elevation in the tissues depends on several factors, including the SPTA intensity, ultrasound frequency, beam width, dwell time along the beam axis, physical properties of the tissue examined, and individual patient factors. Fixed beams produce temperature elevations that reach an asymptote as heat deposition matches heat dissipation from conduction and blood flow. The temperature elevation is lower at a given intensity for focused beams than for unfocused beams because of the rapid conduction of heat from a small region. Ultrasound machines usually display the following three thermal indices: 1) regular soft tissues (TIS), 2) bone at the focus (TIB), and 3) bone at the surface (TIC). The important indices for obstetrical ultrasound are TIS for the first trimester and TIB for the second and third trimesters when bone development occurs. A TIS value in °C indicates the temperature elevation would not be expected to rise above that value.

Mechanical Index

Ultrasonic cavitation potentially causes mechanical damage and the generation of free radicals capable of altering DNA. The mechanical index provides an estimate of the peak negative (rarefactional) pressure amplitude (PRPA) of the ultrasonic beam in the tissues; this value is an important measure of the temporal peak exposure and the I_{SPPA} (spatial-peak pulse-average intensity). The occurrence of cavitation depends on the PRPA. Table 43.8 lists the upper limits for diagnostic ultrasound as formulated in spatial peak temporal average intensity and spatial-peak pulse-average intensity by the US FDA. The values represent values below which there is little risk of adverse effects. Modern ultrasound machines do not typically reach these upper limits. The minimal risk of obstetrical ultrasound implies that diagnostic ultrasound should not be withheld for safety considerations when clinically indicated. Ultrasonography and magnetic resonance imaging are not associated with significant risk to the fetus or mother; hence, these modalities are the imaging techniques of choice for the pregnant patient requiring clinical information for their health.[181]

TABLE 43.8. The US Food and Drug Administration upper limits for diagnostic ultrasound machines. The old tract 1 represents machines pre-1992 without indices displayed, whereas the current tract 3 represents modern machines with thermal and mechanical indices displayed. (United States Food and Drug Administration, USFDA).[179]

TABLE 43.9. American Conference of Industrial and Governmental Hygienists (ACGIH) 2022 threshold limit values (TLVs) for ultrasound based on mid-frequency ranges (10–100 kHz) for one-third-octave-band levels. For frequencies 10–20 kHz, some individuals may experience subjective annoyance and discomfort during exposure in the range 75–105 dB; engineering controls and/or hearing protection may be necessary to prevent subjective effects. Reducing the dB to 80 dB may be necessary for some individuals exposed to frequencies of <10 kHz. With TLV values for frequencies of 25–100 kHz, the values may increase to 30 dB if the ultrasound does not couple with the body by touching water or some other substrate, as occurs when the ultrasound source directly contacts the body. In such situations, the vibration level at the mastoid bone should be applied. Acceleration values of 15 dB above the reference of 1 g rms should be avoided by reducing the exposure or isolating the body from the coupling source.

Frequency (kHz)	Head in Air-Ceiling Value[a]	Head in Air-8-Hour TWA[a]	Head in Water-Ceiling Value[b]
10	105	88	167
12.5	105	89	167
16	105	92	167
20	105	94	167
25	110	—	172
31.5	115	—	177
40	115	—	177
50	115	—	177
63	115	—	177
80	115	—	177
100	115	—	177

Workplace

The basis of ACGIH threshold limit values (TLVs) for ultrasound is prevention of hearing loss and a reduction in the ability to understand normal speech. The 8-hour time-weighted average (TWA) values reflect the TLV for noise (8-hour TWA = 85 dBA). These values refer to sound pressure levels for one-third-octave bands with mid-range frequencies of 10–100 kHz. Verification of the ceiling values involves the use of sound-level meters with slow detection and one-third-octave bands. Table 43.9 lists the ceiling and 8-hour TLVs for exposure to ultrasound.

Audible, high-frequency radiation above 10 kHz may cause nausea, headache, tinnitus, pain, dizziness, and fatigue, depending on the susceptibility of the person, the intensity, and the actual spectrum of high-frequency radiation.[182] Exposure to powerful sources of ultrasound potentially may produce damage to neurovascular structures near the point of contact. No specific OSHA standards or NIOSH recommendations exist for ultrasound. Sound-insulating panels should completely cover the ultrasound equipment to prevent the leakage of sonic radiation; the equipment should be isolated from the floor by rubber seals.

LASERS

The word "laser" is an acronym for **L**ight **A**mplification by **S**timulated **E**mission of **R**adiation. Albert Einstein first conceived of the concept of a laser in 1917, when he postulated that stimulation of atoms would release energy with a specific wavelength and direction.

Figure 43.9 demonstrates a simplified version of the laser. The basic components of a laser include: 1) a lasing medium, 2) an energy source, and 3) a reflecting cavity. Ordinary light sources produce a continuum of wavelengths over the spectrum of visible light; these photons of light diverge rapidly as they leave the source. The laser beam is powerful and highly focused. In contrast to ordinary light sources, laser radiation is monochromatic (i.e., all photons have similar energy, wavelength, and frequency) *and* collimated (i.e., the beam does not diverge).

The wavelength of the laser depends on the lasing medium through which the photons pass. As seen in Figure 43.9, the wavelength emitted by the laser covers infrared and visible portions of the electromagnetic spectrum. The laser has many industrial and military uses, including communications (fiberop-

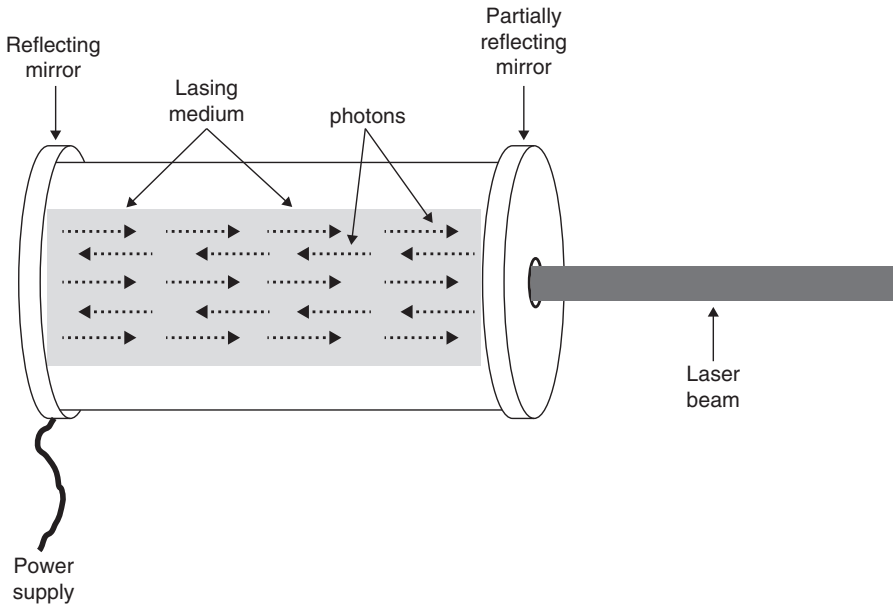

FIGURE 43.9. Simplified version of a common laser with three major parts, including a solid, liquid, or gas lasing medium, two mirrors, and a power supply. The power supply provides the energy to excite the atoms to emit photons. The energies in these photons are amplified as they are reflected by two mirrors in the central axis. Depending on the lasing medium, energy with a specific wavelength discharges as a laser beam through a partially reflecting mirror at the end of the laser.

tic cables, supermarket scanners, laser light shows, holograms), information storage (compact disc players, laser printers), industrial (cutting, welding, soldering), and military (laser-guided missiles, range finding) applications. The US Food and Drug Administration approved the use of Nd-YAG lasers for dental surgery on the gums. The hazards associated with the use of lasers depend on the power of the laser. In general, the main hazards of the laser involve eye injuries, skin burns, and electrical injuries from the energy source.

PHYSICAL PROPERTIES

In contrast to ordinary light, light emitted from a laser possesses the following four characteristics: 1) coherence, 2) monochromaticity, 3) high intensity, and 4) collimation or little divergence.[183] Coherence implies the photons emitted by the laser are in phase with one another; hence, these electromagnetic waves possess the same amplitude, direction, frequency, and phase. Monochromatic light means all of the photons have the same energy, frequency, and wavelength or color. Although most lasers produce monochromatic light, some lasers (e.g., the helium-neon) emit light at three different wavelengths, depending on the specific design. The beam produced by a laser has high-energy density with the power measured in joules (J)/cm^2. Because the effect of a pulsed laser depends on the duration of the pulse, J/second-cm^2 or watts (W)/cm^2 are the common units of measurement for the pulsed laser. Unlike ordinary light, the beam of a laser does not spread far while traveling away from the source, with the unit of measure of divergence measured in milliradians (i.e., ~3 minutes of arc). Typically, a laser (e.g., helium-neon) diverges only by 0.5–1.5 milliradians.

EXPOSURE

Exposure to laser radiation primarily occurs in certain groups including military personnel, research workers in industrial and academic settings, patients, and healthcare personnel. Reflected laser radiation may exceed occupational guidelines for bystanders momentarily viewing a laser procedure within 1 m of the laser contact lens.[184] Diffuse reflections occur primarily with Class IV lasers, and infrared radiation may reflect unexpectedly off objects that do not reflect visible light.[185]

Uses

Medical

The principal lasers used in medical practice include the following: 1) argon, 2) neodymium-doped yttrium aluminum garnet (Nd:YAG), 3) holmium-yttrium aluminum garnet, and 4) carbon dioxide. Important medical advantages of lasers include clearer operative sites as a result of the coagulative properties of lasers, reduced trauma surrounding the wound, and improved wound healing times. Table 43.10 lists the common lasers used in certain medical procedures along with their specific wavelengths.

Dermatology

Powerful pulses of energy from CO_2 lasers heat water in tissue rapidly; these lasers can vaporize tissue with high water content near the surface of the body. In dermatology, CO_2 lasers can remove warts, ingrown toenails, and lip lesions. The blue-green emission from the argon lasers easily passes through the outer surface of the skin; however, hemoglobin absorbs this wavelength well. Consequently, this laser effectively removes hemangiomas (port-wine stains) from adult skin. The less powerful flashlamp-pumped pulsed dye (rhodamine in methanol) laser requires more treatment sessions with less scarring in children. Other types of lasers produce wavelengths that absorb melanin easily; therefore, these lasers effectively remove telangiectasias and pigmented lesions (e.g., moles, freckles, solar lentigines, dark birthmarks). Q-switching is a technique that produces shorter, higher-intensity laser pulses. Carbon and, to a lesser extent, melanin absorb the deep-red, 694-nm wavelength of the ruby laser. Hemoglobin does not absorb this wavelength well; the Q-switched ruby laser pulses (40–80 nsec, 694 nm) effectively remove tattoos without a substantial incidence of scarring or hyperpigmentation, particularly for removing black, blue, and green pigments.[187] Other lasers used for tattoo removal include Q-switched neodymium:yttrium-aluminum-garnet (532 nm – red pigments, 1,064 nm – blue/black pigments) and Q-switched alexandrite (755 nm) lasers.[188,189] The removal of multicolored tattoos requires several different wavelengths; therefore, no one laser system removes all combinations of colors and inks. Successful tattoo removal requires selecting the correct laser for the tattoo color.[190] Adverse effects include textural change, pigmentary alteration (e.g., hypopigmentation), and scarring.

Ear, Nose, and Throat Surgery

CO_2 lasers with infrared radiation and a wavelength of 10.6 μm are routinely used in otolaryngology surgery as effective surgical cutting instruments that provide precision cuts with excellent hemostasis and little collateral damage. Water, blood, and biological material absorb infrared radiation independently of pigment. Ordinary glasses provide sufficient eye protection from corneal burns because glass and plastic readily absorb the emitted radiation. The holmium:yttrium-aluminum-garnet laser produces pulsed infrared output with a wavelength of 2.1 μm; excellent absorption in water-rich tissues favors use of this laser for nasal surgery and tonsillectomies. The neodymium (Nd):YAG laser possesses high tissue penetration (and minimal tissue absorption), making it useful for hemostasis and shrinking lower airway tumors. Oral and maxillofacial uses include coagulation of angiomas, hemostasis of nosebleeds, arthroscopic temporomandibular joint surgery, and palliation of advanced neoplasms.[191] In contrast to the CO_2 laser, this laser produces the majority of its effects below the surface of surrounding tissues. Dedicated goggles opaque to wavelengths of 1.06 μm are necessary to prevent retinal damage. The potassium titanyl phosphate (KTP) laser contains a Nd:YAG laser that emits a green light with a wavelength of 532 by passing the beam through a KTP crystal. The KTP laser is more powerful than the argon laser and produces more refined and better hemostasis than the CO_2 laser.

Ophthalmology

The ruby laser was the first laser used in ophthalmological surgery in the 1970s.[192] Laser technology offers the advantage of less pain and a lower risk of infection compared with open surgical techniques. The neodymium:yttrium aluminum garnet (Nd:YAG) laser produces an intense infrared light that can create openings in the eye for posterior capsulotomies after cataract surgery and the treatment of glaucoma. As an adjunct to retinal surgery, the Nd:YAG laser can cut deep vitreous traction bands. The blue-green pulses from the argon laser selectively heat and seal damaged blood vessels in the retina; these treatments prevent further macular deterioration in patients with macular degeneration or diabetic retinopathy. Both the argon and the krypton lasers are well suited to spot-weld tears in the retina that result from trauma. The excimer laser is a gas laser that cuts precise craters in tissue, which is useful in coronary angiography[193] and anterior corneal surgery.[194] Excimer laser technology is also a popular treatment for myopia (radical keratotomy).[195] Advances in laser technology have resulted in multiple laser platforms for refractive surgeons, including femtosecond-assisted LASIK (laser-assisted *in situ* keratomileusis) with excimer laser corneal reshaping[196] or high-frequency femtosecond laser-assisted SMILE (small incision lenticule extraction) surgery.[197]

Pulmonary

The Nd:YAG laser provides a rapid palliative treatment for obstruction of the large airways (trachea, mainstem bronchus, lobar bronchus) as a result of either benign or malignant lesions, particularly short, polypoid tumors. Benign tracheal stenosis, but not tracheomalacia, is responsive to resection by the Nd:YAG laser. Complications of the pulmonary use of the Nd-YAG laser include air embolism, hemorrhage hypoxemia, ignition of the bronchoscope or endotracheal tube, mucosal edema, and loss of the tip of the laser fiber.[198]

Industrial

Lasers are commonly used in research laboratories and industrial settings. Injuries during these processes usually occur during alignment of the laser beam or other adjustment procedures, resulting in parafoveal damage from looking directly into the laser source. Occasionally, unintentional reflections from a mirror or nearby reflective object (plastic membrane, photographic paper) cause retinal damage. Laser pointers emit a continuous narrow beam of visible light (e.g., diode laser, 670 nm; helium-neon laser, 632.8 nm) with an output power usually ranging from 1–5 mW. The retinal irradiance is similar to staring directly at the sun.[199] Although mild thermal retinal injury may occur following prolonged staring at the laser pointer (i.e., >10–20 seconds),[200,201] the blink reflex and aversion response usually prevent retinal damage.[202] Transient visual incapacitation (e.g., flash-blindness, glare, afterimages) may occur following inadvertent exposure to a laser pointer, resulting in secondary injuries, particularly in a dark-adapted person.

Military

Armed forces commonly use laser-based devices for range finding and guiding "smart" weapons. Laser-based weapons use the laser beam to damage electro-optical sensors that are vulnerable to the same visible and near-infrared radiation as the retina; these weapons have the capacity to produce visual incapacitation. Targets during these activities often involve vulnerable individuals using binoculars many kilometers from the laser source. Typically, military lasers have wavelengths in the visible or near-infrared spectrum with energies of tens of millijoules and pulses lasting nanoseconds.[203]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Consequently, retinal burns occur following military use of these lasers with bilateral eye injuries being much more common than civilian laser injuries.[204]

Laser Design

Lasers are devices that produce and amplify light, resulting in the focusing of radiant power over very small areas with the potential to direct this energy over great distances. The power of the light created by these devices varies from a few mW in the helium–neon gas laser to thousands of watts in the CO_2 laser.[205] Lasers may operate either continuously or intermittently with pulses containing millions of watts of power. A laser has three major components including: 1) a lasing medium (liquid, gas, solid) where photons form, 2) a pumping system that provides a power source for the lasing medium, and 3) an optical cavity (e.g., lenses, mirrors, shutter) that focuses and intensifies the output of the laser.

Lasing Medium

The lasing medium provides the material where electrons are trapped in an exited (metastable) state for up to several milliseconds before decaying to lower, stable states by emitting photons. The four common families of lasers are based on the type of lasing medium. The ruby laser is an example of a **solid-state laser** that uses a solid matrix of aluminum oxide and emits a deep red beam with a wavelength of 695.3 nm. The neodymium-YAG laser uses neodymium atoms in a crystal of **Y**ttrium, **A**luminum, and **G**arnet to produce an invisible beam with a wavelength of 1,064 nm. The **gas lasers** use a gas or a mixture of gases enclosed in a glass tube, including the CO_2 laser (invisible infrared beam with a wavelength of 10,600 nm), the helium-neon laser (632.8 nm), the argon laser (488 nm), and the krypton lasers. **Semi-conductor lasers** are small, highly efficient lasers that produce red and infrared beams by using two opposing layers of semiconductor material as the lasing medium. One layer contains a surplus of electrons, whereas the other material has a deficit of electrons. **Liquid lasers** contain organic dyes as the lasing medium; they can produce a wide range of beams in the visible and near-visible portions of the electromagnetic spectrum.

Pumping System

The production of a beam requires pumping systems to raise electrons to higher energy levels (metastable state) from the ground or lower energy levels. A population inversion develops when the number of electrons in the metastable state exceeds the number of electrons in the ground state. Laser action occurs *only* when a population inversion exists. Gas lasers utilize electron collision pumping, where an electrical charge applied to the tube causes the electrons to excite electrons in the lasing medium. This method allows the formation of continuous output. Solid-state lasers use optical pumping, whereby the electrons in the lasing medium reach an excited state by absorbing photons from strobe-like devices (e.g., xenon flashtubes). Liquid lasers generally use a solid-state laser to pump the lasing material. Other lasers (e.g., hydrogen fluoride) utilize chemical pumping, whereby the formation and destruction of chemical bonds provide the energy to excite electrons in the lasing medium.

Optical Cavity

A system of parallel mirrors enhances the movement of photons through the lasing medium; reverberation of the photons between these mirrors produces a unidirectional and coherent light beam. Reflection of the beam back through the lasing medium increases the number of emitted photons until the number of excited electrons equals the number of photons lost through the mirrors. A continuous, usually low-output beam results from the pumping of the lasing medium at that time. Placing a shutter between the two reflective mirrors allows the formation of short, high-output pulses of energy from the laser. Q-switching is the technique that produces these short, powerful impulses by interrupting the optical cavity with an electro-optical switch (Pockel's cell). Reducing the loss of energy to the lasing material allows a higher population inversion. The sudden restoration of the optical cavity permits the release of a shorter (~30 nsec) but more powerful radiation burst compared with the continuous laser.

Hazard Classification

Damage to the skin and eyes from exposure to laser beams depends on the wavelength, the pulse duration, and the power of the beam. **Radiant flux** is the power received by an object measured in watts. The **irradiance** on the surface of an object is the radiant flux divided by the area of that surface. The unit of irradiance is W/cm^2; this quantity is a useful measure of the power of a *continuous* laser source. The **radiant energy** is the amount of energy emitted by a source; the unit of measure is the joule. The **radiant exposure** is the surface density of the radiant energy in a particular area, as measured in J/cm^2. For *pulsed* beams, radiant exposure is a valid measure of power.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 43.11. Four major United States Food and Drug Administration (US FDA) laser hazard classifications with roughly equivalent International Electrotechnical Commission (IEC) laser classifications. The higher numbers imply a greater hazard. Light-emitting diodes (LEDs) differ from laser diodes; LEDs are not subject to the Federal laser product performance standard. The IEC Class 1M contains lasers usually considered incapable of producing damaging radiation levels except when viewed through certain optical instruments (eye-loupe, telescope), causing diverging or collimated beams. Similarly, IEC Class 2M normally does not cause damage with unaided viewing, whereas the use of certain optical aids produces potentially hazardous situations.

FDA Class	IEC Class	Hazard	Products
I	1, 1M	Considered nonhazardous. Hazard increases if viewed with optical aids, including magnifiers, binoculars, or telescopes (1M)	Laser printers, CD/DVD players
IIa, II	2, 2M	Low-power. Hazard increases when viewed directly for long periods of time. Hazard increases if viewed with optical aids (2M)	Bar code scanners
IIIa	3R	Medium-power. Depending on power and beam area, it can be momentarily hazardous when directly viewed or when staring directly at the beam with an unaided eye. The risk of injury increases when viewed with optical aids	Laser pointers
IIIb	3B	Medium-power. Immediate skin hazard from direct beam and immediate eye hazard when viewed directly	Laser light-show projectors, industrial and research lasers
IV	4	High-power. Immediate skin hazard and eye hazard from exposure to either the direct or reflected beam; may also present a fire hazard	Laser light-show projectors, industrial and research lasers, medical device lasers for eye surgery or skin treatments

Abbreviations: FDA = US Food and Drug Administration; IEC = International Electrotechnical Commission.

For hazard classification, the US Food and Drug Administration, International Electrotechnical Commission, and the American National Standards Institute categorize lasers into four groups, as displayed in Table 43.11. Class I lasers are exempt from regulation because the power (<0.001 mW) produced by these devices does not cause eye damage even when viewed accidentally. Class II lasers are low-output (<1 mW) devices that may require eye protection under certain circumstances. These visible lasers do not usually produce enough power to injure an individual accidentally; however, direct viewing of the beam for >0.25 seconds may cause retinal damage. Class III lasers are medium-power (<0.5 W) lasers that produce eye damage with viewing of the direct or reflected beam (Class IIIb) or require focusing (e.g., binoculars) to cause damage (Class IIIa). Class IV lasers are high-power (>0.5 W) lasers that cause damage to the eye or skin from viewing direct beams or receiving diffuse reflections.

High-power CO_2 lasers in Class IV have various industrial applications, including welding, drilling, and cutting. The power output of the infrared beam from industrial CO_2 lasers ranges from 1–10 kW, with blue light and ultraviolet radiation released from the interaction of the infrared laser with the target.[206] Ordinary glasses composed of plastic absorb the invisible radiation emitted from CO_2 lasers.

DOSE EFFECT

The eye is the primary target organ of lasers, with injuries usually involving the retina. A radiant flux exposure of 10^{-2}–10^{-1} J/cm^2 produces edema, necrosis, and hemorrhage extending into the vitreous, whereas exposure to radiation at a dose of 10^{-3} J/cm^2 causes limited coagulative necrosis.[207] In animal models, short-pulsed lasers produce retinal lesions with energies of a few μJ and retinal holes with vitreous hemorrhage at a few mJ.[208] Continuous-wave lasers produce long pulses in the millisecond range that require more total energy entering the eye, but less corneal power. A krypton laser (586.2 nm) caused a threshold retinal injury at 22.5 mW for 33 msec and 25 mW for 16 msec.[209] Doses of energy of 3–5 orders of magnitude above recommended guidelines from Q-switched lasers (wavelength 532–780 nm) produced sub- and preretinal hemorrhages.[210]

Krypton, argon, ruby, neodymium-YAG, and dye lasers have all produced retinal burns. A dye laser emitting a wavelength of 589 nm for 10 nsec burned the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

macula of a 24-year-old male, resulting in the subsequent development of a macular hole and permanent visual loss (20/100).[211] An infrared laser with a wavelength of 800 nm, an energy density of 0.003 J/cm^2, and a beam diameter of 1 cm caused a central foveal lesion and a permanent reduction in visual acuity.[212] Similar lesions resulted from the radiation from a neodymium-YAG laser with a wavelength of 1960 nm, a peak power of 100 mW, and a pulse duration of 8 nsec.[213] The beam was nonfocused with a diameter of 30 mm.

Absorption of the short-ultraviolet range (UVB, UVC) and the far-infrared region (IRB, IRC) occurs primarily in the cornea, whereas the lens absorbs most of the UVA light. Visible light and near-infrared radiation penetrate the eye, entering the retina with some absorption of IRA occurring in the vitreous humor. Optical radiation of 380–1,400 nm penetrates various ocular structures; however, the blink reflex and the aversion response limit the duration of laser exposure to 0.15–0.25 seconds. Although these actions usually prevent ocular damage from low-power laser pointers (i.e., <5 mW), prolonged exposure (>10 seconds) may cause significant photocoagulation and photodisruption of retinal injuries, particularly with blue light.[214] Natural protective mechanisms are not effective against high-energy lasers (≥500 mW);[215] these lasers may produce severe retinal damage (severe visual loss, macular holes), even after momentary exposure.[216]

Ultraviolet Region (100–400 nm)

The anterior portion of the eye receives most of the radiation from this part of the electromagnetic spectrum. The conjunctiva and the cornea absorb all UVC (100–280 nm) and almost all UVB (280–315 nm) radiation, whereas the cornea absorbs UVA (315–400 nm). Consequently, excessive UVA light may produce thermal damage to the lens; overexposure to radiation from this portion of spectrum can cause keratoconjunctivitis similar to the keratitis seen in arc welders.[217] Insignificant amounts of UVA light reach the retina.

Visible Region (380/400–780 nm)

The eye focuses visible light on the retina with excessive amounts of visible light potentially causing thermal damage to the retina. Lesions on the retina are usually small because of the spatial coherency of most lasers unless the intensity and/or duration of the exposure are high. Image magnification through binoculars or telescopes increases the hazard of a given laser radiation dose. The retinal pigment epithelium is the first layer of the retina to absorb visible light; as the intensity of the visible light increases, progressive damage occurs in the choroid and the nerve structures in the retina. Depending on the irradiance of the visible light, damage to the retina ranges from temporary erythema and edema to hemorrhage and necrosis with significant loss of visual acuity.[218]

Infrared Region (780 nm–1 mm)

The infrared portion of the electromagnetic spectrum contains three approximate band widths: 1) IRA or near-infrared (near-IR) closest to the visible spectrum (0.78–1.3 μm), 2) IRB or mid-infrared (mid-IR, 1.4–3 μm), and IRC or far-infrared closest to microwaves (far-IR, 3.1 μm–1 mm). The consequences of exposure to IRA radiation are similar to the effects of visible radiation, with the retina being the most vulnerable part of the eye. Excessive absorption of IRB (1.4–3.0 μm) and IRC (3.1 μm–1 mm) radiation as emitted by the CO_2 laser causes thermal damage to the cornea and, to a lesser extent, the lens.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The biological effects of laser radiation are qualitatively similar to the effects of ultraviolet, visible, and infrared radiation, but the intensity of this radiation is closer to the radiation produced by the sun, burning magnesium, or arc lights. The eye is particularly vulnerable to laser-induced injuries as a result of the ability of a laser to increase retinal irradiance 10,000-fold over the retinal irradiance produced by the cornea.[208] The amount of damage to the retina depends on the wavelength, the amount of power delivered to the retina (pulse duration, energy of the beam), and the exact location of the damage (i.e., proximity to fovea). Argon and krypton lasers produce thermal damage by increasing local temperature, coagulating proteins, and causing cell necrosis, whereas excimer lasers alter photochemical processes with low power and long pulses.[219] The major characteristics of the laser beam contributing to the amount of tissue damage are pulse duration, pulse repetition rate, wavelength, image of the laser beam on the retina, and power density. Anatomic factors include the amount of pigment in the choroid and retina, the size of the pupil at the time of exposure, and effectiveness of the blink reflex (typically

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. 150 msec). An 8 mm pupil (full dilation) transmits 16 times more radiation than a 2 mm pupil (maximum constriction). The duration of exposure depends on the type of laser involved in the incident. Q-switched lasers have the shortest exposure (<100 nsec); however, the high power density causes the greatest hazard for eye injury. Continuous-wave mode allows exposures ranging from milliseconds to minutes, whereas normal multiple spike mode permits exposures in the range of 0.1–2 msec.

The mechanism of injury to the retina is a complex interaction of thermal, mechanical, and displacement effects. High-intensity laser irradiation produces damage by denaturation of proteins associated with temperature elevations of 10°C and by vaporization of fluid in tissue with associated microstream explosions. The effect of the laser beam on the tissue depends on the percentage of energy absorbed by the tissue compared with the amount of energy transmitted through the tissue. Short bursts of a highly focused beam create an acoustic shock wave that propagates through the tissue as the true cutting edge of the laser.

Pathological Changes

Most serious accidents involving human injury with lasers (e.g., Nd:YAG) result from damage to the posterior portion of the eye by lasers emitting radiation in the visible and near-infrared regions. These lasers rarely produce damage to the anterior segment of the eye. The exact location of injury depends on the wavelength; the retina is particularly vulnerable to visible and infrared radiation because the eye focuses this type of radiation on the retina. The increased density of pigment in the macula along with the reduced thickness of the retina at the fovea result in increased sensitivity of the foveal areas of the retina compared with the extrafoveal areas.[220] In a consecutive case series of 14 patients presenting with sudden visual loss after exposure to high-powered, handheld blue laser devices (450 nm, 150–1,200 mW), macular damage included full-thickness macular hole, premacular subhyoid and subinternal limiting membrane hemorrhage, outer retinal disruption at the fovea, epimacular membrane, and retinoschisis-like cavity.[221] The mean visual acuity was 20/290.

Ophthalmological examination typically demonstrates retinal edema; burns or holes in or near the macula; and subretinal, subhyaloid, or vitreous hemorrhage. Intraocular pressures are typically normal. Secondary degeneration from the release of glutamate and inflammatory mediators may increase the anatomic and functional damage beyond the original lesion, resulting in an expansion of the primary injury over hours to days after the exposure.[222] Subsequently, the lesion begins receding over a few weeks to months with improvement greater for lesions more distant from the fovea.[223] Choroidal neovascularization rarely occurs after laser eye injuries; hemosiderosis bulbi and glaucoma do not usually occur.[208] Lasers emitting radiation in the far-infrared (e.g., CO_2) or ultraviolet region produce damage to the anterior segment of the eye. In experimental animals, the beams from CO_2 lasers cause corneal thickening and a central crater formation that penetrates into the anterior chamber at high power levels.[224]

Cellular vaporization and combustion release steam, cell contents, and pyrolysis by-products into the laser surgical plume; the composition of this plume depends on the irradiance, laser type, and tissue treated. This plume contains a variety of biological and chemical constituents including viable cellular matter and viruses.[225,226] Animal studies suggest the *possibility* that smoke from Nd:YAG laser-induced electrocautery on the respiratory system may produce pulmonary damage (alveolar congestion, emphysematous changes) following prolonged exposure; therefore, smoke evacuation devices are recommended during the procedure.[227] However, there are inadequate epidemiological data to determine the clinical significance of long-term exposure to surgical plumes.

CLINICAL RESPONSE

The health risks associated with the use of lasers include beam hazards (i.e., direct effects on the eyes and skin) and nonbeam hazards (i.e., laser-generated fires, electrical shock, noise, air contaminants).[186] The primary adverse health effect from the use of lasers results from ocular and, less often, dermal exposure to the laser beam. Almost all of the structures in the eye are susceptible to laser-induced injuries, depending on wavelength, duration and intensity of exposure, intraocular location of injury, pupil size, and retinal pigmentation. Most eye laser injuries involve retinal injuries following the use of short Q-switched laser pulses (nanosecond range). Pain is unusual in these cases. The typical clinical course of laser-induced retinal injuries involves sudden loss of vision with marked improvement over a few weeks, and occasionally severe, late complications include blindness in the affected eye. Temporary flash-blindness occurred in two civilian pilots following exposure to 12–15 W argon lasers used in a light show on the ground.[228]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Because of the large voltages used with laser equipment, electrocution has occurred during use. Lasers possess the ability to ignite material including the use of CO_2 lasers near endotracheal tubes or catheters susceptible to ignition by lasers;[229] catastrophic tracheal tube fires may occur during laser surgery.[230] Surgical lasers are the second most frequent ignition source of operating room fires after electrosurgical units; however, in contrast to electrosurgical units, lasers do not require direct contact to produce a fire.[231] Filling tracheal tube cuffs and moistening surgical tape with saline provide partial protection from combustion during CO_2 laser airway surgery.[232] Green nasal cannula prongs are extremely flammable in oxygen following irradiation with a flash-lamp, pumped 585 nm tunable dye laser; however, this laser does not ignite Telfa, gauze, or polyvinyl tubes in room air.[233] Several case reports associate sudden gas embolisms with the Nd-YAG laser in women undergoing endometrial ablation, presumably as a result of the use of air or CO_2 for insufflation and/or cooling the laser tip.[234]

Eye

Immediate

Retina

The eye is the most susceptible organ to laser radiation because the eye transmits radiation in the visible and near-infrared ranges directly to the retina. Many patients sustaining damage from laser radiation did not wear protective eyewear at the time of the accident, despite the importance of eye protection. Damage to the macula can occur from direct viewing of the beam or reflection of the beam from a nearby object (e.g., target, photographic paper).[235,236,237] Injuries from lasers usually, but not always, occur when the unprotected patient is in close proximity to the laser. Ocular damage ranges from minimal retinal burns with complete recovery to extensive necrosis and macular holes with substantial reduction in central visual acuity. The ultimate outcome in terms of visual acuity depends on the location of the burn on the retina.[211] Parafoveal burns may produce paracentral scotoma with visual acuity usually maintained, whereas central foveal burns generally cause permanent loss of visual acuity, with the loss directly proportional to the proximity of the lesion to the fovea.[223,238] Examination of these patients' eyes reveals a parafoveal scotoma and a reduction in visual acuity. Exposure of the periphery to laser radiation may require contrast sensitivity, static perimetry, or dark adaptometry to detect laser-induced damage. Central scotomas usually occur in the presence of foveal lesion, with the range of the scotoma related to the degree of injury; reduction of visual acuity following accidental exposure to laser radiation does not typically occur in the absence of lesions detectable on ophthalmological examination.[207,238] The presence of submacular or vitreous hemorrhage in the absence of other retinal damage is not always associated with decreased visual acuity. Paracentral scotoma may develop in the absence of reduced visual acuity, especially when the dose of energy is several orders of magnitude above the permissible exposure limits.[239] The presence of macular holes indicates a poor prognosis. A case report documented the development of a traumatic macular hole in the central fovea of a physician assistant following the accidental activation of a 755-nm Q-switched laser during routine maintenance.[240] Poor visual acuity and the size of the macular hole remained unchanged at the last follow-up visit 7 months after the injury.

Direct exposure to the beam of a laser is usually associated with the feeling of a flash of light across the eye followed by a shadow (scotoma) of varying size and color. Immediate reduction of visual acuity occurs depending on the extent of edema, hemorrhage, or coagulation of the macula. Most injuries occur on the macula because the macula resides at the center of gaze.

Lens

Lasers producing wavelengths in the ultraviolet or far-infrared region affect primarily the anterior structure of the eye. A few case reports associate the use of the argon laser during the treatment of proliferative retinopathy with the development of cataracts.[241] Light microscopy indicates these spindle-shaped lesions occur mostly in the deep cortical area near the junction of the anterior cortex and the nucleus with extension of the cataract into the nucleus.[242] These cataracts are multiple aggregations aligned perpendicular to the lens capsule; the usual location of these cataracts is posterior to the location of senile cataracts.

Chronic

Sequelae from chronic exposure to laser radiation are not well documented in the medical literature, with ACGIH occupational standards based on the assumption that the total retinal dose from visible illumination encountered in the natural environment is not hazardous.[243,244,245] Unprotected exposure to blue-green argon lasers may produce a cumulative reduction in color contrast sensitivity as defined by a decrease in the tritan threshold (an early manifestation of blue cone photoreceptor injury); the threshold correlates to the number of years of use of the argon laser based on case reports.[246] In a study of 58 Swedish ophthalmologists

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

using argon lasers, there was no significant difference ($P > 0.2$) in color vision between argon laser users and 26 age-matched controls.[247] Examination of 18 research scientists with cumulative blue-green argon laser exposure ranging from 580–7,200 hours with infrequent use of eye protection did not detect a reduction in color contrast sensitivity.[248] A case report associated the use of dermatological lasers with the development of vitreous floaters in the eyes of two dermatological laser surgery fellows.[249] These changes were not associated with a reduction in visual acuity, evidence of retinal injury, or further development of floaters. For several hours after the use of argon blue-green laser, flashbacks may produce reductions in the sensitivity for colors lying along the tritan color-confusion line.[250]

Skin

Skin injuries following exposure to the laser beam are typically minor, consisting of erythema and edema that resolve within hours to a few days; urticaria, erosions, crusting, ecchymoses, and blistering occur uncommonly.[251] Postinflammatory hyperpigmentation and, less commonly, hypopigmentation may develop after the burns heal, depending on the depth of the burn.[186] Scars and indentations occur when full-thickness burns develop. Photoepilation requires a careful balance between maximal therapeutic effect and minimum side effects; skin burns may result from the excessive use of intense pulsed-light lasers used for tattoo removal.[252]

HEALTH SURVEILLANCE

Patients

Precautions for the general population and workers regarding laser use are similar. The reproductive risks of nonionizing radiation from laser therapy for hair removal or other cosmetic procedures are minimal to none because of the limited skin penetration of the laser beam.[253]

Workplace

The four basic categories of controls useful in laser environments include engineering controls, personal protective equipment, administrative and procedural controls, and special controls. The guidelines of the US Occupational Safety and Health Administration are based upon the recommendations of the American National Standards Institute (ANSI) Z 136.1–2007 standard.[254] Accident data indicate US FDA (ANSI) Class I (1, 1M), Class II (2), Class IIa (2M), and Class IIIa (3R) lasers, as listed in Table 43.11, are not usually considered hazardous from a radiation standpoint, unless used inappropriately with optical aids; the numbers in parentheses represent ANSI and IEC classifications analogous to US FDA classifications. Table 43.12 lists the requirements of the American National Standards Institute;[255] for details on controls (engineering, procedural, administrative), training, and exceptions to these requirements, see references[254] and.[255] The ANSI Z 136.1 standard requires a Standard Operating Procedure (SOP) covering administrative and procedural controls under the guidance of a Laser Safety Officer (LSO) for Class IV lasers, whereas ANSI recommends SOPs but requires an LSO for Class IIIB lasers.

Exposure Guidelines

The skin and the eye are the primary target organs potentially damaged by radiation from lasers. The specific area of injury depends on the wavelength; thus, guidelines for exposure are based on the wavelength, duration of exposure, and measures of power

TABLE 43.12. American National Standards Institute (ANSI) requirements for specific laser classifications based on ANSI Z136.1–2014. (Based on American National Standards Institute).[255]

ANSI Class (US FDA Class)	Procedural and Administrative Controls	Training	Medical Surveillance
1 (I)	None	None	None
1M (I)	Required	Application dependent[a]	Application dependent[a]
2 (II)	None[b]	None[b]	None
2M (IIa)	Required	Application dependent[a]	Application dependent[a]
3R (IIIa)	None[b]	None[b]	None
3B (IIIb)	Required	Required	Suggested
4 (IV)	Required	Required	Suggested

[a] Certain uses of Class 1M or 2M may require hazard evaluation including training and medical surveillance similar to Class 3 and 4 lasers. [b] Except for intentional intrabeam exposure applications.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(e.g., radiant exposure for pulsed lasers, irradiance for continuous-wave or repetitively pulsed lasers). The International Commission on Nonionizing Radiation Protection (ICNIRP) and the American Conference of Industrial and Governmental Hygienists (ACGIH) threshold limit values (TLVs) list recommended exposure limits for direct ocular exposure to laser beams based on wavelength, duration of exposure (pulse duration), correction values, and irradiance diameter (spot size) in some circumstances.[244,245] Measurement of irradiance or radiant exposure is an average over the circular areas defined by the limiting aperture. No correction is necessary for a beam size of <1 mm; however, light in the 400–1,400 nm range is hazardous to the retina. Power from the light source should be averaged over a limiting aperture of 7–8 mm (i.e., the maximum size of a dilated pupil). The only exception is a limiting aperture of 10 mm for wavelengths 0.1–1 nm. These TLVs are complicated because of the variability of penetration by different wavelengths and several correction factors for specific wavelengths, including accounting for reduced absorption of melanin, reduced photochemical sensitivity for retinal injury, and preretinal absorption of ocular media. Sources are available to explain the correction factors.[244,255] These organizations apply correction factors for wavelengths 700–1,400 nm and extended sources in the range of 400–1,400 nm that produce different effects than point sources during direct intrabeam viewing. Extended sources (e.g., laser arrays, diffuse reflecting surfaces, diodes) are distinguished from intrabeam viewing by the apparent visual angle (limiting angle subtense) between the eye of the observer and the extended source.

The exposure guidelines of ICNIRP and ACGIH for skin exposure from a laser beam are the same as the guidelines for eyes in UV (180–400 nm) and IRB/IRC (1.4–1,000 μm) wavelengths; however, for visible light and IRA (400–1,400 nm) wavelengths, correction factors are for exposure duration of >10 seconds and beam diameter. Guidelines for laser pointers primarily involve education and training for all persons involved with these products.

Safety Glasses

The primary method of preventing injury to workers is the use of shielding from high-energy beams and eye protection. Eye-protection devices designed to protect against laser radiation should be used when engineering controls are inadequate to eliminate the possibility of potentially hazardous eye exposure with class IIIb (3B) and IV (4) lasers. The filtering characteristics (optical density, OD) of the glasses should be clearly marked and must be effective for the specific wavelength in use. The plastic or glass lenses of protective eyewear may be either absorptive or reflective of laser radiation. The use of protective glasses reduces the amount of radiation received by the eye from the selective spectral absorption of colored lenses or the selective reflection of dielectric coatings on the eyewear. Some types of lasers are tunable, whereas other lasers (e.g., helium-neon) operate at three different wavelengths depending on the specific design. Eye gear should be checked for cracks, scratches (reflective design), and deterioration of the frame. In contrast to absorptive protective eyewear, scratches on reflective eyewear may allow penetration of the beam. Procedures for the operation of the laser should avoid focusing the beam on reflective surfaces; eyewear should provide protection from beams entering the eye from the side or front.

Selection of Eyewear

Optical density is the parameter that defines the amount of attenuation of the beam as it passes through the lens. The optical density is a logarithmic function defined by Equation 43.7.

$$\text{Optical Density (OD)} = \log 10\,(Io/I) \quad \text{(Equation 43.7)}$$

where:

Io = intensity of the incident beam,
I = intensity of the transmitted beam.

If the lens transmits 1% of the incident beam from the laser, then the OD is 2, whereas transmission of 1/1,000,000th of the beam through the lens correlates to an OD of 6. Typically, the intensity of the transmitted beam is the maximum laser beam radiant exposure (J/cm^2) for pulsed lasers and the maximum laser beam irradiance (W/cm^2) for continuous-wave lasers. High visible light transmittance is important because eye fatigue may occur; alterations in the ambient lighting of the work environment may be necessary. The spectral response of the eye at night should be considered if the operation of the laser occurs during periods of darkness because blue-green filters reduce night vision more than red-orange lenses.

Table 43.13 lists the factors important in selecting appropriate eyewear. Damage thresholds are important factors during the operation of high-intensity lasers. A Q-switched pulsed laser produces damage to plastic in the range of 1–100 J/cm^2 and glass in the range of 10–100 J/cm^2.

TABLE 43.13. American National Standards Institute (ANSI) factors for selecting appropriate eyewear. (Adapted from ANSI).[255]

Wavelength of laser output
Potential for laser operation at several wavelengths
Radiant or irradiance values
Maximum permissible exposure (MPE)
Optical density of eyewear at laser output wavelength
Visible light transmission needs
Peripheral vision requirements
Total radiant flux or irradiance during the time eyewear is worn that will not damage the eyewear including transient leaching
Need for corrective glasses
Comfort and fit
Material strength and resistance to photobleaching
Capability of front surface to produce specular reflection

Medical Monitoring

ANSI guidelines suggest medical surveillance for workers using Class IIIb or Class IV lasers, whereas workers operating Class I, Class II, Class IIa, or Class IIIa lasers may need medical surveillance depending on special circumstances (e.g., use of optical aids that intensify the output of the laser, Classes 1M and 2M). Medical surveillance includes baseline Amsler grid, visual acuity, color vision, contrast sensitivity, and ocular history. Medical examinations for incidental personnel (e.g., supervisors, military personnel on maneuvers, custodians, clerks) involve only visual acuity testing. Further ophthalmological examination is necessary if abnormalities are detected on the routine eye exam. Although periodic examinations are not necessary, all personnel should be examined within 48 hours whenever a laser injury is suspected.[256] The American National Standards Institute recommends an annual skin examination for personnel exposed to UV lasers.

TREATMENT

Treatment of laser-induced injuries of the retina is symptomatic, primarily involving the use of corticosteroids with the rationale of reducing cellular inflammation associated with the retinal injury. Primate studies suggest use of methylprednisolone reduces photoreceptor damage at the periphery of the lesion and inhibits subretinal neovascularization;[257,258] however, rodent studies suggest the improvement is short term.[259] Clinical studies are limited by the rare occurrence of laser eye injuries. Surgical intervention is considered for the removal of vitreous and periretinal hemorrhages. The use of a Q-switched Nd:YAG laser may be useful in opening the anterior wall of the bubble of a subhyaloid hemorrhage.[210] Case reports on the success of retinal surgery after injury are mixed. The ultimate visual outcome depends on the location of the injury on the retina and the amount of energy delivered. Improvement in visual function may occur up to 1 year after injury.

Chapter 44

RADIOFREQUENCY RADIATION

HISTORY

Studies on the biological effects of the radiofrequency (RF) portion of the electromagnetic radiation began in the early 1900s with investigations into biophysical mechanisms; later, in the 1920s–1930s, experimentation began on the clinical applications of hyperthermia and diathermy with these energy sources. In England during 1939, John Randall and Harry Boot invented the first cavity magnetron tube that was initially used as a microwave radar device to detect Nazi aircraft and ships during World War II. The American engineer, Percy Spencer, discovered the beneficial effects of microwaves on foods incidentally, while working near radar equipment. He subsequently built and patented the first microwave oven using the magnetron tube in 1945. Extensive research on the health and safety issues of radiofrequency electromagnetic fields began in the early 1950s followed by the development of exposure guidelines from the American National Standards Institute (ANSI) and the Institute of Electrical and Electronic Engineers (IEEE) in the 1960s. Later guidelines were formulated by the International Radiation Protection Association (IRPA) and the International Commission on Non-Ionizing Radiation Protection (ICNIRP). Recommendations were propagated for radar (1950s–1960s), radio/TV broadcasting (1960s–1970s), microwave ovens (1970s–1980s), police radar (1980s), and wireless communication equipment (1990s), including wireless fidelity (Wi-Fi), and Worldwide Interoperability for Microwave Access (WiMAX) for mobile phones, base stations, smart meters, and radiofrequency identification. In the late 2000s and early 2020s, deployment of long-term evolution (LTE) began with 4G cell technology and continued with 5G phone technology, respectively.

PHYSICAL PROPERTIES

Radiation is the transfer of energy through space with electromagnetic radiation of radio waves being nonionizing and possessing much less energy than the visible spectrum. Electromagnetic fields have always existed around the earth. In the lower portion of the electromagnetic radiation spectrum, radiofrequency electromagnetic fields (mobile telephones, base stations, induction heaters, anti-theft devices, radar, radio, and television broadcast facilities) occupy a position between static/extremely low-frequency electromagnetic fields (household electrical appliances, power lines, computers) and infrared radiation as displayed in Figure 44.1.

Electromagnetic waves constitute oscillating electric and magnetic forces that move through space at the speed of light perpendicular to each other. Moving electric charges produce these energy waves; their origin may be natural (e.g., the sun) or artificial (e.g., microwaves, radio, and television transmitters). In the radiofrequency range, tightly coupled electric and magnetic fields propagate the electromagnetic wave (radiation). Knowledge of the magnitude of electric field allows the calculation of magnetic fields and vice versa. Distance from the source affects these calculations. In the reactive near-field close to the source, the electric and magnetic fields associated with energy

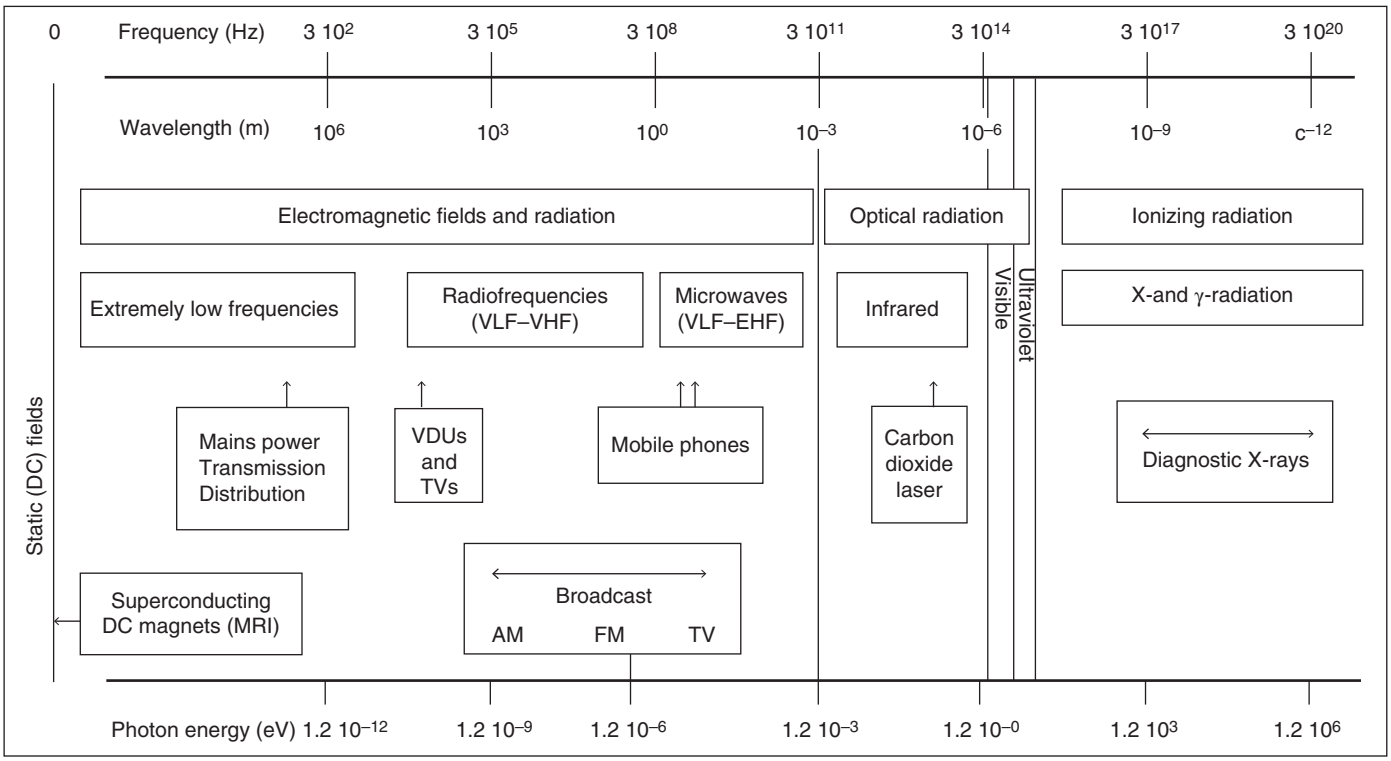

FIGURE 44.1. Electromagnetic radiation spectrum. Radiofrequency electromagnetic fields occupy a position in the nonionizing part of the electromagnetic radiation spectrum between static/extremely low-frequency fields and the infrared portion. (Redrawn from International Agency for Research on Cancer, IARC).[1] *Abbreviations:* AM = amplitude modulation; DC = direct current; EHF = extremely high frequency; eV = electron volt; FM = frequency modulation; MRI = magnetic resonance imaging; TV = television; HF = ultra-high frequency; VDU = visual display unit; VHF = very high frequency; VLF = very low frequency.

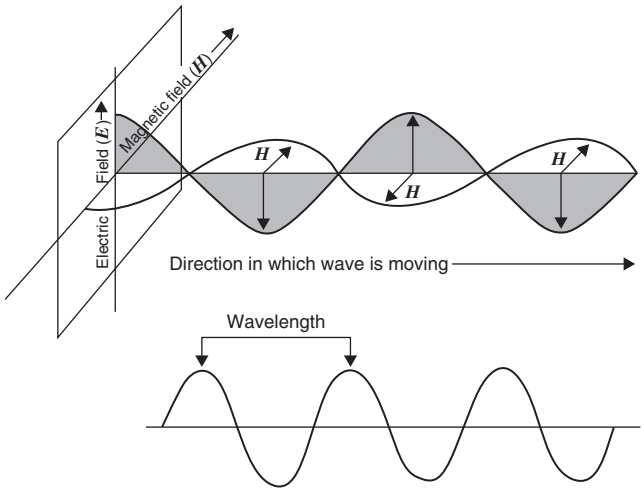

FIGURE 44.2. The electromagnetic monochromatic wave. These waves consist of electric and magnetic forces moving through space at right angles to one another in a wave-like pattern. *Abbreviations:* E = electric field; H = magnetic field.

stored in the vicinity of the source affect radiation emitted from the source, whereas the far-field represents the distance from the source sufficient to have no influence on the energy radiated away from the source. In the latter region, power density can be determined from field strengths. The reactive near-field typically extends approximately a wavelength from the source.

Figure 44.2 illustrates the propagation of an electromagnetic wave characterized by electric and magnetic fields moving at right angles to each other. Several physical parameters describe electromagnetic waves, including: 1) strength or intensity of the electric field (E) in V/m and magnetic field (H) in T (tesla); 2) frequency (f) of the oscillations in Hz; 3) wavelength (λ) in metric dimensions; 4) direction of the E-field or electric polarization (P); 5) velocity of propagation (c); and 6) the Poynting vector (S). Table 44.1 lists the quantities, units, and symbols useful for describing electromagnetic fields in the radiofrequency range.

Wavelength and frequency are inversely related with frequency increasing and wavelength decreasing from the beginning of the electromagnetic spectrum.

TABLE 44.1. Quantities and units useful for describing radiofrequency fields.

Quantity (Symbol)	Unit (Symbol)
Conductivity (σ)	Siemens/meter (S/m)
Current (I)	Ampere (A)
Current density (J)	Ampere/square meter (A/m^2)
Electric field strength (E)	Volt/meter (V/m)
Frequency (f)	Hertz (Hz)
Impedance (Z or η)	Ohm (Ω)
Magnetic field strength (H)	Ampere/meter (A/m)
Permeability (μ)	Henry/meter (H/m)
Permittivity (ε)	Farad/meter (F/m)
Power density (S or Pd)	Watt/square meter (W/m^2)
Propagation constant (K)	Per meter (m^{-1})
Specific absorption (SA)	Joule/kilogram (J/kg)
Specific absorption rate (SAR)	Watt/kilogram (W/kg)
Wavelength (λ)	Meter (m)

In free space, the velocity (c) is proportional to the product of the frequency and wavelength as defined by Equation 44.1.

$$c = \text{frequency}\,(f) \times \text{wavelength}\,(\lambda) \quad \text{(Equation 44.1)}$$

where

c = speed of light.

Radiofrequency waves interact with the medium through which they travel; therefore, the speed of the propagation of the wave depends on the interaction of the matter in the electric field (i.e., permittivity) and the magnetic field (i.e., permeability). Propagation of radiofrequency waves through biological media is vastly different from the propagation of these waves through space. For plane waves, the Poynting vector ($\vec{s}$) represents the magnitude and direction (vector product) of the energy flux density of the electromagnetic field, as defined by Equation 44.2.

$$\vec{s} = (\vec{E}) \times (\vec{H}) \quad \text{(Equation 44.2)}$$

where

$\vec{E}$ = electric field strength,
$\vec{H}$ = magnetic field strength.

The energy of electromagnetic waves propagates as bundles of energy (photons) with the amount of energy in each photon directly proportional to its frequency. The higher frequency implies greater photon energy. Thus, photons in the X-ray portion of the electromagnetic spectrum contain much more energy than photons in the radiofrequency range of the electromagnetic spectrum. By convention, the dividing line between ionizing radiation and nonionizing radiation occurs at a photon energy of 12 eV corresponding to a wavelength of 100 nm or a frequency of 10 MHz.[2] At the upper end of the radiofrequency spectrum (300 GHz) near high-frequency microwaves, the energy/photon is 0.00125 eV, whereas the energy/photon near the lower end of the radiofrequency spectrum (100 kHz) close to AM radio is 4.1×10^{-10} eV. Consequently, photons in the radiofrequency range do not possess sufficient energy to disrupt molecular bonds. The adverse effects of the absorption of these waves result primarily from the production of heat rather than the disruption of chemical bonds. At the very low-frequency range of electric power (i.e., 60 Hz), the electromagnetic waves pass through the human body with minimal energy absorption; thus, little heating and no ionization occur in this portion of the electromagnetic spectrum.

Bandwidth

The spectrum of radiofrequency electromagnetic radiation extends from 30 kHz–300 GHz corresponding to wavelengths ranging from 10 km down to1 mm; some organizations use a lower range of 3 kHz. Radio waves have the longest wavelengths in the electromagnetic spectrum. Table 44.2 lists commercial, medical, and scientific applications of various radiofrequency bands. Microwaves represent the subset of the radiofrequency range of 300 MHz–300 GHz. This division does not imply a significant change in physical properties. Radar, satellite communications, and microwave relay stations typically operate in the 3–300 GHz range, whereas microwave ovens operate at 2.45 GHz.

The International Telecommunications Union separates the radiofrequency region into the following frequency decades: very low frequency (VLF); voice frequency (VF); low frequency (LF); medium frequency (MF); high frequency (HF); very high frequency (VHF); ultra-high frequency (UHF); super-high frequency (SHF); and extremely high frequency (EHF), as displayed in Figure 44.1.

Figure 44.3 illustrates the distribution of bandwidth in the radiofrequency range to various manufactured sources including broadcasting, communication, industrial, scientific, and medical uses. Frequency bands used for broadcasting TV and radio signals are generally similar across different countries, as displayed in Table 44.3. Analog broadcast radio uses amplitude modulation (AM) in the long, medium, and short bands. AM radio is less popular than FM radio because frequency modulation provides a better signal using band II (very high

TABLE 44.2. Various commercial, medical, and scientific applications of radiofrequency bands. (Adapted from World Health Organization, WHO).[3]

Frequency Band	Applications
30–300 kHz	Marine and aeronautical communications, navigation, long-range communications, radiolocation, VDUs, electro-erosion treatment, induction heating and melting of metals, power inverters
300 kHz–3 MHz	Communications, navigation, marine radiophone, amateur radio, industrial RF equipment, AM broadcasting, RF-excited arc welders, sealing for packaging, production of semiconductor material, medical applications
3–30 MHz	Citizen band, amateur radio broadcasting, international communications, medical diathermy, magnetic resonance imaging, dielectric heating, wood drying and gluing, plasma heating
30–300 MHz	Police, fire, amateur FM, VHF–TV, diathermy, emergency medical radio, air traffic control, magnetic resonance imaging, dielectric heating, plastic welding, food processing, plasma heating, particle separation
300 MHz–3 GHz	Microwave point to point, amateur, taxi, police, fire, radar, citizen band, navigation, UHF–TV, microwave ovens, medical diathermy, baby monitors, food processing, material manufacture, insecticide, plasma heating, particle acceleration
3–30 GHz	Radar, satellite communications, amateur, fire, taxi, airborne weather radar, police, microwave relay, anti-intruder alarms, plasma heating, thermonuclear fusion experiments
30–300 GHz	Radar, satellite communications, microwave relay, navigation, amateur radio

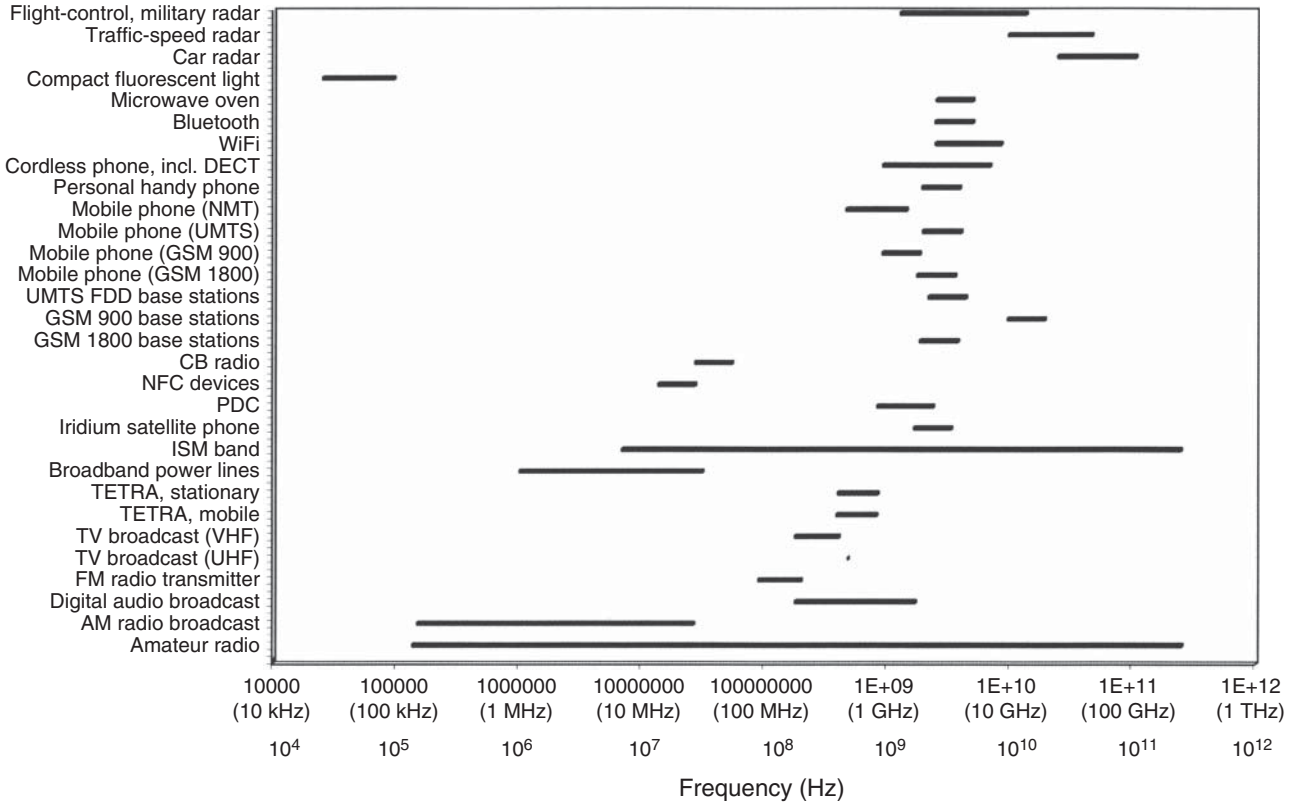

FIGURE 44.3. Distribution of bandwidths in the radiofrequency range for artificial sources. (Redrawn from International Agency for Research on Cancer Working Group on Evaluation of Carcinogenic Risks to Humans).[2] *Abbreviations*: AM = amplitude-modulated radio; CB = citizen band; DECT = digital enhanced cordless telecommunications; FDD = frequency-division duplex; FM = frequency-modulated radio; GSM = global system for mobile communications; ISM = industrial, scientific, medical use; NFC = near-field communications; NMT = Nordic mobile telephony; PDC = personal digital cellular; TETRA = terrestrial trunked radio; TV = television; UHF = ultra-high frequency; UMTS = universal mobile telecommunications system; VHF = very high frequency; Wi-Fi = standard wireless local area network (WLAN technology).

TABLE 44.3. Distribution of frequency bands in the radiofrequency range used in various countries.

Band	Description	Source	Frequency Range (MHz)
Long wave	Amplitude modulation (LF, MF)	AM radio	0.145–0.283
Medium wave		AM radio	0.526–1.606
Short wave	High-frequency band (HF)	International radio	3.9–26.1
FM	VHF, Band II frequency modulation	FM radio	88–108
TV/DAB	VHF band III	Analog/digital TV, digital audio broadcasting	174–223
TETRA	Terrestrial trunked radio		380–400
TV	UHF, bands IV, V	Analog/digital TV	470–854
GSM/UL	Global system for mobile communications, uplink	Mobile phone to base station (European)	880–915
GSM/DL	Global system for mobile communications, downlink	Base station to mobile phone (European)	925–960
DCS/UL	Digital cellular system, uplink	Cellular phones using digital technology (TDMA, GSM, CDMA)	1,710–1,785
DCS/DL	Digital cellular system, downlink	Cellular phones using digital technology (TDMA, GSM, CDMA)	1,805–1,880
DECT	Digitally enhanced cordless telecommunication	Portable phone	1,880–1,900
UMTS/UL	Universal mobile telecommunications service, uplink	Mobile phone, frequency-division duplex base stations	1,920–1,980
UMTS/DL	Universal mobile telecommunications service, downlink	Mobile phone, frequency-division duplex base stations	2,110–2,170
Wi-Fi	Wireless fidelity	Wireless local area network (WLAN), access points	2,400–2,500

frequency, VHF) than amplitude modulation. International radio uses the short-wave band because reflection of this signal off the ionosphere allows the signal from multiple horizontal dipole antennae to travel thousands of kilometers. The original band for television was band III (VHF); however, many countries are transferring television to bands IV/V (ultra-high frequency, UHF) while assigning band III to digital audio broadcasting. Radio and TV broadcast sites typically contain a transmitter building with an RF feeder cable extending to multiple antennae that may cover an area of several square kilometers. Terrain affects the transmission of broadcast signals by creating shadow areas, particularly, UHF signals. Booster transmitters are necessary to increase the distance of the signal by propagating and rebroadcasting it in these shadow areas.

In contrast to the high-power transmitters involved with radio and TV transmissions, cellular communication requires a large number of low-power transmitters (base stations) dispersed over a much smaller service area. Each user requires two-way (duplex) communication with a dedicated communication channel for uplink (phone to base station) and downlink (base station to phone) signals. Each base station has limited capacity; therefore, higher cell phone use necessitates more base stations in the area, particularly in densely populated urban locations. Cellular networks have limited frequency channels, requiring the reuse of frequency channels that cause interference in the cells; consequently, design requirements result in minimization of the use of adjacent cells and the reduction in RF frequency exposure.[2]

Mobile phone technology involves five generations (1G–5G), with the first generation (1G) introduced in the 1980s no longer in operation and 5G now being deployed. In the 1990s, second-generation (2G) began operations that continue today. This technology involves the use of time-division multiple access (TDMA), including Global System for Mobile communication (GSM) in Europe, Personal Digital Cellular (PDC) in Japan, and Personal Communication Systems (PCS) in North America. The introduction of code-division multiple access (CDMA) in North America was a 2.5-generation system. With TDMA, the time-domain

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

signal from a cellular phone appears as a continuous carrier wave that is pulse-modulated at a fixed frequency. Code division multiple access (CDMA) is a competing technology that looks more like an irregular train of 1.25-msec-side pulses of a carrier wave with widely varying amplitudes. TDMA and CDMA have their unique established carrier frequencies. The carrier frequency is always higher than the signal frequency, regardless of the type of signal (i.e., continuous or analog vs. digital).

The era of the smartphone began in the early 2000s with the introduction of third-generation (3G) systems that provided comprehensive data access. This system was compatible with 2G systems depending on the management of the network traffic. The next generation (4G) systems use orthogonal frequency-division multiplexing (OFDM) for Long-Term Evolution (LTE) systems and Worldwide Interoperability for Microwave Access (WiMax) for other systems. These technologies overlay 2G and 3G systems resulting in multiple access modes as some RF spectrums are reallocated to 3G and 4G cellular systems.

Deployment of fifth-generation (5G) systems augments current 4G technology. 5G technology transmits much greater data at higher speeds for a variety of applications than the preceding cellular technology, partly due to the use of higher frequencies in the millimeter wave range (MMW, 30–300 GHz) and greater bandwidth than older generations.[4] The MMW range typically includes radar and microwave links. This system provides the basis for the Internet of Things (IoT), where machines communicate directly with other machines. Additionally, 5G allows direct communication between personal devices and the environment (smart cities, other smart phones, autonomous vehicles, industrial Internet, home). Consequently, 5G will be a network or networks rather than a single radio access interface, necessitating higher infrastructure density from the shorter ranges of higher frequencies.[5] 5G networks operate in several frequency bands with the first phase involving lower frequencies (e.g., median $\cong$ 3.5 GHz).[6] Table 44.4 lists the applications and advantages of 5G subdivisions.

Absorption

Radio waves, including microwaves, pass through space at the speed of light until objects in their path reflect, diffract, absorb, or transmit the waves. Microwaves account for a very small portion (i.e., 0.01%) of solar radiation, depending on solar activity. Cloud cover, skin pigmentation, or altitude do not affect microwaves; however, the amount of microwave radiation is inversely related to latitude and strongly dependent on solar activity (sunspots). The relative permittivity represents a measure of a dielectric material to store energy. Greater permittivity implies greater interaction of the matter with the electric field. The velocity of microwaves decreases during transmission through biological media, depending on tissue permittivity and permeability. Tissues containing large amounts of water (brain, muscle, skin) are particularly effective at reducing the propagation of these waves; therefore, higher energy absorption (i.e., higher SAR) occurs in these tissues compared with tissues (fat, bone) containing smaller amounts of water. The human body acts like an antenna for radio waves. The amount of energy absorbed by the body from radio waves depends on several factors including the following: 1) **frequency** and energy of the wave; 2) **orientation** of the electric field relative to the long axis of the body; 3) **relative size** of the body compared with the wavelength; 4) the **shape** of the body; 5) **distance** between the body and the source; 6) local **environment** (reflection, resonance); and 7) **dielectric properties** of the tissues.[7]

Dissipation of the absorbed energy occurs through the production of electric current (conduction loss) and molecular rotation (dielectric loss). An increase in the kinetic energy of the molecules in the tissue corresponds to attenuation of radio waves and heating of the tissue. The degree and extent of temperature elevation in the tissue depend on the physical characteristics/distribution of the electromagnetic field in the body and the body's thermoregulation (e.g., conduction, convection, radiation, evaporative cooling).[8] The physical characteristics of the electromagnetic field include power density, polarization, frequency, and duration.[9]

TABLE 44.4. Anticipated 5G frequency spectrum subdivisions. (Adapted from Simkó and Mattsson).[6]

Frequency	Applications	Advantages/Disadvantages
<1 GHz	Network coverage, IoT	Overlaps with older systems, lower infrastructure costs, longer range
1–6 GHz	Network coverage, Internet of Things (IoT), improved data transfer	More available spectrum, shorter range, poorer performance than higher frequencies
>6 GHz	Very high data capacity	High-speed data transfer, short latency times, short range

Metallic Implants

Metallic implants (e.g., disks, metallic pins/clips, needles, plates, prostheses, rings, rods) act as antennas, enhancing local electric fields when the patient receives radiofrequency waves. The degree of enhancement of the electromagnetic fields depends on the implant dimensions, orientation, shape, and location. Maximum thermal effects occur at the resonant frequency of the implant. Individuals with metallic implants located in far-fields associated with radiofrequency sources do not typically experience adverse effects because the electromagnetic fields are weak. The situation is much more complex for the general public in near-fields as a result of the more complicated interaction of the electromagnetic field with the exposure, implant, and person. Theoretically, substantial rises in SAR values can occur on a small scale near implant corners and tips; however, experimental and computational studies indicate electromagnetic field enhancement around implants is unlikely to cause excess heating of >1°C consistent with the lack of case reports documenting adverse effects.[10] Numerical modeling of worst-case scenarios of workers with a metallic implant exposed to radiofrequency electromagnetic fields suggests implants may reduce the safety limit for RF exposure by ~25% compared with workers without an implant.[11]

Dental work poses little risk from exposure to radiofrequency radiation because the teeth are relatively heat-resistant and the mouth effectively dissipates heat.[7] Current shielding of pacemakers largely prevents interference with pacemaker functions; however, strong electric fields may cause interference with some pacemakers.[12] Programmable pacemakers have security systems that usually prevent interference with radiofrequency radiation; the effect of radiofrequency exposure (duration, strength, frequency, modulations) on pacemaker function depends on the individual pacemaker. Radiofrequency radiation can produce interference with cochlear implants, simulating auditory illusions.[13]

Perception

Humans do not reliably sense the presence of radio waves, and this type of radiation is invisible to the human eye. In a study of 5,933 adults in the Netherlands using a health survey and electronic health records, the perception of radiofrequency exposure correlated poorly to estimated RF exposure based on prediction models, distance to high-voltage overhead power lines, and self-reported use of indoor electrical appliances.[14] The association between perceived RF exposure and self-reported nonspecific symptoms was stronger than the association between symptoms reported in the health records and their perceived RF exposure. Cutaneous perceptions of heat and pain are not reliable indicators of the presence of hazardous levels of RF radiation.[15] Pulse radiofrequency radiation (e.g., radar) can produce a clicking sound from the heating of the cochlear fluid.[16] Perception of microwaves results from the stimulation of the sensations of temperature and pain. Reported thresholds for heat range from 27–200 mW/cm^2 (270–2,000 W/m^2), depending on the area irradiated, frequency, and duration of exposure.[3] In an experimental study of thresholds for a warm sensation on forehead skin during *continuous* exposure to 3 GHz microwave radiation, the threshold ranged from 1 second (Pd = 58.6 mW/cm^2) to 4 seconds (Pd = 33.5 mW/cm^2).[17] Exposure to 10 GHz reduced the power densities (Pd) by ~2.7-fold. The threshold for burning pain on the inner forearm of 6 men during *continuous* exposure to 3 GHz microwave radiation ranged from 20 seconds (Pd = 3,100 mW/cm^2) to 120 seconds (1,000 mW/cm^2).[18]

EXPOSURE

RF electromagnetic fields in proximity to the body generate nonuniform electric and magnetic fields that induce currents in the tissues. The induced field strengths are approximately proportional to the time-averaged radiated power and inversely proportional to the distance from the source. These fields vary by several orders of magnitude at local hot spots.[2] The most obvious effect of the absorption of radio waves is the production of heat in the medium. The calorimetric measure of radiation intensity in SI terminology is irradiance in units of W/m^2; however, the traditional measure of radiofrequency exposure is incident power/unit area (power density), typically measured in $\mu W/cm^2$ or mW/cm^2. Power density (i.e., the energy of the RF wave) is a measure of external dose that represents the time rate of energy flow/unit area across a surface area determined by the intensity of the electric and magnetic field strengths. The power density of summer sunshine peaks at ~1,000 W/m^2 (100 mW/cm^2). Analytical instruments measure power density indirectly by quantitating induced voltages and currents.

Very complex field distributions may occur from several factors, including perturbations of electrical properties and variations in the shape, size, and orientation of objects within the field. These complex

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

fields produce nonuniform fields and fluctuating depositions of energy within biological systems. At lower frequencies (<300 MHz) under near-field conditions, measurements of electric field (E) and magnetic field (M) strengths are necessary to determine power density, particularly for the quantitation of biological effects.[19] At frequencies of >300 MHz (i.e., wavelengths >1 m), far-field conditions usually exist, resulting in a constant ratio between the magnetic and electrical fields. Hence, calculation of the power density requires only measurements of the electric fields.

Far-Fields

The simplest exposure to radio waves occurs when the electromagnetic field is sufficiently removed from the receiver that the source of the field can be considered a point. At this distance, the antenna is large enough so that the radiation from each part of the antenna is in phase with the receiver and the radiation travels as plane waves. The conditions of a far-field or plane wave exist for horn antennas when the distance (d) between the transmitter and the receiver exceeds the value Equation 44.3.[20]

$$\text{Far-field pattern exists when } d = >2\,L^2/\lambda \qquad \text{(Equation 44.3)}$$

where

L = the largest dimension of the source aperture,
λ = wavelength.

Under far-field conditions, Equation 44.4 describes the power flux density; this value decreases inversely with the square of the distance from the source as measured in watts/square meter (W/m^2).

$$\text{Pd} = E \times H \qquad \text{(Equation 44.4)}$$

where

E = electric field strength (V/m),
H = magnetic field strength (A/m),
Pd = power density (W/m^2).

Under far-field conditions (>300 MHz, wavelength >1 m), the free space impedance, Z_o, in air is a constant, as described by Equation 44.5.

$$Z_o = E/H = 377\,\Omega \qquad \text{(Equation 44.5)}$$

This conversion factor allows the calculation of the power density from either the electric field strength (E) or the magnetic field strength (H), as defined in Equation 44.6.

$$\text{Pd} = E^2/377 = 377\,H^2 \qquad \text{(Equation 44.6)}$$

Hence, the electric and magnetic field strengths are equally valid measures of radiant energy flow under the conditions of plane wave exposure. The primary measurement is usually the electric field.

Near-Fields

Radiating Near-Fields

The near-field is the region close to the source antenna. As demonstrated in Figure 44.4, the near-field is divided into the reactive near-field region (i.e., closest to source) and the radiating near-field region (i.e., closest to far-field). The radiation pattern varies with distance in the radiating near-field, whereas source fields influence the field in the reactive near-field region. When the longest dimension (L) of the source antenna exceeds the wavelength (λ), the inverse square law no longer applies at distances $<2L^2/\lambda$ from the source. For horn antennas, the power density varies in an inverse linear relationship until distances are $<2L^2/\lambda$, where reflective interference complicates the calculation of the power density. Similarly, the conversion factor for power density and electromagnetic fields no longer applies. For dipole antennas where the dimension of the aperture (L) is < wavelength (λ), the near-field extends to a distance of $\lambda/2\pi$. In the near-field, most of the energy is deposited in the 20% of the total body volume closest to the antenna feed point.[21]

Reactive Near-Fields

The reactive zone is the area in the immediate vicinity of the antenna where energy is stored rather than transmitted. Objects located within this field (e.g., probes) may alter the field significantly. The electric and magnetic fields become less coupled at lower frequencies, particularly when the wavelength is large compared with the physical size of the source. From a practical perspective, near-fields at frequencies below 1 MHz represent the greatest hazard (e.g., highly localized RF-induced currents called RF hot spots).[3]

Sources

A wide variety of commercial and military applications emit radiofrequency waves, including linear beam tubes (klystrons), power grid tubes, solid-state devices, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 44.4. Schematic illustration of relative positions of the reactive near-field, radiating near-field, and the far-field with horn and dipole antennas. Within the near-fields, the strength of the radiofrequency electromagnetic fields varies rapidly with distance. The electromagnetic field of the source influences the fields in the reactive near-fields, whereas the electromagnetic fields in the radiating near-fields are related to the distance from the source. Measurement and calculation of the electromagnetic fields in the far-field are easier because the fields have the characteristics of radiation with the power density inversely related to the distance squared. The distance to the far-field depends on the longest dimension of the source antenna and wavelength rather than the distance from the source. (World Health Organization).[3] *Abbreviations:* λ = wavelength; L = longest distance to the source antenna.

crossed-field devices. These RF sources operate in one of the following three modes: 1) continuous (e.g., communications); 2) intermittent (e.g., heating); and 3) pulsed (e.g., radar, digital communication).[22] The dominant RF radiation sources for the public are transmitters held close to the body (e.g., handheld devices), whereas RF radiation sources in the near-field are the primary source of RF exposure for workers. Environmental sources near the public typically emit relatively modest field strengths; however, potential high-field strengths may occur in the industrial setting, depending on the design and operation of the equipment.[23] Electromagnetic fields vary substantially around radiofrequency sources. Consequently, spot measurements may not reflect average exposures, particularly when analyses are designed to detect maximum exposures exceeding published guidelines and workers spend substantial time away from the antennae.

Natural sources of radiofrequency radiation exposure are small compared with man-made sources (e.g., navigation, communication, industry, medicine).[24] The earth emits electromagnetic radiation (black-body radiation) at a level of ~0.003 W/m^2 (0.3 μW/cm^2) in the RF range.[3] The human body also generates electromagnetic fields internally and externally with power densities in the RF range of ~0.003 W/m^2. RF waves in the frequency range of 10 MHz–37.5 GHz can penetrate the atmosphere; however, the amount of radiation emitted by extraterrestrial sources is small compared with that from man-made sources. RF radiation sources in the home include cellular phones, microwave ovens, dimmer switches, wireless toy controllers, walkie-talkies, televisions, radios, personal computers, and electric motors that contain sparking brushes.[25] These RF sources produce variable amounts of electrical fields depending on the type and location of the antenna, phone operation, distance from base station, RF traffic conditions, output power of the antenna, directions of transmission, attenuation of interfering objects, and scatter from trees and buildings. Most appliances do not emit RF radiation, except for those that produce static on radios or televisions.

Broadcast and Telecommunications

Broadcast antennae direct the VHF/UHF signal toward the horizon in all directions; hence, field strengths

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

are lower at ground level and at distances from the antennae as the waves diffuse through the air. Consequently, exposure of the public to electromagnetic fields from the transmitters is substantially less than that of workers with access to the antenna towers. The estimated median RF exposure for the US population in 1978 was ~0.02 μW/cm^2 with 98–99% of the population being <1 μW/cm^2.[26] During the early 1980s, the estimated median power density in US urban areas was 50 μW/m^2.[27] In more recent studies, the VHF-FM-UHF-cellular bands continue to contribute most of the power density with negligible contributions from the AM bands; these power densities remain substantially below recommended limits.[28] The RF field exposure of ~1% of the population exceeded 10 mW/m^2. The main source of RF exposure for the general population is broadcasting services in the UHF and VHF range.[3] Field strengths surrounding radio transmitters and transmitter towers produce relatively small RF-field exposures (<1 μW/cm^2) to the general population located in the adjacent areas. However, near-field conditions may occur near the base of these towers because of the long wavelength of RF waves used to broadcast. The electric field strengths at the base of UHF and VHF towers in the near-field are highly variable, with values ranging from 1–20 V/m for UHF television, 1–30 V/m for VHF television, and 2–200 V/m for FM radio transmitters.[29] Current studies suggest the change from analog to digital broadcasting has not significantly altered RF exposure for the general population. In a German study of 300 spot measurements around Munich and Nuremberg before and after changing from analog to digital broadcasting, the median electric field exposure for analog transmission was 11 mV/m compared with 27 mV/m for digital signals.[30] The electric field strength for FM radio signals was similar to that of analog television signals. The values of RF-field exposure were highly variable with a range of two orders of magnitude around the median.

The strength of the electromagnetic field near the antenna of portable transmitters can be high, even for low-output transmitters. Field strengths of several hundred V/m and up to 0.6 A/m at distances of >10 cm from a mobile source with a power range of up to 300 W may occur. The correlation between radiated power and field strength is typically poor; field densities decrease rapidly 50 cm from the antenna in the 10–30 MHz frequency range. For frequencies of >100 MHz and distances of >50 cm, the inverse square law applies to the power density. Data are available for the assessment of hazards from mobile transmitters based on SAR rather than field strength in the near-fields.[31]

High-level exposures occur primarily for workers near the antennas of high-power transmitters.[24] Aerial riggers working on VHF/UHF equipment in the 30–1,000 MHz region sustain intermittent electric field exposures to the whole body and extremities of 60 V/m and 140–270 V/m, respectively. In comparison, measurements of RF fields from medium frequency (MF) transmitters in urban areas indicate few residents are exposed to electric field strengths exceeding 1 V/m. In a French study of 184 urban and rural residents wearing personal dosimeters during the weekday, the electrical field strength was always <1.5 V/m as measured by the personal monitors.[32] The FM band had the highest percentage (12.3%) of measurements above the threshold of detection (0.05 V/m).

In a study of 15 cities with MF broadcast transmitters, the median electric field exposure was 0.28 V/m with 98% exposure to field strengths of >0.07 V/m.[29] Only 3% of the urban population was exposed to fields of >1 V/m. RF beam power density usually decreases with increasing distance; however, the relationship between exposure and distance from the antenna is very complex, depending on the relation to phasing in the near-source zone, scattering attenuation and reflection of interfering objects, type of building construction, and other RF sources. For exposure to electric fields 1–2 m from antennae for MF broadcast transmitter strengths of 1–50 kW, the electric field strengths ranged from 95–720 V/m and 2.5–20 V/m at 100 m from the antennae.[29]

Mobile Phones

Handheld Cell Phones

Although cell phone subscriptions increased rapidly over the last two decades, improving technology lowered the time-averaged RF power emitted from these mobile devices. Most analog phones ceased functioning around the year 2000. The power of analog mobile phones is typically higher than that of digital phones, with average time-averaged power output of up to 600 mW; however, this output translates to an average SAR in the brain below the 1998 INSI/IEEE recommended limit of 8 W/kg over 6 minutes.[33] In a study modeling analog mobile phone use with phantoms, the maximum rise in tissue temperature from peak SAR was small (<0.04°C), even during continuous (>6 minute) use of a 600 mW source.[34] The maximum SAR level in the brain ranged from 0.12–0.83 W/kg, with the highest levels closest to the phone. In comparison, the average metabolic rates for the whole body and heart muscle are 2 W/kg and 60 W/kg, respectively.[25]

The energy absorption by different tissues depends on phone design (e.g., antenna location), position of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the phone by the head,[35] and distribution of current in the tissues; the former two factors may result in 20-fold and 10-fold differences in the exposure, respectively.[36,37] The shape of a child's head results in a closer proximity of the brain to a cell phone adjacent to the ear and higher RF exposure by a factor of ~2 compared with an adult.[38] The peak SAR over 1 g of tissue during 2G mobile telephone use in the 1990s reached 0.25–0.5 W/kg.[39] Studies of later systems indicate peak spatial SARs have not significantly changed during the replacement of analog phones with digital ones; the analog phones probably produced greater overall SAR to the brain because of the greater size and diffuse distribution of the electromagnetic fields.[2] The power absorption from the antenna of a handheld telephone occurs in the near-field; therefore, strength of the electromagnetic field is nonhomogeneous depending on radiated power, frequency, antenna design, anatomical position of the head in relation to the phone, and the duty cycle.[40] Maximum time-averaged output power of 2–4G cell phones usually ranges from 125–250 mW because lower duty factor (i.e., time during cycle switched off) substantially reduces the maximum power (0.25–2 W). In a study of 500 volunteers in 12 countries using 2G, software-modified GSM phones to measure exposure parameters, the average power was ~50% of the maximum power, with a 2–3-fold difference between countries and cell phone users.[41] The mean output power/call was 133.3 mW (900 MHz) and 64.2 mW (1,800 MHz); at 900 MHz, this value ranged from 92 mW in Israel to 171 mW in New Zealand and 47 mW in Israel to 88 mW in Finland at 1,800 MHz.

Several techniques reduce maximum operating power listed by manufacturers, including operating 3G and 4G phones at power rates far below maximum power to reduce interference, lowering duty factors during nontalking portions of a conversation, and normal use of mobile phones in positions other than worst-case scenarios calculated by manufacturers. Third-generation (3G) phone technologies reduced absorbed energy (i.e., SAR) in the brain by almost two orders of magnitude compared with GSM phones.[2] The estimated temperature rise in the brain using a 3G handheld cell phone is ≤0.1°C. Emitted power from mobile phone is minimal when not in use; some RF-field exposure occurs during the transmission of texts and emails.

In a European study of public electromagnetic field exposures estimated from 12 bands used in communication equipment and 28 exposure scenarios with selected spot measurements, the highest outdoor exposures resulted from GSM (Global System for Mobile Communications) and DCS (Digital Cellular System) downlink signals, with estimated electric field strengths

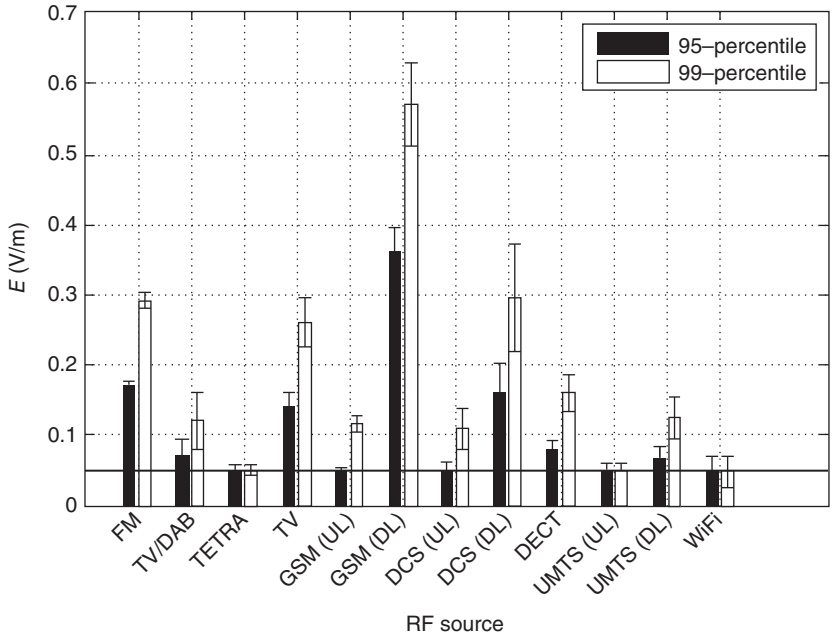

FIGURE 44.5. Upper bound personal monitor measurements (95%, 99%) of electric fields in 12 radiofrequency bands during 28 outdoor scenarios involving walking outdoors in an urban environment. Table 44.3 defines the frequencies and sources of the 12 bands. The horizontal black lines represent the sensitivity of the personal meters. (Adapted from Joseph et al.).[42]

ranging up to 0.52 V/m.[42] Figure 44.5 illustrates the range of upper 95 and 99% electric field strengths for 12 RF bands estimated during 28 urban scenarios. GSM and DCS uplink signals from mobile phones inside moving trains or buses produced the highest total electrical field exposure. Using the upper 99% values, the estimated whole-body specific absorption rate (SAR) ranged up to 5.01 μW/kg. Data analysis from summing exposure to nine RF communication bands in this study indicated that daytime walking in the city produced the highest total electric field strengths.[43] For a 1-year-old infant in this scenario, the highest upper 95% whole-body SAR calculated from the total electric field strength was 11.5 μW/kg. The upper 95% value for electric fields produced by Wi-Fi in the 20 urban scenarios ranged from 0.36–0.58 V/m, whereas the maximum upper 95% field strength for DCS (cellular phones) was 0.33 V/m. In a French study of urban and rural residents monitored for 24 hours with a personal dosimeter, electric field strengths increased close to the antenna, with maximum field strengths developing when the beam intersected with the ground. The maximum electric field strengths of GSM and DCS waves in this study occurred 280 and 1,000 m from the antennas.[32]

Data are limited on the radiation exposure from 5G devices, primarily because the infrastructure is in a distribution phase. The 5G networks and associated IoT will substantially increase the number of wireless devices and require highly dense, multiple lower power transmitters (small cells) on utility poles and buildings for much more mobile data volume per geographic area. However, the 5G antennas require narrow antenna beams with direct alignment to receiving devices. Potentially, this infrastructure may significantly mitigate the environmental radiation exposure from very large numbers of 5G network components.[6] Although 5G networks share bandwidth with preceding 2–4G systems, 5G systems also operate in the higher frequency millimeter wave band (MMW, 30–300 GHz), previously reserved for automotive collision avoidance systems, airport scanners, and perimeter surveillance radar. MMW does not penetrate building materials, vegetation, or the outer layer of human skin. Overall, RF radiation from the 5G system is not forecast to significantly alter current RF exposures, with most radiation exposure resulting from uplink signals from personal devices.[4] However, the more superficial energy deposition, higher frequency, ultra-wideband pulsed fields, local networks and small cells for machine-to-machine communication, and use of beam forming will complicate exposure assessments.

Cordless Phones

Modern cordless phones use digital technology (Digital Enhanced Cordless Telecommunications, DECT) operating in the microwave portion of the electromagnetic spectrum (0.90 GHz, 1.88–1.90 GHz, 2.40 GHz, 5.80 GHz). This system uses TDMA technology, producing discontinuous signals of 0.4 msec each at peak power levels of 250 mW; a duty cycle of 4% reduces the time-averaged power to 10 mW. Although DECT phones do not use adaptive power control, the signal travels over short distances (i.e., few tens of meters). DECT phones emit ~5 times less RF radiation than GSM mobile phones. The handset does not emit RF waves unless the device is sending or receiving, whereas the base stations for DECT systems transmit signals in standby mode with a duty cycle of 0.8%. For a person standing in a room, the RF exposures from DECT base stations and mobile phone base stations in the neighborhood are similar.[2]

Bluetooth

The use of handsfree devices or a fixed antenna wired to the cellular telephone minimizes exposure of the brain to low-frequency radiation; studies of wired and wireless handsfree devices connected to mobile phones using GSM900, GSM1800, and UMTS1950 under maximized current coupling produce considerably lower RF exposure than handheld mobile phones.[44] These devices operate with power in the range of 1 mW. Bluetooth wireless hands-free devices emit ~100 times less RF radiation as measured by maximum peak special (psSAR) than mobile phones, reducing RF exposure to <10% of the exposure associated with holding a cell phone to the ear.[45] Wired devices may cause a local increase in RF-field exposure to the ear.

Base Stations

The height and emitted power of mobile phone base stations are highly variable. In a UK study of >30,000 base stations, radiated power ranged from 0.1–200 W, at heights of 3–60 m above ground level.[46] A group of base station antennas 15–25 m above ground emitting powers ranging from 20–100 W probably represent macrocells that provide the primary network coverage, whereas another group of base stations 2–6 m high with average power of 2 W are probably microcells relaying the signal in densely populated urban areas. As demand grew for cell phone service, base stations split the single omnidirectional signal into 3 sectors with up to 6 antennas that provided 32 signals in each sector; each signal served 1 call. Studies of maximum recorded power density from personal dosimeters in areas near cell phone base stations

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

indicate RF electromagnetic field exposures are well below current public standards (e.g., ICNIRP). In an Australian study of CDMA800, GSM900, GSM1900, and 3G UMTS sites, the maximum power density was 7.8 mW/m^2, representing 0.2% of the ICNIRP public reference level.[47] Spot measurements of the >30,000 cell phone base stations in the UK study reached a maximum of 8.6% of the ICNIRP reference value with the range typically of 0.002–2% of the reference level.[46] Mobile phones held within 1 cm of the body are the dominant source of RF-field exposure compared with more powerful base stations at greater distances (i.e., >10 m). Similarly, exposure from a cell phone operated within 1 m of an individual also produces higher RF exposure than base stations in the far-field based on numerical computations using phantoms.[48] Distance from the base station is not necessarily a good proxy for RF exposure in the near-field situation because of variability in antenna design, reflections, and shielding, whereas distance more closely reflects RF exposure for TV and radio transmitters than cell phone base stations.[49]

Long-term evolution (LTE) began with 4G radio technologies. In a study of 30 locations in Stockholm, Sweden, following the deployment of LTE technology, LTE contributed 4.1% of the total average power density produced by RF sources similar to digital enhanced cordless telecommunications (DECT, 4.4%); these values are substantially less than GSM900 (35.6%), GSM1800 (26.2%), and universal mobile telecommunications system-high speed packet access (UMTS-HSPA, 26.4%).[50] The average electric field strength was 0.18 V/m with a maximum of 0.8 V/m; these values are substantially below ICNIRP reference levels of 61 V/m.

Terrestrial Trunked Radio (TETRA)

Emergency personnel and other professionals use the TETRA cellular radio system (380–470 MHz, selected bands near 900 MHz) typically in a handheld position with a push-to-talk function. The location varies from a handheld device adjacent to the mouth to a transmitter mounted on a vehicle. Typically, peak powers for the handheld device are 1–3 W, whereas mounted transmitters range from 3–10 W.[51] Spatial averaging of the SAR over 10 g produced by the handheld devices ranged from 0.24–0.53 W/kg in front of the face to 0.88–2.88 W/kg for the side of the face. Although normal use does not exceed current guidelines, the maximum SAR during continuous use over 6 minutes by the side of the head may exceed these recommendations by ~50%.[52] Other professional mobile radio systems operate in the VHF and UHF portions of the spectrum with radiating powers of 1–5 W. These systems use the push-to-talk mode, resulting in relatively low duty factors and limited transmission time.

Wireless Networks

A Wi-Fi network is a wireless local area network (WLAN); however, Wi-Fi is not the only type of WLAN. Technically, WLAN is any radio technology local network device, whereas Wi-Fi is a type of WLAN that uses a local hub (e.g., access point) to connect to the local area network and is the predominant type of WLAN today. Wi-Fi operates in several frequency bands in the ranges of 2.4–2.5 and 5–6 GHz, with some devices using multiple RF frequencies. The radiated powers usually range from a few mW to ~30 mW, with the highest powers transmitted during saturation of the network with traffic.[53] The signals from Wi-Fi are short bursts of transmitted data lasting 0.01–1 msec, depending on the need to retransmit corrupted data; hence, weak signal strength does not necessarily imply less RF exposure because of the increased duty cycle. Duty factors for laptops usually are <1% compared with <10% for access points; the latter drops to ~1% when data transfer ceases.[2] In general, Wi-Fi signal strengths are far lower than other RF signals in the same environment. In a study of American and European Wi-Fi networks in residential, commercial, healthcare, and educational sites, the maximum time-averaged power density in the 2.4 GHz band 1 m from a laptop loading and transmitting files was 7 mW/m^2 (i.e., 0.07% of ICNIRP public reference level of 10 W/m^2).[54] The highest power densities occur near the transmitting devices (i.e., access points). Local temporal peak values may reach ~100–200 mW/m^2 in these areas; however, maximum temporal peak power density spatially averaged over body dimensions is much lower (e.g., 20 mW/m^2).[55] Consequently, the RF exposure in the brain is less than mobile phones operated at the ear. Laptops typically have built-in antennas around the edges at greater distances from the head than cell phones; consequently, the estimated SARs are much less than cell phones. Using a power of 100 mW and a duty factor of 1 at 2.4 GHz, the highest localized SAR value in the head was 5.7 mW/kg based on calculations for a 10-year-old sitting voxel model.[56] In a Palestinian study of 271 measurements from 69 indoor sites (e.g., educational institutions, homes, hospitals) with radiofrequency exposure from wireless local area networks (WLAN), power density levels 1 m from WLAN systems ranged from 0.001 to ~1.9 μW/cm^2 with a mean of 0.12 μW/cm^2.[57] These values were >200-fold below

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the currently recommended ICNIRP public exposure guidelines.

Radar

Radar is an acronym for RAdio Detection And Ranging. Most radar systems generate highly directional beams with high gain at frequencies of >600 MHz, typically 1–10 GHz. High-power sources are defined by the ability to produce a main-beam density of 1 W/m^2 at 100 m; some high-power radar beams generate main-beam densities exceeding 1 kW/m^2 at that distance. Most of the radar systems are pulsed with the signal duration of a microsecond over a pulse period of a millisecond, resulting in power densities much lower than the peak power densities by a factor of 100–10,000-fold. The actual exposure depends on several variables including the duty factor, the metric of interest (e.g., average vs. peak), the time in the rotating beam, and the position of the body in relation to the beam.

Police Units

Police radar units operate by emitting a low-power microwave signal toward a specific target (e.g., speeding automobile) that reflects the signal back to the radar unit at a different frequency. Based on the Doppler principle, the difference in frequency between the emitted and reflected signals determines the speed of the target. The US Federal Communications Commission (FCC) designated the following three frequency bands for police radar units: 1) X-band, 10.525 GHz; 2) K-band, 24.150 GHz; and 3) Ka-band, 33.700–36.000 GHz. The use of police radar to detect speeding traffic began in the 1950s, with much more common use beginning in the 1970s.[58] Early traffic radar devices used X-band frequency ranges during the 1970s and early 1980s, whereas K-band radar guns were introduced in the middle of the 1970s and became popular later. During the 1990s, Ka-band radar guns were developed using higher frequencies and lower power than X-band radar units. These radar units operate in the Doppler mode that involves continuous-wave radiation rather than pulsed or intermittent radiation. Handheld radar units operate only in stationary patrol vehicles. Operation of these units occurs primarily in urban areas (e.g., intersections), where these units allow the measurement of vehicle speeds in more than one direction. The technology of mounted units allows use both in moving and stationary patrol cars; however, these units measure vehicle speeds only in one direction.

Maximum Exposure The amount of microwave radiation produced by radar units is relatively small compared with household appliances and police radios. The typical police radar unit operates at ~15–50 mW compared with 600 W for a microwave oven and 50 W for mobile police radios. The emitted power of traffic radar devices is lower than or comparable with that of garage door openers, cellular telephones, and infant monitors.[58] The *power density* refers to the intensity of microwave radiation striking a flat surface per unit time (mW/cm^2). The maximum power density external to the radar device is the aperture power density; this value occurs immediately in front of the radar antenna at the interface between the radar antenna and open space. The aperture power density does not vary with changes in power supply voltage; however, operation of the device at cold temperatures can increase the aperture power density up to 15% higher than room temperature.[59] In general, K-band radar units possess significantly lower aperture power densities than corresponding X-band units as a result of more sophisticated electronic circuits and higher frequency. In a study of the power intensity (mW/cm^2) emitted by over 5,000 radar units, the mean aperture power densities for K-band and X-band handheld radar units were 0.69 mW/cm^2 and 2.66 mW/cm^2, respectively.[59] A fixed-mounted, X-band unit produced the highest aperture power density (6.4 mW/cm^2).

External Dose The amount of external radiation received by an operator of police radar depends on the frequency (X, K, Ka), type of mount (handheld, dash-mount, rear-deck mount), distance from the unit, and temperature. The proper operation of radar devices is unlikely to produce microwave exposure levels exceeding 0.02–0.05 mW/cm^2 based on laboratory and field studies.[58] The radiation received by the operator of a handheld radar device usually is <1% of the aperture power density, except in unusual circumstances (e.g., use in the lap of the operator with reflection from nearby metal surfaces) when the external exposure may reach 5% of the aperture power density.[59] These studies indicate the operator of a rear-mounted radar device receives an external radiation dose in the range of <1–3% of the aperture power density. Passengers in vehicles receiving radar impulses are not exposed to significant amounts of microwave radiation. Directly in front of the radar gun, the radiation level decreases below 1% of the aperture power density at a distance of 12 ft from the radar gun.[59] Other studies confirm the relatively low amount of microwave radiation produced by radar guns.[60] An experimental study simulated the use of a cross-section of radar guns including handheld, rear deck-mounted, and dash-mounted

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

units.[61] Measurements of power density at the estimated level of the eye and testicle of the operator demonstrated values ranging from nondetectable ($\leq$0.02 mW/cm^2) to 0.033 mW/cm^2 and nondetectable to 0.034 mW/cm^2, respectively. The highest power density (5.34 mW/cm^2) occurred immediately in front of a Ka-band, dash-mounted unit. However, none of the power density measurements at simulated sites in the body of the operator exceeded current occupational recommendations.

Air Traffic Control Units

Most moderate-range systems operate at frequencies of 2–4 GHz compared with 1–2 GHz for long-range systems. The antennae are usually mounted sufficiently high to obstruct signals from other buildings with narrow beams that sweep full circle around the sky every few seconds. The signal attenuates vertically to prevent reflection of the beam from the ground. The pulses of RF radiation are relatively high with emitted power up to a few megawatts. Air traffic control radar units produce a relatively greater hazard compared with police units because the power densities of air traffic control units are ~4-fold greater than police units. A power density of 100 W/m^2 occurs at 132 m from the source of surveillance radar compared with 33 m from the source of tracking radar.

Marine/Military Radar

The range of marine radar is shorter than that of air traffic control equipment, with the beam emitted from rotating antennae above the ship and focused at sea level. Typical operating frequencies are 2–4 and 8–12 GHz with mean power ranging from 1–25 W and peak power up to 30 kW.[62] Marine vessels contain a variety of RF sources in addition to radar X- and S-bands including radio transmitters (VHF, medium frequency/high frequency), satellite communication, and navigation. In a study of radio frequency electromagnetic fields emitted from seven transmitters on a marine ship, the measured electric fields were lowest on the upper deck (0.82–0.86 V/m) and highest on the bridge roof (2.15–3.70 V/m), with intermediate values on the bridge deck (0.47–1.15 V/m).[63] The ICNIRP guidelines for the public were exceeded only on the bridge roof, whereas all measurements were below occupational standards. Military installations use tracking radar to follow aircraft and missiles. These systems generally emit more power than navigation systems or civilian radar. These systems typically use RF in the range of 2–8 GHz with high mean power densities (e.g., >10 mW/cm^2).

Industrial Applications

Microwave Heating

Magnetron electron tubes inside domestic microwave ovens produce microwaves at a frequency of 2.45 GHz, with power output ranging from 200–2,000 W. The power output of commercial microwave ovens may reach 3,000 W. The most important source of microwave exposure during oven operations results from the leakage of microwave radiation from door seals; however, the power densities decrease rapidly with distance. Compared with current standards, RF electromagnetic field exposures are usually relatively low, with peak local SAR values of 0.256 W/kg at the emission limit of 5 mW/cm^2 at 5 cm from the source.[20] In a Palestinian study of 117 microwave ovens aged 1 month to 20 years, the leakage 1 m from the ovens ranged from 0.43–16.4 μW/cm^2 with a mean of 3.64 μW/cm^2.[64] Leakage is correlated to age and operating power, with a stronger dependence on the former.

The attenuation of microwaves within several meters and intermittent microwave exposure typically reduce RF-field exposure below current exposure limits.[65] Microwaves in the upper frequency range (i.e., 10 GHz) do not penetrate skin well, but very powerful microwaves in this range could produce heat on the skin. Microwave anti-intrusion alarm systems are typically low-power devices with power densities near 0.01 mW/cm^2 within 0.5 m of a 10 mW-microwave alarm system.[3]

Radiofrequency Heating

Induction heating involves low RF and extremely low-frequency (ELF) ranges to heat conducting materials by the formation of eddy currents in strong magnetic fields created by large coils. Applications of this type of heating include production of plasmas, mixing alloys, hardening surfaces, and melting metals. Exposure of workers occurs during activities near or within the coils. Radiofrequency sealers generate heat in materials by producing oscillating electromagnetic fields in the frequency range of 10–80 MHz. In an industrial setting, these machines heat, melt, and cure various materials including PVC plastic, rubber, and wood glue. Power ranges from <1 to tens of kW for sealers up to over 100 kW for glue dryers.[2] Although leakage from radiofrequency sealers generally ranges up to 200 V/m or 0.5 A/m, these electric and magnetic field strengths may reach 2,000 V/m and 10 A/m, respectively.[66] The high RF voltage in the sealer generates intense electric fields in workers close to the sealer, producing currents aligned longitudinally along the limbs and torso toward the lower legs.[67] The concentration of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

current in a small cross-sectional area creates high local SAR with the maximum current occurring in the feet under grounded conditions. Direct correlation of power density to electric and magnetic fields near these sealers is limited because of nonuniform electromagnetic fields and lack of a simple mathematical equivalency between power density and electromagnetic fields in the near-field (i.e., <1–5 wavelengths from the source). Hence, direct measurement of SAR is necessary to evaluate an exposure. Because these sealers operate at frequencies near the region of human resonance, operators of RF sealers have the potential to absorb substantial amounts of radiofrequency radiation.

Smart Meters

Smart meters transmit data on electricity, gas, and potentially water consumption to central collection locations including frequency of use, time of consumption, amount used, and location. Most smart meters operate as wireless mesh networks that communicate with other neighboring meters to relay usage data to a data collection point in the region. These devices emit RF pulses at variable times throughout the day with relatively low duty cycles (i.e., <1%); consequently, RF fields typically appear around the smart meters for only a few minutes daily. Although there is no standardized approach, this technology involves wireless home area networks using radio communications (CDMA, GSM, 3G/4G/5G, LTE, Wi-Fi). The pulsed transmissions usually operate on unlicensed frequency bands (902–928 MHz, 2.4–2.48 GHz) or other nearby frequencies.[68] Smart meters eliminate the need to manually read utility meters.

Baby Monitors

These devices are radio systems that remotely monitor an infant visually and audibly with transmitter and microphone operating mostly in the microwave range (40, 466, 864, 2,450 MHz); peak operating power ranges up to 500 mW. Assuming far-field conditions with the monitor placed 1 m from the infant, the estimated maximum 10 g averaged spatial peak SAR and power flux densities are 1–2-fold below current reference levels.[69]

Whole-Body Scanners

Security screening in airports and other facilities involves ionizing (X-rays) and nonionizing (radiofrequency) radiation. These active systems direct the radiation toward the body and analyze the scattered radiation. Passive systems monitor thermal radiation emitted by the body in the RF portion of the spectrum without emitting radiation. Limited data are available from manufacturers due to security issues. Whole-body millimeter wave imaging technology used in airports and security checkpoints operates in the extremely high frequency millimeter wave range (30–300 GHz), with absorption of electromagnetic radiation confined mainly to the dermis. Manufacturers claim the active scanners are substantially less powerful than standard household devices (e.g., mobile phones, wireless handsets, Wi-Fi), with power densities below 1 mW/m^2 (<0.0001 mW/cm^2) and wavelengths of 3–10 mm in air.[2] Scanners designed to passively detect broadband microwave radiation do not expose the scanned body to electromagnetic waves.

RF Identification (RFID)

RFID technology uses radio waves to identify and track items with readers and labels; the latter contain integrated circuits and antennas to process and transmit information within several meters of the reader.[70] Various RFID applications range from access control and animal identification (≤135 kHz) and smart labels/item management in libraries (13.56–27.28 MHz) to asset tracking up to 100 m (433 MHz) and road tolling systems (5.8 GHz).[69] Passive systems for mother–newborn identity reconfirmation use RFID technology with the RF exposure depending primarily on reader-tag specifications, distance of the reader from the body, and duration of use.[71] Other healthcare industry uses for RFID include the tracking of supplies and medications in the hospital supply chain, operating room, and patient care areas.

Medical

The millimeter wave (MMW) frequency range is a subset of radio wave radiation that comprises frequencies of 30–300 GHz. In Russia, MMW therapy centers treat a broad spectrum of illnesses including cancers of the skin, ear, nose, and throat, atopic dermatitis, tuberculosis, gastroduodenal ulcers, unstable angina, and hypertension;[72] however, there are few randomized controlled clinical trials on the clinical efficacy of these therapies. The long-term benefits of radio wave therapy for analgesia remain controversial.[73] Magnetic resonance imaging (MRI) employs radiofrequency fields in conjunction with static and slowly fluctuating magnetic fields.

Physiotherapy

Physiotherapy departments use microwave diathermy (433.92 MHz, 915 MHz, 2,045 MHz) and shortwave diathermy (13.56 MHz, 27.12 MHz, 40.68 MHz) for the treatment of musculoskeletal pain with approximate powers of 200 W and 400 W, respectively. The most common shortwave diathermy devices use 27.12 MHz,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

whereas 2,045 microwave diathermy devices are uncommon now. Under normal operating conditions for microwave diathermy, operator exposure to power density levels of >10 W/m^2 occurs transiently to the part of their body <1 m from the source.[20] Treatment areas receive incident power densities in the range of 1–2 kW/m^2; however, irradiation may be nonuniform. The orientation and position of the shortwave diathermy applicator and the cables in relation to the control console produce significant variation in the RF exposure of the operator. Electric field strengths of 300 V/m extend up to 0.4 m from the cables; magnetic field strengths of 0.8 A/m exist at 0.25 m from the cables, depending on the power settings of the diathermy machine.[74] Shortwave diathermy operators are usually ~1 m from the applicator; electric fields range from 2–315 V/m around their console. A review of studies reporting RF electromagnetic field strengths (27.12 MHz) in physiotherapists' workplace indicates current ICNIRP occupational limits may be exceeded when physiotherapists stand within 2 m of an operating continuous shortwave diathermy machine, 1.5 m of an operating pulsed shortwave diathermy machine, or <1 m from a microwave diathermy device.[75]

A systematic review of management therapies for chronic spinal pain suggests some evidence for the efficacy of lumbar and cervical radiofrequency neurotomies (level II – multiple relevant moderate or low-quality randomized controlled trials), but little evidence for thoracic RF neurotomies.[76] Because of the limited penetration of this type of radiation, thermal injuries are potentially possible in the first 1–2 mm of human skin and cornea.[77]

Electrocautery

The use of electrocautery involves a handheld electrode that cuts or coagulates tissues with an operating frequency of ~500 kHz, up to 200 W of power, and ~10 A/cm^2 of current. Ablation of atrial fibrillation uses unipolar and bipolar radiofrequency energy sources for minimally invasive treatment of atrial fibrillation. The energy source operates in the range of 100–1,000 kHz, producing restive heating in a narrow band of tissue in direct contact with the electrode or between the electrodes.[78] The lesion size depends on electrode-tissue contact area, interface temperature, current, power, and duration of RF energy. Minimally invasive surgery for tumor ablation uses 9.2 GHz with ~20 W of power with coaxial lines in a slender needle.[79]

Cancer Therapy

Percutaneous radiofrequency and microwave ablation are therapeutic options for short-term amelioration of some types and stages of tumors (e.g., liver, kidney, bones, adrenal glands) when curative interventional treatments are not efficacious.[80] Tumors are more sensitive to heat than normal tissue; hyperthermia has a direct cytotoxic effect that may sensitize the tissue to other radiation.[81] Radiofrequency ablation uses electric current, whereas microwave ablation uses an electromagnetic field. Although both methods rely on thermal-induced tumor destruction, the latter has the advantages of more predictable ablation zones, larger coagulation volumes, and shorter procedural times.[82] Radiofrequency ablation devices used to treat tumors operate at 13.56 MHz with an output of 1,000 W.[83] The use of microwave-induced hyperthermia includes the treatment of chest wall metastases of breast cancer,[84] head and neck cancer,[85] ablation of functional menorrhagia,[86] and transurethral microwave thermotherapy for benign prostatic hyperplasia.[87] The latter is an alternative to transurethral resection of the prostate (TURP) and alpha-blockers for treating symptomatic benign prostatic hyperplasia in men without urinary retention or previous prostate procedures and prostate volumes of 0–100 mL.[88] However, TURP provides lower symptom scores, better urinary flow, and fewer subsequent treatments than transurethral microwave thermotherapy. Simulation studies suggest that treatment of head and neck cancer with hyperthermia by prolonged, intense radiofrequency heating (60 minutes at 434 MHz) produces peak 10 g spatial-averaged specific absorption rate in the adjacent eye exceeding current ICNIRP and IEEE guidelines up to 10-fold.[85] Although predicted SAR correlated to eye temperatures, relatively large variations (i.e., >100%) occurred in the temperature–SAR relationship. Medical review of records from 16 patients treated with hyperthermia at these RF doses did not detect any visual changes or other ocular effects, including cataracts during up to 18 months postexposure.

DOSE EFFECT

Specific Absorption Rate (SAR)

For high-frequency electromagnetic fields, the specific absorption rate (SAR) is the dose of energy transferred to the body expressed as watts/kilogram (W/kg). Absorption of energy from radiofrequency radiation depends primarily on the frequency of the source, the shape and size of the organism, the geometry of the incident, and the dielectric properties of the tissue. In biological materials, only the electric field contributes

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to energy absorption (SAR). Because of scattering, reflection, and absorption within tissues of different dielectric properties, the distribution of the energy from radiofrequency radiation is highly nonuniform throughout the body.[89] Consequently, biological effects are more closely related to the quantity of energy absorbed and the distribution of that energy in the body than to measures of exposure (e.g., incident power density). Specific absorption (SA) represents the *dose*. The specific absorption rate (SAR) is the rate at which radiofrequency radiation imparts energy to an area of mass in a biological body, as defined by Equation 44.7. Therefore, SAR is a measure of the *dose rate* of RF radiation received by the body.

$$\text{SAR} = E^2\sigma/\rho \qquad \text{(Equation 44.7)}$$

where

E = electric field strength (V/m);
ρ = electrical conductivity of medium (Siemens/m);
σ = density of medium (kg/m^3).

Frequency-Dependent SAR

Based on the absorption characteristics of the human body, the SAR varies in the following four regions of the RF portion of the electromagnetic spectrum: 1) the subresonance range (<30 MHz); 2) the resonance range (30–300 MHz); 3) the "hot-spot" range (400 MHz–3 GHz); and 4) the surface absorption range (>3 GHz). Surface absorption predominates in the human body, except for the head and neck at frequencies in the subresonance region. At incidence power densities of >100 W/m^2 (>10 mW/cm^2), energy absorption decreases with increasing frequency; the size of the hot spots decreases from several cm (915 MHz) to 1 cm (3 GHz).[3] In the surface absorption range of the RF spectrum, temperature elevations occur locally at the surface of the body. Peaks of SAR can vary up to an order of magnitude above a whole-body average; thus, a safety factor of 10 is appropriate to protect against the development of hot spots within the body due to variations in energy deposition.[90] In general, little absorption of heat occurs following exposure to radiofrequency waves at frequencies of <10 MHz; the greatest absorption of radiofrequency waves occurs near frequencies of 70 MHz.

Average SAR

The SAR is a measure of internal exposure. The whole-body average SAR represents the total energy transferred to the body per unit time divided by the total mass; this quantity depends on the biological characteristics of the body, environmental materials, and physical parameters of the RF source including frequency and polarization in the far-field situation. Table 44.5 lists the multiple factors affecting the absorption of radio waves in a body.

During exercise, heat production in the body may reach 3–5 W/kg. The whole-body SAR aids in the extrapolation of animal data to humans; however, such calculations do not account for differences in spatial distribution between animals and humans. For a worst-case scenario (i.e., extreme conditions of humidity and temperature, resonant frequency), whole-body SAR doses of 1–4 W/Kg at 70 MHz raise the core temperature in humans by ~2°C within 1 hour.[24]

Humans

The medical literature contains few reports of adverse effects on humans exposed to RF electromagnetic fields other than microwave-induced burns. Nine radio linesmen were exposed to a radiofrequency of 4.1 GHz and a power density of 4.6 mW/cm^2 for no more than 90 minutes.[91] The maximum estimated SAR for the skin was 3.8 W/kg and 1.2–1.5 W/kg for the lens. Minor changes in the posterior subcapsular region of the lens developed in the two individuals with the highest

TABLE 44.5. Factors affecting the absorption of radiofrequency radiation. (Adapted from Michaelson and Lin).[19]

Parameters	Factors
Biological	Size, geometry, dielectric properties (primarily water content), spatial relationships, relation to polarization of waves
Environmental scatter	Metallic/nonmetallic objects in electromagnetic field, shielding, internal implants, grounds, conduction plates, containers
Physical	Frequency, polarization, modulation (AM, FM, pulse), power and power density, distance from source (near-field, far-field, uniform/nonuniform field, calibration/measuring techniques, transmitting/radiation equipment, chamber dimensions/materials)

exposure. One subject reported insomnia and irritability. Follow-up medical examinations detected no long-term sequelae.

Animals

Thermal effects result from exposure to specific absorption rates (SAR) levels of >1 W/kg, whereas nonthermal effects occur at SAR levels of <0.1 W/kg;[92] there are limited animal and human data to support the existence of permanent adverse effects from exposure to RF radiation below a few W/kg.[93,94] For a healthy adult, an SAR of 4 W/kg is associated with a 1°C rise in temperature; the ICNIRP guidelines add a 50-fold safety factor (0.08 W/kg) for public reference values. *In vitro* cell system studies do not demonstrate a consistent pattern of cell abnormalities following RF exposures below levels producing detectable heating; similarly, a variety of animal models with varying RF exposure levels and signal modulation have not demonstrated evidence of health effects below current guidelines.[69] Temperature in the tissue is the critical variable in animal experiments using frequencies of >100 kHz. At frequencies of <100 kHz, increased sensitivity to induced currents becomes important because the current produces interactions with excitable tissues (e.g., muscles, nerves).[3] RF fields can produce sufficiently high currents to cause pain and burns at frequencies of <100 kHz, whereas burns predominate at frequencies in the range of 100 kHz–100 MHz. Acute, localized delivery of microwaves at intensities of >100 mW/cm^2 over 15 minutes produced cataracts in animal models; however, the production of microwave-induced cataracts is difficult without exposing the animals to lethal radiation levels.[95]

The absorption of energy from radiofrequency waves is frequency-dependent, with resonant frequency being the portion of the spectrum producing the highest energy absorption. The resonant frequency in animals and humans varies significantly; the resonance frequency for a 70-kg man is 70 MHz compared with a resonance of 3,000 MHz for a small rodent. Hence, exposure of rodents to 2,450 MHz would cause much greater energy absorption (SAR) than human exposure to the same frequency. Consequently, extrapolation of animal data to humans must consider differences in specific absorption rates. Frequency scaling is the best means of extrapolating the effects radiofrequency radiation from animals to humans; however, such extrapolations are limited by physiological and physical differences.[8]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

The primary effect of RF radiation in the body is the heating of tissue; the absorption of RF energy generates an oscillating current that creates motion of charged particles and strongly dipolar water molecules. Potential mechanisms for the interaction of radio waves with biological systems also include nonthermal mechanisms (e.g., membrane excitation below 1 MHz, field-induced molecular forces, induced tissue dipoles). Several reviews of thermodynamic and biophysical parameters indicate physiological effects are unlikely at RF electromagnetic field exposures that do not cause temperature increases in the tissues, with the exception of free radical formation.[96,97] However, the evidence that RF radiation affects oxidative stress or alters the concentrations of reactive oxygen species is weak.[2] Experimental studies do not provide sufficient evidence that alteration of immune function following RF radiation exposure increases cancer incidence at any site.

Adverse effects from radiofrequency radiation result primarily from the absorption of energy and the production of heat in the body. Maximum production of heat occurs at the resonant frequency ranging from 70–300 MHz. At frequencies below the resonant frequencies, the penetration of tissue is substantial; therefore, little energy absorption occurs. At radiofrequencies above resonance, penetration of the skin is limited, and thermal effects develop on the skin. Table 44.6 lists the electromagnetic properties of tissues with high water content.

A common adverse effect of microwave use is the development of burns from the differential heating between foods and their containers (e.g., jelly rolls, popcorn, baked potatoes, teas, formula bottles).[98,99] Factors favoring differential heat production in microwave-heated food include variable water content, high viscosity, and low homogeneity. The latter two factors impede convection and conduction in the food, whereas increased water content increases heat production.[100] Water molecules effectively absorb microwaves; therefore, heating occurs more rapidly in substances with higher water content. Consequently, some foods (e.g., jelly rolls) will heat nonuniformly because the jelly contains more water than the surrounding pastry portion of the roll. Microwaves pass through glass, paper, and plastic without producing heat, whereas metal objects reflect microwaves. As a result, the exterior of a formula bottle may be cool while the milk is very hot. Allowing heated food to stand for several minutes

TABLE 44.6. Variability of electromagnetic properties of high-water-content tissues (e.g., muscle, skin) with a range of radiofrequencies. (Adapted from Michaelson and Lin).[19]

Frequency (MHz/GHz)	Relative Permittivity	Conductivity (S/m)	Penetration into Body (cm)
1 MHz	2,000	0.400	91.3
10 MHz	160	0.625	21.6
27.12 MHz	113	0.612	14.3
40.68 MHz	97.3	0.693	11.2
100 MHz	71.7	0.889	6.66
200 MHz	56.5	1.28	4.79
300 MHz	54	1.37	3.89
433 MHz	53	1.43	3.57
750 MHz	52	1.54	3.18
915 MHz	51	1.60	3.04
1.5 GHz	49	1.77	2.42
2.45 GHz	47	2.21	1.70
3.0 GHz	46	2.26	1.61
5.0 GHz	44	3.92	0.788
5.8 GHz	43.3	4.73	0.72
8.0 GHz	40	7.65	0.413
10.0 GHz	39.9	10.3	0.343

allows the heat to disperse throughout the food by conduction; the temperature of infant formula should not exceed 100°F. Microwave heating can increase the temperature of food with high fat content to 500°F. At this temperature, the transfer of the plastic polymers and, to a lesser extent, the food is possible when the food is in direct contact with the plastic; however, currently there is no evidence of toxic effects from such a transfer. Microwave-heated compresses and gel packs may heat nonuniformly and retain heat longer than other materials (e.g., cotton compresses, towels).

Pathological Changes

Microwave-induced burns produce a distinctive pattern of relative sparing of tissues with relatively low water content (e.g., subcutaneous fat, muscle, skin) compared with the features of electrical burns that cause charring and nuclear streaming.[101] Although case reports associate the development of second-degree burns with exposure to leakage from a microwave oven and the use of a transdermal patch, an *in vitro* study of transdermal delivery systems exposed to a maximum power density of 800 W/m^2 from a microwave diathermy unit demonstrated only a small increase in temperature of 2.2°C.[102]

Microwave irradiation at a frequency of 2.45 GHz produces cataracts in laboratory animals.[103] Incident power densities capable of inducing cataracts in rabbits include a single 35–40 minute exposure to 250 mW/cm^2 and 20 consecutive daily exposures of 180 mW/cm^2 lasting 1 hour.[104] Although the initial clouding of the posterior layer of the lens cortex may result from heating in the rabbit model, microwave irradiation apparently induces changes in the equatorial epithelial cells that migrate posteriorly to form an aberrant epithelial layer under the posterior capsule.[105] The scattering properties of the orbital bones and the periorbital tissue produce differences in the threshold for the development of cataracts in various species. Power densities of 500 mW/cm^2 produce facial burns in monkeys, whereas exposure to 180 mW/cm^2 causes cataracts in rabbits.[106]

CLINICAL RESPONSE

Environmental Exposure

Skin

In a retrospective cohort study using National Electronic Injury Surveillance System data from 1990–2010, US emergency departments treated an estimated 156,000 patients for microwave oven-related injuries. The most common injuries were burns to the hands and fingers from spilling microwave-heated substances on the skin. Case reports associate the ingestion of microwave-heated products with burns of the upper airway, including third-degree oropharyngeal burns from the ingestion of formula,[107] airway obstruction from the aspiration of tea,[108] and acute laryngeal burns from the ingestion of baked potatoes.[109] Serious burns occurred on the hands from holding microwave-heated liquids

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

during complex partial seizures;[110] steam-induced corneal abrasion developed following the opening of a bag of microwave-heated popcorn.[111] The development of high-current radiofrequency ablation increased the risk of thermal burns on the skin surrounding the grounding pad.[112] These injuries are typically first- and second-degree burns; however, full-thickness burns may occur with delayed healing and scar formation.[113]

Eye

A study of 16 patients with head and neck cancer treated with RF ablation did not detect any serious acute ocular effects following 74 total treatment sessions.[85] A simulation study indicated RF radiation in these patients exceeded current guidelines for peak 10 g spatial-averaged SAR (10 W/kg) and peak tissue temperature increase (1°C) by a maximum of 10.4-fold and 4.6-fold, respectively.

Cochlear Implant

Cochlear implants comprise an external speech processor and an internal implant that receive heat from radio waves during mobile phone use; however, numerical modeling studies do not suggest these exposures exceed current ICNIRP guidelines of a maximum 1°C rise in temperature. Using a worst-case scenario (antenna operating at nominal full power, metallic hook behind the ear holding the speech processor, antenna adjacent to the hook and internal ball electrode), a 900 MHz half-wave dipole antenna generating continuous-wave 250 mW power produced a maximum 10 g averaged SAR of 1.31 W/kg near the hook and ball electrode.[114] The maximum temperature increase in the skin adjacent to the hook was 0.33°C. For the 1,800 MHz antenna operating at 125 mW, the maximum 10 g averaged SAR was 0.93 W/kg, and the maximum temperature increase was 0.16°C.

Electromagnetic Hypersensitivity

A few members of the population report a variety of nonspecific, multisystemic signs and symptoms that they relate to common, low-level electromagnetic radiation exposures from electronic devices and wireless communication systems. The clinical features of this phenomenon display no consistent association with a specific portion of the radiofrequency band. In some of these patients, the severity of these symptoms impairs their ability to function normally. Commonly reported signs and symptoms include headaches, difficulty concentrating, poor memory, general malaise, weakness, dizziness, fatigue, nausea, sleep disturbances, night sweats, myalgias, restless legs, paresthesias, blurred vision, tinnitus, and palpitations.[115] No specific constellation of signs and/or symptoms describes electromagnetic hypersensitivity (idiopathic environmental intolerance attributed to electromagnetic fields).[116] The geographic distribution of this perceived disorder across the world does not correlate ecologically to measured electromagnetic radiation exposures. Most of these patients also report the ability to sense electromagnetic radiation in the environment (electromagnetic sensibility).

Most mainstream medical organizations do not accept the clinical features of electromagnetic hypersensitivity as causally related to electromagnetic radiation exposure. A review of 46 blind or double-blind provocation studies involving 1,175 self-declared electromagnetic hypersensitivity patients did not detect robust evidence to support the existence of electromagnetic hypersensitivity as a biological entity.[117] The vast majority of the studies failed to find any significant effect of measured electromagnetic radiation on symptom severity. A meta-analysis of 7 studies involving 182 self-reported electromagnetic hypersensitivity patients and 332 controls (nonhypersensitive individuals) did not demonstrate a statistically significant difference between patients and controls in the ability to detect the presence or absence of electromagnetic radiation.[118] The pooled correct field detection rate better than chance for these electromagnetic hypersensitivity patients was 4.2% (95% CI: -2.1% to -10.5%). In a home-based, double-blind, provocation study of 42 volunteers (mean = 55 years, range 29–78, 76% women) with the self-described ability to detect electromagnetic radiation (electromagnetic sensibility), no participant could correctly identify sham and electromagnetic radiation exposure better than chance.[119] The scientific basis for electromagnetic hypersensitivity remains equivocal.

Occupational Exposure

Eye

In animals, cataracts develop in the eyes of rabbits (but not monkeys) following exposure for ≥30 minutes to very high, localized RF fields (e.g., 2.45 GHz), producing dose rates (≥150 W/kg) and temperatures (≥41°C) far exceeding current guidelines.[120,121] The difference in response of the two animal species to this radiation level reflects differences in head anatomy and the subsequent absorbed energy (i.e., SAR). Since 1952, over 50 case reports have associated cataracts with acute exposure to high-intensity radiofrequency radiation, mostly in the occupational setting;[122] however, the lack of adequate

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

exposure data limits the interpretation of the threshold effect of the development of cataracts in humans and the causality. The results of epidemiology studies of workers exposed to radiofrequency radiation do not support a consistent association between cataracts and intermittent exposure to incident power densities within current guidelines (<10 mW/cm^2).[69,123] The lack of accurate exposure measurements and the health worker effect prevent the extrapolation of this threshold level to chronic exposure.[93] A retrospective study of military and industrial workers exposed to microwaves demonstrated an increased incidence of minor lens defects related to job specialization; however, the study did not directly assess the incidence of cataracts. The authors did not consider the lens changes as precursors to cataracts.[124] In this study, the development of lens opacities correlated most strongly to age. Several studies of military and industrial workers exposed to radiofrequency radiation have not detected any distinct morphological features of the lens that distinguish RF-exposed workers from control populations.[125,126,127]

Gastrointestinal Tract

A 42-year-old man developed diffuse inflammation of the small bowel and gangrene of the appendix within 6 hours of a 1-minute exposure to a radar beam.[128] The exact exposure was not measured; however, the history suggests he stood in front of the radar beam until the sensation of heat in his abdomen became intolerable. He died from gram-negative sepsis 10 days later. A 42-year-old male pilot stood in front of a functioning microwave radar system for approximately 5 minutes.[129] A biopsy of a persistent neck mass 1 month later was consistent with coagulation necrosis from thermal injuries. The level of this exposure was not documented.

Central Nervous System

Surveys of Soviet and Eastern European workers associated RF exposure with the development of a neurasthenic syndrome characterized by nonspecific symptoms (e.g., headache, fatigue, irritability, anorexia, depression, emotional instability, poor concentration, insomnia). The lack of exposure data and absence of adequate controls limit conclusions about the causal relationship between exposure to radiofrequency radiation and the development of a neurasthenic syndrome.[130] Most of these workers improved after being removed from the occupational setting.

During 1953–1976, occupants of the American Embassy in Moscow received clandestine RF radiation (0.5–9 GHz) with maximum power densities up to 15 μW/cm^2 for 18 hours/day; no adverse health effects were detected in the occupants.[93] The extremely low levels of radiofrequency radiation and the short follow-up period limited the power of the study to detect adverse effects.

Carcinogenesis

Although large, stable increases in cancer incidence including CNS cancers have not been detected in various countries despite rapidly increasing subscription rates,[131] the International Agency for Research on Cancer lists radiofrequency fields as possibly carcinogenic (Group 2B) based on limited evidence in experimental animals and humans, primarily the association between wireless phones and central nervous system cancer (glioma, acoustic neuromas).[2] The latter association is relatively weak, and a causal relationship is unsupported with current evidence as a result of potential selection and information bias regarding RF exposure and methodological limitations. Brain cancer rates have not increased proportionally with cell phone use.

The majority of the epidemiological evidence for determining if an association between cell phone use and CNS cancer comes from the large international, multicenter case-control (INTERPHONE) study[132,133] and a large Swedish case-control study, primarily at higher exposure levels (i.e., more than regular use).[134] Long-term rodent studies using RF radiation do not demonstrate statistically significant increases in the incidence of benign or malignant tumors in any organ site, including tumor-prone animal models. Similarly, most, but not all, studies on rodent models of initiation and promotion (i.e., through cell proliferation or enhanced transcription) did not demonstrate consistent enhancement of carcinogenesis by RF radiation exposure.[135,136] Most experimental data in animals indicate RF fields are not mutagenic. The tumor incidence was not increased in cocarcinogenesis studies, except for vascular tumors of the mesenteric lymph nodes in MX-treated Wister rats[137] and ethyl-nitrosourea-treated pregnant B6C3F1 mice.[138] The US National Toxicology Program does not list radiofrequency radiation as a possible or probable carcinogen.[139]

In most of the epidemiological studies, the surrogate for absorbed RF dose is cell phone use (subscribers, self-reported use); however, several factors affect the absorbed dose including communication system and frequency band, tumor location, duration of use, and amount of use.[140] Recall bias potentially causes exposure misclassification, particularly from the use of questionnaires, billing or network records, location or duration

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of use, research diaries, or battery use.[141] RF dosimeters have design issues that limit useful information (e.g., bulky design requiring measurements away from the ear, insensitivity to magnetic fields). Software-modified phones record exposure parameters (e.g., date, time of call, output power level, frequency band); however, the phone does not record the position of the phone or power level fluctuations. Hardware-modified phones allow the measurement of exposure parameters, power fluctuations, and cell phone location. Cost, complexity of use, and design issues limit the application of the latter to cell phone studies. Exposure misclassification may be differential when cases and controls have similar levels of difficulty recalling mobile phone use, whereas nondifferential misclassification occurs when cases and controls recall mobile phone use differently. The former may result in an underestimation of the risk in epidemiology studies, whereas differential misclassification produces unpredictable effects. Conditions of use (indoor/outdoor, moving/stationary, urban/rural), adaptive power control (except Code Division Multiple Access networks), and discontinuous transmission are minor factors in determining the total absorbed RF dose. In a study of 500 volunteers using 2G software-modified phones for a mean of one month, frequent indoor use and use in a moving vehicle did not significantly affect the average output power.[41] Output power was higher with short calls than long calls and higher in rural areas than urban areas.

Environment

Residence

Overall, ecological studies using distance as a proxy for exposure suggest an increased risk of adult and childhood leukemia with proximity to an RF source, whereas studies using better analytical design and exposure assessment demonstrated no increased risk of these diseases. A cancer cluster study of cancer incidences near the Sutton Coldfield television and FM radio transmitter in West Midlands, England, detected significant reduction in incidence of adult leukemias, skin melanoma, and bladder cancer with increasing distance from the transmitter.[142] The risk of adult leukemia within 2 km of the transmitter was 1.83 (95% CI: 1.22–2.74). A follow-up study of cancer incidences in this area did not detect a similar reduction in the risk of adult skin cancer, adult bladder cancer, childhood leukemia, or childhood brain cancer with increasing distance from the transmitters.[143] Although some decline in the incidence of adult leukemia occurred with increasing distance from the transmitters, the follow-up study did not observe an excess incidence of adult leukemia within 2 km of the transmitters (OR = 0.97, 95% CI: 0.78–1.21). In an Australian ecological study comparing cancer incidences between municipalities with and without TV towers, the rate ratio for total leukemia incidence was 1.24 (95% CI: 1.09–1.40).[144] The rate ratios for brain cancer were not increased. The calculated power density of the radiofrequency radiation in the surrounding area ranged from 8.0 $\mu W/cm^2$ near the towers to 0.2 $\mu W/cm^2$ 4 km from the towers.

Evidence from well-designed studies on a link between childhood leukemia and exposure to RF electromagnetic fields is limited. The cancer cluster study on RF radiation from the Sutton Coldfield transmitters did not detect an increased risk of childhood leukemia. In a South Korean case-control study comparing children living within 2 km of 31 AM radio transmitters and children living >20 km from the transmitters, the OR was 2.15 (95% CI: 1.00–4.67). However, the risk of leukemia was not dose-related and was marginally statistically significant. The odds ratio for leukemia in children living 2–4 km from the towers compared with referents (>20 km) was 0.95 (95% CI: 0.56–1.61), whereas the odds ratio of leukemia in the quartile with the highest exposure compared with the lowest quartile was 0.77 (95% CI: 0.54–1.10). The rate ratio for childhood leukemia in an Australian ecological study was 1.58 (95%CI: 1.07–2.34); however, other ecological studies demonstrated negative results.[143,145] A German case-control study of childhood leukemia using the German Childhood Cancer Registry data analyzed 1,959 cases and 5,848 controls for RF radiation from 16 AM and 8 FM transmitters with powers of >20 kW.[146] The RF exposure was estimated 1 year before diagnosis using a field-strength prediction program. Conditional logistic regression analysis for all subtypes of childhood leukemia did not detect an increased risk of leukemia (OR = 0.86, 95% CI: 0.67–1.11) when comparing upper and lower quantiles of RF electromagnetic field exposures. Ecological studies of environmental exposure to RF emissions from fixed transmission sources do not indicate an increased risk of brain cancer or other malignancies from these exposures.[2]

Mobile Phones

The number of mobile phone subscriptions increased dramatically in the 1990s with the deployment of the Global System of Mobile Communication (GSM, 2G); by 2016, the overall number of mobile phone subscriptions exceeded the worldwide population.[147] Epidemiological evidence for an association between radiofrequency radiation from mobile phone use and cancer is relatively limited and conflicting; however,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the possibility of epigenetics and/or long-term (i.e., >10 years) effects remains because of poor quality and limited quantity of well-designed studies (i.e., mostly case-control) as well as poor exposure data from self-reported duration of use.[148] Changing patterns of use (e.g., increased phone use to view data on the screen vs. holding the phone near the ear to hear voices) and the adoption of more power-efficient phone technology beginning with Universal Mobile Telecommunications System (3G) dramatically reduced RF-EMF exposure in the brain. Hence, these technologies substantially reduce cumulative maximum phone emission levels and the impact of increasing duration of use.[149,150]

Multiple methodological issues (reporting bias, recall bias, selection bias/low participation rates, misclassification from imprecise, primarily self-reported exposure assessments, inadequate statistical power from rare incidence/long latency of brain tumors) limit definitive conclusions regarding cancer risks in mobile phone users. Several,[151,152,153] but not all,[154] case-control studies, biological data, animal experiments, brain tumor incidence trends, and reviews suggest that 10–15 years of mobile phone use have not significantly increased glioma risks for regular cell phone users, particularly for fast-growing tumors (e.g., malignant glioma). The relative short observation period for slow-growing tumors (e.g., meningiomas, acoustic neuromas) limits definitive conclusions regarding causal connection between these tumors and long-term cell phone use including cell phone use in childhood; current data associating cell phone use with increased meningioma risks are insufficient, whereas the data for acoustic neuromas are limited.[153,155,156] There are few data on the risk of RF radiation exposure to children under the age of 15 years.

Although hypothesis-generating studies and case series of cancer clusters suggest the *possibility* of an association between RF fields (i.e., radio and television transmitters) and several adult and childhood cancers (e.g., some central nervous system cancers, leukemia, melanoma, testicles, bladder);[157,158,159,160] generally, the relative cancer risks in these studies were low (i.e., <1.5–2), exposure data were poor, and the results were inconsistent with more robust epidemiological studies.[161] The epidemiology data for an association between RF radiation and cancer are strongest for central nervous system cancers (glioma, acoustic neuroma) and minimal for meningiomas or other CNS cancers. There is insufficient evidence of an association between mobile phone use and leukemia or lymphoma, with little evidence of an increase in malignancies other than those previously mentioned.[2]

Although exposure-response data are inconsistent, there are positive data on RF radiation and some central nervous system tumors (gliomas, acoustic neuromas rather than all brain tumors) with latency periods of 10 years or more, particularly with ipsilateral use. Multivariant analysis of a case-control study of brain cancer and cellular phone use suggests a marginally increased risk (OR = 2.62, 95% CI: 1.02–6.71) of brain cancer in the area associated with radiofrequency exposure from ipsilateral telephone use after adjusting for exposure to laboratory and diagnostic medical X-rays.[162] The contralateral use of cellular phones was not associated with an increased risk (OR = 0.97, 95% CI: 0.36–2.59) of brain cancer. Exposure to cellular phones was based on responses to questionnaires rather than direct measurement; the intensity of cell phone use was not quantified. A case-control study of 469 patients with primary brain cancer and 422 matched controls without brain cancer did not demonstrate a statistically significant difference in the use of cellular phones.[163] The exposure criteria were hours per month and years of use. There was no statistically significant correlation between histological categories and cellular phone use. In a meta-analysis of cellular phone use with a latency period of at least 10 years, the odds ratio (OR) for cell phone use and ipsilateral acoustic neuroma was 2.4 (95% CI: 1.1–5.3) and 2.0 (95% CI: 1.2–3.4) for gliomas.[164] No consistent association between cell phone use and meningiomas was detected. Higher numbers of cell phone users and longer follow-up are needed to determine causal associations, if any, between cell phone use and brain tumors.

Glioma In an international, interview-based, case-control (INTERPHONE) study of 2,708 glioma, 2,409 meningioma cases, and matched controls, there was no clear evidence of an increased risk of glioma for regular cell phone users ($OR_{glioma} = 0.81$; 95% CI: 0.70–0.94).[132] There was no dose-related increase with increasing cumulative use, with the exception of 364 high-use participants (>1,640 hours of cumulative cell phone use); the OR for this group was 1.40 (95% CI: 1.03–1.89). The authors noted that some self-reported cell phone use in this group was implausible, suggesting recall bias. The participation rate was low (64% in glioma cases; 53% in controls). A pooled analysis of Swedish mobile phone and cordless phone use from 1997–2003 included 1,148 cases of glioma and 2,438 controls.[134] The OR of glioma increased with increasing cell phone use as follows: 1–1,000 hours, OR = 1.2 (95% CI: 0.98–1.4); 1,001–2,000 hours, OR = 1.5 (95% CI: 1.1–2.1), and >2,000 hours, OR = 2.5 (95% CI: 1.8–3.5). The values

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for cordless phone use were similarly increased. Information bias remained an issue in this study. Neither of these two studies found an increase in the risk of meningiomas following RF radiation exposure.

A large Danish cohort study of 358,403 mobile phone subscription holders and 10,729 cases of central nervous system (CNS) tumors demonstrated a risk of CNS tumors near unity for both men and women.[165] There was no dose-related increase in the risk of CNS tumors with increasing lengths of mobile phone subscriptions. For the group with the longest mobile phone subscriptions (>13 years), the incidence rate ratio was 1.03 (95% CI: 0.83–1.27) in men and 0.91 (95% CI: 0.41–2.04) in women.

Acoustic Neuroma Most case-control studies of acoustic neuroma do not demonstrate an increased risk for regular mobile phone users; however, there is some evidence of an increased risk in the groups with the highest cumulative phone use. Several early case-control studies[166,167] and the Danish cohort study[165] did not support an association between RF radiation and acoustic neuromas. The results for acoustic neuroma and gliomas in the INTERPHONE study were somewhat similar for the 1,105 acoustic neuroma cases (participation rate, 82%) and 2,145 controls (participation rate, 53%).[133] The odds ratio for acoustic neuroma in regular users was not increased (OR = 0.85, 95% CI: 0.69–1.04). Although there was no consistent trend in the exposure-response relationship in the first nine deciles of RF exposure, the odds ratio was significantly increased statistically in the highest cumulative RF exposure group of ≥1,640 hours (OR = 2.79, 95% CI: 1.51–5.16) when recording exposure at 5 years. The risk estimate for acoustic neuroma was higher for ipsilateral use in long-term mobile phone users (OR = 3.74, 95% CI: 1.58–8.83; $n = 28$), but not for contralateral use in these users (OR = 0.48, 95% CI: 0.12–1.94; $n = 4$). In a pooled analysis of 2 Swedish case-control studies involving 243 acoustic neuroma cases, the odds ratio for individuals using digital mobile phones was 1.5 (95% CI: 1.1–2.1) and 1.5 (95% CI: 1.04–2.0) for cordless phone use.[168] When compared with controls (nonuse of mobile or cordless phones), the odds ratio for acoustic neuroma increased for ipsilateral use (OR = 1.7, 95% CI: 1.1–2.6), but not for contralateral use (OR = 1.3, 95% CI: 0.8–2.0). In a Japanese case-control study involving 787 cases of acoustic neuroma, regular cell phone use was not associated with an increased risk of acoustic neuroma based on self-administered postal questionnaires. The overall risk ratio was 1.08 (95% CI: 0.93–1.28) for regular mobile phone use until 1 year before diagnosis and 1.14 (95% CI: 0.96–1.40) for regular mobile phone use until 5 years before diagnosis.[169] The risk ratio increased to 2.74 (95% CI: 1.18–7.85) for mobile phone use >20 minutes daily 1 year before diagnosis and 3.08 (95% CI: 1.47–7.41) for mobile phone use >20 minutes 5 years prior to diagnosis. Potential selection and recall bias limit conclusions regarding causality in this study.

Workplace

There is no clear association between RF exposure in the occupational setting and the incidence of brain cancer. However, maximum exposures may exceed existing exposure limits for broadcasting and telecommunication transmitters, security scanners, plasma devices, radiofrequency identification, and dielectric heating. In contrast, excessive occupational exposures are rare for radar applications and microwave heating. Most cohort studies of leukemia and lymphoma following occupational exposure to RF radiation involve a small number of cases and limited exposure assessment. A study of mortality and incidence of hospitalization in a US Navy cohort of 20,000 electronic equipment repairmen did not demonstrate a statistically significant increase in the incidence of leukemia or brain cancer.[170] There was no dose-response relationship between exposure to microwave radiation based on indirect measures (length of exposure, occupational duties, and power of equipment) and mortality from malignant neoplasms including leukemia and brain cancer. A mortality study of 40,581 US Korean War navy veterans suggested an association between RF radiation and leukemia; however, limited exposure data based indirectly on job title and expert assessment along with possible confounding complicate interpretation of the data. Evaluation of the high (usually <1 mW–100 kW/cm^2) and low (<1 mW/cm^2) exposure subcohorts demonstrated a relative risk (RR) of 1.48 (95% CI: 1.01–2.17) for all leukemias and 1.87 (95% CI: 0.98–3.58) for acute nonlymphocytic leukemia.[171] The highest RR for all leukemias (RR = 2.60; 95% CI: 1.53–4.43; $n = 23$) occurred in the job with the highest estimated exposure (aviation electronics technicians). The risks were not adjusted for confounding exposures.

Brain

A statistically significant increase in the risk of brain tumors (RR = 2.9) and glioblastomas (RR = 3.4) occurred in assemblers and repairmen in the radio and television industry;[172] however, a follow-up study of a cohort with high exposure to radiofrequency radiation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

did not detect the development of malignancies in the occupational cohort with relative high exposures to radiofrequency radiation.[173] The relatively short follow-up periods and the difficulty separating cellular telephone use among categories complicate the interpretation of occupational studies on the carcinogenic effect of radiofrequency radiation. A retrospective cohort cancer incidence study among 22,197 Canadian police officers did not detect an increased standardized incidence ratio (SIR = 0.84, 95% CI: 0.48–1.36) for brain cancer.[161] A nested case-control study of US Air Force personnel did not detect an exposure-response trend between categories of RF electromagnetic field exposure intensity and the occurrence of brain tumors.[174] Exposure was based on reports of overexposure without any direct measurements of RF exposure.

Leukemia

A mortality study of amateur radio operators demonstrated a slight but nonsignificant elevation of the all-leukemia standardized mortality ratio (SMR) and significantly elevated SMR of 176 for acute myeloid leukemia (n = 15 observed, n = 8.5 expected).[175] A Norwegian study of radio/telegraph operators and radio/TV repairmen detected an elevated incidence (SIR = 2.8, 95% CI: 1.3–5.4) of leukemia based on national occupation and cancer registries.[176] There were no direct measurements of cumulative exposure to radiofrequency radiation, and job titles were surrogates for exposure. The possession of an amateur operator's license was a surrogate for exposure to radiofrequency radiation, and there was no direct measurement of exposure or examination of confounding variables. A Swedish study did not detect an increased SMR for leukemia in television/radio repairmen or assemblers.[172] No increase in the amount of chromosomal damage was found in Australian radio linesmen exposed to radiofrequency radiation at or below occupational RF exposure limits.[177] A retrospective cohort cancer incidence study among 22,197 Canadian police officers did not detect an increased standardized incidence ratio for leukemia (SIR = 0.6, 95% CI: 0.31–1.05).[161]

Reproductive Abnormalities

Humans

The association between exposure to radiofrequency radiation and teratogenesis in the absence of temperature elevation from microwave radiation remains unproven based on inconsistent epidemiology studies and methodological limitations (e.g., reporting and recall bias, misclassification). A detailed study of the incidence of congenital abnormalities at a military base did not detect an increased risk of adverse pregnancy outcomes above surrounding levels.[178] Although cross-sectional studies of paternal radiofrequency exposure on Norwegian fast patrol boats during the 90 days prior to conception suggested an increased risk of stillborn babies and congenital abnormalities,[179,180] lack of control of confounding variables, recall bias, and the absence of a clear dose-response relationship limit conclusions regarding causation. Anecdotal case reports associate the development of congenital abnormalities with the use of diathermy for the treatment of various pelvic conditions during pregnancy;[181] however, epidemiological studies have not demonstrated a consistent, statistically significant elevated risk of adverse pregnancy outcomes above baseline rate.

A nested case-control study of physical therapists detected an increased risk of miscarriage (OR = 1.28, 95% CI: 1.02–1.59) in mothers reporting the use of microwave or shortwave diathermy anytime during or 6 months prior to the first trimester as assessed by mailed questionnaires.[182] The risk of miscarriage was not associated with the reported use of shortwave diathermy equipment (OR = 1.07, 95% CI: 0.91–1.24). A case-control study of Danish physiotherapists initiated by a cluster of 4 cases of congenital malformation among 25 pregnancies among a physiotherapy staff detected a statistically nonsignificant positive association (OR = 1.7, 95% CI: 0.6–4.3) between pregnancy outcomes and radiofrequency radiation.[183] A study of all registered physiotherapists in Finland from 1973–1983 demonstrated a statistically significant increase in the risk (OR = 2.4, 95% CI: 1.0–5.3) of congenital malformations in the low exposure group, but not in the high exposure group.[184] In this study, heavy exertion was a risk factor for spontaneous abortion. In the Norwegian Mother and Child Cohort Study conducted from 1999–2009, there was no association between maternal prenatal or paternal preconceptional cell phone exposure based on reported cell phone use and studied pregnancy complications, including outcomes (total congenital malformations, perinatal mortality, low birth weight, preterm birth, preeclampsia, abruptio placentae) after adjustment for parity, maternal age, and smoking.[185] A case-control study of maternal exposure to RF radiation from macrocell base stations did not detect an association or exposure-response relationship between estimated RF exposure and the incidence of early childhood cancers up to age 4 years in the central nervous system, leukemia, non-Hodgkin's lymphomas, or all cancers combined.[186] The study did not account for cell phone use.

Animals

Hyperthermia is a well-recognized cause of teratogenicity in animals; consequently, RF electromagnetic field-induced hyperthermia is expected to produce developmental abnormalities. Radiofrequency radiation from shortwave diathermy units in rats[187] and microwaves in Chinese hamster cells suggest radiofrequency radiation may be teratogenic and mutagenic, respectively, *when* hyperthermia results from these radiation exposure.[188] Most animal teratology studies do not demonstrate consistent detrimental effects from prenatal exposure to a variety of RF signals commonly used in mobile telecommunications,[189,190] with the exception of some subtle, transient changes (e.g., delayed ossification, serum chemistry, RBC parameters).[191,192] In general, animal experiments indicate RF radiation does not produce damage to DNA, chromosomes, or the reproductive potential of animals in the *absence* of hyperthermia.[22,193] Limited epidemiological data do not support an association between adverse outcomes of pregnancy and exposure to radiofrequency radiation.[194,195] There is no clear evidence that genetic effects occur below power densities of 100 mW/cm^2; animal studies indicate that power densities above this level are necessary to produce testicular damage.[196]

DOSIMETRY

Incident electromagnetic fields are forces external to the body that are not the result of any interaction with biological material. The incident fields couple with the human body to induce EMF and currents inside the body; the strength of the electric and magnetic fields inside the body (i.e., induced electric and magnetic fields) differs substantially from the incident electromagnetic fields. The widely divergent tissues and anatomy within the body produce large, local variations in energy absorption, resulting in differences over a thousandfold.[2] Factors determining the induced electromagnetic fields include: 1) direction, distance, and relative orientation of the source and obstacles between the field and the receiver; 2) direction and angle of wave propagation from the source; and 3) polarization, modulation, frequency, and power of the source.[197] For far-fields, the power density can be calculated from the electric field or the magnetic field strength using the simple conversion factor of space impedance. The most potentially hazardous electromagnetic fields occur close to the source in the near-field with strong field gradients (e.g., contact currents from touching towers or fences exposed to strong EM fields transmitting antennas). The characterization of power density in the near-field is much more complex because of the presence of reactive and radiation components. These components produce temporal and spatial variations in the fields depending on the physical environment and the character of the radio waves. Hence, direct measurements of each individual situation with a probe are necessary to accurately characterize the field in a near-field situation. The probe should be oriented for the maximum reading measuring only the designated field parameters (i.e., *H*-field and not the *E*-field).[24] Probe sensitivity varies with frequency; the presence of the operator of a handheld device may alter the reading from the near-field. Small errors in distance between the probe and antenna may introduce large errors in the field strength close to the source. There is no single measurement technique that is effective over the whole range of radiofrequencies; instruments that measure frequencies in the microwave range of >1 GHz are not suitable for use at lower frequencies.

Exposure Assessment

Collection of specific data on an exposure to radiofrequency radiation is necessary to calculate the specific absorption rate and correlate the radiation dose received with expected biological effects. Examination of the site of exposure is important because field enhancement may result from reflection of radiofrequency waves from the ground or nearby metal objects (e.g., metal frames on glasses, safety helmets).[198] The use of protective clothing (e.g., headgear, eyeglasses, heavy clothing) and climatic conditions may affect the thermal load produced by radiofrequency radiation.

Table 44.7 outlines the important parameters and values for the investigation of an exposure to radiofrequency radiation. Most current instruments (i.e., densitometers) measure field strength and power density in a broadband field. Broadband *E*-field instruments are available to monitor a range of 3 kHz–40 GHz; however, a single instrument will not measure the entire RF range.

Analytical Methods

Safety guidelines are based on measurements of the specific absorption rate (SAR) averaged over the whole body (i.e., whole-body-averaged SAR, wbSAR) or over a small sample of volume or tissue mass (i.e., maximum peak spatial SAR, psSAR); the psSAR does not usually correlate to specific tissues or typical exposures. For frequencies up to a few GHz, including most wireless communications, the SAR is typically averaged over 1

TABLE 44.7. Parameters to quantify radiation exposure in the radiofrequency range. (Adapted from Hocking et al.).[91]

Parameter	Data
Radiation exposure	Frequencies transmitted, modulation characteristics (peak/average values), polarization, power transmitted including harmonics, system losses, antenna characteristics (type, size, gain, beam widths, radiation patterns), height from ground level, orientation limits, distance between source and exposure, presence of scattering objects influencing radio wave propagation, duration of exposure
Environment	Temperature, humidity, wind, work performed, protective gear worn (head gear, eyewear, clothing)
Instrumentation	Position of instrument, time and value of all measurements

or 10 g. High-frequency millimeter waves in 5G systems do not penetrate the skin; therefore, surface-dominated absorption predominates. The mass-averaged SAR depends primarily on the blood perfusion rate and the depth of radio wave penetration. For localized RF fields close to the body (<20 cm), assessment of compliance with local SAR and current density limits requires measurements and numerical simulations.[67] Noninvasive measurement of these values is extremely difficult *in vivo*, particularly in these near-field conditions; therefore, simulations of worst-case scenarios using phantoms help predict the RF exposure inside the human body. However, the standard head and body phantoms recommended for compliance testing are homogeneous rather than the heterogeneous constituents of human tissues. Numerical techniques use anatomically realistic computer (voxel) models to estimate the distribution of induced electric fields and the resulting SAR values based on methods using Maxwell's equations to analyze data from phantoms in finite-difference time-domain (FDTD) and, less often, finite-element models.[199] These models determine the compliance of commercial communication devices with safety guidelines.[36] Each voxel represents a volume of a few cm^3 with several million voxels combining to simulate a human head or body based on distributions determined anatomically from medical images (e.g., MRI, CT). These models incorporate the frequency-dependent dielectric properties of the tissues (i.e., conductivity, permittivity) into the voxels to approximate the interaction of induced electric fields within human tissues; these dielectric properties vary with water content, age, and physiological state of the tissues. Differences in the effect of RF exposure between children and adults primarily reflect differences in dielectric properties and physical size. Reflection of RF fields from bodies and secondary resonant structures necessitates the use of additional assessments for determining RF exposures in epidemiology studies.

Diode-based field probes consisting of field sensors, detectors, scatter-minimizing transmission lines, and display electronics are commonly used to assess near-field RF exposures; the primary limitation of these devices is their inherent nonlinearity over their dynamic frequency range. Other broadband *E*-field probes include true square-law detectors (thermocouple and thermistor probes) and electro-optical sensors (active, passive). The latter allows sensitive measurements of the RF domain and phase while limiting electric field interference. Thermistors provide higher resolution than thermocouple probes; however, the former requires careful calibration on multiple parameters that affect RF exposure.

Thermistor- and optical-based temperature probes allow direct measurement of SAR, whereas infrared photography (black-body equivalent radiation) is a noninvasive technique. The latter method measures only surface temperatures and has relatively less sensitivity than the former. Direct and indirect calorimetric techniques measure average wbSAR without providing data on SAR distribution. Measuring SAR in the near-field requires very complicated computer analysis of several hundred positions in a three-dimensional phantom. Analysis of RF fields under far-field conditions (e.g., radio/television broadcast antennas, mobile phone base stations, radar installations) is much simpler than in near-field situations using broadband-measurement single- and 3-axis sensor probes. Accuracy of the data from these survey meters depends on limiting sources of uncertainty including linearity, frequency response, calibration, time-domain response, and temperature response.

Protocols and instrumentation designed to test worst-case scenarios for compliance testing provide conservative estimates of maximum RF exposure. Application of this testing to personal exposure for epidemiology studies may not represent actual real-life RF exposure. Accurate analysis of personal exposure using these techniques requires evaluation of induced rather than incident RF-field exposure, analysis of the multiple sources of RF exposure operating in real-life situations, and analysis of multiple factors (e.g., geographical, usage, and temporal) applicable to the relevant exposure period of interest.

Biomarkers

The main measure of exposure to RF of >100 kHz is the specific absorption rate (SAR) in SI units of W/kg. This measure of energy absorption and potential temperature increase in tissues is usually reported as a value averaged over time (e.g., 6 minutes) and mass (1 or 10 g). The whole-body-averaged SAR (wbSAR) is the total power from an electromagnetic field absorbed by a body divided by its mass. The maximum peak spatial SAR (psSAR) is averaged over a cubic volume containing 1 g of tissue (psSAR-1g) or 10 g of tissue (psSAR-10g). To enhance the biological meaning of these values, the psSAR often refers to power absorbed by specific tissues or organs. For radio waves of <10 MHz, current densities and electric field strengths averaged over an 8 mm^3 volume enhance measurements of internal electromagnetic field exposure.

In addition to the characteristics of the body and the incident electromagnetic field, the effect of the field on the body depends on the ratio of wavelength/body size. Consequently, the RF portion of the electromagnetic spectrum is divided into ranges based on the resonance frequency of the body (10 MHz) as follows: 1) below body resonance (30k–10 MHz); 2) body and partial-body resonances (10 MHz–2 GHz); and 3) surface-dominated absorption (2–300 GHz). At frequencies below body resonance (<10 MHz), the body is a poor conductor; the primary concern is contact currents induced by near-field sources with strong field gradients (e.g., transmitting towers). Above body-resonance frequencies (>2 GHz), absorption of RF energy occurs predominately on the surface of the body. Local anatomy of the skin, fat, and muscle alters the absorption rates with the development of local hot spots in the nonhomogeneous tissues. Thus, some difference in the intensity of RF exposure occurs in children and adults. The resulting temperature elevation depends on the thermal conductivity and perfusion of the tissues.

HEALTH SURVEILLANCE

Environmental Monitoring

The most authoritative organizations establishing safety standards and guidelines for RF exposure are the World Health Organization-associated International Commission on Nonionizing Radiation Protection (ICNIRP) and the Institute of Electrical and Electronics Engineers International Committee on Electromagnetic Safety (IEEE/ICES). Review of the BioInitiative Report: A Rationale for a Biologically based Public Exposure Standard for Electromagnetic Fields (BIR) by these organizations indicates the weight of scientific evidence does not support the 2007 BIR recommendations on safety limits for exposure to RF radiation.[200] Basic restrictions are recommendations to prevent adverse direct effects based on the interactions of RF fields within the body, primarily whole- and partial-body heating. In contrast to the Western approach, countries in Eastern Europe (Bulgaria, the Czech Republic, Hungary, Poland, Russia) use nonthermal effects from chronic exposures to low-level exposures for safety standards based on power load (intensity × duration).[201] Indirect effects result from an interaction between incident RF fields, an external object, and the human body that has the potential to cause burns.

Scientific Basis

The biological basis of current guidelines for the RF range of 10 MHz–few GHz is a threshold effect of increasing body temperature by >1°C at a whole-body specific absorption rate (wbSAR) of 4 W/kg for ~6 minutes or ~30 minutes. The most sensitive measure of this biological effect is reversible, behavioral disruption in animals (e.g., agitation, startle, vigilance task alteration, evoked body movements) following an acute exposure to a whole-body-averaged SAR of 4–8 W/kg body weight.[202,203] The deposition of energy in the tissues adds to the heat created by resting metabolism (i.e., ~1 W/kg) and vigorous exercise (5 W/kg); however, the RF-induced temperature elevations under normal circumstances are relatively small compared with the heat generated by the body and normal temperature fluctuations in the body. For RF fields of 100 kHz–10 MHz, whole-body heating remains the primary direct effect; however, the coupling of the fields to the body becomes progressively weaker as the wavelength becomes progressively longer than the body dimensions. At RF frequencies below 10 MHz, thermal effects remain important determinants of guidelines; however, restricting induced current densities in tissues also becomes important. Above 10 GHz, energy absorption from the RF fields occurs in the first few mm; hence, guidelines are based on surface heating. Pulse-modulated RF waveforms (e.g., some radar signals) may cause pulsed thermal expansion of tissues in the head, resulting in potentially stressful and harmful microwave auditory effects. Additional guidelines were added to avoid this effect. The RF radiation guidelines are designed to allow repeated exposure without causing adverse health effects, including safety factors to accommodate potentially sensitive individuals. Consequently,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the recommended guidelines do not represent a fine line separating safe and dangerous levels of RF radiation.

Guidelines

Compliance with basic restrictions using wbSAR is not easily measured; consequently, reference levels in addition to SAR limits are formulated in values of measurable field quantities (current density, *E*- and *H*-field strengths, power density) to assess compliance with basic restrictions. Basic restrictions are reduced below the threshold for adverse effects by safety factors to accommodate uncertainty in the calculations and ensure exposures do not cause adverse effects. Recommended guidelines for occupational exposure are 10-fold below the recognized threshold for potential adverse effects (4 W/kg), whereas an extra 5-fold safety factor below the occupational recommendations is added for the public to account for potential differences in sensitivity to thermal effects from age and general health. The value of 0.08 W/kg for the public is 50-fold below the threshold (4 W/kg) and 12.5-fold below the basic metabolic rate (1 W/kg). Table 44.8 displays the guidelines for ICNIRP through 2005. In 2020, the ICNIRP replaced their 1998 radiofrequency guideline for the general public exposed to RF radiation in the range of 100 kHz to 300 GHz with more complicated basic restrictions by dividing the restrictions into average intervals of <6 minutes and ≥6 minutes (https://www.icnirp.org/cms/upload/publications/ICNIRPrfgdl2020.pdf). Additionally, the ICNIRP separated the restrictions into RF ranges of 100 kHz–6 GHz and >6 GHz–300 GHz with some exposure scenarios not requiring compliance. The IEEE updated their general public exposure criteria and associated limits for electric, magnetic, and electromagnetic fields in the frequency range 0 Hz–300 GHz. (https://ieeexplore.ieee.org/stamp/stamp.jsp?arnumber=8910342).

The 1998 ICNIRP guidelines recommended a localized SAR limit of 2 W/kg averaged over any 10-g mass of tissue in the head.[204] Exceeding these recommendations is unlikely during normal use of phones with duty cycle-weighted powers of <0.6 W for 900 MHz fields and 0.4 W for 1.8 GHz fields based on antenna to head separation of 1.4 cm and the radiation of all available power, particularly with the lower power associated with 3G and 4G mobile phones. The high-frequency millimeter waves in 5G systems do not penetrate the skin; therefore, surface-dominated absorption predominates and the risks of adverse effects are expected to be lower than in previous 3G and 4G systems.

British standards require leakage from microwave ovens of <50 W/m^2 (5 mW/cm^2) at 5 cm from the oven. At an average distance of 0.7 m from the oven, the power density emitted from a microwave oven leaking the maximum 50 W/m^2 decreases to 0.26 W/m^2 (0.026 mW/m^2). US federal regulations limit the maximum microwave leakage to 10 W/m^2 (1 mW/cm^2) at 2.5 cm from the oven when new and 50 W/m^2 (5 mW/cm^2) during the lifetime of the product. Independently operating interlocking switches are built into most microwave ovens to stop operation of the oven when the door opens. Metal

TABLE 44.8. International Commission on Non-Ionizing Radiation Protection (ICNIRP) and Institute of Electrical and Electronics Engineers (IEEE) guidelines on public (uncontrolled) exposure to radiofrequency fields based on specific absorption rates (SAR). Each organization has specific restrictions, including differences in the frequency range, averaging times, mass volumes, and definitions of extremities. This table was tabulated to compare the values of the recommendations made by different organizations at different times. Guidelines and regulations change with time. The organization website should be consulted for any updates on the specific restrictions and recommendations. Although the IEEE revised their guidelines in 2005, some countries still use the 1999 guidelines. The head-and-trunk guidelines apply to mobile phone communications.

Region	ICNIRP (1998)	IEEE (1999)	IEEE (2005)
Whole-body SAR (100 kHz–10 GHz)	0.08 W/kg	0.08 W/kg	0.08 W/kg
Localized SAR			
Head and trunk	2 W/kg	1.6 W/kg in 1-g of mass	2 W/kg in 10-g of mass
Extremities	4 W/kg	4 W/kg in 10-g of mass	4 W/kg in 10-g of mass
Current density (30 kHz–10 MHz)			
Whole body	—	157 mA/m^2 (rms)	—
Head and trunk	(f/500) mA/m^2 (rms)[a]	—	—
Power density (10 GHz–300 GHz)[b]	10 W/m^2	—	—
Whole-body induced electric field (30 kHz–10 mHz)	135 mV/m	—	—[c]

Abbreviations: f = frequency in Hz; rms = root mean square.
[a] 2 mA/m^2 for the central nervous system. [b] Spatial maximum power densities averaged over 1 cm^2 should not exceed 200 W/m^2. [c] 294.5 mV/m for the brain.

screens on the oven doors and microwave-absorbing door seals reduce the leakage of microwaves.[205] A proper screen or a thin metal foil provides 100% screening of all microwaves. Safety measures for reducing RF electromagnetic field exposure during the use of microwave ovens include always operating the oven with the door closed, keeping a tight seal with clean surfaces around the door, and maintaining the oven in good repair. Exposure guidelines for millimeter wave whole-body scanners used in public facilities use 10 W/m^2 averaged over a time interval that decreases with increasing frequency (6 minutes at 10 GHz to 10 seconds at 300 GHz) based on avoiding mild whole-body heat stress and excessive local tissue heating.[206]

Occupational Monitoring

Occupational exposure limits for radiofrequency radiation are designed to prevent excessive thermal exposure. The body absorbs radiofrequency radiation at frequency-dependent rates with maximal absorption occurring at the resonant frequency of the body. This resonant frequency varies inversely with size. An average of 70 MHz is the resonant frequency for the average 70-kg man, whereas 3 GHz is the resonant frequency for small rodents.

Guidelines

As listed in Table 44.9, most consensus-based recommendations (IEEE, ACGIH, NCRP/Health Protection Agency, ICNIRP) use similar RF exposure guidelines based on a whole-body-averaged SAR limit of 0.4 W/kg and localized SAR limit of 8–10 W/kg for the head and trunk. These guidelines assume the primary biological effects of RF radiation are thermal and nonstochastic (i.e., biological effect depends on dose rate above a specific threshold); these guidelines are designed to prevent excessive heating of local tissue with safety factors for high levels of ambient temperature, humidity, and physical activity.[207] Consequently, these regulations average the exposure over a specific time to determine the acceptable frequency and time-dependent exposure. The threshold level for most of the reported adverse effects occurs at whole-body specific absorption rates (SAR) of >4 W/kg.[208] This SAR is equivalent to the heat generated by moderate physical activity (e.g., housecleaning, driving a truck); the body usually dissipates this heat with normal thermoregulatory mechanisms.

TABLE 44.9. International Commission on Non-Ionizing Radiation Protection (ICNIRP) and Institute of Electrical and Electronics Engineers (IEEE) guidelines on occupational (controlled) exposure to radiofrequency fields based on specific absorption rates (SAR). Each organization has specific restrictions including differences in the frequency range, averaging times, mass volumes, and definitions of extremities. This table was tabulated to compare the values of the recommendations made by different organizations at different times. The organization website should be consulted for specific restrictions and recommendations. Although the IEEE revised their guidelines in 2005 (https://ieeexplore.ieee.org/stamp/stamp.jsp?arnumber=1626482), some countries still use the 1999 guidelines. In 2020, the ICNIRP replaced their 1998 radiofrequency guideline for occupational RF radiation exposure in the range 100 kHz to 300 GHz with more complicated basic restrictions by dividing the restrictions into average intervals of <6 minutes and ≥6 minutes (https://www.icnirp.org/cms/upload/publications/ICNIRPrfgdl2020.pdf). Additionally, the ICNIRP separated the restrictions into RF ranges 100 kHz–6 GHz and >6 GHz–300 GHz with some exposure scenarios (e.g., 100 kHz–400 MHz) not requiring compliance with guidelines for other RF radiation (i.e., >400 MHz–6 GHz). The organization website should be consulted for any updates on specific restrictions and recommendations.

Region	ICNIRP (1998)	IEEE (1999)	IEEE (2005)
Whole-body SAR (100 kHz–10 GHz)	0.4 W/kg	0.4 W/kg	0.4 W/kg
Localized SAR			
Head and trunk	10 W/kg	8 W/kg in 1-g mass	10 W/kg in 10-g mass
Extremities	20 W/kg	20 W/kg in 10-g mass	20 W/kg in 10-g mass
Current density (30 kHz–10 MHz)			
Whole body	–	350 mA/m^2 (rms)	–
Head and trunk	10 mA/m^2 (rms)[a]	–	–
Power density (10 GHz–300 GHz)[b]	50 W/m^2	–	–
Whole-body induced electric field (30 kHz–10 mHz)	270 mV/m	–	–[c]

Abbreviations: f = frequency in Hz; rms = root mean square.
[a] 10 mA/m^2 for the central nervous system. [b] Spatial maximum power densities averaged over 1 cm^2 should not exceed 1,000 W/m^2. [c] See 2005 IEEE website above.

The 1999 ANSI/IEEE revision (C95.1-1999) reaffirmed this value and a safety factor of 10.[209] The Risk Assessment Working Group found no reliable scientific data that RF exposure to a SAR of <0.4 W/kg (i.e., 4 W/kg divided by a safety factor of 10) produced adverse health effects in humans. The ICNIRP and IEEE reviewed the scientific basis for their guidelines, concluding that the lack of evidence of any adverse effects below the basic restrictions indicated an immediate revision of the guidelines was not necessary.[62,210] The biological basis of their recommendations remained the avoidance of tissue damage from excessive localized heat and disruption of workplace activities by mild whole-body heat stress. A subsequent ICNIRP workshop confirmed that RF-induced temperature elevations under normal circumstances are very small relative to the magnitude of normal temperature fluctuations with the largest impact on thermal effects following RF exposure related to factors independent of the RF-generated heat (i.e., thermoregulation).[211] The group indicated international guidelines for whole-body RF exposure were valid; however, they suggested the large uncertainty around this value indicated averaging over 30 minutes may be more appropriate than 6 minutes to prevent local hot spots. Subsequently, the ICNIRP changed their guidelines to separate the basic restrictions to reflect different basic restrictions for averaging RF exposure above and below 6 minutes.

In tabular form, Table 44.10 lists the ACGIH recommendations for RF exposure based on limiting exposure below the threshold SAR of 0.4 W/kg and frequency-dependent variations of energy absorption.[212] The basis of the recommendations of the American Conference of Governmental Industrial Hygienists is a threshold whole-body SAR of 0.4 W/kg averaged over 6 minutes plus a safety factor of 10 for radiofrequencies of >3 MHz. At frequencies of <3 MHz, a limiting value of 1 W/m^2 for plane-wave free-space power densities (S) minimizes electric field-induced reactions at the body surface and shocks from grasping large, ungrounded metallic objects. The ANSI/IEEE guidelines are similar to the ACGIH recommendations listed in Table 44.10. Figure 44.6 displays the ACGIH guidelines for radiofrequency and microwave radiation graphically, as tabulated in Table 44.10. For frequencies below 100 MHz, the recommended parameters include electric field strength, magnetic field strength, and induced currents rather than plane-wave free-space power densities.[212] The frequency range 0.1 MHz–6.0 GHz includes the resonance range for

TABLE 44.10. American Conference of Governmental Industrial Hygienists (ACGIH) recommendations for occupational exposure to radiofrequency radiation ranging from 30 kHz–300 GHz based on an SAR of 0.4 W/kg and frequency-dependent variation of energy absorption. The recommendations were established to limit tissue heating above 0.1 MHz and stimulation of nerves and muscles at RF 0.03–01 MHz. For RF 100 MHz–300 MHz, the near-field of the source defines the electric and magnetic fields. (American Conference of Governmental Industrial Hygienists).[212]

Frequency (Hz)	Power Density (S)[a] (W/m^2)	Electric Field Strength (E)[b] (V/m)	Magnetic Field Strength (H)[b] (A/m)	Maximum Current (mA)	Averaging Time for S, E, and H (Minutes)
30–100 kHz		1,842	163	Both feet: 2000[c] Either foot: 1000[c] Grasping: 1000[c]	6
100 kHz–1 MHz		1,842	16.3/f	Both feet: 200[d] Either foot: 100[d] Grasping: 100[d]	6
1–30 MHz		1842/f	16.3/f		6
30–100 MHz		61.4	16.3/f		6
100–300 MHz	10	61.4	0.163		6
300 MHz–3 GHz	f/30				6
3–30 GHz	100				33,878.2$f^{1.079}$
30–300 GHz	100				67.62$f^{0.476}$

Abbreviation: f = frequency (MHz).

[a] The power density for frequencies >30 GHz is the value over any contiguous body surface area of 0.01 m^2. [b] The electric and magnetic field strengths are spatially averaged over an area equivalent to the vertical cross-section of the human body. The maximum (peak) electric field intensity for all exposures is 100 kV/m. [c] The averaging time is 0.2 seconds for freestanding workers with no contact with metallic objects; for possible contact with metallic objects, conditions of grasping contact apply. For touch contact, the maximum RF-induced current is 50% of the maximum grasping value with a ceiling value of 500 mA. Startle reactions and burns may occur from transient discharges within the current limits. [d] The averaging time in this frequency range is 6 minutes.

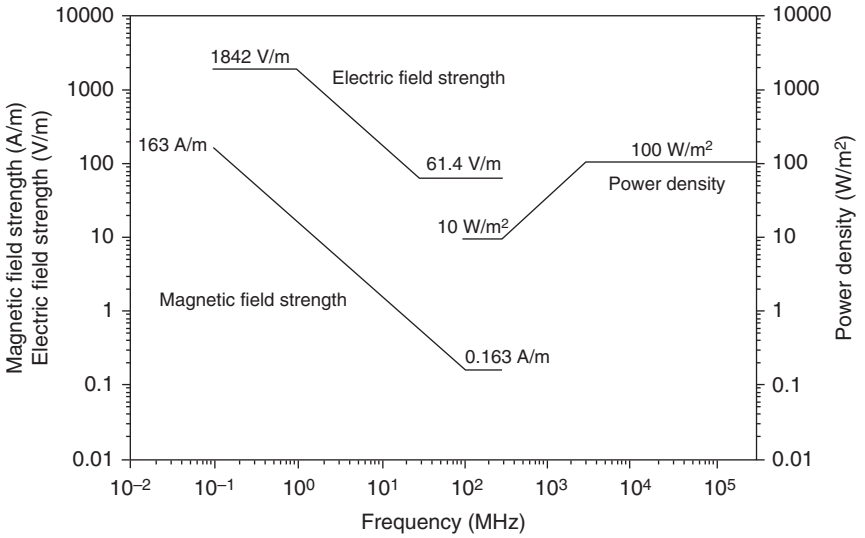

FIGURE 44.6. Graphic representation of American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit values (TLVs) for radiofrequency radiation including microwaves in the workplace. The electromagnetic field strengths and power density are formulated to comply with the whole-body specific absorption rate (SAR) of < 0.4 W/kg at the frequencies noted on the graph. (Redrawn from American Conference of Governmental Industrial Hygienists).[212]

humans; therefore, exposure guidelines decrease in this range compared with frequencies above 6 GHz. These recommendations for frequencies of >6 GHz are based on power density. In the frequency range <0.1 MHz, electrostimulation of biological tissue becomes more important than thermal changes. The primary parameter is internal current density rather than power density. Because of the localized nature of electromagnetic fields in the near-field (i.e., within 1 wavelength), the associated whole-body averaged SARs are below those induced by the far-field equivalent field strengths; therefore, these recommendations apply regardless of the distance from the source.[213] Measurements of field strengths should be at least 5 cm from any object.

Some low-power devices (e.g., mobile car phones, marine transmitters, citizens' band radios) generate localized fields that exceed some recommended guidelines; however, the whole-body exposure is usually below current standards, particularly with the lower power of the 3G, 4G, and 5G cell phones compared with earlier versions.[213] Some modern RF devices use ultra-wideband (UWB) radiation, including short-range wireless communication systems, security systems, car radar, and location tracking. These signals typically consist of extremely short pulses (<10 nsec) with rapid rise times (<200 psec), resulting in a very wide bandwidth characterized by a bandwidth greater than the central frequency. The ACGIH and IEEE consider the limits recommended for exposure to continuous-wave or pulsed RF and microwave radiation sufficient to protect workers from adverse effects following UWB exposure.[212]

Protective Measures

When surveys of electromagnetic fields indicate RF exposures exceed recommended limits, workplace surveillance should be conducted, particularly if RF hot spots may be present. RF hot spots are very rapid spatial variations of the RF fields that produce localized, partial-body exposure on the surfaces of nearby objects including humans. A measurement of the contact current between the person and the re-radiating object provides an alternative evaluation of the peak SAR to measurements of the RF field.

Engineering and Administrative Controls

Engineering and administrative controls are preferable to personal protection equipment as a method of reducing exposure to RF fields to acceptable limits. Engineering controls that limit exposure to the workers and the general public include design, placement, and installation of generating equipment.[3] Special techniques (e.g., grounding of metal fences and other metal objects) may be necessary to reduce exposure to excessive contact currents. Typically, leakage (stray) fields from telecommunications equipment occur at such low frequencies that electromagnetic interference is more important than RF-induced health effects. Administrative controls (e.g., limiting access, warning signs,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

restrictions on the number of workers, and the duration of exposure) supplement engineering controls.

Personal Protective Clothing

Although protective clothing (conductive suits, gloves, safety shoes) may be used for safety reasons, few commercial RF shielding suits are available; microwave suits provide protection only over a narrow range.[214] Protective clothing and eye shields are available to reduce RF exposure; however, routine use of protective equipment is not usually recommended because of the hazards of reflection and the development of secondary sources of electromagnetic fields.[19] Specific safety shoes are available to reduce high local SAR.[215] There is no convincing evidence that safety glasses are an effective measure to reduce exposure to RF fields.

Medical Surveillance

Other than a preemployment physical examination, routine surveillance of workers exposed to RF fields is not necessary unless the RF exposure exceeds current recommendations. For epidemiological purposes, assessment of the health status of workers before, during (especially after documented overexposure), and after employment ceases may help detect any early signs of adverse health effects in those workers where exposure to RF fields exceeds current limits; however, there are no unique clinical syndromes that would identify excessive RF exposure. Keeping precise records provides documentation for future studies, especially regarding the duration and degree of exposure.

Chapter 45

STATIC AND EXTREMELY LOW FREQUENCY MAGNETIC AND ELECTRIC FIELDS

ELECTROMAGNETIC SPECTRUM

Extremely low frequency (ELF) electric and magnetic fields including static fields comprise the lowest frequencies and longest wavelengths of the electromagnetic spectrum; these frequencies are well below the upper limit of nonionizing radiation near the upper end of ultraviolet radiation region of the electromagnetic spectrum, as demonstrated in Figure 45.1.[1] Electromagnetic waves in the nonionizing portion of the spectrum lack sufficient energy to break chemical bonds and form ions, resulting in significantly different health effects than ionizing radiation. Frequency, wavelength, and energy characterize electromagnetic radiation. The energy of radiofrequency, and ELF radiation possesses relatively long wavelength, low photon energy, and low frequency compared with other electromagnetic waves in the electromagnetic spectrum. Telecommunication applications (e.g., wireless networks, mobile phones, radio/television broadcasting) dominate the uses of radiofrequency radiation, whereas the generation, distribution, and use of 50 and 60 Hz appliances dominate exposure to ELF radiation. Table 45.1 lists the physical characteristics of ELF radiation compared with radio waves and microwaves.

By convention, the primary descriptor of the nonionizing radiation region (e.g., static, ELF, radiofrequency) of the electromagnetic spectrum is wavelength (λ, meters or fractions thereof), whereas photon energy (electron volts, eV) usually characterizes γ- and X-ray radiation.[2] Table 45.2 outlines the nomenclature used to describe the frequencies covered by the portion of the nonionizing portion below infrared radiation.

HISTORY

The biological effects of ELF electromagnetic fields were studied before the time of the mystic and doctor Paracelsus (1493–1541).[3] A footnote in *Historiae Naturalis* XXXVII by the Roman naturalist Pliny the Elder (23–79 AD) attributes the discovery of a magnetic substance to the shepherd Magnes while walking in the Turkish mountain called Ida; he found a piece of mineral lodestone (magnetic Fe_3O_4) in the ground after sensing a strong attraction of the earth to the nails in his sandals.[4] The pre-Socrates Greek philosopher postulated that the attraction of a magnet to iron and amber to cloth and paper meant that these substances had a soul. Greek physicians prescribed amber for hemorrhages, and the priests of Samothrace sold magnetic rings to cure arthritis.[4] In 1289, Peter Peregrinus first described the importance of the compass for sea navigation in his *Epistola*. Many myths surrounded the use of magnets during the Middle Ages, including the ability to draw poison from a wound, cure gout, treat melancholy, enhance sexual powers, and draw gold from wells. Medieval practitioners used magnets to treat strangulated hernias and retrieve iron splinters from the eyes of workers. Paracelsus believed magnets could attract all martial humors in the human system and treat epilepsy, hemorrhage, and diarrhea. William Gilbert (1544–1603), the president of the Royal College of Physicians and personal physician of Queen Elizabeth I, created the science of terrestrial magnetism by proposing that the action of a compass resulted from interaction with the earth as a huge magnet. Interest in magnetism and electricity

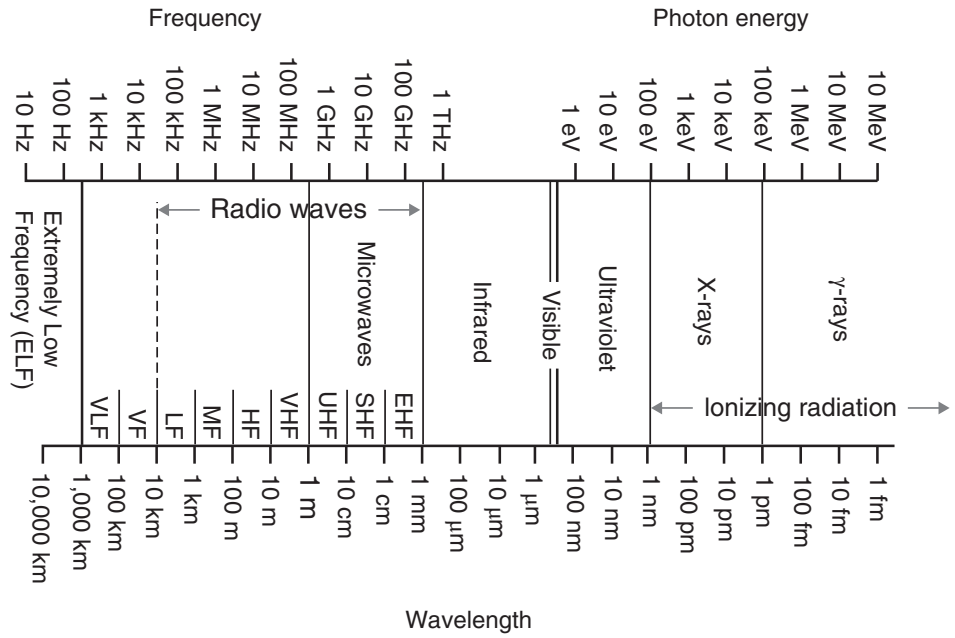

FIGURE 45.1. Electromagnetic Spectrum. Frequency increases from left to right with the symbols for frequency units and bands defined in Table 45.2. The units of frequency are multiples of the hertz (Hz) including kilohertz (kHz, 10^3), megahertz (MHz, 10^6), gigahertz (GHz, 10^9), and terahertz (THz, 10^{12}). Radiofrequency radiation includes the low frequency (LF), medium frequency (MF), high frequency (HF), very high frequency (VHF), ultra-high frequency (UHF), super-high frequency (SHF), and extremely high frequency (EHF) ranges; the latter three ranges (UHF, SHF, EHF) comprise the microwave region. The extremely low frequency (ELF) region lies below radio waves, microwaves, and the voice frequency (VF)/very low frequency (VLF) range. Beyond radio waves lie infrared, visible, and ultraviolet radiation along with X-rays and γ-rays. By convention, frequency describes the nonionizing portion of the electromagnetic spectrum (ultraviolet region and below), whereas photon energies (electron volts, eV) describe the higher frequencies including all ionizing radiation. (Adapted from International Agency for Research on Cancer, IARC).[1]

TABLE 45.1. Physical characteristics of extremely low frequency (ELF), microwaves, and radio wave radiation.

Region	Wavelength	Frequency	Photon Energy
Extremely low frequency (ELF)	1,000–10,000 km	30–300 Hz	1.2–0.12 peV
Microwave	1 m–100 km	300 MHz–3 kHz	1,200–0.12 neV
Radio wave	1 mm–1 m	300 GHz–300 MHz	1.2–0.0012 meV

flourished in the 18th century, particularly in France and Germany. Benjamin Franklin postulated that all matter contained magnetic fluid distributed throughout the body and condensed in one part of the body when magnetized. The strength of magnet depended on the force required to start the fluid in motion.

Strong, durable magnets were available throughout Europe by the middle of the 18th century. In the late 1770s and early 1780s, shortly before the French Revolution, the Viennese physician Anton Mesmer established a successful practice using magnets in dramatic clinical settings to treat medical illnesses. He obtained a supply of magnets from the Jesuit priest, court astrologer to Queen Marie Antoinette, and Professor of Astronomy at the University of Vienna, Father Maximilian Höll (1720–1792). Subsequently, Mesmer claimed his healing powers resulted from a universal force (animal magnetism) rather than the magnets themselves; his abilities included the transfer of his healing powers to his patients. Disease resulted from an obstacle to the body's natural flow of "fluidum" channeled from the stars to the body by animal magnetism. Magnets restored the normal magnetic polarity in organs that became misaligned. After a series of investigations, King Louis XVI

TABLE 45.2. Nomenclature of bands designated in the extremely low frequency (ELF) and radio wave frequencies of the electromagnetic spectrum. (Hitchcock and Patterson).[2]

Frequency Range	Designation	Acronym
<30 Hz	Sub-extremely low frequency (static)	Sub-ELF
30–300 Hz	Extremely low frequency	ELF
300–3,000 Hz	Voice frequency	VF
3–30 kHz	Very low frequency	VLF
30–300 kHz	Low frequency	LF
300–3,000 kHz	Medium frequency	MF
3–30 MHz	High frequency	HF
30–300 MHz	Very high frequency	VHF
300–3,000 MHz	Ultra-high frequency	UHF
3–30 GHz	Super high frequency	SHF
30–300 GHz	Extremely high frequency	EHF

appointed a committee in 1784 that included Benjamin Franklin, Antoine Lavoisier, and medical faculty from the University of Paris; this group concluded Mesmer's claims of successful healing resulted from the power of suggestion in susceptible or naive patients rather than any special powers.[5] Then, the emphasis of the scientific community shifted from animal magnetism to subconscious motivation, hypnosis, and the power of suggestion. Few scientific studies on the medical effects of magnets were published during the 18th and early 19th centuries; most of these studies were unable to demonstrate any influence of magnets on biological or pathological processes.[6] However, during the late 19th and early 20th centuries, Dr. C.J. Thatcher, Dr. Rodney Maidson, and Gaylord Wilshire of Los Angeles used radio advertising and mail-order merchandizing to promote magnetic devices and garments as cures for a variety of diseases. Although evidence for the efficacy of magnetic fields in the treatment of any disease is lacking, products claiming the benefits of magnetic fields currently remain on the market and Internet.[7] During the early days of the US space program, concern about the astronauts' exposure to changing magnetic fields led to research on the effects of magnetic fields on primates.[8,9] The introduction of MRI machines into clinical practice in the 1970s resulted in substantial research and guidelines on exposure to ELF electric and magnetic fields.

PHYSICAL PROPERTIES

Radiation travels through space or other media in the form of waves or particles. Electromagnetic radiation typically encountered in the environment refers to energy propagated as sinusoidal waves carried by electric (E) and magnetic (H) fields. These fields are vector quantities that are perpendicular to each other and the direction of energy propagation, as displayed in Figure 45.2. They vary in terms of frequency, peak and mean intensity, waveform, direction of the field, and duration; the biologically important parameters of the field are not clearly identified. Electric and magnetic fields surround all conductors carrying electric current. These fields decrease in strength as the distance from the conductor increases. Electric and magnetic fields are considered separately because they do not possess a constant relationship in areas close to radiofrequency sources. Hence, **direct** measurements of both fields are necessary to characterize an exposure in the non-radiating near-field, where the ELF wavelengths are measured in many kilometers. In contrast to ionizing radiation, electromagnetic fields do not deposit energy in the body; similarly, electromagnetic fields do not transfer heat to tissue as microwave radiation does.

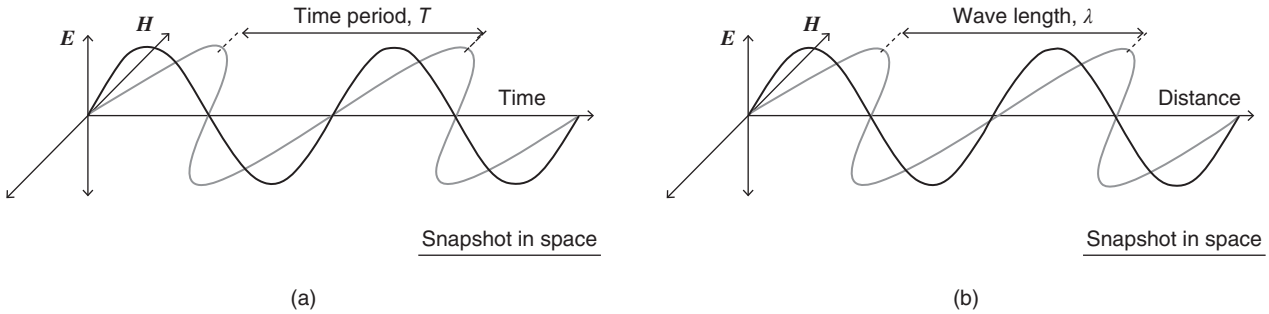

FIGURE 45.2. Schematic representation of electromagnetic waves in (a) time and (b) distance. Variation in electric and magnetic field strength depends on the source with most industrial sources of electromagnetic waves manifesting as sinusoidal waves that change over time. (Adapted from International Agency for Research on Cancer, IARC).[1]

Magnetic Fields

Definition

Conceptually, a field is a number of lines of force (i.e., flux) that traverse a specific cross-sectional area. The field intensity is directly proportional to the number of those lines. Magnetic fields result from the *movement* of electrical charges (i.e., current), whereas electric fields occur as a result of the *separation* of charges (voltage). All circuits from major power lines to kitchen appliances produce magnetic fields. A static magnetic field forms as a result of direct current, whereas alternating currents produce time-varying magnetic fields. Neither animals nor humans distort magnetic fields; therefore, the strength and frequency of a magnetic field are similar inside and outside the body. Within the body, external magnetic fields induce the flow of currents, depending on the radius of the current path and the magnetic field's frequency and strength.[10] Time-varying magnetic fields induce eddy currents within the body that may exceed naturally occurring currents. Current densities induced by magnetic fields are greatest at the periphery of the body, where the conducting paths are longest; however, the magnitude of the induced current depends on the tissue conductivity. The latter varies substantially throughout the body.

Units

The two vector quantities describing a magnetic field are field strength (H) and magnetic flux density (B). The magnetic field strength is the force exerted on an element of current at a specific point within the field; the unit for magnetic flux density is the tesla (T). By convention, magnetic flux density (B-field) describes the magnetic fields produced by the flow of current in the conductors of transmission lines and substations. The magnetic permeability (μ) is a property of the medium that correlates the magnetic field strength to the magnetic flux density as described in Equation 45.1. For biological materials, the value of the permeability (μ) is near the value of permeability for free air (μ_o).

$$B = \mu \times H \qquad \text{(Equation 45.1)}$$

Table 45.3 lists the important quantities used to describe magnetic fields in SI units. The strength (E) of magnetic fields depends on the geometry of the circuit, the amount of current in the conductors within the circuit, and the distance from the circuit. In general, the magnetic field varies inversely with the square of the distance from the conducting elements of the circuit.

TABLE 45.3. Quantities and units important to describe the properties of electromagnetic fields.

Quantity	Symbol	Unit Name	Unit Symbol
Wavelength	λ	Meter	m
Frequency	f	Hertz	Hz
Energy	Q	Joule	J
Power	P	Watt	W
Power density	S or Pd	Watt/m^2	W/m^2
Magnetic field strength	H	Ampere/meter	A/m
Magnetic flux density	B	Tesla	T[a]
Electric field strength	E	Volt/meter	V/m
Current	I	Ampere	A
Current density	J	Ampere/m^2	A/m^2
Impedance	Z or η	Ohm	Ω
Conductivity	σ	Siemens/meter	S/m
Permittivity	ε	Farad/meter	F/m
Permeability	μ	Henry/meter	H/m
Propagation constant	K	Per meter	m^{-1}

[a] Conversion factor 1 mT = 10 gauss (G).

Electric Fields

Definition

Electric fields result from the separation of charge; these fields are much more difficult to quantify than magnetic fields because of the variability of electric fields with time. The electric field is a measure of the force a unit charge experiences at a specific point in space. Voltage measures the separation of charges, with larger voltages producing stronger electric fields. If a conductor connects two areas of separated charges, then current will flow. Because almost everything in our environment conducts charge, electric fields constantly adjust in magnitude to the movement of charge as physical objects move in the environment. Both perturbation and shielding of the electric fields contribute to the difficulty of measuring exposure to electric fields.

In general, the body attenuates external ELF electric fields by a factor of 10^5–10^7;[11] therefore, the electric field is localized primarily to the surface of the body. The strength of the electrical field at the surface of the body and the intensity of the induced current within the body depend on the following factors: 1) physical characteristics (strength, frequency, spatial direction) of the field; 2) the location of the body relative to the ground and to other conductors; 3) the shape of the body; and 4) the conduction of currents from the body to external grounds.[12] Hence, the current induced by the same electric field will be different in a human and a laboratory

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

animal.[13] Changing magnetic fields create electric fields. When these electric fields are inside a conductive object (e.g., the human body), motion-induced currents (i.e., eddy currents by displacement) develop.

Units

The unit for an electric field strength is the volts/meter (V/m), as noted in Table 45.3. similar to magnetic fields, the electric field strength (E) and the electric flux density (D) are vector qualities related to each other by Equation 45.2.

$$D = \varepsilon \times E \qquad \text{(Equation 45.2)}$$

where

ε = permittivity (property of the medium)

Equation 45.3 describes the relative permittivity (ε_r) as the ratio of the permittivity (ε) to the permittivity of a vacuum (ε_o).

$$\varepsilon_r = \varepsilon/\varepsilon_o \qquad \text{(Equation 45.3)}$$

For free air, the $\varepsilon_r = 1$; however, the value of ε_r in the tissues is substantially greater. Therefore, the body greatly attenuates electric fields in contrast to the relative uniformity of internal and external magnetic fields. The permittivity or dielectric constant of tissue varies widely; consequently, structural variations in the body and the heterogeneity of living tissue complicate the prediction of induced currents.

EXPOSURE

ELF fields occur during the generation, transmission, and consumption of electricity. All humans are exposed to a wide variety of electric and magnetic fields that result from a variety of objects in the environment, including electric current flow in domestic appliances, electric power distribution systems, and specialized medical devices. In contrast to the coupled electric and magnetic (i.e., electromagnetic) fields of radiofrequency sources, ELF sources (e.g., power lines, electric appliances) have separate electric and magnetic fields that can be evaluated as if they are independent sources. These fields vary in frequency and strength with time and space in residential settings, complicating the measurements of exposure to these fields. Exposures to ELF fields are diverse; direct measurements are necessary to accurately categorize exposure to these fields. The body attenuates electric fields. Exposure to a 1 kV/m-electric field at 60 Hz produces an internal electric field ranging from 1–100 mV/m.[14] Electric fields vary from location to location; however, these fields remain relatively constant over time because electric fields depend on voltage that usually remains relatively constant. In contrast, magnetic fields depend on current that varies widely over time *and* location from the source. Figure 45.3 demonstrates the variation in intensity of 60-Hz electric and magnetic fields as a function of the distance from the source. Because of the long wavelengths of ELF fields, electric and magnetic fields are separate and independent at any practical observation point. These power-frequency fields are always in the near-field in contrast to RF radiation, which operates in the near- and far-fields, depending on the distance from the antenna.

Figure 45.4 compares the magnetic field strength (μT) of various environmental sources of ambient exposure to 60-Hz magnetic fields. Measurement of environmental exposure typically includes electric and magnetic fields. For measurement of the magnetic field, the geometric mean (log-weighted average) is a better measure of the central tendencies than the mean or median values because these values tend to clump in the lower range with a few higher values. In a study of 24-hour personal exposures to magnetic fields in the US environment, the geometric mean was 0.09 μT with 44% of the samples >0.1 μT, ~14% >0.2 μT, ~2.5% >0.5 μT, and <1% >0.75 μT.[15]

Natural Sources

Magnetic Fields

The natural magnetic field is the combination of the internal field from the earth acting as a permanent magnet and the smaller external field composed of magnetic activity in the environment from solar and atmospheric activity. The internal field results from the variable current flow in the upper layer of the earth's core; the strength of this field varies from a nadir near the equator to a maximum at the magnetic pole. Additionally, the geomagnetic field fluctuates continuously because of diurnal, lunar, and seasonal variations manifested as short-term perturbations. The vertical component of the static magnetic field is ~67 μT at the magnetic pole, whereas the horizontal component of the static field is maximal (i.e., ~33 μT) at the magnetic equator.[10] The corresponding perpendicular vectors (i.e., horizontal vector at the magnetic pole, vertical vector at the magnetic equator) of these static magnetic fields at the point of maximal strength will be zero. The natural 60 Hz magnetic field is ~10^{-6} μT, whereas the magnetic field in homes averages up to 100 μT; the magnetic field around household appliances

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 45.3. General comparison of ground-level variation in electric and magnetic field densities (strength) as a function of distance from common sources, including transmission lines, distribution lines, and appliances, as measured by microtesla (μT, SI units) and milligauss (mG, conventional units).

ranges up to several hundred μT close to the source.[11] In comparison to natural magnetic fields, the magnetic field below 1,100 kV transmission lines is also much stronger. At 1 m above the ground, under the centerline at the midspan of the transmission lines, the levels of the magnetic fields usually range up to 35 μT.

Electric Fields

The dominant static component and the smaller time-varying component comprise the natural electric field that is directed radially as a result of the negative charge of the earth. The field strength is highest in the temperate latitudes and lowest near the poles and equator; however, the intensity of the electric field may vary up to 500 V/m with weather, altitude, season, and time of day.[17] The strength of the static electric field near the surface of the earth is ~120 V/m as a result of the separation of charges between the atmosphere and the earth's surface.[18] Alternating low-frequency electric fields result from thunderstorms and magnetic pulsations that induce currents in the earth (telluric currents).[11]

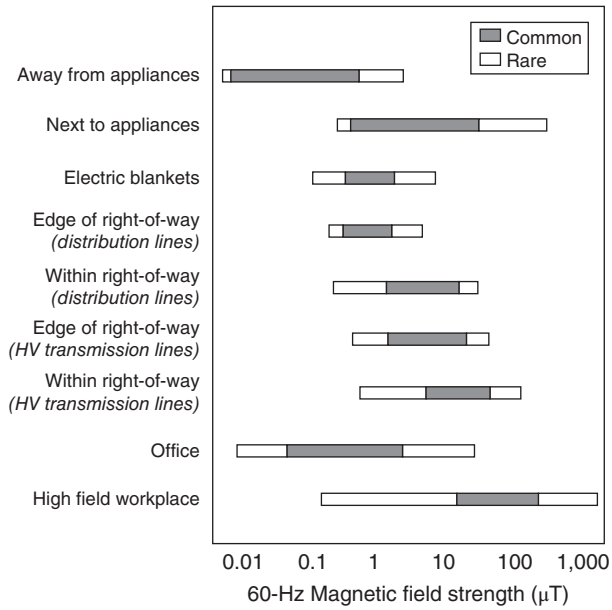

FIGURE 45.4. Approximate variability in magnetic field densities with general distances from appliances and transmission lines. (Adapted from Mader and Peralta).[16]

Residential Sources

Static and extremely low frequency (ELF) fields cover the range of the electromagnetic spectrum from 0–300 Hz, whereas low-frequency fields range from 0.3–100 kHz. The most common frequencies among ELF fields result from the transmission of electricity by sinusoidal waveforms at 50 Hz in Europe and 60 Hz in North America. Exposure to electric and magnetic fields occurs through a wide variety of human activities involving the use of electrical energy at various frequencies. At power frequencies (i.e., 50–60 Hz), electromagnetic fields from human activities are several thousand-fold greater than natural fields; the dominant sources of time-varying fields involve human activities. The major sources of magnetic and electrical fields in residential settings include multiple grounded, current-carrying plumbing and electrical circuits, appliances, and adjacent power lines (service lines, drop lines).[17] European exposure to commercial and residential magnetic fields is typically lower than exposures in North America because the higher main voltage is associated with lower currents in Europe than in North America.

Magnetic Fields

The major residential sources of ELF magnetic fields are currents flowing in conducting pipes, electrical grounds, appliances, and distribution circuits. High-voltage power lines do not typically contribute significantly to residential magnetic fields.[17] Direct measures of exposure to magnetic fields are necessary because actual measurements in residences vary over 10-fold depending on electricity consumption, wiring practices, and supply voltages. In an analysis of 27 studies reporting the intensity of residential magnetic fields in the United States and Europe measured over ≥24 hours, background field intensities followed a log-normal distribution with a US geometric mean of 0.06–0.07 μT (arithmetic mean = 0.11 μT) and a UK geometric mean of 0.036–0.039 μT (arithmetic mean = ~0.05 μT).[19]

Figure 45.5 compares the approximate ambient background level of magnetic fields in the home with sources outside the home.[20] A study of adult residents in Maine indicated the average exposure of a resident away from home was ~0.2 μT (2 mG).[21] The magnetic field at a distance of 30 cm from a home appliance ranged from ~0.03–30 μT; at 150 cm from the source, the magnetic field for the highest source was <0.5 μT.[22] In a study of 69 homemakers exposed primarily to 60-Hz fields, the time-weighted average exposure (TWA) to ELF magnetic fields was 0.113 μT with a range of 0.22–0.403 μT as measured by integrating personal magnetic-field exposure meter.[23] In a study of 301 Danish volunteers using Positron personal dosimeters with monitoring time of >7 hours, the geometric mean ± standard deviation of the magnetic field exposure in residences far from power lines was 0.04 ± 2.1 μT; the corresponding value for residences near high-power lines with a mean distance of 23 m and a range of 0–68 m was 0.29 ± 2.8 μT (maximum, 2.24 μT).[24]

Exposure to magnetic fields from appliances depends on the duration of use, the distance from the appliance, and the magnetic field strength. The magnetic flux density decreases rapidly with distance, varying inversely with the square of the cube of the distance from the appliance, beginning at a distance several times greater than the diameter of the appliance.[25] At 1 m, the value of the field approximates the background flux density. Consequently, the total chronic whole-body exposure is an order of a magnitude (i.e., ~0.02 μT) below other residential sources.[16] The domestic appliances producing the highest magnetic field contain heaters, transformers, and motors. Table 45.4 lists the magnetic flux density at 50 Hz near common UK household appliances; the magnetic field strength varied widely within groups of different appliances.[26] During the use of electric blankets, magnetic flux densities vary by an order of magnitude between the side of the body closest to and the side farthest from the electric blanket. In a study of individuals

using electric blankets, the mean whole-body flux density was 2.2 μT with a range of 1.5–3.3 μT during use.[27]

Electric Fields

Exposures to ELF electric fields in the home result from distribution lines, electrical wiring in the building, electric heat (e.g., heated waterbeds, electric blankets), electric hot water heaters, and electrical appliances (e.g., kitchen devices, hair dryers). The electric field in the center of a typical American home ranges from ~1–20 V/m, whereas electric fields 30 cm from some appliances average ~10 V/m, with values up to several hundred V/m near domestic appliances (e.g., electric boiler) or cables.[28]

Figure 45.6 compares the average background levels of electrical fields in the home with those from sources outside the home. The shielding of external electric fields significantly limits the contribution of transmission and distribution lines to the magnitude of the electrical field within the home; however, these power lines do contribute substantially to the overall magnetic field.[29]

Transmission Sources

The most prevalent ELF fields in the environment result from the transmission of electricity through power lines. High-voltage lines frequently consist of three lines with differing time phases; consequently, the voltages and the currents reach peak values at different times. Power lines operate at voltages ranging from residential wires (120 V in the United States, 220–240 V in Europe) to high-voltage power lines (765 kV).[30] The vector of the surrounding ELF fields is the sum of the fields produced by each line; the vector moves in an ellipse rather than a sinusoidal pattern for an individual line. The magnetic fields around power lines themselves produce an electric field strength inside the body; however, the induced electric field is ~15% of the strength of the electric field produced by the power lines.[31] Under power lines, the orientation of the electrical field is perpendicular (i.e., vertical) to the surface of the earth, whereas the orientation of the magnetic field is parallel (i.e., horizontal) to the surface of the earth. Although high-voltage power lines in different countries follow similar principles, differences in power-line design produce differences in the fields surrounding power lines in different countries.

Magnetic Fields

Magnetic fields always appear when current flows through conductors (e.g., transmission lines). Besides the geometry of the conductor, the magnitude of the current determines the strength of the magnetic field

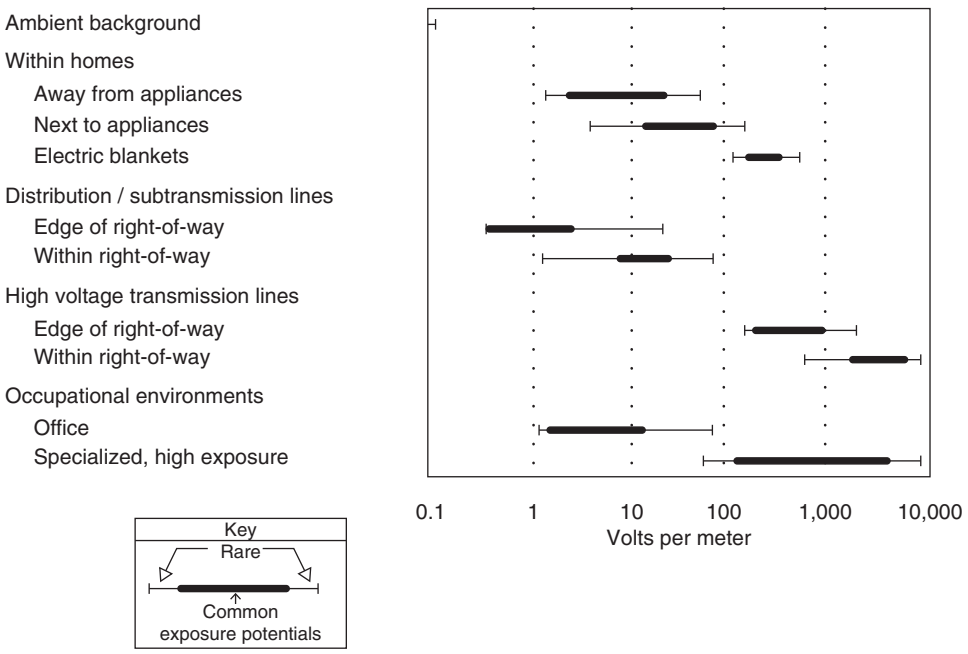

FIGURE 45.6. Approximate range of 60-Hz electric field strengths in the home, adjacent environment, and workplace in units of V/m. The solid portion of the range connotes common occurrences of the magnetic field strength in V/m, whereas the thin line connotes rare occurrences at that specific value. (Adapted from Savitz et al.).[20]

surrounding the transmission lines. The day-to-day variation in the magnetic fields surrounding power lines is usually small; however, magnetic fields under 500 kV transmission lines can double during the ~1% of the time peak loads occur.[32,33] The strength of the magnetic field decreases with the lateral distance from the conductor. The maximum ground-level strength of the magnetic field under transmission lines ranges from ~10–50 μT, depending on the height of the power lines and the distance from the centerline. Typical magnetic flux densities directly beneath overhead power lines range up to ~10 μT for 380 kV lines and 30 μT for the less common 765 kV lines; the former value decreases to <3 μT 20 m from the centerline of the transmission wires.[34] Figure 45.7 demonstrates the values of the magnetic field for lateral distances from high-voltage transmission lines. Magnetic field strengths usually return to background values within 50–300 m from the high-voltage power lines, depending on design, current, and background factors.[17] Although this type of field can induce currents in the body, the magnitude is sufficiently small (<25%) compared with the strength of the electric field; consequently, the electric field around transmission lines is the usual exposure parameter for evaluation of health effects. Distribution lines typically run directly to residential and commercial facilities with average magnetic fields ranging from 1–2 μT for overhead and underground lines; typical maximum values for overhead and underground distribution lines are 7 μT and 4 μT, respectively.[32]

Electric Fields

The unperturbed electric field at the point of maximum field strength near the outer conductor of a high-voltage (750 kV) transmission line is ~10 kV/m. Figure 45.8 demonstrates the approximate values of the electric field near high-voltage lines. The strength of the electric field surrounding transmission lines and substations depends on a number of factors that shield the body from the electric field including trees, buildings, and other electrically grounded objects. Outdoor substations do not usually increase residential exposure to electric or magnetic fields.[35] Electric fields in buildings usually result from internal wiring and appliances rather than power lines.[35]

Electromagnetic Pulse

An electromagnetic pulse (EMP) occurs following the detonation of thermonuclear weapons above the surface of the earth. The atmosphere converts only a small portion of the energy released into the atmosphere to EMP because of the production of Compton recoil electrons. The two types of EMP are the relatively slow magnetohydrodynamic EMP that lasts ~0.01 second and the fast, high-amplitude pulse called tachy-EMP.[36] The latter type of EMP can generate currents in the kiloampere range.[37] Mechanical damage results from the induction of currents at frequencies below 100 MHz in communication equipment, computers, power lines, cables, and rails.

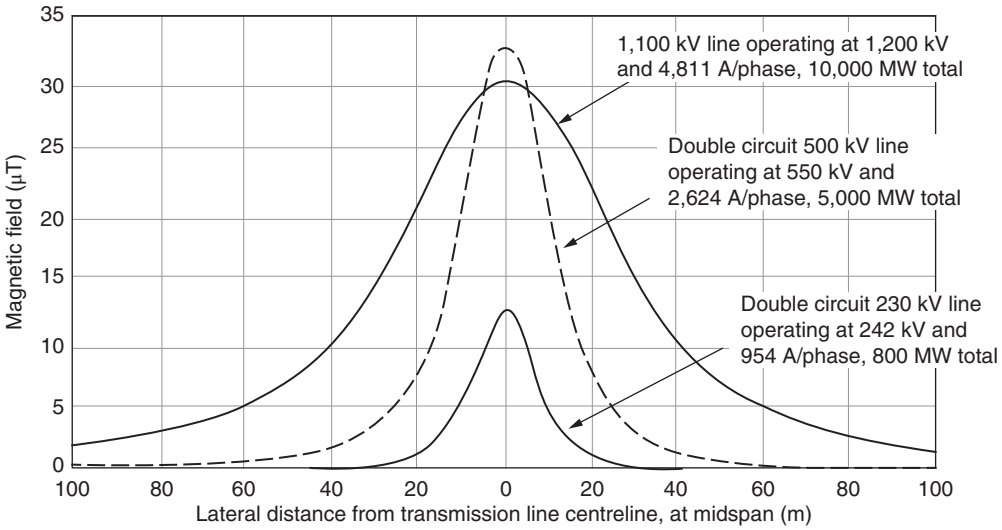

FIGURE 45.7. Calculated 60-Hz magnetic field strengths at 1 m above ground for 230 and 500 kV double circuit power lines with estimated approximate magnetic field strengths for 1,100 kV line. (Adapted from International Programme on Chemical Safety).[10]

Occupational Sources

Magnetic Fields

Exposure to magnetic fields in the occupational setting results primarily from working near industrial equipment operating with high current loads (e.g., overhead power lines, underground cables, power stations), particularly busbars close to power station generators. Magnetic field exposures may vary substantially within the same job category as a result of differences in activities and tasks. Because high-current sources are more prevalent in industry than high-voltage sources, exposures to magnetic fields are more common than exposures to electric fields in the workplace. Examples of jobs with potential chronic exposure to high-strength magnetic fields include work near utility operations (linesmen, electricians, substation operators, generation facility workers), induction furnaces, electrical transportation systems, electrical distribution vaults, cranes and hoists, railroad engines, welding machines, and small motors. In a study of 1,098 Swedish workers from a broad range of jobs, direct measurement of ELF magnetic fields with personal dosimeters calibrated at 50 Hz demonstrated a skewed curve for the workday average. The workday arithmetic mean and median were 0.28 μT and 0.14 μT, respectively.[38] The upper 95th percentile of the workday exposure was 0.66 μT, with a maximum reading of 18 μT. The study suggests occupations with potentially high exposures to magnetic fields include welders, electrical technicians/engineers, electronics engineers/technicians, train engine drivers, and glass, ceramic, and brick workers. The geometric mean of the time-weighted average exposure of six women working in industrial settings was 0.265 μT with a range of 0.054–3.436 μT as measured by an integrating personal magnetic-field exposure meter.[23] In a Canadian study of ELF magnetic fields in jobs commonly held by women, jobs estimated to exceed a weekly time-weighted-average magnetic field exposure of 0.23 μT included bakery workers, cashiers, cooks, and kitchen workers, with the highest estimated exposures in electronics workers in an assembly plant (0.70 μT) and sewing machine operators in textile factories (0.68 μT) and shoe factories (0.66 μT).[39]

Table 45.5 lists the magnetic flux densities of common industrial sources for high magnetic field exposures. The average magnetic flux density near facilities with large electrical equipment (substations, overhead power lines, power stations) is ~50 μT.[10] Magnetic flux densities in the range of 200–400 μT occur only in specialized, high-voltage occupational environments (e.g., certain types of arc welders).[40] Older video display terminals produce power frequency and higher ELF electromagnetic fields ranging from 15–35 kHz. In a study of VDT operators, the median magnetic field strength in the ELF range was 0.21 μT and 0.03 μT for the 15–35 kHz range, whereas the median electric field strength for these ranges was 20 V/m and 1.5 V/m, respectively.[41]

TABLE 45.5. Occupational sources of high exposures to magnetic fields. (Adapted from International Programme on Chemical Safety).[10]

Source	Magnetic Flux Density (μT)	Distance From Source (cm)
Welding arcs (0–50 Hz)	100–5,800	0–80
50-Hz electroslag welding	500–1,700	20–90
Induction heaters (10–50 Hz)	900–65,000	10–100
50-Hz ladle furnace	200–8,000	50–100
50-Hz furnace	<1,000	200
10-Hz induction stirrer	200–300	200
Electrolyte process (0–Hz)	7,600 (mean)	Operator position
Isotope separation (static field)	1,000–50,000	Operator position
Video display terminal	<0.28	30

Electric Fields

Except for occupations where high-voltage sources are present, electric field exposures in most occupations are similar to those in residential settings. Occupations with high exposure to electric fields typically involve the utility industry (e.g., utility electricians, linesmen, substation operators). In a UK study of 50 Hz electric fields surrounding substations and below power transmission lines, the intensity of the electric fields ranged up to 22 kV/m and 11 kV/m, respectively.[42] Some objects (e.g., long unearthed metal fences, large vehicles) can develop substantial potential differences in large electrical fields. The human body can become the pathway for current between such objects. Steady-state short-circuit current of up to 1 mA can flow into the body from these fields, depending on the height of the person, the strength of the electric field, and the frequency. In a 10-kV/m, 60-Hz electric field, a 1.7-m-tall person carries a short circuit of ~0.16 mA.[11] A jeep wagon in a 10 kV/m field conducts 1.1 mA of current to the earth. Electric field strengths near arc welders are usually ~1 V/m and rarely exceed 50 V/m.[40]

DOSE EFFECT

Although the nonionizing radiation dose is usually measured in units of energy and the dose rate in units of power, the dose of extremely low frequency radiation has no universally accepted definition. The lack of a definition results, in part, from a scarcity of information regarding the mechanism of biological action of ELF fields. The bodies of humans and animals significantly alter the spatial distribution of low-frequency electric fields (1 Hz–100 kHz). The induced internal electric field is considerably smaller than the external electric field (e.g., five to six orders of magnitude at 60 Hz) and strongest when the feet are electrically grounded. Tissue conductivity determines the distribution of induced current within the body, whereas body shape, posture, and size determine the total current flowing in the grounded body. Extrapolation of animal data to humans is limited because electromagnetic fields vary with the size, shape, and orientation of the body. Therefore, no single animal model simulates exposure to humans.

In contrast to electric fields, human and animal bodies do not perturb magnetic fields. Tissue and air permeability in humans and animals are similar, resulting in similar internal and external magnetic fields. The application of magnetic fields to the body induces internal electric fields and currents depending on the magnetic field strength, orientation, and body size, whereas the distribution of the induced electric fields depends on tissue conductivity. The magnitude of induced current densities from ambient static magnetic, time-varying magnetic, and electric fields is at least several orders of magnitude below the endogenous currents produced by normal physiological processes. A 60-Hz magnetic field with an intensity of 0.1 μT induces a current density of 0.19 μA/m^2, whereas an electric field of 10 kV/m produces a maximum current density of ~2 μA/m^2.[13] Although many animals detect electric fields at 1–5 kV/m, there are no data demonstrating that these levels produce adverse effects. *In vitro* studies demonstrate equivocal effects at levels >1,000 times higher than the levels present in residential homes.

Magnetic Fields

Static magnetic fields up to 2 T have not been associated with significant adverse health effects in humans.[10] In an experimental study of 25 volunteers exposed to static magnetic fields up to 8 T, an average increase of 3.6 mmHg in systolic blood pressure occurred in the highest exposure group.[43,44] Otherwise, no significant changes occurred in cognitive function, heart rate, respiratory rate, diastolic blood pressures, electrocardiogram, rhythm strip, finger pulse oxygenation levels, or core body temperature as measured by the external auditory canal temperature. Static magnetic fields may produce dizziness and vertigo during motion in the field, depending partly on individual sensitivity. Mild-to-moderate dizziness developed in 8 of 10 subjects exposed to a magnetic field change (dB/dt) of 4.7 T in 1.9 seconds, whereas no subjects reported any response during exposure to 50 msec pulses of 2 T/second in amplitude.[45]

Time-varying magnetic fields and rotational motion in a uniform static field induce the flow of currents in the body, whereas linear motion within a uniform static field does not induce current. Health effects associated with these induced currents are difficult to predict within an order of magnitude; however, the induction of currents of 10 mA/m^2 has not been associated with clinically significant biological effects. In the range of 10–100 mA/m^2, short-term exposure produces minor biological changes. The human body can sense a magnetic field by detecting the presence of magnetophosphene (i.e., the sensation of flickering light that occurs following exposure to magnetic fields with an intensity >10 mT and frequencies >10 Hz). At induced current densities of >100 mA/m^2 (>50–500 mT at 50/60 Hz or 1–10 T at 3 Hz), stimulation of excitable

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

tissue and the development of adverse health effects are possible.

Electric Fields

Because the body attenuates electric fields, predicting health effects from the strength or density of electromagnetic fields is much more difficult for electric than magnetic fields. Similar to magnetic fields, no single animal model adequately simulates human exposure to electric fields. Sensitivity to electric fields results from the sensation of tingling in the hair at field strengths of >10 kV/m. Workers in contact with electric fields may experience contact currents or spark discharges (microshocks). A study of the detection threshold for electric fields indicated the threshold for hairless skin on the palm was >115 kV/m, whereas the value for hairy skin on the dorsum of the hand was 30–65 kV/m.[46] The detection threshold was much lower in the fall than in the summer, when lower humidity reduced the relative permittivity of the skin.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Static Magnetic Fields

The major biological properties of static magnetic fields include 1) induction of electric currents from motions within an inhomogeneous field (motion-induced currents or eddy currents by displacement); 2) Lorentz force; 3) magnetic force; 4) magnetic torque; and 5) radical pair effect.[47] Lorentz forces operate perpendicular to the direction of the electric charge flow. The magnetically-induced potential could impede blood flow; however, static magnetic fields up to 9.4 T did not significantly affect cardiovascular function.[48] Magnetic force in a spatially inhomogeneous magnetic field moves susceptible material in the direction of the steepest field gradient (missile or projectile effect), whereas magnetic torque orients certain diamagnetic materials (e.g., fibrin, collagen) and some cells (osteoblasts, Schwann cells). *In vitro* studies suggest static magnetic fields alter the shape and orientation of osteoblasts.[49] Although strong static magnetic fields did not enhance cell proliferation, cell differentiation and matrix synthesis were upregulated. Magnetic fields cause effects by the induction of internal currents.

Some organisms use the static magnetic field of the earth for orientation and/or direction (e.g., sharks, rays, migratory birds, the waggle dance of bees, the kinetic movements of mollusks, magnetotactic bacteria).[10] *In vitro* studies on the biological effects of electromagnetic fields indicate these fields can increase the permeability of the cell membrane to calcium[50] and alter the concentrations of some enzymes (e.g., adenosine triphosphate, ornithine carboxylase).[51]

ELF Electric and Magnetic Fields

No *single* theory provides a biological basis for health effects of ELF electromagnetic fields, particularly at the low field strengths in this part of the electromagnetic spectrum. Potential mechanisms for health effects include induced electric fields in neural networks, altered reactive free radical concentrations, and the effect of these electromagnetic fields on ferromagnetic material (i.e., magnetite) within the body. ELF electric and magnetic fields couple poorly within the body; in contrast to radiofrequency and microwave exposures, the body absorbs little energy from the ELF portion of the light spectrum at ELF levels present in the environment. Therefore, the effects of ELF do not result from the heating of tissue. The cell membrane is a likely site for the biological effects of ELF fields. The dielectric constants of the cell membrane are sufficiently high that induced currents occur almost exclusively on the cell surface; consequently, the cytoplasm is shielded from the effects of the ELF field. A major difficulty in the development of a unifying theory is understanding how cells can detect weak electromagnetic fields that deposit relatively small amounts of energy compared with the much larger levels of random thermal energy in the body.

Although most physiological indices are unaffected by exposure to ELF fields, subtle biological effects may occur after short-term exposure to these fields. These physiological changes do not apparently cause serious or permanent adverse reactions. Exposure of humans to ELF electric fields may stimulate sensory receptors by hair vibration or the induction of current in the body, resulting in transient sensory effects (e.g., nausea, vertigo, magnetophosphenes).[52] The exact mechanism responsible for magnetophosphenes is unclear; however, the mechanism of action probably does not involve ELF-induced heating or deposition of energy in tissue.

There is no **direct** evidence from animal experiments linking exposure to electric and magnetic fields in the 50–60 Hz range with cancer.[32,53] Extremely low frequency fields do not break chemical bonds or ionize tissue as higher energy sources (e.g., γ-rays, X-rays) do. Electric and magnetic fields at the frequency and intensity encountered in residential and occupational settings do not typically produce chromosome breakage,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

elevated rates of sister chromatid exchanges, or disruption of DNA repair processes. Most, but not all, *in vitro* studies of the genotoxic potential of extremely low frequency electric and magnetic fields do not demonstrate increased genetic damage as assessed from DNA strand breaks, incidence of chromosomal aberrations, micronuclei, and sister chromatid exchanges, when compared with control cells.[54,55] In two eukaryotic cell systems (human blood lymphocytes, DBY747 *Saccharomyces cerevisiae*), extremely low frequency electric and magnetic fields did not induce DNA damage or affect gene expression.[56] The energy imparted by man-made electromagnetic fields is small compared with currents produced by normal neuromuscular events in the body. Because magnetic fields have not induced mutations, the hypothesized mechanism of induction of cancer is the promotion or enhancement of growth via cell membrane-associated receptors rather than initiation.[57]

Promotion at the later stages of carcinogenesis is a possible stage of cancer at which electromagnetic fields would operate; however, animal studies have not consistently demonstrated such an effect.[58]

CLINICAL RESPONSE

Environmental Exposure

Although exposure to ELF electric and magnetic fields may produce some biological effects in animals, there is no consensus that these changes are hazardous, except for the production of internal currents above the threshold for stimulation of nerve tissue.[59] The Committee on the Possible Effects of Electromagnetic Fields on Biological Systems of the US National Research Council reviewed the evidence for adverse effects from electromagnetic fields.[60] They concluded that the current body of evidence did not support an association between exposure to power-frequency electric and magnetic fields and adverse health effects (neurobehavioral, reproductive, developmental).

Electromagnetic Hypersensitivity

Some practitioners involved with idiopathic environmental intolerance attribute a constellation of nonspecific symptoms (i.e., electromagnetic hypersensitivity) to exposure to electromagnetic fields involving ELF fields (e.g., power lines, electric appliances) as well as radio frequency waves. This syndrome is not well defined and has no clear diagnostic criteria. A review of 29 studies published in the medical literature on electromagnetic hypersensitivity demonstrated no consistent pattern of objective changes in subjects with the diagnosis of electromagnetic hypersensitivity exposed to electromagnetic fields and sham controls.[61] A systematic review of 22 studies on the severity and frequency of nonspecific physical symptoms and electromagnetic field exposure detected no consistent or dose-related association between electromagnetic exposure and the occurrence of these symptoms in the general population.[62] Most studies suggested either no significant effect from higher electromagnetic exposure (fatigue-related problems OR = 1.15, 95% CI: 0.59–2.27) or negative results (headache frequency OR = 1.01, 95% CI: 0.66–1.53).

Mood and Neuropsychological Function

Most studies have not demonstrated differences in psychiatric diseases or neuropsychiatric testing between residents exposed to electromagnetic fields and controls; additionally, most experimental studies of human subjects have not detected significant changes in mood or neuropsychological function following exposure to environmental levels of electromagnetic fields. A study of 72 volunteers exposed to an average vertical electric field of 36 kV/m for 5.5 hours did not demonstrate significant changes in mood or verbal reasoning skills.[63] A case-control study of depression and personality abnormalities in residents of high-rise buildings raised concern about the possible association of suicide with exposure to electromagnetic fields from overhead high-voltage transmission lines.[64] A follow-up study indicated the suicide cases were exposed to more intense magnetic fields; however, the difference between the mean exposure of cases and controls (0.087 μT vs. 0.071 μT) was small.[65] A mortality study of 8,000 persons living within 30 m of electric transmission facilities did not support an association between suicide and exposure to electromagnetic fields.[66] Overall, the weight of the evidence does not support a causal association between electric or magnetic fields and the development of neurophysiological or psychological changes in residents near power lines.[67]

Occupational Exposure

Mood and Neuropsychological Function

Several uncontrolled studies of Russian workers in industries with high exposure to electromagnetic fields suggest these workers had an increased incidence of neurasthenic and depressive symptoms. In the 1960s, several surveys of Russian workers exposed to electric fields with intensities up to 26 kV/m demonstrated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

an excess of complaints related to the CNS and the autonomic system (e.g., dizziness, nausea, sleep disturbances, decreased libido, anorexia, headache, irritability, fatigue).[68] The lack of reference groups for comparison in these studies represents a severe limitation in the establishment of causal relationships between these neuropsychological symptoms and exposure to electric fields. Comparable, controlled studies of European and North American workers have not detected the excess of symptoms displayed in the Russian studies. A study of men with occupations associated with high exposure to electromagnetic fields did not support an association between suicide and exposure to electromagnetic fields.[69] A mortality study of 31,068 US members of the International Brotherhood of Electrical Workers suggested a small, but statistically significant increase in suicide rates of the cohort compared with the NIOSH life table (proportional mortality ratio = 115, 95% CI: 104–124, $n = 505$ cases, $P < 0.05$).[70]

A survey of 390 electrical power transmission and distribution workers found no significant correlation between exposure to electric fields and an excess of neurological symptoms.[71] Measurement of the electrical fields surrounding 28 of these workers over a period of 2 weeks indicated that these workers were exposed to electrical fields averaging 30 kV/m. A cross-sectional study of 53 workers with over 5 years of exposure to electric fields from 400 kV substations did not find any statistically significant decrements in neurasthenic symptoms, psychological tests, or EEG.[72] A study of workers exposed to a mean electric field strength of 2.8 ± 0.35 kV/m and a mean magnetic field intensity of 23.3 ± 4.2 μT did not demonstrate any acute abnormalities on neuropsychological testing (simple reaction time, color word vigilance, perceptual test – symbol digit, memory test – digit span).[73] The measurements also included an EEG, a mood scale, and a questionnaire on subjective symptoms. A study of physicists and technicians exposed to peak field strengths of 2 T with average yearly levels equivalent to 0.5 T for 3 days did not reveal any adverse sequelae.[74]

Neurological Disease

There is no clear association between occupational exposure to electromagnetic fields and the development of early dementia or amyotrophic lateral sclerosis (ALS).[75] A cohort study of Danish utility workers suggested an association between EMF exposure-based job exposure matrix and death from amyotrophic lateral sclerosis but not from dementia or multiple sclerosis.[76] This study used the Danish National Mortality Register. A retrospective case-control study of three clinical series of patients with Alzheimer's disease suggested a link between Alzheimer's disease and occupations with "probable medium to high exposure" to electromagnetic fields.[77] The analysis of electromagnetic exposure was retrospective, and the exposure analysis was based on occupation rather than direct measurement. Subsequent cohort study of electric utility workers[78] and case-control study of former electrical workers[79] did not support the association between electromagnetic exposure and Alzheimer's disease.

A large US death certificate based, case-control, hypothesis-generating study suggested an association between motor neuron disease and 60 Hz magnetic field exposure in cases younger than 65 years, but not among cases 65 years of age or older. The odds ratio for mortality from motor neuron disease was 1.63 (95% CI: 1.10–2.39) based on a job exposure matrix.[80] In a population-based US cohort study (National Longitudinal Mortality Study), there was no association between mortality from motor neuron disease including ALS and exposure to magnetic fields as measured by a population-based job-exposure matrix.[81] There was no dose-related effect; the adjusted hazard ratio (i.e., age, sex, education) for the highest exposure group (>0.2664 T) was 0.98 (95% CI: 0.39–2.50) compared with the control group (<0.155 T).

A meta-analysis of 42 peer-reviewed publications reporting occupational electric and magnetic field exposure and neurodegenerative diseases (Alzheimer disease, motor neuron diseases) did not support a causal association.[82] Although there was a modest increase in risk estimates for both diseases, misclassification of the diseases and imprecise exposure of data contributed to substantial heterogeneity and lack of a definite causal connection.

Cardiovascular Disease

Experimental studies of human subjects have not detected consistent adverse cardiovascular effects following exposure to electromagnetic fields. A cross-sectional study of 53 workers with over 5-year exposure to electric fields from 400 kV substations did not find any significant cardiovascular effects (symptoms, blood pressure, ECG).[72] A mortality study of cardiovascular disease in a cohort of 138,903 male electric utility workers from 5 US companies over the period of 1950–1988 suggested a possible association between occupational magnetic fields and arrhythmia-related heart disease.[83] Employment in exposed occupations (plant operators, linesmen, electricians) for ≥20 years was associated with a statistically nonsignificant elevation of deaths from arrhythmia-related conditions

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(RR = 1.47, 95% CI: 0.96–2.24, $n = 60$ deaths). The rate ratio for deaths from acute myocardial infarction in this group was significantly increased (RR = 1.41, 95% CI: 1.28–1.55, $n = 1{,}073$ deaths). The rate ratios were also elevated for the highest cumulative career magnetic field exposure (≥4.3 μT-years) for arrhythmia-related deaths (RR = 2.4, 95% CI: 1.48–3.89, $n = 34$ deaths) and acute myocardial infarction (RR = 1.62, 95% CI: 1.45–1.82, $n = 510$ deaths). Overall, the standardized mortality rate for these workers was below the US population for ischemic heart disease (SMR = 0.77) and heart disease (SMR = 0.74). Later studies have not confirmed this association. The Netherlands (prospective) Cohort Study of 120,852 workers aged 55–69 at baseline and followed for 10 years did not detect an association between high exposure to ELF based on a job-exposure matrix and total cardiovascular mortality (hazard ratio = 1.02; 95% CI: 0.99–1.06).[84] Additionally, there was no significant elevation of any other cause-specific subtype of cardiovascular mortality including arrhythmia-related deaths.

Carcinogenesis

The IARC lists extremely low frequency magnetic fields as possibly carcinogenic to humans (Group 2B) based on limited evidence in humans for the carcinogenicity of extremely low frequency magnetic fields in relation to childhood leukemia and inadequate evidence in experimental animals.[17] The evidence for the carcinogenicity of ELF magnetic fields as a cause of all other cancers was inadequate. Additionally, the evidence for the carcinogenicity of ELF electric fields, static electric fields, and static magnetic fields was inadequate. Although current evidence does not exclude the possibility of an association between exposure to ELF magnetic fields and an increased risk of cancer (i.e., childhood leukemia), there is no convincing evidence that industrial or environmental exposure to ELF fields in the range of 50 Hz initiates or promotes cancer.[76]

Concern over the health consequences of the possibility of an association between electromagnetic fields and cancer results primarily from the ubiquity of the exposure rather than the magnitude of risk of inducing cancer. Establishing a causal link between electromagnetic fields and the development of cancer is limited by two important elements of causation: 1) the lack of a plausible biological hypothesis confirmed in animal studies; and 2) the scarcity of data that associates direct measurements of ELF electric and magnetic fields with an increased incidence of cancer.[85] Although some epidemiological evidence suggests an association between ELF radiation and childhood leukemia, expert reviews by world health organizations did not find consistent and strong laboratory or mechanistic evidence to support the association.[17,30] Consequently, the relationship between measured electromagnetic fields and the development of cancer remains unproven, based on the lack of supporting animal data, the absence of a dose-response effect, and inconsistent measures of exposure to electric and magnetic fields.

Childhood Cancers

Early studies on children exposed to electric and magnetic fields living in proximity to ELF sources (e.g., transmission and distribution lines, electrical substations, electrical appliances) suggested an ~50% excess risk of childhood leukemia using wire-code classifications as surrogates of electromagnetic field exposure; however, these measures correlate poorly with spot measurements of residential 60 Hz magnetic fields and the small relative risk (i.e., <1.5–2.0) suggests other factors associated with wire-code classifications may be responsible for the elevated risk. In two pooled analyses of the risk for childhood leukemia published before 2000, the OR for exposures of ≥0.4 μT was <2.[86,87] A case-control study of children that used codes for residential wiring as an indirect gauge of exposure to electromagnetic fields detected a 2–3-fold increase in the incidence of childhood leukemia and childhood brain tumors.[88] However, random measurements of the actual electromagnetic fields in these homes did not demonstrate a statistically significant difference in the homes divided on the basis of wiring codes. Interpretation of these studies is complicated by study design issues including recall and selection bias, lack of control of exposure confounding variables, and random misclassification of exposure, obscuring weak associations.

More recent studies have less consistently demonstrated elevated leukemia risks with some positive and negative results.[89] The elevated odds ratio (OR) for leukemia in exposed children was often statistically nonsignificant with wide confidence intervals; however, increasing estimated magnetic field strengths (e.g., >0.4 μT) tended to increase the odds ratio. A systematic review of published studies on the influence of exposure to ELF fields and childhood leukemia concluded that these studies did not confirm or exclude an association between the two.[90]

Exposure Surrogates

No technique exists for the direct measurement of electromagnetic fields within the human body; consequently, these fields are estimated using numerical

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 45.6. Types of exposure measurements used in studies on ELF fields.

Measure of Exposure	Technique
Wire code	Distance to major electrical energy delivery devices (high-tension power lines, transformers)
Calculated magnetic fields	Theoretical calculation of magnetic field based on historical electrical loads on surrounding power lines
Spot measurements	Instantaneous measurement of magnetic field in a specific location in residence
Average measured fields	Repeated spot measurements averaged over 24 hours
Personal average measured fields	Repeated personal measurements averaged over 48 hours

simulations. High-voltage power lines produce electric fields, whereas appliances and electric motors produce magnetic fields as a result of current flow. Because almost all electrically conductive material distorts electric fields, residential exposure to ELF sources usually involves magnetic rather than electric fields.[20] Table 45.6 lists the types of measurements used to quantitate ELF exposure for epidemiological studies on the association of ELF with childhood cancer. Each type of measurement has specific limitations.[91] Measurements using wire codes and calculated fields remain fairly consistent over the period that cancer would develop; however, calculated fields do not include all sources of exposure (e.g., home appliances, ground currents), and the reliability of wire codes as a quantitative measure of magnetic fields is variable.[92,93]

Leukemia

Childhood leukemia accounts for ~1/3 of all childhood cancers with an annual incidence of ~4–5/100,000 children. The etiology of childhood leukemia is probably multifactorial with most risk factors unknown. A majority of these leukemias are acute lymphoblastic leukemia (ALL) with the rest being primarily acute myelogenous leukemia (AML). During the 1970s–1990s, when much of the data on ELF and childhood cancers were collected, the incidence of childhood leukemia was increasing by ~0.6%/year.[94] A substantial number of epidemiological studies on ELF fields and childhood leukemia have odds ratios of <1.5–2 when comparing exposures of >0.3–0.4 μT with the lowest exposure categories (<0.1 μT);[95,96] however, many of these comparisons are not statistically significant, and the issue remains regarding causation for the relatively weak association.[97] In 1979, Wertheimer and Leeper published the first case-control study of children, demonstrating a 2–3-fold increase in mortality from leukemia in children from homes with electrical wiring configurations suggestive of high-current flow.[98] This seminal study used wiring codes as a surrogate for exposure to magnetic fields based on a nonblinded visual inspection of the power lines to assess the power load and the distance of the power lines from the homes. This design flaw allows potential exposure bias to complicate the interpretation of the results. Other epidemiological studies that used wiring codes as surrogate measures of ELF demonstrated inconsistent findings with both positive[88,99] and negative[100,101] associations with childhood leukemia. The positive studies demonstrated elevated odds ratios of 1.8 for exposures >0.6 μT, but elevation of odds ratios for individual cancers has been inconsistent and lacking in a dose-response effect.[102]

Reanalysis of data from an earlier case-control study[88] using modifications of the Wertheimer–Leeper wire codes generated an elevated odds ratio for childhood leukemia (OR = 2.9, 95% CI: 1.5–5.5) and childhood brain cancer (OR = 2.5, 95% CI: 1.1–5.5).[103] Identifying and controlling potential confounders in these studies is difficult because there are few known causes of childhood leukemia and acute lymphocytic leukemia. All these studies contain potential design flaws that include selection bias (controls),[98] confounding, and the use of different types of leukemia as endpoints. In these studies, the risk of cancer mortality was more strongly correlated with wiring codes than with direct measurements of the magnetic fields;[104] the individual exposure to magnetic fields varies over a greater range than the wiring codes do.[105]

Several Nordic studies[106,107,108] and a British study[109] assessing exposure using calculated fields provided marginal support for some increased risk of childhood leukemia following exposure to ELF. Feychting et al. demonstrated statistically significant increased risk of childhood leukemia in children born to fathers with occupational exposure to ELF magnetic fields of ≥0.3 μT (RR = 2.0; 95% CI: 1.1–3.0).[110] Maternal occupational exposure to ELF magnetic fields was not associated with childhood cancers in offspring. Overall, the number of cases in these studies was small with limited data in the higher ranges of exposure.

Early studies of ELF fields and childhood cancer typically used indirect measures of ELF exposure (i.e., wire code method using distance from normal-to-high-voltage overhead power lines), adjusting for the location of the lines and wire size. Beginning in 2001, these studies used more direct measures to estimate ELF field exposures, including spot measurements in bedrooms to determine mean exposure values while

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

accounting for the distance from high-voltage power lines. Studies using spot measurements of ELF generally have not demonstrated more consistent results on the risk of leukemia in children exposed to ELF magnetic fields than indirect measures.[111] The UK Childhood Cancer Study used a case-control design to compare the cancer rates of children in England with estimates of exposure to power-frequency electromagnetic fields based on historical and spot measurements.[112] The study provided no evidence that exposure to magnetic fields increased the risks for childhood leukemia; the adjusted odds ratio of acute lymphoblastic leukemia in children with mean ELF field exposure to >0.2 μT compared with children exposed to <0.1 μT was 0.92 (95% CI: 0.47–1.79) and 0.90 (95% CI: 0.49–1.63) for all leukemias. In a German case-control study of 514 cases of acute childhood leukemia using spot and 24-hour room measurements, the odds ratio (OR) of leukemia in children with ELF exposure of ≥0.4 μT compared with controls (≤0.1 μT) was 5.81 (95% CI: 0.78–43.2); the OR for ELF exposures below 0.4 μT were smaller and not statistically significant.[113] In a Japanese case-control study of 312 children (0–15 years) with ALL and 634 controls (<0.1 μT) using spot and 7-day TWA measurements of ELF exposure, the OR for children exposed to ≥0.4 μT was 4.67 (95% CI: 1.15–19.0).[114] The OR for exposures to <0.4 μT was not statistically significant.

Other Cancers

Besides childhood leukemia, the most common cancers associated with positive, but not necessarily statistically significant elevations of odds ratios for magnetic field exposure, include lymphomas, soft tissue sarcomas, and brain tumors. Current epidemiological data do not support a causal association between these tumors and childhood exposure to ELF.[115,116] Several early studies suggested an association between ELF and brain cancer in children,[88,98] but later studies using wire codes,[117,118] calculated fields,[107,119] and measured fields[117] did not support the positive observations in the earlier studies. The UK Childhood Cancer Study did not detect a significant association between ELF field exposure and childhood cancers. Comparing children with mean ELF field exposure of >0.2 μT with children exposed to <0.1 μT, the relative risk of all malignant diseases combined was 0.87 (95% CI: 0.56–1.35) and 0.46 (95% CI: 0.11–1.86) for central nervous system tumors. Postnatal exposure to electric blankets has been associated with a small increase in the incidence of childhood cancer (OR = 1.5) and in particular with acute lymphocytic leukemia, but the confidence limits in this study were wide and the odds ratios were not statistically significant.[120]

Adult Residential Exposure

Studies of adult cancers and exposure to electromagnetic fields have not demonstrated effects as consistent or as strong as studies of childhood leukemia with most studies being negative.[89,121] Although most of these studies focused on the association between exposure to magnetic fields from overhead power lines and electric substations with leukemia, only one study detected a significant association in the range of a ~2-fold increase in the risk of developing leukemia.[122] Other case-control studies of exposure to magnetic fields from electricity substations[66,123] and overhead power lines[124] do not support the association between exposure to magnetic fields and the development of cancer; however, these studies lack sufficient power to exclude a small (i.e., odd ratio <2) increase in risk of acquiring leukemia. A case-control study of the use of electric blankets in 382 *postmenopausal* women demonstrated an elevated but statistically nonsignificant increase (odds ratio = 1.31; 95% CI: 0.88–1.95) in the incidence of breast cancer for women using electric blankets continuously throughout the night, when compared with 439 age- and education-matched community controls.[125] However, the lack of a dose-response for continuous use of electric blankets during the past 10 years and breast cancer (OR = 1.25, 95% CI: 0.73–2.16) did not support the hypothesis that magnetic fields increase the incidence of breast cancer by suppressing the normal nocturnal rise in pineal melatonin. In a subsequent case-control study of 290 *premenopausal* women, the odds ratio for breast cancer in women reporting daily use of electric blankets during the winter season continuously throughout the night for the previous 10 years was 1.10 (95% CI: 0.59–2.05) when compared with controls (randomly selected residents of the same two counties matched for age).[126] This value was lower than the risk of breast cancer in women using an electric blanket at any time in the last 10 years (RR = 1.18; 95% CI: 0.83–1.68) when compared with controls.

Occupational Exposure

Over the last several decades, considerable concern has developed over the health effects of extremely low frequency electromagnetic fields, primarily with the development of leukemia and, to a lesser extent, non-Hodgkin lymphoma and brain cancer. Although a meta-analysis of occupational exposure to ELF fields suggests a small increase (i.e., 10–13%) in the risk estimates for brain cancer and leukemia, the lack of a clear pattern of ELF field exposure and outcome risk suggests

the increased risk was probably not attributable to ELF field exposure.[127] Overall, the scientific evidence associating occupational exposures to ELF fields with adverse health effects is relatively weak and inconsistent when exposure levels are estimated by indirect means (e.g., jog titles).[102] In a comparative analysis of studies of electrical workers published before 1999, the estimated increased risk of leukemia and brain cancer following chronic exposure to magnetic fields was small.[128] The estimated relative risk of leukemia for a 10 μT-year exposure was 1.09 (95% CI: 0.98–1.21) and 1.12 (95% CI: 0.98–1.28) for brain cancer. The strongest evidence for health effects in adults is chronic lymphocytic leukemia in occupationally exposed adults; however, the overall excess risk of leukemia and in particular of acute myelogenous leukemia is small (20% and 45%, respectively) in the epidemiological studies that associate these cancers with occupations identified as exposed to electromagnetic fields.[58] The major uncertainty in these studies is the lack of a direct assessment of magnetic and electric fields and the substitution of indirect measures of electromagnetic fields that probably do not accurately reflect the strength of these fields. Mechanistic studies and animal experimentation have not confirmed the associations between ELF exposures and cancer suggested by the epidemiological studies. Nonetheless, the ubiquity of exposure to electromagnetic fields causes concern about the potential health consequences of exposure to electromagnetic fields.

The ICNIRP does not base ELF exposure guidelines on the risk of cancer following ELF exposure as a result of the lack of positive animal data and the weak epidemiological data (e.g., childhood cancer).[129,130] Recent data from studies with more sophisticated exposure data have not produced greater consistency or stronger associations between ELF and cancer, including brain tumors, salivary cancer, leukemia, acoustic neuroma, or malignant ocular melanoma. In a study of 81,842 UK electricity generation workers, there was no statistically significant increase in the incidence of brain tumors, leukemia, or leukemia subtypes, when compared with national rates.[131] A mortality study of Danish utility workers did not detect an increased risk of cancer or neurodegenerative diseases in these cohorts.[132]

Leukemia/Lymphoma

The most consistent finding of studies on the incidence and mortality of cancer in workers exposed to electromagnetic fields is a small increase in leukemia risks, particularly chronic lymphocytic leukemia and, to a much lesser extent, acute myeloid leukemia.[133] Proportional mortality studies of workers (e.g., telephone linesmen, electronic engineers) exposed to ELF fields demonstrate a small (~20%) increase in the risk of developing leukemia and, in particular, acute myelogenous leukemia.[134] A meta-analysis of 38 studies of leukemia and electromagnetic forces revealed an overall increase in risk of 18% (RR = 1.18, 95% CI: 1.12–1.24).[135] Another review of 11 studies of electrical occupations revealed a similar relative risk of 1.18 (95% CI: 1.09–1.29) for all leukemias in all electrical occupations.[134] The association with electrical workers is stronger for acute leukemias than chronic leukemias[136,137] and in particular for acute myeloid leukemia (RR = 1.46).[134] A Swedish case-control study demonstrated a positive, dose-related association between exposure to ELF and chronic lymphocytic leukemia (OR 3.0, 95% CI: 1.6–5.8 at highest exposure) based on the job held longest during the 10-year period before diagnosis. There was no association (OR = 1.0, 95% CI: 0.6–1.9) between the highest ELF exposure and acute myeloid leukemia.[138]

These studies are limited by poor exposure assessments that preclude the direct analysis of the effects of duration, latency, and magnitude of exposure to electromagnetic fields. Exposure categories were based on job titles rather than direct measurements of exposure; however, misclassification of exposure tends to underestimate rather than overestimate the associated risk. American[139] and Canadian[140] case-control studies found weak associations between exposure to ELF and the risk of leukemia, but there were no clear dose-response trends with increasing exposure and no consistency among different work sites. A cohort and nested case-control study of 36,211 electric utility workers found no consistent association between ELF exposure and mortality from leukemia, even after comparing different levels of exposure and latency periods.[141] Exposure assessment included job title analyses and direct magnetic field measurements of current job classifications.

Examination of specific occupations within the electrical industry demonstrates no consistent relationship between electromagnetic fields exposure in specific jobs and various types of cancer. Cohort studies of workers are less supportive of an association with cancer than mortality and case-control studies.[121,142] A cohort study of 83,997 UK electricity generation and transmission workers did not detect increased mortality from leukemia based on comparisons with national mortality rates.[143] Additionally, there were no significant increases in the risk of leukemia with increasing recent or lifetime exposure to magnetic fields, irrespective of leukemia subtype. Among occupations studied in Sweden, an increased incidence of chronic lymphocytic leukemia (which is not caused by

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ionizing radiation) occurred in power linesmen, who are presumably among the workers most highly exposed to magnetic fields.[144] The incidence of acute myelogenous leukemia was not elevated in these linesmen or welders exposed to high levels of magnetic fields. A review of cancer rates in welders revealed an increased incidence of lung cancer but not of leukemia.[145] A study of electrical workers in New Zealand demonstrated an increased risk of leukemia (odds ratio = 1.62) that was concentrated in the category of chronic leukemias including chronic lymphocytic leukemia,[146] whereas a large study of US Navy personnel did not confirm an increased incidence of leukemia in electrical workers.[147] Electrical workers may be exposed to other leukemogenic agents (chemicals including benzene, ionizing radiation) both inside and outside the work environment. These studies do not distinguish between different potential causes of leukemia, and the lack of a clear pattern of exposure to electromagnetic fields limits conclusions regarding the etiology of leukemia. Hence, the association between electrical occupations and leukemia does not necessarily imply a causal link.

Epidemiological data for a causal association between exposure to magnetic fields and non-Hodgkin lymphoma are weak. In an Australian study of 694 cases of non-Hodgkin lymphoma and occupational exposure to power frequency magnetic fields, the adjusted odds ratio for workers in the upper quartile of exposure (>9.85 μT-year) was 1.48 (95% CI: 1.02–2.16) when compared with the referent group (randomly selected local residents).[148] Exposure was based on a population-based job exposure matrix. The odds ratio for non-Hodgkin lymphoma was not statistically different for the other three quartiles when compared with the referent group or for the adjusted odds ratio ($OR_{adjusted}$ = 1.33, 95% CI: 0.90–1.96).

Brain

Compared with leukemia, the evidence supporting an association between exposure to electromagnetic fields and brain tumors is weaker and less consistent.[137,149] A case-control study of electrical workers suggested a small increase in the risk for brain tumors (e.g., astrocytoma);[150] however, most epidemiological studies do not demonstrate a statistically significant increased risk of brain tumors in occupations associated with relatively high ELF exposures. A mortality study of 2,173 deaths from primary brain cancer in electricians compared with other occupations demonstrated a statistically significant, increased adjusted odds ratio of 1.4 (95% CI: 1.1–1.7) with larger adjusted odds ratios for telephone workers (OR = 1.6, 95% CI: 1.1–2.4, n = 9 cases/44 controls), electric power workers (OR = 1.7, 95% CI: 1.0–2.7, n = 5 cases/30 controls), and electrical engineers/technicians (OR = 2.7, 95% CI: 2.1–3.4, n = 29 cases/95 controls).[150] A 19-year follow-up study of Swedish workers revealed an increased risk for the development of brain tumors in assemblers and repairmen in the radio and TV industries, but there was no significant increase in the risk of brain tumors for electrical engineers, linesmen, or electronic engineers.[144] A study of workers from three major utilities demonstrated a ~2-fold increase (OR = 1.95, 95% CI: 0.76–5.0) in the incidence of brain cancer in the 10% of the workers with the highest exposure to magnetic fields. The number of cases was small, the confidence interval was wide, and the results were not statistically significant.[140] A Swedish case-control study demonstrated no statistically significant, dose-related association between exposure to ELF and brain cancer (OR 1.4, 95% CI: 0.9–2.1 at the highest exposure level) based on the job held longest during the 10-year period before diagnosis.[138] A cohort and nested case-control study of 36,211 electric utility workers found no consistent association between ELF exposure and mortality from brain cancer, even after comparing different levels of exposure and latency periods.[141]

A meta-analysis suggested a small increase (10–20%) in the relative risk for a broad group of electrical occupations, but there was considerable heterogeneity among the studies.[151] The relative risk appeared higher (~30–35%) for specific occupations (e.g., electricians) that developed gliomas; however, conclusions regarding causation were limited by the lack of adequate information on exposure and the absence of a clear dose-response effect.

Breast

A case-control study of electrical workers reported a nearly 2-fold increase in the risk of developing breast cancer in men exposed to any job with exposure to electromagnetic fields based on job titles.[152] The OR was borderline increased for developing breast cancer (OR = 1.8, 95% CI: 1.0–3.7). The highest odd ratios appeared in the group of electricians, telephone linesmen, and electric power workers (OR = 6.0, 95% CI: 1.7–21), as well as a statistically nonsignificant increase in radio and communications workers (OR = 2.9, 95% CI: 0.8–10). The wide confidence intervals and marginally increased risks indicate a weak association.

The prospective Netherlands Cohort Study containing 120,852 men and women aged 55–69 years at the time of enrollment in 1986 and followed for a mean of 17.3 years did not detect an association between breast

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. cancer incidence in men and exposure to ELF magnetic fields.[153]

Studies of the association between breast cancer in women and exposure to ELF fields are inconsistent. In a study of women recruited for a breast cancer study, the occupations (e.g., housewives, teachers, nurses, administration support personnel) typically associated with an increased risk of breast cancer did not have magnetic field exposures exceeding the average of the study.[23] In a population-based case-control study examining occupational exposure to electromagnetic fields and the incidence of breast cancer among 843 women with breast cancer and 773 controls, the odds ratio for lifetime cumulative exposure to ELF fields was close to null; the study demonstrated no dose-response patterns.[154] The odds ratio adjusted for age and state of residence for breast cancer in 6,213 women occupationally exposed to electromagnetic fields was 1.06 (95% CI: 0.99–1.14) for low exposure, 1.09 (95% CI: 0.96–1.23) for medium exposure, and 1.16 (95% CI: 0.90–1.50) for high exposure.[155] Randomly selected, age-matched women ($n = 7{,}390$) were the controls. An industrial hygienist estimated the amount of exposure based on the job title. A Norwegian case-control study of women with occupational exposures to magnetic fields and breast cancer compared women with the highest exposure based on exposure matrix data with unexposed women.[156] The odds ratio was 1.13 (95% CI: 0.91–1.40).

Reproductive Abnormalities

The ability of electromagnetic fields to produce reproductive damage in humans remains unproved; the majority of studies of miscarriages following exposure of the mother to video display terminals do not demonstrate an association between the electromagnetic fields produced by these machines and increased fetal loss. The reproductive effects of electromagnetic fields are not well studied. One study of women who used video display terminals for more than 20 hours per week demonstrated an 80% increase in the rate of spontaneous abortions.[157] The nonionizing radiation from flat panel screens is below levels associated with video display terminals. Other studies have not duplicated these results. A study of women exposed to electric fields through the use of electric blankets, heated waterbeds, and ceiling cable heat suggested increased fetal loss during the wintertime.[158]

Humans

Little data are available on the association between exposure to ELF magnetic fields and pregnancy outcomes. There are inadequate data to determine conclusively whether or not static or ELF electromagnetic exposure causes any adverse reproduction outcomes, in part, because of the lack of well-designed studies with adequate exposure data and control of confounding variables.[159] Some epidemiological studies suggest the possibility of an increased risk of spontaneous miscarriage associated with ELF magnetic field exposure; this association is stronger for maximum value and variability of the magnetic field than time-weighted average field levels. A nested case-control study of 177 cases of clinical miscarriage among members of the northern California Kaiser Permanente medical care system and 550 controls did not demonstrate a statistically significant association between miscarriages and ELF magnetic fields. However, examination of quartiles of exposure suggested an association between maximum ELF exposure and the rate of change of the magnetic field.[160] A prospective cohort study of 969 subjects did not detect an increased risk of miscarriage using time-weighted-average (TWA) magnetic field exposure; the study did find an increased risk of miscarriage using maximum magnetic field strength of >0.6 μT (OR = 1.8, 95% CI: 1.2–2.7).[161] The association was stronger for early miscarriages (<10 weeks of gestation). A case-control study of women who developed spontaneous miscarriages suggested a borderline increased incidence (OR = 5.1, 95% CI: 1.0–25) of early pregnancy loss after high residential exposure (>0.63 μT) to ELF magnetic fields.[162] However, the limitations of the data including the small number of heavily exposed women indicate the need for cautious interpretation of the data.

Epidemiological studies of workers and mothers using electric blankets suggest the possibility of a small increase (RR = 1–5) in the risk of birth defects and miscarriages; the small size of these studies, the lack of good exposure data, and the dearth of supportive experimental data limit the conclusions about causal relationships. An ecological study of adverse reproductive outcomes revealed significant seasonal variation in the frequency of miscarriages in women with exposure to electromagnetic fields from electric blankets[163] and ceiling cable electric heat.[158] However, the causal relationship is not convincing because of the lack of the expected delay between exposure and fetal loss. Recall bias and the failure to separate spontaneous miscarriages from induced abortions further limit the interpretation of the relationship between cause and effect.

A retrospective Swedish study of electrical substation workers revealed an increased frequency of heart defects, facial clefts, and hydroceles in the offspring of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

male workers exposed to electromagnetic fields based on job title; there was no evidence of an increased rate of fetal loss.[164] Retrospective case-control studies of male workers exposed to electromagnetic fields suggest the possibility of an association between the development of neuroblastomas in offspring and electromagnetic fields, particularly in the repair or manufacture of electrical and electronics equipment and in electronics workers. A population-based, case-control analysis of the birth certificates of 157 children succumbing to neuroblastoma reported that children of fathers employed in occupations with electromagnetic field exposures based on job title had a statistically nonsignificant increased risk of developing neuroblastoma (OR = 2.14, 95% CI: 0.95–4.82, $n = 13$ cases/12 controls) compared with 314 randomly selected population controls.[165] The occupations included electricians, electric/electronics workers, linesmen, utility employees, and welders. An Ohio case-control study of 101 incident cases of neuroblastoma demonstrated variable adjusted odds ratio of 0.5–1.9 in cases with occupational electromagnetic field exposures, depending on the definition of the jobs with potential exposure to electromagnetic fields.[166] The authors urged cautious interpretation of the data because of the imprecise odds ratio estimates and the questionable biological plausibility. A retrospective study of the Medical Birth Registry of Norway suggested the possibility of an association between *parental* exposure to 50 Hz electromagnetic fields for >24 hours/week and an increased risk of spina bifida (OR = 2.48, 95% CI: 1.18–5.25).[167] The statistical significance of the relationship between *maternal* exposure to electromagnetic fields and adverse CNS outcomes disappeared after adjustment for chemical exposure. There was no direct measurement of electromagnetic exposure; an expert panel estimated the electromagnetic field exposure from retrospective evaluation of job classification.

More recent results do not demonstrate an adverse effect of the ELF magnetic fields on reproductive function in humans. A Canadian cohort study of >700,000 live births in Montréal and Québec City during 1990–2004 did not detect an increased risk of adverse pregnancy outcomes (preterm birth, low birth weight, small for gestational age) and distance between residence and the nearest power line.[168] No increased risk of adverse pregnancy outcomes occurred in the >12,000 births classified in the highest exposure category (<50 m from the power line). The adjusted ORs in this group were 0.99–1.04 with an upper confidence limit of <1.10. Limitations of the study included the address being available only at the time of birth, no information on power line voltage, and inadequate control of confounding variables (e.g., earlier reproductive outcomes, lifestyle, smoking). A large English cohort study of 140,000 live singleton births in 2004–2008 examined the association between exposure metrics (residential proximity to power lines, cables, substations, towers) based on postal codes and pregnancy outcomes (preterm birth, low birth weight, small for gestational age).[169] Limited information was available on confounders (e.g., smoking, lifestyle). The main analysis did not reveal any significant associations. An analysis using the mean birth weight of all babies rather than the proportion of markedly reduced birth weight reported a significantly lower birth weight for residences within <50 m of the closest ELF source ($n = 89$ children). The authors did not report whether the analysis of the mean birth weight was prespecified or carried out post hoc. The validity of the exposure classification based on postal codes rather than house coordinates is unproven.

Cross-sectional studies of fertility in aluminum workers exposed to static magnetic fields up to 10 mT and alternating fields up to 0.1 mT did not detect significantly altered fertility in male workers.[170] The portion of male offspring in women exposed to static magnetic fields was significantly reduced; however, misclassification probably accounts for the difference. A case-control study of 692 potroom workers exposed to static magnetic fields ranging from 4–30 mT and 588 unexposed male workers from the same aluminum plants demonstrated a statistically significant increase in the birth rate of the exposed workers (relative birth-rate ratio = 1.1; $P < 0.001$).[171]

Animals

Animal test systems have produced inconsistent findings on the effects of electromagnetic fields on reproduction as a result of wide variations in the intensity, type of exposure (pulse, frequency), and poor control of confounding variables (background exposures, spark discharge).[172] Low-frequency magnetic fields have adverse effects on chick embryo development;[173] however, the threshold of these effects and their relevance to humans remain unclear.[174] Although adverse effects occurred in some dams and weight gain occurred in exposed offspring, multigenerational rat studies have not demonstrated a clear association between exposure to electromagnetic fields and adverse reproductive or developmental effects.[175] Under environmental conditions studied in animal testing, neither electric nor magnetic fields are conclusively teratogenic or embryotoxic.[30,174,176]

DOSIMETRY

Static Fields

With proper techniques, methods for measuring external magnetic fields are relatively accurate using point measurements and space-integrated values for static magnetic fields. Magnetic flux density is the most common parameter used to correlate the strength of the magnetic field to health effects.[177] The most common method uses the Hall probe in personal dosimeters. The battery-operated, portable magnetic dosimeter contains thin-film Hall sensors that record the magnetic induction (B) along three orthogonal axes. During consecutive sampling intervals of ~75 msec, Hall generators in pulsed mode determine the time rate of change of the magnetic induction (dB/dt) for recorded values of B.[178] The temperature coefficient of the Hall voltage limits the accuracy of these instruments. Fluxmeters and ballistic galvanometers can directly measure variations in the magnetic flux using a search coil, providing an average magnetic field value over the volume of the coil.[179] Valid analyses of static magnetic fields require instruments that withstand strong magnetic fields without altering the external magnetic fields.

ELF Fields

External extremely low frequency electric and magnetic fields induce electric fields and currents inside the human body; in contrast to the similarity of internal and external magnetic fields, the electric fields inside the body are five to six orders of magnitude less than the external electric field.[30] The physical assessment of exposure to electric and magnetic fields requires parameters other than the field strength and frequency of a source. The two main types of instruments available to measure magnetic fields are: 1) multiturn loops with portable voltmeters; and 2) gaussmeters. Most popular commercial devices available to measure the strength of the magnetic field use the Hall probe or the shielded coil. Internal electric fields and the induced currents in humans are not easily measured; differences in body shape, posture, and size seriously limit the use of animals to model these effects in humans. Numerical simulations are necessary to estimate electric fields and currents inside the body from external electric and magnetic fields because no technique exists for direct measurements.[47] The strongest induced currents occur when the body is electrically grounded through the feet, whereas the weakest currents occur when the body is insulated by air. Tissue conductivity determines the distribution of the induced current in the body; hence, the distribution of current in the body is very heterogeneous between various tissues and organs.

Magnetic Fields

Human and animal bodies do not significantly alter external magnetic fields. The magnetic fields in these bodies are similar to the external magnetic field as a result of the similarity of magnetic permeability between the body and air. The main interaction of a magnetic field with the body is the induction of an electric field and associated current in a large variety of conductive tissues present in the human body. The induced electric field and current depend on the orientation of the external field with the highest fields typically aligned front-to-back or occasionally side-to-side depending on the individual organ. The consistently lowest induced electric fields usually occur during the orientation of the external magnetic field along the vertical axis of the body. For magnetic fields, the size of the body is the major determinant of the induction of internal currents because the body does not contain magnetic material and does not attenuate the magnetic field. Magnetic fields vary substantially in different metals and metal configurations (e.g., mesh vs. solid structures). Many epidemiological studies use the 24-hour time-average of the 60 Hz magnetic field as a measure of magnetic field strength.

Electric Fields

Because of the substantial attenuation of electric fields in the body, electric fields are not usually measured during exposure to ELF radiation. External electric fields near 1 MV/m are necessary to produce an internal electric field similar to the transmembrane potentials existing naturally.[180]

For electric fields, the induction of internal electric fields and currents depends on several factors in addition to field strength and frequency including: 1) resistance of the current flow from the body to the ground; 2) shielding of the source from the body (e.g., trees, buildings); 3) distance from the body to the source; 4) orientation of the body to the source; and 5) size and shape of the body.

(ICNIRP) based their 1998 recommendation of ELF electric and magnetic field exposure on a threshold current density of 100 mA/m^2 for acute changes in central nervous system function (i.e., brain and spinal cord), particularly in the frequency range of 4 Hz–1 kHz.[130] General consideration of neural physiology suggests threshold current density rises above and below this range. In the 2010 guidelines, the ICNIRP used an induced electric field strength threshold in CNS tissue of the head (brain, retina) of 50 mV/m in the range of 10–25 Hz based on the production of retinal phosphenes.[129] The phosphene threshold rises rapidly outside this range with the threshold for peripheral and CNS myelinated nerve stimulation intersecting the phosphene threshold at 400 Hz, as displayed in Table 45.7. Above this value, the latter threshold applies. For workers knowledgeable about acute effects working in a controlled environment, the induced electric field threshold increased to 800 mV/m based on a peripheral and central myelinated nerve stimulation threshold of 4 V/m reduced by a factor of 5. The threshold for the general public was 10 mV/m in the range 10–25 Hz (i.e., reduction factor of 5) and 400 mV/m for induced electric fields of >1 kHz (reduction factor of 10).

The Institute of Electrical and Electronics Engineers (IEEE) bases its guidelines on protection against painful electrostimulation in frequencies ranging from 0 Hz–5 MHZ and excessive heating in frequencies ranging from 100 kHz–300 GHz. The 2002 guidelines used an induced electric field strength threshold of 53 mV/m at 20 Hz for changes (e.g., magnetophosphenes, synaptic interactions) in brain function for 50% of healthy adults.[181] The phosphene threshold rises above 20 Hz following a frequency-proportional ratio up to 760 Hz; their recommendations are based on peripheral nerve stimulation up to 100 kHz. The recommended IEEE thresholds for workers exposed to electric and magnetic fields are 20 kV/m and 2.71 mT at 60 Hz, respectively. In comparison, the guidelines for exposure for the general public are 5 kV/m and 0.9 mT, respectively. In 2019, the IEEE updated their guidelines (IEEE Std /C95.1-2019, https://standards.ieee.org/ieee/C95.1/4940/) to separate exposures into unrestricted and restricted environments. Differences in the IEEE and ICNIRP guidelines result from differences in thresholds, safety factors, and transition frequencies.

Environmental Monitoring

Although several epidemiological studies associate chronic, low-intensity exposure (i.e., >0.3–0.4 μT) to power frequency magnetic fields with an increased risk of childhood leukemia, the ICNIRP concluded the evidence is not currently causal. Therefore, the guidelines for public exposure are based on acute effects. Table 45.8 displays the 2010 ICNIRP guidelines for public exposure to electric and magnetic fields in the sub-radiofrequency range (1 Hz–30 kHz). The 400 mT limit recommended by ICNIRP for the general public restricts acute biological effects of the static magnetic

TABLE 45.7. International Commission on Non-Ionizing Radiation Protection (ICNIRP) threshold values for induced internal electric fields for human exposure to time-varying electric and magnetic fields. All values are rms. Radiofrequency basic restrictions may apply at frequencies above 100 kHz. (ICNIRP 2010, https://www.icnirp.org/).

Exposure	Tissue	Effect	Frequency Range (Hz)	Internal Electric Field (V/m)
Workplace	CNS head	Phosphenes	1–10	0.5/f
		Phosphenes	10–25	0.05
		Phosphenes	25–400	0.002f
		Nerve stimulation	400–3,000	0.8
		Nerve stimulation	3,000–10,000,000	0.00027f
	All tissues	Nerve stimulation	1–3,000	0.8
		Nerve stimulation	3,000–10,000,000	0.00027f
Public	CNS head	Phosphenes	1–10	0.1f
		Phosphenes	10–25	0.01
		Phosphenes/nerve stimulation	25–1,000	0.0004f
		Nerve stimulation	1,000–3,000	0.4
		Nerve stimulation	3,000–10,000,000	0.000135f
	All tissues	Phosphenes/nerve stimulation	1–3,000	0.4
		Nerve stimulation	3,000–10,000,000	0.000135f

TABLE 45.8. International Commission on Non-Ionizing Radiation Protection (ICNIRP) reference levels for *public* exposure to time-varying electric and magnetic fields below 30 kHz in unperturbed rms values. Some of these guidelines are modified for exposure to nonsinusoidal and multiple frequencies. (Modified from International Commission on Non-Ionizing Radiation Protection).[129]

Frequency	Electric Field Strength (kV/m)	Magnetic Field Strength (A/m)	Magnetic Flux Density (T)
0–1 Hz			0.4
1 Hz–8 Hz	5	$32{,}000/f^2$	$0.04/f^2$
8 Hz–25 Hz	5	$4{,}000/f$	$0.005/f$
25 Hz–50 Hz	5	1,600	0.0002
50 Hz–400 Hz	$250/f$	1,600	0.0002
400 Hz–3 kHz	$250/f$	$64{,}000/f$	$0.08/f$
3 kHz–30 kHz	830	21	0.00002

Abbreviation: f = frequency in Hz.

field; however, this value is substantially above the level at which mechanical forces can move external and internal ferromagnetic objects (e.g., heart valve prostheses, contraception implants, dental implants, metallic surgical clips, and stents).[177] Although many modern implants are not ferromagnetic, electromagnetic interference can occur in low-intensity static magnetic fields during the operation of some medical devices including cardiac pacemakers/defibrillators, neuromuscular stimulators (e.g., muscle, bladder), electronically operated prosthetic devices (e.g., inner ear, limbs), and infusion pumps (e.g., insulin, analgesics). The ICNIRP recommends limiting static magnetic fields for these individuals to <0.5 mT.

Occupational Monitoring

Guidelines

The ACGIH recommends limiting ELF exposure (1 Hz–30 kHz) to ceiling values inducing current densities of <10 mA/m^2 (i.e., values below the current densities normally present in the body), as displayed in Table 45.9; the ACGIH has insufficient information to promulgate TLV values for sub-radiofrequency magnetic or electric fields. These guidelines are based on current density substantially below values necessary to affect nervous system functions rather than a value near levels that cause adverse effects.[129] Although some US

TABLE 45.9. American Conference of Governmental Industrial Hygienists (ACGIH) threshold limit values (TLV) for sub-radiofrequency magnetic fields including static magnetic and electric fields. These ceiling values are promulgated as root-mean-square (rms) values. (ACGIH 2013, https://www.acgih.org/science/tlv-bei-guidelines).[179]

Frequency (f)	Exposure	Ceiling Value
	Magnetic fields	
0 Hz (static)	Whole body – general occupational	2 T
0 Hz (static)	Whole body – special training or controlled environment	8 T
0 Hz (static)	Limbs	20 T
1–300 Hz	Whole body – general occupational	$60/f^a$ (mT)
1–300 Hz	Arms, legs	$300/f^a$ (mT)
1–300 Hz	Hands, feet	$600/f^a$ (mT)
300 Hz–30 kHz	Whole or partial body	0.2 mT
1 Hz–2.5 kHz	Point contact current limit	1.0 mA
2.5 kHz–30 kHz	Point contact current limit	$0.4f^b$ (mA)
	Electric fields	
0–220 Hz	Whole body – general occupational	25 kV/m
220 Hz–3 kHz	Whole body – general occupational	$5.525 \times 10^3/f^c$ (kV/m)
3 kHz–30 kHz	Whole body or partial body	1.842 kV/m

Abbreviations: f^a = frequency in Hz and value in mT; f^b = frequency in kHz and value in mA; f^c = frequency in Hz and value in kV/m.

TABLE 45.10. International Commission on Non-Ionizing Radiation Protection (ICNIRP) reference levels for *occupational* exposure to time-varying electric and magnetic fields below 30 kHz in unperturbed rms values. Some of these guidelines are modified for exposure to nonsinusoidal and multiple frequencies. The guidelines for static magnetic field exposures are spatial peak exposure limits. (International Commission on Non-Ionizing Radiation Protection, https://www.icnirp.org/).[182]

Frequency	Electric Field Strength (kV/m)	Magnetic Field Strength (A/m)	Magnetic Flux Density (T)
0–0.66 Hz			2 (head, trunk)[a]
			8 (limbs)
0.66 Hz–1 Hz			2 (head, trunk)[a]
			8 (limbs)
1 Hz–8 Hz	20	$1.63 \times 10^5/f^2$	$0.2/f^2$
8 Hz–25 Hz	20	$2 \times 10^4/f$	$0.25/f$
25 Hz–300 Hz	$500/f$	800	0.001
300 Hz–3 kHz	$500/f$	$2.4 \times 10^5/f$	$0.3/f$
3 kHz–30 kHz	0.17	80	0.0001

Abbreviation: f = frequency in Hz.

[a] For special work applications with a controlled environment and appropriate work practices, static magnetic fields up to 8 T as a spatial peak exposure limit are allowed for exposure to the head and trunk. The ICNIRP recommends some restrictions on movement in static and time-varying magnetic fields to prevent sensory effects including limiting changes in the magnetic field over 3 seconds to 2 T.[182]

states set limits on exposure to ELF fields, currently there are no federal limits in the United States on exposure to fields below the radiofrequency frequency range. Workers with cardiac pacemakers or implanted ferromagnetic medical devices are particularly susceptible to electromagnetic fields; lacking specific information on implanted ferromagnetic or electronic devices, these workers should be exposed to a maximum of 0.1 mT at power frequencies (i.e., 50/60 Hz), 0.5 mT in static magnetic fields, and <1 kV/m in sub-radiofrequency electric fields. Higher ceiling values were promulgated for static magnetic ceiling TLVs for workers involved in special training and controlled workplace environments where there is no significant risk of projectile objects. These workers may experience transient sensory effects during motion in strong static magnetic fields and startle reactions associated with spark discharges or contact currents from ungrounded conductions with electric fields of >5–7 kV/m. However, these effects are not expected to cause persistent adverse effects unless they are associated with trauma.

The ICNIRP bases recommendations on time-varying electric and magnetic fields of <100 kHz on the induced electric fields in the brain for the central nervous system (retinal phosphenes) and the peripheral nervous system (direct neuromuscular stimulation); effects are monitored as peak fields averaged over a volume of tissue depending on frequency (see Table 45.7). For the 50 Hz power frequency, this restriction translates to 33 V/m/T for CNS effects and 60 V/m/T for PNS effects as measured in rms values. The reference values for exposure to electric fields up to 25 Hz include a sufficient margin to prevent stimulation from contact currents under most practical conditions. Table 45.10 displays the ICNIRP guidelines for occupational exposure to electric and magnetic fields in the sub-radiofrequency range (1 Hz–30 kHz). The objective of ICNIRP recommendations on exposure to static, time-varying magnetic fields of <1 Hz and the resulting induced internal electric fields and currents is the avoidance of peripheral nerve stimulation and sensory effects including nausea, vertigo, a metallic taste, and magnetophosphenes that may impair working ability.[182]

Protective Measures

Engineering methods to reduce electromagnetic fields exceeding guidelines are typically the first method of choice for protective measures (e.g., improving machine design, use of health protection mechanisms) along with administrative controls (e.g., limited access, audible and visible warnings). Methods to reduce exposure to high-intensity magnetic fields include: 1) distance; 2) time; 3) magnetic shielding; and 4) cancellation. Shielding is the simplest way to decrease the strength of electric fields (*E*-fields). The metal conductivity is 10^{16} times greater than air conductivity; therefore, grounded metal will terminate the electrical field by conducting the electrical charges to the ground. Most metals can shield *E*-fields when they are grounded. Isolated equipment

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. requires nickel alloys, ferromagnetic materials, or other special alloys with high magnetic permeability.[183] Separation is an effective means of reducing the electric and magnetic fields when sufficient space is available. The magnetic field intensity decreases directly with distance for single wires, distance squared for parallel wires (power lines, residential electric lines), and cube of the distance for wire loops (electric stoves, motors). Because the external magnetic flux density decreases with distance from the source, the fundamental protective measure is the separation of people from the source. The use of shielding on large installations often is limited in comparison to separation. Cancellations involve the addition or rewiring of lines to produce fields with the opposite phase compared with the existing electrical field. This technique is useful where leakage of electrical fields results from inadequate grounding of equipment.[184] The use of personal protective clothing (e.g., insulated gloves) is an option when engineering and administrative controls are inadequate; however, the goal is limited exposure to values below guidelines.

Biological Monitoring

Because the basic mechanisms of adverse effects from ELF magnetic and electric fields are unknown, the most important biological index of exposure (e.g., frequency, waveform, intermittency, magnitude of magnetic field or induced electric currents, time-average fields, time above a threshold) is also unclear.

Medical Surveillance

Both static and time-varying magnetic fields may interfere with the functioning of demand pacemaker. Some demand pacemakers revert to an asynchronous mode of operation in time-varying fields with time rate changes over 40 mT/s, while static magnetic fields exceeding 1.7–4.7 mT may close the reed switch relay of other pacemakers depending on the composition of the pacemaker.[185] The displacement of metallic implants (surgical clips, prostheses, catheters) as a result of strong magnetic fields may result in internal injury. Additionally, sharp metallic objects may become missiles with high momentum in intense magnetic fields.

Chapter 46

ULTRAVIOLET, VISIBLE AND INFRARED RADIATION

HISTORY

Ultraviolet (UV) radiation from the sun provides several benefits to human health including cutaneous production of vitamin D, stimulation hormones that regulate circadian rhythms and mood, and temporary darkening of the skin in light-skinned people. However, excessive UV radiation produces adverse health effects, including skin damage, photoaging, skin cancer, cataract formation, and immunosuppression. In the late 19th century, Unna and Dubreuilh first associated chronic sun exposure with degenerative changes in the skin of sailors and vineyard workers, including actinic keratoses and skin epitheliomas.[1,2] By the early 20th century, Hyde associated the development of skin cancer with excessive sun exposure in light-skinned races.[3] Findlay confirmed the occurrence of skin cancer following excessive sun exposure in animal experiments during the 1920s.[4] In the late 1920s, Hausser and Vahle first quantitatively documented erythema as a wavelength-dependent effect.[5] The UVB portion (280–320 nm) of the solar spectrum is the highest energy band in the UV portion of the electromagnetic spectrum; subsequent animal studies demonstrated that sunburn and photocarcinogenesis result primarily from UVB radiation.[6] Kligman first reported the accelerated aging effects of UV solar radiation in 1969.[7] He used the term "photoaging" to describe the skin changes associated with chronic sun exposure.

PHYSICAL PROPERTIES

Ultraviolet radiation lies in the electromagnetic spectrum between X-rays with shorter wavelengths (<100 nm) and visible light (400–760 nm) with longer wavelengths. The UV section (UVA, UVB, UVC) of the electromagnetic spectrum is the nonionizing radiation portion that lies in the wavelength range of 100–400 nm. Although the International Commission on Illumination defines the break between UVA and UVB as 315 nm, many scientists use 320 nm as the break point. Radiation with a wavelength of 100 nm possesses the minimum photon energy (12.4 eV) required to break the weakest macromolecular bonds; this wavelength divides ionizing and nonionizing radiation. Radiation with a wavelength below UVC (i.e., <100 nm) is considered ionizing radiation; consequently, X-rays possess ionizing properties, whereas visible light is nonionizing. The air absorbs UV radiation with wavelengths of <180 nm (i.e., 100–180 nm) within the first few centimeters; therefore, this area of the UV spectrum (i.e., vacuum UV region) has no direct biological effect on terrestrial humans.[8] The sun is the main source of UV radiation. Most artificial sources (e.g., sun lamps) of UV radiation emit a spectral continuum of UV light with characteristic peaks and troughs across the UV range of wavelengths.

Irradiance is the physical measure of UV exposure defined by the amount of energy over a demarcated surface of an object measured in watts per square meter

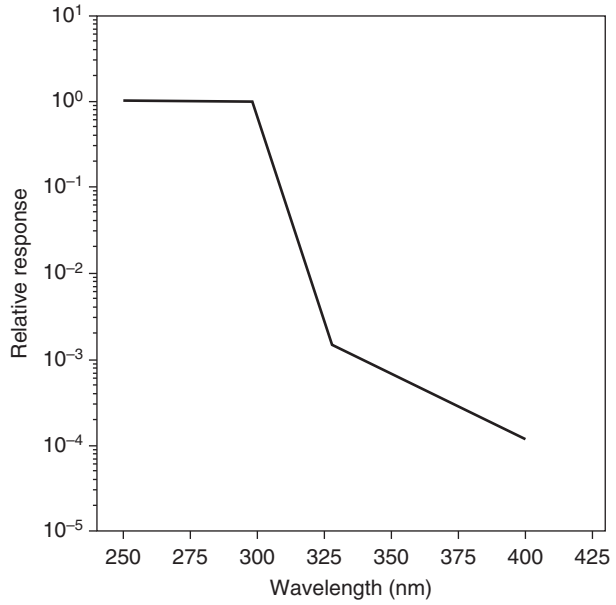

FIGURE 46.1. Action spectrum for minimal erythema at wavelength 298 nm.

(W/m^2), whereas radiant exposure is the accumulated radiant energy per unit area (J/m^2). The biological effect of a UV spectral band depends on the wavelengths displayed for minimal erythema in Figure 46.1.

Consequently, quantifying the biological effects of environmental UV radiation exposure requires conversion of physical dose into biologically meaningful dose parameters based on the response to individual wavelengths in the spectrum. The action spectrum is a graphic representation of the relative effectiveness of specific wavelengths of radiation required to produce a biological response (e.g., erythema).

Biologically weighted radiometric quantities are derived from spectral data by multiplying the spectral wavelengths by the action spectrum of relevant biological reactions (e.g., minimal erythema, DNA damage, skin cancer). Equation 46.1 determines the biologically effective solar spectral irradiance, E_{eff} (W_{eff}/m^2) by integrating the biologically effective irradiance (E_{eff}) over the spectral range. The biologically effective dose rate (i.e., effective radiant exposure), H_{eff} (J_{eff}/m^2), is the biologically effective irradiance (E_{eff}) integrated over time (e.g., 1 day for daily dose).

$$E_{\text{eff}} = \int E_{\lambda}(\lambda) \times S_{\lambda}(\lambda)\, d\lambda \qquad \text{(Equation 46.1)}$$

where

$E_{\lambda}(\lambda)$ = solar spectral irradiance ($W/m^2/nm$);
$S_{\lambda}(\lambda)$ = action spectrum (relative units);
λ = wavelength (nm).

Figure 46.1 demonstrates the action spectrum for minimal erythema at the reference wavelength of 298 nm. The relative response depends on the specific biological reaction being monitored.

EXPOSURE

Solar Radiation

Although the sun emits energy across a broad band of wavelengths, the vast majority of the energy falls in the nonionizing visible and near-infrared regions. Approximately 9% of the total energy released by the sun appears in the UV portion of the electromagnetic spectrum at the beginning of the atmosphere, whereas the visible spectrum (400–700 nm) accounts for ~40% and infrared for ~51% of the total solar energy *entering* the earth's atmosphere.[9] Both the quality (spectrum) and quantity (irradiance) of solar radiation vary with the elevation of the sun above the horizon and the solar zenith angle, as well as a variety of other factors (e.g., reflectance, atmospheric modification). The geometry of the exposure and the position of the sun in the sky are major determinates of the irradiance on the skin and eye, with geometry more important to the exposure intensity for the eye than the skin; the eyelids and eyebrow ridge provide significant protection for the eye from UV radiation.[10] Consequently, UV-induced changes in the eye occur primarily in the lower nasal part of the outer eye. Table 46.1 displays the characteristics and mitigating factors of solar radiation entering the atmosphere. The intensity of UV exposure is greatest at the equator, high altitudes, and midday in the summer (1,100–1,500).

The lens of the eye absorbs UV radiation, resulting in a sharp drop in visual acuity in the 380–420 nm range;[11] therefore, UV radiation is invisible. The epidermis also strongly absorbs UVA radiation with little UVB and UVC radiation reaching the dermis.[12]

Figure 46.2 demonstrates the average penetrance of solar radiation of <1,500 nm through human skin. The depth of penetration depends on reflection, scatter, and absorption. Luminographs of the skin using UV radiation produce greater definition of surface detail than conventional photographs as a result of reduced scattering of reflected rays; this illumination (e.g., Woods lamp or black light) allows detailed examination of forensic material (e.g., wounds, fluorescent liquids).[13] UV radiation penetrates human skin less deeply than visible light and much less deeply than infrared radiation.

TABLE 46.1. Solar radiation entering the earth's atmosphere with mitigating factors. (Adapted from Loggie and Eddy).[9]

Mitigating Factors	Ionizing	Ultraviolet	Visible	Infrared	Microwave
Wavelength	γ-rays (<10^{-3} nm),	UVA: 320–400 nm	400–700 nm	Near: 700–7,000 nm	25 μm–1 mm
	X-rays (1 nm–1 pm), particulates	UVB: 290–320 nm		Far: >7,000 nm–25 μm	
		UVC: 100–290 nm[a]			
% Total solar energy	<10%	UVA: 6.8%	39.7%	Near: 51%	0.01%
		UVB: 1.7%		Far: <1%	
		UVC: 0.6%			
Solar activity (sunspots)	Marked	Moderate	Weak	Weak	Marked
Altitude	Strong	Strong	Weak	Strong	Weak
Latitude	Direct	Inverse	Inverse	Inverse	Inverse
Absorption atmosphere	Strong	UVA: strong	Weak	Strong	Variable[b]
		UVB: strong			
		UVC: marked			
Skin type (pigment)	None	Yes	Yes	Marginal	Weak
Cloud cover	No	Yes	Yes	Partial	Weak

[a] The portion (100–180) absorbed at the beginning of the atmosphere is called the vacuum UVC. [b] The longer wavelengths pass through the Earth's atmosphere similar to radio waves, whereas the atmosphere absorbs some of the shorter-wavelength microwaves.

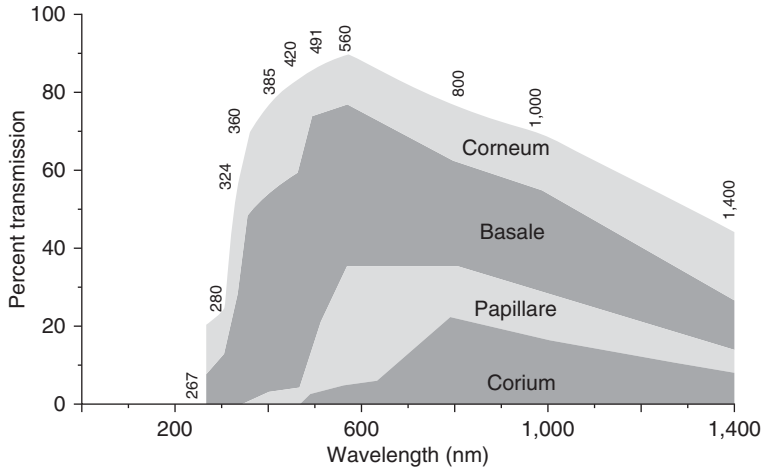

FIGURE 46.2. Estimated average penetration of radiant energy of 1,500 nm through thin human skin. The stratum basale is the deepest of the five layers comprising the avascular epidermis, whereas the stratum corneum is the most superficial epidermal layer. The papillary layer is the superficial layer of the dermis (corium) composed of loose connective tissue (collagen and elastin fibers) that projects into the stratum basale. (Adapted from West et al.).[13]

Atmospheric Modifications

As solar radiation passes through the atmosphere, molecular oxygen and ozone absorb and scatter UV radiation with ~2/3 of the radiation reaching the earth's surface; the annual variation in solar radiation at the beginning of the atmosphere is ~10%.[14] UV radiation increases by ~10–12% every 1,000 m (3,280 ft) in altitude; consequently, this type of radiation increases by ~170–290% at the cruising altitude of 35,000 ft, when compared with the earth's surface.[15] The ozone layer prevents the penetration of all UVC radiation and almost all of the UVB spectrum; thus, UV radiation exposure at the surface of the earth primarily involves the wavelengths of 290–400 nm, as demonstrated in Figure 46.3.

A number of factors affect the amount and spectral distribution of solar radiation reaching the surface of the earth (UV irradiance), as listed in Table 46.2.

Variation is much smaller for solar radiation from the source than atmospheric attenuation; consequently, the variation in the amount of UV radiation is greater at the earth's surface than at the upper edge of the

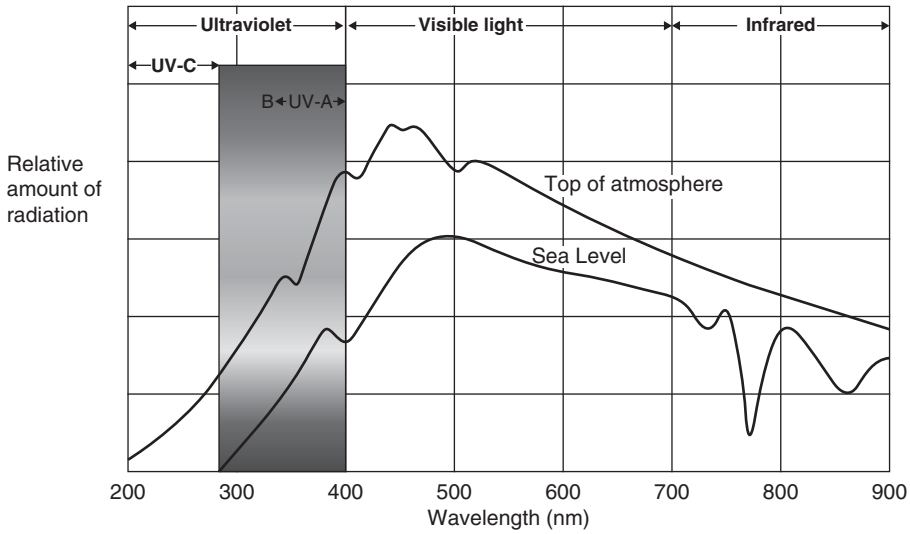

FIGURE 46.3. Amount of solar radiation penetrating the atmosphere based on a wavelength of <900 nm. The solid area represents the UV radiation spectrum (290–400 nm) reaching the terrestrial environment. (Adapted from International Programme on Chemical Safety).[8]

TABLE 46.2. Factors affecting the amount and spectral distribution of solar radiation (UV irradiance) reaching the surface of the earth (global UV). Shadowing by surrounding objects also reduces UV irradiance in the shadow. (Based on International Programme on Chemical Safety).[8]

Factor	Location	Magnitude of Effect on Solar Radiation
Altitude	Atmosphere	↑ above sea level
Clarity	Atmosphere	Mean cloudy sky = 22–38% less than clear sky[16]
Absorption or scattering	Atmosphere	↓ with ↑ airborne aerosols and pollutants
Shadowing or reflectance on the ground	Ground	Reflectance increases 16-fold at snowy to nonsnowy terrain interface[17]
Ozone concentration	Mostly stratosphere	↓ with ↓ozone thickness or vertical distribution
Solar spectrum	Atmospheric edge	Variable
Solar zenith	Atmosphere	Varies with daytime, latitude, and season (↓ 7% summer to winter)
Wavelength	Source	↓↓ 100–180 nm (vacuum UV)

atmosphere. The seasonal variation in UV radiation is much lower near the equator than in temperate zones. Approximately 20–30% of the daily UV radiation dose occurs between 11 AM and 1 PM, whereas ~75% of the dose is received between 9 AM and 3 PM.[18] The spectral irradiance decreases by $\sim^1/_3$ between the peak at 12 noon and after 3 PM.[19] Solar activity probably does not produce significant changes in the amount of damage caused by UV radiation. Sunspots are an index of solar activity that follows an 11-year cycle; however, increases in the amount of radiation across the UV portion of the spectrum are ~1% during solar flares.[20]

The stratosphere contains ~90% of the ozone in the atmosphere; the ozone layer accounts for most UV radiation absorption; thus, reduction of the ozone layer potentially increases the risk of damage from chronic UV radiation exposure, including photoaging and skin cancer.[21] The ozone layer is thinnest at the equator and thickest at the poles. Instruments on satellites orbiting the earth (e.g., TOMS and OMI/Aura) measure ozone, cloud cover, and aerosols in the atmosphere; however, information on long-term global changes in terrestrial UV radiation was limited before the launching of orbiting satellites. Radiative transfer analysis of satellite-based O_3 measurements from 1979–1992 demonstrated substantial increases in surface UVB levels in all latitudes (e.g., several less percentage points over Northern mid-latitudes) except the tropics,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. assuming other factors (e.g., cloud cover, local pollutant levels) remained constant.[22,23] These changes affect primarily the transmission of UVB to the surface of the earth. Currently, ozone column amounts are no longer decreasing, with the return to 1980 atmospheric O_3 concentrations in the mid-latitudes expected before mid-century.[24]

Irradiance is the radiant flux density falling on a surface, usually measured in W/m^2. The most sun-exposed surfaces of the skin are the forehead, nose, and upper ears; UVB exposure of these surfaces varies by up to one order of magnitude compared with less-exposed surfaces of the body (e.g., underneath the chin). The maximum summer UV irradiance is greater in the southern than the northern hemisphere because of the lower ozone concentrations in late summer and less separation between the earth and sun in early January.[25] UVB intensity can increase at a rate of 6%/km altitude, with the rate increasing somewhat more above 5 km as a result of the clearer atmosphere, assuming other factors affecting solar irradiance remain constant.[26] Scattering of UV radiation by air molecules also occurs near the earth's surface; therefore, reduced air pressure and air mass increase the amount of UV radiation at the surface of the earth near areas of high altitude and low air pressure.[27] Figure 46.4 demonstrates the seasonal and diurnal variation in UVB irradiance (307 nm) at latitude 45°S.

UVA (320–400 NM)

UVA or long UV is not visible to the human eye, but the eye will see the fluorescence of certain substances under black light. The intensity of UVA increases 2-fold from winter to summer, compared with a 10-fold increase in UVB.[1] The greater effectiveness (i.e., ~5–10-fold) of UVB radiation in producing cutaneous erythema obscures the importance of UVA as a cause of skin damage. Because the cutaneous and erythematous effects are much less potent for UVA (320–400 nm) than UVB, the cutaneous effects from UVB radiation usually occur long before sufficient amounts of UVA light can be absorbed to cause skin damage. Unlike recurrent UVB exposure, UVA exposure does not significantly induce protective factors against further UVA exposure (e.g., tanning).[28] The ability of UVA to penetrate the epidermis suggests a role for UVA in skin aging. Potentially, UVA may contribute to the development of photocarcinogenesis, immunosuppression, and drug photosensitivities.

UVB (290–320 NM)

UVB or short UV is the primary portion of the UV spectrum responsible for tanning, sunburn, and skin cancer. About 90% of the 25-OH vitamin D results from the interaction of UVB and 7-dehydrocholesterol in the skin.[29] As displayed in Figure 46.3, the clinical

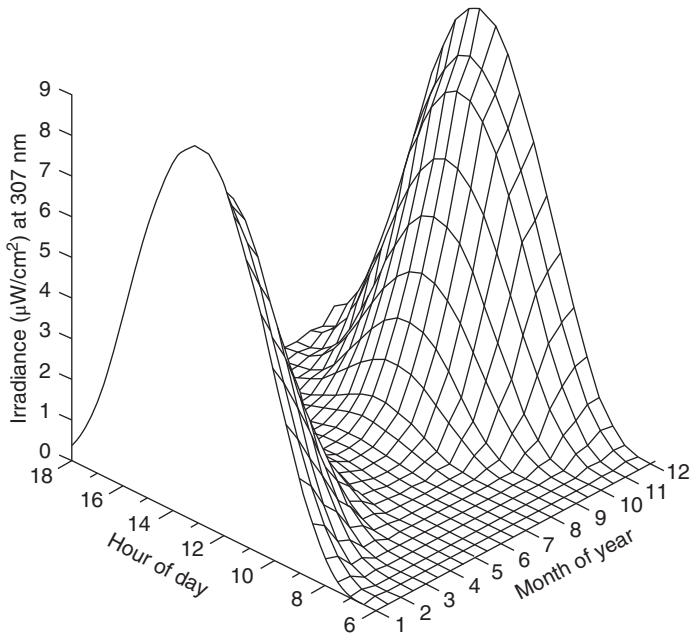

FIGURE 46.4. Seasonal and diurnal variation in UVB irradiance (307 nm) at latitude 45°S. (Redrawn from McKenzie and Elwood).[25]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. effects of UVB radiation are more important at the surface of the earth than UVA radiation. Although much more (i.e., 10–100 times more) UVA reaches the earth's surface than UVB, the latter is 1,000 times more effective at producing erythema.[30] Window glass does not transmit wavelengths of <310 nm; hence, window glass blocks UVB but not UVA radiation. Compared with UVA radiation, the atmosphere attenuates UVB to a much greater extent. Consequently, a sunbather receives relatively greater UVA doses in the summer and during noontime periods. UV radiation of <380 nm does not pass through the acrylic windows of airplanes.[31]

UVC (100–290 nm)

Atmospheric ozone absorbs almost all UVC radiation; consequently, biologically relevant UVC sources involve primarily arc welding and germicidal lamps (250–265 nm); the latter also emit a modest amount of UVB radiation. Gas welding typically does not emit significant amounts of UV radiation. Although UVC radiation has more energy than UVB or UVA, UVC radiation penetrates the skin poorly, as noted in Figure 46.2. UVC is attenuated at any altitude by four times more than UVA.[9] Vacuum UV (100–180 nm) refers to the wavelength range where a vacuum is necessary to propagate the energy because these wavelengths are easily absorbed in the presence of air. Molecules in the atmosphere absorb UV radiation of <200 nm within a few centimeters; therefore, these wavelengths occur in biologically significant amounts only in space. Vacuum UV does not contribute significantly to skin changes in humans on earth.

Artificial Sources

Broad-spectrum UV radiation has a variety of industrial and medical uses, including the diagnosis and treatment of medical illnesses (e.g., psoriasis, eczema, vitamin D deficiency, neonatal jaundice), dental restorations, food/medical instrument sterilization, commercial polymerization reactions (e.g., photo-curing protective coatings), welding, glassblowing, and tanning (sunbeds). Most of these processes involve UVA spectrum as the principal operating wavelengths; however, many of these sources also emit some UVB, UVC, and violet light. Only artificial sources emit UVC radiant energy. Prior to the mid-1970s, mercury lamps emitting UVB and UVC were the main source of UV radiation; subsequently, UVA sources replaced mercury lamps emitting 95–99% UVA radiation with typical peaks at 340, 350, and 366 nm. Artificial sources of UV radiation include incandescent (tungsten) lamps, gas-discharge lamps (mercury, xenon, hydrogen, flash tubes), electric-discharge lamps (carbon arcs, welding arcs), arc lamps, metal halide lamps, fluorescent lamps, electrodeless lamps, and some lasers (gas, dye, excimer). Xenon arc lamps encased in UV protective coatings have replaced the older carbon arc lamps used in older movie theaters; the latter emitted substantial amounts of UVB radiation.[32] In contrast to most artificial sources of UV radiation, laser units emit UV radiation at a specific wavelength (i.e., the usual range, ~300–350 nm). The exceptions to this range of wavelengths are argon excimer lasers (193 nm) and krypton excimer lasers (222 nm, 248 nm). Although exposure to artificial sources of UV radiation is common, the sun is the major source of UV exposure for most people. Exceptions include medical therapy and cosmetic tanning.

Light Sources

Artificial, low-intensity UV radiation sources include sunlamps, black-light lamps, and low-pressure mercury-vapor lamps, whereas high-pressure mercury-vapor and xenon arc lamps, welding arcs, plasma torches, and xenon-mercury arc lamps are high-intensity UV sources. An analysis of general lighting and special fluorescent lamps by the National Radiological Protection Board indicates illumination levels associated with these lamps do not emit sufficient radiation to produce an acute or chronic hazard.[33] In general, UVB and UVC emissions from fluorescent light lamps are extremely low because the soda lime glass envelope attenuates wavelengths of <320 nm. The intensity of UV emissions from older commercial UVB lamps was high; UV radiation exposure potentially exceeded permissible exposure limits within 10 minutes.

Incandescent (heated filament) lamps are usually not a retinal hazard; these sources produce peak spectral emissions in the infrared range with relatively small amounts of UV radiation. Tungsten (quartz halogen) lamps operate at higher temperatures (2,900–3,450°K) and power than incandescent lamps; these halogen lamps can emit sufficient UV radiation to cause photokeratitis and erythema. UV radiation exposure is usually higher in TV studios than theater stages because TV studios use metal halide lamps more extensively.[34] A survey of these devices indicates the permissible exposure time ranged from 2–50 minutes. Low-pressure mercury discharge (germicidal) lamps produce a monochromatic emission at the wavelength of 253.7 nm that is a potential UV hazard. High-density discharge (HID) lamps used for industrial and commercial lighting emit blue/green/white light from mercury vapor along with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

large amount of UV radiation; however, the outer glass bulb usually absorbs most of the residual UV radiation. Compact (mercury, xenon) and linear arc lamps used as search lights and solar simulators produce very high luminance that can approach the luminance of the sun; these lamps possess the greatest potential for thermal retinal and UV-induced injuries. Flash lamps and flash tubes generate integrated radiance in the range of 10^4 J/m^2 ×sr (steradian) with a pulse duration of 2–4 msec. The envelopes of most flash tubes absorb UV radiation of <300 nm; however, some flash tubes used for lasing can produce significant quantities of UVB and UVA radiation.

Sunbeds

Currently distributed sunbeds usually emit ~95% UVA radiation with <5% in the UVB spectrum; however, evaluation of UVA lamps in tanning parlors and solaria typically requires individual evaluation. Reduction in UVA and UVB emission occurs with the aging of the lamp in the range of ~20–50% after 1,000 hours of use. Pre-1980 tanning lamps usually emitted primarily UVB radiation. The European standard for the erythemal-effective irradiance for sunbeds is ≤0.3 W/m^2; some sunbeds may exceed this recommendation. In a study of 402 English artificial tanning units, the mean irradiance was 0.56 ± 0.21 W/m^2 with a range of 0.10–1.32 W/m^2.[35] Four lamp types used in tanning equipment include: 1) UVB, filtered high-intensity discharge lamps; 2) UVB, low-pressure fluorescent tubes; 3) UVA, filtered high-intensity discharge lamps; and 4) UVA, low-pressure fluorescent tubes. UVB lamps are no longer common.[8]

Occupational Exposure

Outdoor Work

Indoor workers typically receive ~300 standard erythemal doses (SED) defined as 10 mJ/cm^2 annually, primarily from recreational exposures, whereas outdoor workers at the same latitude receive ~3–5-fold greater UV exposure (i.e., >1,000 SED).[36] Workers with the greatest potential exposure to substantial amounts of solar radiation include construction workers, gardeners, agricultural employees, seafarers, water sport instructors, and lifeguards, whereas traffic police, mailmen, military personnel, and highway workers are typically less exposed depending on work activities and sun protection (e.g., hats, glasses, sunscreens, time/duration of sun exposure). A population-based survey of 889 French outdoor workers exposed to solar and artificial UV radiation demonstrated the highest UV doses in gardeners, construction workers, agricultural workers, and culture/art/social science workers as measured by median daily standard erythemal UV doses.[37] The portion of the body receiving the highest radiation dose depends on the activity and time of year. A study of 32 Italian vineyard workers demonstrated the back received 53–87% (median = 72%) of ambient sun exposure during spring compared with 36–77% (median = 50%) during the summer. The arms received 30–60% (median = 44%) during the spring compared with 19–43% (median = 29%) during summer.[38]

The springtime sun exposure exceeded the assumed threshold for sun-adapted skin in Mediterranean subjects defined as 10 SED (standard erythemal dose). In a study of 838 watermen from Chesapeake Bay, the estimated annual facial dose ranged from 30–200 MED (minimal erythema dose) based on the face receiving 5–10% of the ambient sun exposure. Assuming that the face absorbs 20% of the ambient solar radiation, the annual facial dose increases to 80–500 MED.[39] A study of Swiss outdoor workers suggests horizontal body locations receive 2.0–2.5-fold greater sun exposure than vertical locations; in this study, eating lunch outdoors daily added the equivalent of an extra day/week of occupational-related sun exposure.[40] Indoor workers with high-potential UV exposure include welders, television studio/theater staff, workers using photo curing equipment (dental, paper, graphics), and some medical/scientific workers.

Glassblowing

Most craft glassblowers use soda-lime glass, whereas scientific glassblowers usually handle borosilicate, cobalt, or quartz glass materials. During the heating and melting of glass materials, scientific glassblowers use lathes and tabletop heating systems; craft glassblowers use furnace systems. A cross-sectional survey of optical radiation associated with glassblowing suggests limited radiation in the near-UV wavelengths (315–400 nm). Potentially high irradiance occurs in the visible wavelengths (400–700 nm).[41] Glassblowing with soda-lime glass may also produce excessive irradiance in the near-infrared range (700–1,400 nm). Ocular abnormalities may develop in the cornea, lens, or retina as a result of excessive irradiance, including cataracts, keratitis, chronic dry eyes, and reduced visual acuity.

Welding

Welding arcs are the predominant and most intense artificial sources of UV radiation in the workplace.[42]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

UV radiation emitted from arc welding is complicated and highly variable, depending primarily on the metal welded and the shielding gas with several other factors modulating the UV spectrum. including electrode type, arc voltage/current, arc gap, shielding flux, fumes/smoke generated, time during the process, and joint geometry.[43] The optical radiation generated by welding includes UV, infrared, and visible radiation, depending on the specific process used.[44] Gas welding produces minimal optical radiation hazards. Oxyacetylene and oxyhydrogen flames burn at temperatures of >2000°K; these flames emit some UV radiation mostly in the UVA range. Oil, coal, and gas flames emit essentially no UV radiation. Arc welding fuses metals with the heat (~3,870°C) of an electric arc. The UV irradiances associated with arc welding are high enough to produce photokeratitis up to 20–30 m from the source.[45]

DOSE EFFECT

Biological effects of UV radiation depend on the wavelength. Because the absorption of UV radiation occurs superficially over a surface, the most common radiometric quantity used to describe the amount of exposure is the radiant energy defined as the incident energy divided by the receptor surface area and designated H_e (J/m^2). Irradiance measures the dose over a specific time, defined as the incident power divided by the receptor surface area and designated E_e (W/m^2). The proper determination of a hazard from UV radiation requires spectral emission data that sums the total irradiance over all wavelengths emitted. These data are normalized by a biological or hazard weighting factor to determine the biologically effective irradiance over the exposure period, called the biologically effective radiant exposure ($J_{effective}$/m^2).

Skin

Sunburn

Sources of UV radiation are characterized by the radiometric units of energy or dose (mJ/cm^2) and power or dose rate (mW/cm^2). The minimal erythemal dose (MED) is the UV exposure that produces barely visible erythema 8–24 hours after irradiation of the skin. This dose varies in individuals based on skin type and prior skin exposures.[46] Consequently, a standardized unit is also used, defined as standard erythemal dose (SED) equal to 10 mJ/cm^2. Table 46.3 compares the MED and SED for different skin types. The UV Index is an estimate used in public health settings to measure the sunburn risk during specific meteorological conditions; this value corresponds to 0.9 SED/hour (0.025 W/m^2). The UV Index ranges from low (<2) and moderate (3–5) to high (6–7), very high (8–10), and extreme >11. The minimal erythema dose (MED) is a unit of effective dose (dose weighted to produce a specific biological effect); this value represents the effective radiant exposure of UV radiation necessary to cause adverse effects in the skin. Unlike thermal exposure, the onset of erythema is delayed by 1–6 hours, depending on the UV dose. Blistering occurs at 6–10 MED.[47]

TABLE 46.3. Skin types and average threshold exposure necessary to produce sunburn with and without adaptation as measured in Minimal Erythema Dose (MED) and Standard Erythema Dose (SED). (Adapted from International Commission on Non-Ionizing Radiation Protection).[46]

Skin Type (Phototype)	MED Without Adaptation[a] (SED)[b]	MED with Adaptation[a] (SED)[b]
I–II (Celtic)	2	5
III–IV (Mediterranean)	5	12
V (Asian)	10	60
VI (Black)	15	80

[a] Three weeks of tanning from solar re-exposure without erythema defines adaptation. [b] The SED approximates the average MED as a result of wide variation in MED values between skin types.

The MED ranges from 15–200 mJ/cm^2, depending on several factors, including skin type (i.e., higher in dark skin),[48] the skin thickness,[49] UV intensity, wavelength, and environmental factors (e.g., wind, humidity, season, time of day).[8] The maximum sensitivity of the skin occurs in the UVB range at 295 nm.[50] For white skin, the MED averages ~20–30 mJ/cm^2 varying 4-fold between individuals with this type of skin pigment.[51] For indoor workers in mid-latitudes (40–60°N), the annual solar radiation dose to the face is ~40–160 MED compared with ~250 MED for outdoor workers;[14] outdoor workers receive ~10% (range, 7–18%) of the total available annual UV irradiance measured on a horizontal plane, whereas indoor workers and children receive 2–9-fold less (~3% with a range of 2–4%).[52]

Although up to 800–1,000 times more UVA radiation is necessary to produce the same amount of erythema as UVB radiation, UVA may contribute up to 15% of the erythematous dose at noon because UVA is much more abundant at that time of day.[53] Table 46.4 compares the ability of each type of UV radiation to produce skin changes.

The minimal erythema dose (MED) for nontanned, lightly pigmented individuals ranges from 6–30 mJ/cm^2, with skin pigmentation and conditioning changing the MED by one order of magnitude.[55]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 46.4. Skin changes associated with subsets of UV radiation. (Adapted from Pathak).[54]

Effect	UVC (200–290 nm)	UVB (290–320 nm)	UVA (320–400 nm)
Minimal erythema dose (MED, mJ/cm^2)	10–25	20–70	20–100
Onset erythema (hours)	0.5–1.5	2–6	4–6
Peak erythema (hours)	6–8	20–24	10–12
Duration erythema (hours)	48–72	72–120	36–48
Immediate tanning	None	Low	High
Melanogenic	Low	High	Moderately high

Wind intensifies the adverse erythematous effects of UV radiation on the skin based on animal experimentation.[56] Compared with UVB intensity at sea level, the amount of UVB radiation increases by 4% with each 1,000 ft increase in elevation.[1] Clouds absorb infrared radiation better than UV radiation. The amount of UV radiation absorbed by clouds is variable, ranging from 10–80% and averaging ~40%. Reflective surfaces (e.g., snow, ice) may increase UV exposure by reflecting most of the incident UV radiation. Reflection of UV radiation from water is usually small (~5% at midday), depending on the angle of the sun in the sky, the contour of the surface of the water, and the clarity of the water.[1] Outdoor activities may provide substantial cumulative UVB exposure, particularly among athletes (e.g., golfers, mountain climbers, cyclists, marathon runners, skiers).

Snow skiers are susceptible to sunburn because of the increased amount of UV radiation from the altitude, reflectance, and wind.[57] In a study of young skiers evaluated by shoulder dosimeters, the median UVB dose for 4–5 hours of skiing was 2.1 SED with a range of 0.7–4.9 SED.[58] The median daily UV exposure for a group of hikers was 8.1 SED as measured by shoulder dosimeters, whereas tennis players received a daily median dose of 7.5 SED during training as measured by wrist dosimeters.[59]

Tanning

Melanin is the ideal sunscreen because it absorbs all UV radiation and limits the action of free radicals in the skin. Although all races possess similar numbers of melanocytes, the packaging and distribution of the melanocytes in black skin increases the MED up to 30 times compared with Caucasian skin.[1] Adaption to UV radiation results from hyperplasia of the epidermis, principally from increased production of melanin and expansion of the stratum corneum.[60] In patients with psoriasis, tolerance to UV radiation increases the MED up to 28-fold (mean = 13-fold) above pretreatment values; tolerance decreases over 6 weeks to <2 times the pretreatment MED.[61] UVA is much less effective at stimulating an increase in the horny layer of the epidermis. Most wavelengths in the UVB spectrum produce tanning and erythema.[53]

Photoaging

Skin changes associated with chronic solar radiation include solar lentigines, mottled pigmentation, dry/rough skin, wrinkles, leathery texture, and benign/malignant tumors. In a Japanese study, the estimated average annual UVB radiation dose in central Japan was 200 MED (minimal erythema dose) with a cumulative dose of 4,000 MED at age 20 years based on 1 MED equivalent to 20 mJ/cm^2.[62] The maximum daily UVB dose was 22 MED. The mean *daily* sun exposure time to maintain sun-exposed skin without solar lentigines (i.e., the most sensitive effect of sun exposure) until 80 years of age was 2.54 minutes (0.14 MED) for unprotected skin and ~2 hours for the use of SPF 50 sunscreen. The lens and cornea typically shield the retina from the acute effects of UV radiation; however, in aphakic monkeys, the threshold for acute photoretinitis is ~500 mJ/cm^2.[63]

Eye

The cornea and conjunctive strongly absorb UVB and UVC radiation. The external UV dose received by the eye depends on several factors including facial anatomy, solar elevation angle, altitude, atmospheric modification (ozone, air pollution), time of day, and ground reflectance.[64] In contrast to the large variation in individual responses of skin to UV radiation, all racial types are susceptible to cataracts and UV radiation-induced eye diseases. The threshold radiant exposure for corneal injuries ranges from <1 mJ/cm^2 at 270 nm (UVC) to 10.6 mJ/cm^2.[45] Maximum sensitivity of the eye occurs at 270 nm.[65] Two nurses were accidentally exposed for 4–6 hours to a germicidal lamp (UVC/UVB) with an estimated skin and eye effective irradiance of 194 times and 126 times, respectively, according to the ICNIRP guidelines.[66] They developed bilateral keratoconjunctivitis (conjunctival injection, blurred vision, tearing)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and facial erythema 12–24 hours after cessation of exposure. The facial skin demonstrated chronic erythema, swelling, and telangiectasia 2 months after exposure; superficially punctuated keratopathy with lacrimal hyposecretion (dry eyes) persisted over 1 year after the initial injury.

Repeated UV exposure does not reduce the threshold for corneal injury in humans. Exposure of pilots to UV radiation during flight is highly dependent on the UVA-blocking properties of the airplane windshield and the use of sun glasses; epidemiology studies did not detect significant exposure to UVB radiation in pilots.[67] Corneal injury from UVA radiation requires >1,000 mJ/cm^2.[68] In rodent studies, thresholds for the development of transient opacities vary dramatically with wavelength (15–1,260 mJ/cm^2).[69] Additionally, animal studies suggest sensitivity to UVB-induced cataract formation decreases with increasing daily exposure.[70]

Immune System

A single dose of UVB in the range of 100 mJ/cm^2 alters Langerhans cell function and IgA receptors resulting in decreased antigen-induced contact sensitivity based on volunteer and rodent studies.[71] A single dose of UVB radiation in the range of 60–80 mJ/cm^2 almost completely eliminated Langerhans cell markers, whereas pemphigus antigens of keratinocytes were unaffected. Electron microscopy demonstrated ultrastructural changes only in Langerhans cells in the epidermis at UVB doses of 15–30 mJ/cm^2 or UVA doses of 1×40 to 2×100 mJ/cm^2. Rodent studies suggest exposure to UV radiation doses of <1 MED exacerbates a variety of infections (e.g., *Herpes simplex*,[72] *Mycobacterium lepraemurium*[73]).

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Most, but not all ecological studies of UV radiation and mortality suggest a beneficial effect of UV exposure because of vitamin D production by UVB (290–320 nm). Radiation in this spectrum converts 7-dehydrocholesterol to previtamin D that the liver and kidneys transform into the active form of vitamin D. Lack of vitamin D production in the skin increases the risk of adverse bone and skeletal effects in workers without adequate sun exposure (e.g., underground miners, long-haul flight crews, shift workers).[43] Many American indoor workers do not meet their daily minimum (600 IU) or optimum (≥1,200 IU) vitamin D_3 requirements, particularly darker skin types (III–VI) and older workers (>59 years), even with a 2–3 week summer vacation.[74]

UV radiation is nonionizing; this type of radiation affects biological molecules either by altering the electron energy levels of the atoms or by altering their rotational, transitional, or vibrational energies. These changes result in electron excitation that potentially produces the following effects: 1) degradation into heat, 2) formation of free radicals, 3) fluorescence or phosphorescence, or 4) dissociation of the molecule. DNA is a critical target for excessive UVB and UVC radiation, which cause a variety of adverse effects including chromosome changes, mutations, morphological transformations, and cell death.[8] Although damage to cell membranes and organelles may contribute to the toxic effects of UV radiation, the primary species produced by the interaction of UV radiation with cells are reactive species (free radicals). UV radiation can activate some genes and viruses including HIV, but *in vitro* studies indicate UVA radiation-induced activation differs from UVB and UVC radiation.[75]

Skin

The skin contains molecules or chromophores that scatter UV rays and absorb solar radiation (UVB, UVA, visible, infrared radiation); melanin and primarily eumelanin are the main chromophores in the skin. UV radiation doses exceeding the absorptive capacity of melanins produce an erythematous reaction (sunburn) from the release of a variety of inflammatory mediators including cytokines, chemokines, nitric oxide, histamines, and prostaglandins. UVA causes an immediate tanning response that begins soon after exposure from the release of preformed melanin; this response quickly fades. The melanotic reaction results primarily from UVB-induced stimulation of melanocyte production.[54] UVB radiation-induced delayed tanning increases melanin synthesis and the transfer of melanin via dendrites to adjacent keratinocytes. Several factors influence UV radiation-induced melanin synthesis, including inflammatory mediators, cytokines, and growth factors. Black/brown eumelanin is the primary type of melanin in dark skinned individuals, whereas yellow/red pheomelanin predominates in light-skinned, freckled individuals (skin types I–II); the latter is much less photo-protective than the former. The type of melanin in the skin accounts for differences in skin susceptibility to sun exposure. Eumelanin is a stable free radical that transforms UV energy into heat by internal conversion; pheomelanin lacks this property and produces reactive oxygen species following overexposure to the sun.[76]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Major alterations in the histology of the epidermis involve the replacement of Langerhans cells by dyskeratotic and vacuolated keratinocytes (sunburn cells).[77] Mast cell degranulation with perivascular edema occurs acutely in the dermis along with a more protracted alteration of the endothelial cells that coincides with the period of maximum erythema. UVA radiation produces fewer sunburn cells but greater dermal infiltrate and vascular damage compared with UVB radiation[1]; consequently, UVA radiation also contributes significantly to photoaging, immunosuppression, and photocarcinogenesis.[78] The effects of UVB and UVA radiation on dermal thickness are substantially less than those on the epidermis. The effect of visible (400–700 nm) and the higher energy portion of infrared radiation (700–3,000 nm) on skin pathology is generally considered small; however, this portion of solar radiation may contribute to erythema, pigmentation, thermal damage, free radical production, and photoaging.[79] In contrast to the photochemical reactions produced by UV radiation, infrared radiation typically causes molecular vibration and increased temperature; however, infrared radiation may enhance UV radiation-induced generation of reactive oxygen species.[80]

Experimental evidence suggests the sunburn response decreases and evolves more slowly following UV exposure in the elderly.[81] An increase in the number and thickness of amorphous elastic fibers in the upper dermis is the most prominent histological change in skin chronically exposed to the sun.[7] Other chronic skin changes include thickening of the epidermis (keratinocyte proliferation), tortuous and dilated dermal vessels, the appearance of actinic keratosis and facial telangiectasias, increased number and prominence of freckles, and a hypercellular dermis manifested by an increase in mast cells and fibroblasts. The amount of mature collagen in skin chronically exposed to the sun decreases with photodamage. The mechanism of toxicity involves the UV radiation formation of reactive oxygen species, resulting in the expression of transcription factors (e.g., AP-1, TGF-β) that enhance collage breakdown and downregulate collagen synthesis.[82] The shorter UV wavelengths (UVB, UVC) damage collagen, whereas all wavelengths in the UV spectrum cause hyperplasia of elastic fiber and increased glycosaminoglycans.[83]

Eye

Ocular tissues affected by UV radiation include the eyelids, conjunctiva, cornea, crystalline lens, and retina. Ocular damage because of UV radiation occurs primarily in the cornea and lens; however, retinal injury can occur, particularly in persons without lenses to absorb UV radiation. Snow blindness and arc welders' photokeratitis are examples of acute corneal damage from UVB exposure. Retinal injuries in sun-gazers probably result from exposure to the shorter wavelengths of the visible spectrum as well as UV exposure.[84]

The cornea consists of the following five zones (exterior to interior): 1) 5-layered, ~50 μm thick, nonkeratinized squamous epithelium with apoptotic cells on the outer layer; 2) Bowman layer of randomly oriented, fine collagen fibrils ~10 μm thick; 3) the relatively thick stroma consisting of 60–70 successive layers of obliquely oriented, tight collagen fibrils (corneal lamellae) embedded in an extracellular matrix composed primarily of sulfated glycosaminoglycans; 4) a thin, PAS-positive endothelial basement membrane (Descemet membrane); and 5) a monolayer of nonmitotic, hexagonally flattened mesothelial cells (corneal endothelium). Nucleic acids and amino acids function as corneal chromophores to absorb wavelengths of >295 nm. The cornea attenuates almost all UV radiation of <290 nm, whereas the lens eliminates most UV radiation of 300–370 nm. The shorter wavelengths (UVB, 280–315 nm) contain more energy than UVA (315–400 nm); therefore, UVB light possesses greater potential to produce damage to the cornea and lens than UVA or visible light (400–700 nm). The corneal transmittance of UV radiation increases between ~280 and 320 nm, with maximum transmittance in the visible spectrum; the epithelium absorbs most of the UVA light (315–400 nm).[85] Maximum sensitivity of the cornea to UV radiation occurs at 270 nm.[86] Although some thickening of the epithelium may occur during the summer months, the cornea does not readily adapt to repeated UV exposure as the skin does.[87]

The three fundamental types of solar radiation-induced damage are: 1) thermal; 2) mechanical; and 3) photochemical.[88] Thermal and mechanical damage occur following the use of lasers. Photochemical damage results from prolonged exposure to large amounts of blue and ultraviolet radiation. Photokeratitis is the acute response to excessive UV radiation (e.g., snow blindness, welders flash) that manifests by damage to the epithelium and, in more serious injuries, to the stroma (keratocytes) and endothelium. Depending on the severity of the UV exposure, slit-lamp examination reveals debris in the tear film from cells shed from the epithelium, haze and granules (tiny bluish amorphous opacities) in the epithelium, opacities in the stroma, and keratic precipitates in the endothelium. The anterior chamber may demonstrate flare (scattering of light beam on small particles) as a result of the release of plasma proteins from local blood vessels. Corneal

edema may develop with alteration in corneal thickness and vision. Chronic UVB radiation exposure may damage the endothelium, resulting in enlargement of the remaining (nonmitotic) cells and bulging of the endothelial membrane.[89] The amount of retinal damage (e.g., solar retinitis, arc welders' maculopathy) depends on the wavelength, power, and duration of exposure. The human lens contains a group of chromophores that absorb radiation near the UV range; these cells increase in number with age. At wavelengths >290 nm, tryptophan residues are the major chromophores; oxidative damage to the components of the lens accounts for the initiation of cataracts.[90]

Immune System

UV radiation-induced immunosuppression is a complex process involving multiple pathways, mediators, and T/B cell types.[91] Although UV radiation is a potent inflammatory agent that activates macrophages, neutrophils, and T-lymphocytes, it also causes immunosuppression by downregulating cell-mediated immunity in the mouse model.[92] Langerhans cells are mobile, dendritic, antigen-presenting cells present in all stratified epithelium. These cells originate from CD34+ (cluster of differentiation 34 positive) T cells that process exogenous antigens deposited on the skin and present these antigens to T cells; these cells may also activate mast cells in the epidermis and regulatory cells (e.g., natural killer T cells) in the draining lymph nodes. Suppression of immune responses probably results from UV radiation-induced release of soluble mediators and cytokines (IL-4, IL-10) that alter the presentation of antigen by Langerhans and other cutaneous dendritic cells. The resultant reduction in T-helper-1 cell activity increases susceptibility to infection.

Certain patients respond to solar radiation by developing photodermatological disorders. Photosensitivity disorders occur from the spectral activation of certain chemicals by UV radiation (phototoxicity) and the direct activation of the immune system (photoallergy). The presence of dense perivascular round-cell infiltrates distinguishes photoallergic reactions from phototoxic reactions. Photoimmunological diseases include polymorphous light eruptions, chronic actinic dermatitis, and cutaneous lupus erythematosus. The former displays many histological features of a delayed-type hypersensitivity reaction. Within a few hours after exposure of patients with polymorphous light eruptions to solar radiation, CD4+ T cells begin infiltrating the area of the skin exposed to UV radiation followed in the next few days by CD8+ T cells. UVA and, less commonly, UVB radiation (rarely UVC) are most commonly associated with this disease.[93] A variety of other molecules facilitate the migration of T cells to the UV radiation-exposed skin including intercellular adhesion molecule-1, vascular cell adhesion molecule 1, and adhesion molecules E-selectin (CD62).[94] These patients are more resistant to the immunosuppressive effects of UV radiation than patients without this disease. Patients with chronic actinic dermatitis are highly photosensitive; UVB radiation causes a subacute to chronic inflammatory process in sun-exposed areas; the lesion may progress to the skin without sun exposure. UVA radiation and visible light also may cause this disease. The pathophysiology of this disease is not well described.

Carcinogenesis

Skin cancers associated with solar radiation include basal cell carcinoma, squamous cell carcinoma, and melanoma. UV radiation is a complete carcinogen causing direct damage to genes that regulate growth/proliferation (e.g., *RAS*-family proto-oncogenes, *MAPK*-family,) and/or tumor suppression (e.g., *TP53*, *PTCH*-family). UVB is the most effective portion of the solar spectrum to cause DNA damage, including the formation of cyclobutane pyrimidine dimers between adjacent thymine or cytosine residues and pyrimidine (6-4) pyrimidone photoproducts among adjacent pyrimidine residues.[95,96] Animal and experimental studies suggest peak carcinogenic effects of UV radiation for squamous cell carcinoma occur at 293 and 305 nm, with smaller secondary peaks at 354 and 380 nm.[97,98] The maximal wavelengths for basal cell carcinoma and DNA damage are also primarily in the 302–306 nm range. There are insufficient data above 390 nm to determine the contribution of visible and infrared radiation; however, current evidence suggests that the effect is relatively small compared with UVB radiation below 320 nm.[64]

Chronic, excessive UV radiation exposure causes disruption of cellular control mechanisms and oxidative damage to DNA, resulting in skin inflammation, immunosuppression, photoaging, and carcinogenesis. UV radiation-induced effects enhancing the development of skin cancer include the formation of reactive oxygen species, reactive nitrogen species, and immunosuppression. The former two types of reactive oxidative species produce DNA damage (e.g., single-stranded breaks, DNA-protein crosslinks, altered DNA bases); guanine bases are particularly susceptible to oxidative conversion to 8-hydroxyguanine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

forming 7,8-dihydro-8-oxoguanine. UVA radiation is more effective than UVB in producing the latter reaction,[99] particularly the 360–380 nm portion, as a result of increased susceptibility of basal keratinocytes to UVA-induced mutations.[100]

DNA damage from UV radiation-induced immunosuppressive effects involves modification of the antigen-presenting function of cutaneous dendritic cells (i.e., Langerhans cells, dermal dendritic cells, macrophages/monocytes), generation of effector T cells, and stimulation of epidermal keratinocytes to produce immunosuppressive cytokines.[93] Immunosuppressed renal transplant patients have a 10-fold increased risk of basal cell carcinomas, whereas the risk of cutaneous squamous cell carcinomas in these patients is 65–250-fold.[101] Activation of T cells requires antigen-presenting cells (i.e., cutaneous dendritic cells including Langerhans cells). Alteration of these antigen-presenting cells by UV radiation promotes effector T cell production by stimulating interleukin 12 (IL-12). UV radiation does not affect the *number* of regulatory (suppressor) T cells. The net result is a suppressed immune response.[102] Reprogramming of regulatory T cells produced following UV radiation also suppresses skin immunity by increasing the immunosuppressive cytokine IL-10 (CD4+, CD25+, CTLA4+, FoxP3+), tumor necrosis factor, PGE2 (prostaglandin E2), and Th2 cytokine IL-4 (Natural Killer/T cell-induced interleukin-4). The latter suppresses anti-tumor immunity.[103]

A variety of other soluble mediators produced following UV radiation contribute to immunosuppression and DNA damage, including α-melanocyte-stimulating hormone, neuropeptides (e.g., calcitonin gene related peptide), serotonin, platelet activating factor, and *cis*-urocanic acid. The latter three mediators produce immunosuppression by inhibiting DNA repair processes, including direct repair, base excision repair, double-strand break repair, mismatched base repair, and nucleotide excision repair.[104] UV radiation upregulates the p53 protein that blocks cell replication prior to DNA repair process. Typically, functional cellular repair systems eliminate the UV-induced DNA damage with ~50% of the cyclobutane pyrimidine dimers repaired within the first day.[105] Severe damage activates the apoptotic pathways that eliminate the damaged cell. UV radiation also generates reactive oxygen and nitrogen species capable of inducing oxidation, including molecules listed in Table 46.5. In the skin, UVA radiation appears more efficient than UVB in inducing oxidatively generated damage to DNA bases and 2-deoxyribose moieties.[106]

TABLE 46.5. UV radiation-induced reactive oxygen and nitrogen species in skin receiving solar radiation.

Reactive Oxygen Species (ROS)	Reactive Nitrogen Species (RNS)
Hydroxyl radical (·OH)	Nitric oxide (NO)
Superoxide radical ($\cdot O_2^-$)	Nitrogen dioxide (NO_2)
Singlet oxygen ($^1O_2$, O=O)	Peroxynitrite anion ($OONO^-$)
Hydrogen peroxide (H_2O_2)	
Ozone (O_3)	

CLINICAL RESPONSE

Skin

Sunburn/Tanning

Following exposure to UV radiation, a biphasic pattern of tanning begins. Immediate pigment darkening results from the UVA-induced photooxidation of preformed melanin. This process results from the oxidation of preexisting melanin and redistribution of melanosomes from perinuclear to peripheral dendritic locations in melanocytes rather than synthesis of new melanin. Immediate pigment darkening is minimally photo-protective; this response fades within several hours with delayed pigment darkening beginning within 3 days and peaking 7–10 days after exposure. Table 46.6 outlines the six skin types based on the self-reported history of sunburn and suntan.[107]

Photosensitivity

Photosensitivity disorders occur because of the spectral activation of certain chemicals by UV radiation (phototoxicity) and the direct activation of the immune system (photoallergy). Agents that produce phototoxic reactions include drugs (sulfonamides, thiazides, nonsteroidal anti-inflammatory drugs, tetracycline), topical agents (benzocaine), and plant constituents. Psoralens (i.e., the parent compound of furocoumarin compounds) are a major group of chromophores in plant phototoxicity; exposure to citrus (limes, lemons, oranges), pine wood, perfumes, parsley, carrots, parsnips, figs,[108] or celery can cause a phototoxic reaction,[108,109] particularly when these compounds are consumed immediately prior (e.g., 1 hour) to UVA radiation exposure from commercial tanning booths.[110] The appearance of photoallergic reactions includes erythema, vesiculation, and urticaria; these lesions may resemble type IV hypersensitivity reactions, chemical burns, and atopic dermatitis.[111] Often, a transient pruritus precedes the rash.

TABLE 46.6. Six types of skin responses to solar radiation. The Fitzpatrick classification divides these skin types by scoring genetic predisposition, reaction to sun exposure, and tanning from 0–4. (Adapted from Council on Scientific Affairs).[53]

Skin Type (Sun Sensitivity)	Sunburn History	Appearance	Tanning
I (Very sensitive)	Always burns easily	Red hair with freckles	Never
II (Moderately sensitive)	Always burns easily	Fair-skinned and fair-haired Caucasians	Minimal, light
III (Moderately insensitive)	Burns moderately	Darker Caucasians	Medium[a]
IV (Insensitive)	Burns minimally	Mediterranean type: Caucasians, some Hispanics	Dark[b]
V (Insensitive)	Rarely burn	Some Hispanics/blacks	Naturally brown[c]
VI (Insensitive)	Never burn	Darker blacks	Naturally black[d]

[a] Gradually tans light brown uniformly. [b] Always tans moderate brown. [c] Tans dark brown profusely. [d] Deeply black pigmented.

Polymorphous light eruption is the most common type of idiopathic photosensitive reaction; this condition affects 14–28% of the young adult female population in Europe. In other parts of the world, the prevalence of this disease varies from 1–21%.[112,113] Typically, this pruritic, papular, erythematous rash develops in sun-exposed areas of the skin in the late spring or early summer, beginning in patients during the second or third decade of life. This condition results from exposure to UVA radiation; therefore, sunscreens may not protect the skin of these patients.[114] Patients with chronic actinic dermatitis develop an exquisite photosensitivity beginning in sun-exposed areas; the skin lesion may become chronic and progress to skin without direct sun exposure.

Photoaging

Chronic sun exposure produces dose-dependent skin changes ranging from solar lentigines, spotty pigmentation, wrinkles, dry skin, alteration in texture (rough, leathery, furrowed, poor elasticity) of the outermost skin layers, telangiectasia, and benign/malignant skin cancer depending on skin type.[115] In light skin types, the 3–5-fold thickening of the stratum corneum within 1–7 weeks of several UVB exposures provides protection from excessive sun exposure in addition to tanning; however, the affected skin returns to normal thickness 1–2 months after sun exposure ceases.[46] In studies of Japanese subjects, the first signs of photoaging are solar lentigines that may occur as early as 20 years of age.[62] Fine wrinkles may appear after 30 years of age with seborrheic keratoses, and benign skin tumors begin appearing after 35 years of age. In contrast to deep furrows and leathery appearance of photoaging, fine lines and modest skin laxity are associated with the skin changes of chronological aging.

Eye

Keratoconjunctivitis (Welder's Flash)

Excessive short-wave UV radiation (<300 nm; maximum sensitivity, 270 nm) produces conjunctivitis, erythema of periocular skin, photophobia, lacrimation, and blepharospasm depending on the dose. The foreign body sensation, light sensitivity, and pain typically develop within 6–12 hours, with resolution within 48 hours as re-epithelialization of corneal surface occurs. Permanent ocular injury from keratoconjunctivitis is unusual.

Anterior Segment

An acute keratoconjunctivitis (photokeratitis) is a common adverse effect of arc welding.[116] Photophobia, a gritty feeling, and tearing typically develop several hours after exposure, depending on the radiation intensity. Although slight improvement in vision may occur initially as a result of the shedding of epithelial cells, vision deteriorates as stromal edema develops along with swelling (chemosis) and conjunctival injection. Symptoms usually resolve within several days because of the rapid regeneration of corneal epithelium. Pterygium, pinguecula, and chronic visual disturbances (photophobia, chronic blepharoconjunctivitis, climatic droplet keratopathy) may result from continuous, excessive exposure to solar UV radiation.[117] However, a study of 77 journeymen welders did not demonstrate an increased incidence of visual abnormalities or alteration of the anterior segment of the eye.[118] Although phototoxic compounds (e.g., psoralens) may reach the avascular cornea via tears, air, or aqueous humor, the cornea is much less sensitive to phototoxic agents than the skin.

The development of cataracts is multifactorial including age, diabetes, nutrition, obesity, cigarette smoking, genetics, alcohol, steroids, and brown irises.[119,120] UV

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

radiation is a potential risk factor for the development of cataracts based on studies associating an increased incidence of cataracts with high UV radiation levels,[121,122] latitude,[123] and sunny locations;[124] however, UVB exposure alone does not account for the development of cataracts with age. A study of 2,520 65–84-year-old community-dwellers in the United States revealed a modest (13%) attributable risk for cortical opacity in patients with high UVB exposure.[125] In the cross-sectional Beaver Dam study of 2,646 women and 2,082 men, average annual ambient UVB exposure as measured by questionnaires was associated with cortical opacities in men (OR = 1.36; 95% CI: 1.02–1.79), when comparing men above and below the average sun exposure in Wisconsin.[126] The odds ratio in women for the two sun exposures was not significant (OR = 0.94, 95% CI: 0.70–1.26). Although the human cornea filters out all UVC (100–280 nm) and some UVB light (280–295 nm), the transmission characteristics change with age.[127]

Currently, there is sufficient evidence in animals to link cortical and posterior subcapsular cataracts to chronic exposure to UVB, but the evidence for causation in humans is limited.[8] Consequently, insufficient evidence is available to determine the number of cataracts attributable to UV radiation or separate the contribution of UV radiation from other causative factors in the formation of cataracts. A study of 838 watermen demonstrated a positive association between UVB radiation and the development of cortical cataracts, but there was no correlation between UVB or UVA radiation and nuclear or posterior subcapsular cataracts.[128]

Posterior Segment

The absorption of UV radiation in the anterior segment of the eye usually limits the effects of UV radiation on the retina unless the lens is absent. Retinal damage is more likely near the UVA range of ~235–441 nm.[129] Virtually no UV radiation reaches the retina in people over 25 years of age, whereas UV transmission is ~75% in people under 10 years of age.[130] Measurement of cone sensitivity in patients who had undergone bilateral cataract extraction demonstrated a 1.7 times reduction in cone sensitivity after 5 years.[131] The cross-sectional Beaver Dam study did not detect an association between posterior cataracts or nuclear sclerosis and UVB exposure in men or women.[126]

Immune System

Animal studies suggest UVB radiation alters antigen processing during the development of contact hypersensitivity in addition to initiating damage to DNA in the nucleus of replicating cutaneous cells. Both UVA and UVB radiation impair the function of Langerhans cells.[132]

Some chemicals can sensitize the skin to UV radiation, particularly the UVA portion. The photosensitization reaction is proportional to the magnitude of the UV exposure. Photosensitizers include bacteriostatic soaps, cosmetics, sunscreens, antiseptics, plants, anthraquinone dyes, antimicrobials, and furocoumarins.

Reproductive Abnormalities

There are few data to indicate UV exposure causes reproductive abnormalities. A study of pregnancy outcomes following exposure to methoxsalen photochemotherapy (PUVA) did not indicate that PUVA was a potent teratogen.[133] In a study of 504 infants born to women after PUVA treatment and 689 infants born after treatment, no increased incidence of infant mortality or congenital malformations occurred.[134]

Carcinogenesis

The International Agency for Research on Cancer (IARC) and the US National Toxicology Program list solar radiation and broad-spectrum UV radiation (UVC, UVB, UVA) as known human carcinogens (cutaneous malignant melanoma; skin squamous cell carcinoma; skin basal cell carcinoma; lip cancer; conjunctival squamous cell carcinoma; choroid and ciliary body melanoma) based on sufficient evidence in epidemiology studies and animal models. Additionally, the IARC lists the use of welding (ocular melanoma) and UV-emitting tanning devices (choroid and ciliary body melanoma, skin squamous cell carcinoma) as carcinogenic in humans.[14] Solar and artificial UV exposure are the predominant environmental risks with host pigmentation (i.e., skin type) and sun sensitivity as major modifying factors. Cutaneous malignant melanoma and basal cell cancer correlate to measures of intense, intermittent sun exposure (i.e., sunburn) rather than cumulative UV radiation doses, particularly when the intermittent exposures occurred in childhood or adolescence.[135] In contrast, squamous cell carcinoma and lip cancer more closely correlate to cumulative exposure than intense, intermittent sun exposure. Associations between sun exposure and other cancers (e.g., non-Hodgkin lymphoma, breast, prostate, colon) are weak.

A prospective study using multivariate-adjusted Cox proportional hazards models and erythemal UV radiation doses for July based on satellite measurements

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from the NASA Total Ozone Mapping Spectrometer suggested an increased risk of death among elderly non-Hispanic US whites for cancer (men), cardiovascular disease, respiratory disease, and stroke (women).[136] The hazard ratio for the highest vs. lowest quartiles for cancer deaths was 1.06 (95% CI: 1.02–1.11). Several issues limit conclusions regarding the effect of UVA and UVB on disease rates including the effect of ozone on UV radiation (UVB≫UVA), the association of nonmelanoma skin cancers (i.e., primarily basal cell carcinoma) with UVA radiation, and the use of obesity data at the beginning of the study 12–14 years earlier.

Keratinocyte Skin Cancer

In Caucasian populations, UVB radiation is a causal factor in the development of basal and squamous cell carcinomas of the skin in most epidemiological studies, as measured by recalled episodes of acute, sun-related skin damage (multiple sunburns) and clinical signs of accumulated, sun-induced skin damage (actinic keratoses, photoaging, squamous cell carcinoma).[137] Squamous cell carcinoma has a more direct relationship to cumulative (or occupational) sun exposure in cohort studies.[14,138] In a meta-analysis of squamous cell cancer, the relative risk in outdoor workers was 1.8 (95% CI: 1.4–2.2) compared with indoor workers after adjustment for squamous cell carcinoma risk factors.[139] Basal cell carcinoma is more closely associated in a dose-related response with intense, intermittent sun exposure (i.e., sunburn) and signs of photoaging (actinic keratoses),[140] particularly recreational UV radiation exposure in youth.[141] The highest incidence (1,372 cases/100,000 population in men) of nonmelanoma skin cancer occurs in Queensland, Australia.[142]

Basal cell carcinoma is the most common skin cancer in US Caucasians of 40–79 years of age with an incidence rate four times higher than squamous cell carcinoma of the skin.[143] In a population-based Australian study of 2,374 participants with 5,150 keratinocyte cancers, most basal cell carcinomas were on the head/neck (40.2%) and trunk (33.4%), whereas 33.4% of squamous cell carcinomas were on the head/neck and 34.9% on the upper limbs.[144] The squamous/basal cell carcinoma ratio on the hand was 14:1. The higher incidence of basal cell carcinomas in less-sun exposed areas suggests the association of this keratinocyte skin cancer is more complex than that of squamous cell carcinomas.

Occupational studies of light-skinned outdoor workers suggest an increased risk of basal cell carcinomas in sun-exposed areas of the skin compared with indoor workers.[145] In a meta-analysis of 19 case-control and 4 cohort studies published before 2012 on occupational UV exposure and the incidence of basal cell carcinoma, the pooled OR comparing outdoor and indoor work was 1.43 (95% CI: 1.23–1.66, $P = 0.0001$).[146] The OR for the 19 case-control studies was 1.43 with a 95% CI of 1.19–1.72 ($P = 0.0001$), whereas the OR for the four cohort studies was 1.48 with a 95% CI of 0.83–2.66 ($P = 0.19$). Sources of heterogeneity were latitude, age, sex, and recreational UV sun exposure. Basal cell carcinoma is extremely uncommon in black skin. UVB radiation is both an effective inducer and promoter of skin cancer in rodents.[147]

The oncogenicity of UVA remains unclear. Animal studies suggest that UVA radiation possesses tumor-promoting effects as well as cocarcinogenic effects with UVB radiation.[148] A study of 4,799 Swedish patients treated with UVA radiation (PUVA) and psoralen for skin disorders demonstrated a dose-dependent increase in the incidence of squamous cell cancer of the skin.[149] Although the number of squamous cell cancers was small during the average follow-up of 7 years, the relative risk for the development of squamous cell cancer at doses of UVA radiation exceeding 1,200 J/cm^2 was high. The relative risks of highly exposed men and women were 27.2 (95% CI: 11.3–53.6, $n = 225$) and 13.2 (95% CI: 0.3–73.3, $n = 180$), respectively. Epidemiology data on the risk of nonmelanoma skin cancer and sunbed use are limited; most,[150] but not all,[151] existing data suggest little increased risk of nonmelanoma cancers following sunbed use.

Melanoma

The incidence of melanoma tripled from 1950–1990 in the United States,[152] increasing annually by 2.8% since 1981 in all histological subtypes and thicknesses, with some flattening the curve in recent years. The lifetime risk of developing an invasive melanoma in the US population is 1/56 for Caucasian women and 1/38 for Caucasian men.[153] Although the prevalence of cutaneous malignant melanoma is higher in Caucasian men, the recent annual increase in CMM incidence in Caucasian women of <44 years of age was 6.1%.[154] Worldwide, the incidence of cutaneous malignant melanoma is highest in Australia, followed by the United States and parts of Europe. The relationship between UV radiation and cutaneous malignant melanoma (CMM) is more complex than that between nonmelanoma skin cancers, including a less direct relationship between incidence rates and latitude with the development of CMM in areas of the body exposed to limited sun.[155] The latter may represent alternate pathways for the development of cutaneous malignant melanoma with different environmental and genetic risk factors.[156] Melanomas of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the head and neck are associated with actinic keratoses (i.e., sun damage), whereas melanomas on the trunk are associated with nevi rather than sun exposure.

Histological Subtypes

The most common type of melanoma is superficial spreading melanoma (~70%) followed by nodular melanoma (~20%). Lentigo maligna accounts for ~5–10% of the melanomas, and this subtype usually develops on the face of elderly patients. Acral lentigines melanoma is the rarest type of melanoma, occurring primarily in the palms, soles, nail beds, and mucous membranes. A meta-analysis of 24 observational studies of risk factors for cutaneous malignant melanoma subtypes suggests different risk factors for CMM subtypes on sun-exposed and intermittently sun-exposed body sites.[157] Lentigo maligna melanoma subtype occurs in older patients with a history of solar damage including nonmelanoma skin cancer, whereas superficial spreading melanoma and nodular melanoma histological subtypes occur more often in intermittently sun-exposed areas without sun-induced skin damage. Except for lentigo maligna, the location of melanomas does not match the areas of greatest sun exposure.

UV Exposure

In contrast to nonmelanoma skin cancer, the risk of cutaneous malignant melanoma in Caucasians increases less with long-term chronic UV exposure (e.g., outdoor occupation) than acute, intermittent, high-dose UV exposure (e.g., sunburn), particularly when UV exposure occurs during childhood.[158,159,160] In a systematic review of 23 case-control studies on the incidence of cutaneous malignant melanoma and intermittent, occupational, and total sun exposure, summary estimate of the odds ratio for intermittent sun exposure and CMM was 1.71 (95% CI: 1.54–1.90).[161] Sixteen of these studies demonstrated statistically significant associations; however, there was significant heterogeneity. Excluding three studies with outlying odds ratios, the overall OR was 1.87 (95% CI: 1.67–2.09). The overall OR for occupational sun exposure and cutaneous malignant melanoma was not increased (OR = 0.86; 95% CI: 0.77–0.96), whereas the OR for total sun exposure was marginal (OR = 1.18; 95% CI: 1.02–1.38; $n = 11$ studies) with substantial heterogeneity. Excluding three outlying odds ratios, the overall OR was 1.20 (95% CI: 1.00–1.44). Potentially, the prevalence of indoor workplaces in Western countries may limit the range of cumulative sun exposures in these studies.

Presentation

Clinical characteristics of a skin lesion suggesting melanoma include asymmetrical shape, irregular and well-defined border, multiple shades and colors, large diameter (>5 mm), and a raised lesion. In contrast to nonmelanoma skin cancer, CMM typically spares the face, hands, and forearms.[162] The EUROCARE study demonstrated summer peaks in melanoma incidence in Caucasian women (OR = 1.38, 95% CI: 1.31–1.44) and men (OR = 1.21, 95% CI: 1.14–1.29) from Western countries but not Central European countries.[163] The odds ratios for seasonal variability were higher for upper (1.44, 95% CI: 1.32–1.58) and lower limbs (1.46, 95% CI: 1.38–1.56) than head/neck (1.09, 95% CI: 0.99–1.20) or trunk (1.20, 95% CI: 1.12–1.29) regions. Although the lack of increased ascertainment on typically unexposed sites (e.g., trunk) suggests a pathological effect (e.g., late promotion effect), the confounding of greater skin exposure and increased observations of skin cancer limits conclusions regarding this association. Many melanomas appear in preexisting nevi.[164]

Risk Factors

Cutaneous malignant melanoma is a multifactorial disease with factors other than sun exposure contributing to the development of melanomas. Risk factors associated with melanoma beside solar radiation and sunbed use include Caucasian race; total acquired melanocytic (dysplastic) nevi; gender (men > women); family history of melanoma; familial atypical multiple mole melanoma (FAMMM) syndrome (cyclin-dependent kinase inhibitor 2A, cyclin-dependent kinase 4 mutations); and skin phenotype including expression of polymorphic melanocortin 1 receptor (*MC1R*) gene that determines pigment.[153] Most patients with CMM have fair skin, brown or blonde hair, blue or green eyes, and a propensity to develop sunburn following intense sun exposure.

Recent data suggest the use of sunlamps/sunbeds increases the risk of CMM (and nonmelanoma skin cancer), particularly in adolescents and frequent users of <35 years of age;[165] however, many of the studies have limited statistical power resulting from the small numbers of participants. In a meta-analysis of nine case-control and 1 cohort studies comparing "ever" and "never" use of sunlamps, the summary odds ratio was 1.25 (95% CI: 1.05–1.49) with significant heterogeneity.[166] Compared with never using sun lamps, the estimated risk of developing CMM increased with "first exposure as a young adult" (summary OR = 1.69; 95% CI: 1.32–2.18, $n = 5$ studies) and "longest duration or highest frequency of exposure" (summary OR = 1.61; 95% CI: 1.21–2.12; $n = 6$ studies). The latter studies had no significant heterogeneity. In a meta-analysis of 27 observational studies published before 2013, the summary relative risk of cutaneous malignant melanoma

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. comparing "ever" use with "never" use was 1.20 (95% CI: 1.08–1.34). Restricting sun lamp use to adults and children <35 years of age increased the RR to 1.87 (95% CI: 1.41–2.48, $n = 13$ studies).[167] The dose-response was marginally significant with each use of a sunbed during the year, increasing CMM risk by 1.8% (95% CI: 0–3.8%).

Lip Cancer

Cancer of the lip is a very rare cancer that is strongly associated with tobacco use; the incidence of this cancer is declining with the reduction in smoking prevalence. Descriptive studies suggest an association between lip cancer and cumulative sun exposure. This cancer is more common in males than females. The incidence rate is also higher in light-skinned populations than in dark-skinned populations living in the same geographic area.[168] In a study of 2,341 cases of lip cancer identified in the nationwide Danish Cancer Registry, the odds ratio for lip cancer in relation to outdoor work after adjusting for covariates was 1.67 (95% CI: 1.38–2.03) as estimated by conditional logistic regression models.[169] In a Spanish case-control study of 105 males (aged 20–70 years) with squamous cell carcinoma of the lip, multiple logistic regression analysis demonstrated increased lip cancer risk associated with lifetime cumulative tobacco and alcohol consumption but not estimates of cumulative sun exposure during leisure time or holidays.[170] Although lip cancer was associated with sun exposure early in life and cumulative sun exposure during outdoor work (OR = 11.9; 95% CI: 1.3–108.9), the wide confidence limits and lack of a dose-response limit conclusions about causality.

DIAGNOSTIC TESTING

Analytical methods for quantitating UV radiation include chemical detectors (passive dosimeters) and physical detectors (broadband radiometers) with filters to select specific wavelengths. The former technique involves direct measurement of irradiance using actinometric solutions, photographic emulsions, and UV-sensitive plastic films. The latter detectors use photoelectric (detection of photons) and radiometric (detection of heat) devices to measure the solar spectrum and Equation 46.1 to calculate the biologically effective UV dose. Experimental studies suggest the erythema irradiance may vary by <20% with broadband radiometers and by <40% for passive dosimeters when compared with calculations using a spectroradiometer.[19] Photoelectric devices provide immediate feedback on current UV exposure, whereas passive film dosimeters sum the UV dose over a specific time period and require laboratory analysis. Currently, multifrequency imaging detectors on meteorological satellites measure solar UV radiation on the earth.

Extrinsic biological dosimeters are well suited for measuring exposure to UV radiation and the biological implications of environmental exposure including skiing, hiking, and sun tanning.[171] These dosimeters calculate the biological effectiveness of the different UV wavelengths in the sun exposure along with any interactions. The complexity of these dosimeters depends on the measured biological effect (e.g., photochemical changes, provitamin D_3, uracil thin layers, DNA, T7 bacteriophages, *E. coli* and *Bacillus subtilis* bacteria).[172] The values from these dosimeters represent relative biological responses at different wavelengths rather than absolute dimensions of a biological effect; consequently, the results of dosimeters measuring two different biological processes may be related but are not necessarily numerically comparable. A UVB DNA-dosimeter using mini-dots of purified and dried bacteriophage λ on UV transparent biofilm measures photo-induced DNA damage from the blockage of DNA synthesis during a polymerase chain reaction.[173] The reduction of amplified products in the UVB-exposed DNA compared with control DNA indirectly reflects DNA damage. Other dosimeters include spore dosimeters (e.g., *B. subtilis* mutant strain), mammalian cell dosimeters (e.g., quantitative polymerase chain reaction of human genomic DA fragments), and vitamin D dosimeters (e.g., photosynthesis of previtamin D).[174]

HEALTH SURVEILLANCE

Environmental Monitoring

Guidelines

The American Conference of Governmental Industrial Hygienists (ACGIH) and the International Commission on Nonionizing Radiation Protection (ICNIRP) publish similar guidelines for human exposure based on an envelope action spectrum involving cutaneous and ocular effects. The guidelines for the eye are generally considered ceiling values that apply under worst-case conditions of normal incidence; however, the skin guidelines typically are desirable goals that depend on skin type because the risk of adverse effects differs between Celtic and more heavily pigmented skin types.[46] The ACGIH recommends threshold limit values for persons exposed to broadband UV radiation (excluding lasers), provided these individuals are not photosensitive and have intact

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. lenses. These exposures include carbon and welding arcs, fluorescent/incandescent/germicidal lamps, gas/vapor discharges, and solar radiation. These recommendations are designed to prevent adverse health effects (e.g., erythema, photokeratitis) in nearly all healthy, nonsensitized workers using relative spectral effectiveness calculated in Equation 46.1 with the values in Table 46.7. The use of UV radiometers with built-in spectral responses that mimic the relative spectral effectiveness values in Table 46.7 is a practical alternative to calculations.

Table 46.8 lists the ACGIH recommended duration of UV exposure based on the effective irradiance, E_{eff} (W/m^2 or mW/cm^2 for continuous exposure) by a weighting formula; recommendation for time-limited or pulsed exposures of the skin or eye use radiant energy, H_{eff} (J/m^2 or J/cm^2).[175] For daily UVA exposure of <17 minutes, the dose is limited to 1,000 mJ/cm^2, which is the maximum recommended exposure as the dose increases (and the recommended duration decreases). A variety of factors affect the risk of adverse effects (e.g., erythema), including skin type, eye color, familial melanoma history, latitude, time of day, hypersensitivity, degree of UVA exposure, sunscreens, and air pollution.

The International Commission on Nonionizing Radiation Protection (ICNIRP) guideline for maximum human biologically efficient radiant exposure of the skin is 3 mJ/cm^2 (i.e., 1.0–1.3 SED or ~0.5 MED for fair skin). For a germicidal lamp, the limit of 3 mJ/cm^2 is equivalent to 10 SED. These recommendations assume a normal 8-hour work shift and a 24-hour light/dark cycle that allows cellular repair after cessation of exposure. The ICNIRP also recommends limiting UV radiation (180–400 nm) for unprotected eyes to ≤3 mJ/cm^2 based on effective spectrally weighted factors.[176] The total (unweighted) ultraviolet radiant exposure for unprotected eyes in the spectral region

of 315–400 nm should not exceed 1,000 mJ/cm^2. Ocular exposure to UV radiation rarely exceeds ICNIRP guidelines, except in unusual circumstances (e.g., sunny days in snowy locations).[46]

For the most sensitive, healthy skin without protection, UV radiant exposure (180–400 nm) should not exceed 3 mJ/cm^2 effective dose spectrally weighted using the spectral weighting factors in Table 46.7. The exposure limits are less than a 5–10 minute UV exposure to skin for overhead, noonday, summer sunlight at 10°–40° latitude (2–4 times less than 1 MED). Pupillary constriction and squinting reduce outdoor UV exposure in bright, sunlit environments; however, some lamp sources (e.g., low-pressure mercury lamps) allow prolonged exposure because these UV sources emit little visible light. The American National Standards Institute (ANSI) produces technical standards for lamps and lamp systems based on the following four potential photobiological risk categories: 1) no hazard; 2) group 1, low risk; 3) group 2, moderate risk; and 4) group 3, high risk.[177]

Protection

Concern for sun exposure occurs in the tropics (30°N–30°S) all year round for individuals with white skin, whereas sun awareness is important in the temperate latitudes (40°–60°) in the 3 months before and after the summer solstice (i.e., April–September). Avoiding sun exposure around noontime in the spring–summer period and seeking shade when possible (e.g., breaks) helps reduce unnecessary UV radiation exposure, particularly for Celtic-type skin. The shadow rule (length of shadow < height) suggests the need for protective precautions to prevent excessive UV radiation exposure; this rule corresponds to a UV Index of ~4 resulting from a solar elevation angle and solar zenith angle of 45°. At this exposure level, unadapted, white-skinned individuals will develop sunburn after 2 hours of exposure. Protective measures include wide-brimmed hats, clothing (long-sleeve shirts, long trousers), umbrellas, wrap-around protective glasses, sunscreens, and shade structures; the value of clothing varies substantially depending on ambient temperature, safety requirements, culture, and occupation. Most clothing absorbs solar UV radiation relatively uniformly with protection factors ranging from >10 (summer clothing) to >10,000 (heavy denim coveralls).[46]

Engineering control measures (shade structures, trees, canopies, awnings, glass enclosures, shielding) are preferable to protective measures for some excessive UV exposures including artificial sources. In contrast to solar radiation, UV radiation from artificial sources is typically relatively uniform in quality (spectrum) and quantity (effective irradiance). The potential health risk from artificial sources depends on the distance/position of the worker in relation to the source, duration of exposure, and source spectrum/biologically effective UV radiation emissions; for the skin (but not the eye), skin type also affects the risk. Glass typically blocks UVB radiation, but the absorption of UVA radiation is variable. Most plastics (e.g., polymethylmethacrylate, polycarbonate) limit UV radiation to <370 nm, whereas some glass transmits radiation above 310 nm.

Sunscreens

Sunscreens are the most common method to reduce UV radiation exposure in recreational environments; however, clothing is usually preferable for skin protection in occupational settings. Sunscreens (i.e., SPF 15–30) are recommended for melanin-compromised (type I–II) skin when the UV Index is ≥3 and for melanin-competent skin when this value is ≥5.[46,178] Re-application may be necessary every 2 hours depending on the conditions. Sunscreens help prevent acute

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cutaneous burns as well as retard the development of skin cancer and photoaging of the skin. There are two main types of sunscreens: 1) physical (inorganic agents, primarily ZnO and TiO_2); and 2) chemical (organic). Inorganic sunscreens scatter, reflect, or absorb solar radiation depending on particle size. Reduction of particle size to the microparticle and nanoparticle range (<100 μm) significantly improves the desirability and transparency of these sunscreens without significantly increasing the systemic absorption of these compounds.[179,180] The addition of titanium dioxide nanoparticles to sunscreens increases the UVA protective factors to ~10; however, like all pigment-based sunscreens, the sunscreen is visible on the skin at the recommended dose of 2 μL/cm^2.[181]

Before 1990, most sunscreens blocked only UVB radiation; subsequently, broad-spectrum sunscreens were introduced to protect against UVB and UVA radiation. Organic sunscreens absorb UVB and/or UVA radiation, depending on the individual chemical; these sunscreens absorb energy from photons, emitting energy as heat or fluorescence. Most organic sunscreens absorb UVB radiation with a few effective in the UVA-2 range (320–340 nm); only avobenzone protects against UVA-1 (340–400 nm).[182] The main organic sunscreens include aminobenzoates (UVB), benzophenones (UVB/UVA), camphor derivatives (UVB/UVA), cinnamates (UVB), and salicylates (UVB).[183] Table 46.9 lists the approximate absorption spectrum of sunscreens available in the US market.

The SPF is the ratio of the minimum UV dose required to produce erythema in a sunscreen-protected patient to the minimum UV dose required to produce erythema in unprotected skin, as described in Equation 46.2.

$$\text{SPF} = \text{MED of sunscreen}-\text{protected skin} / \text{MED of unprotected skin} \quad \text{(Equation 46.2)}$$

where

MED = minimum erythemal dose.

The sun protection factor (SPF) refers to protection against UVB radiation and sunburn. Photosensitivity disorders (polymorphic light eruption, drug-induced photosensitivity) require protection against UVA radiation;[181] consequently, the SPF is not an indicator of UVA exposure or the ability of a sunscreen to prevent damage caused by UVA radiation (e.g., photoaging, photosensitivity reactions) unless specifically determined for a specific sunscreen. The actual effectiveness of a sunscreen also depends on the thickness of the

TABLE 46.9. Absorption spectrum of inorganic and organic sunscreens. The ranges are approximate as each type of sunscreen may not block the entire spectrum listed. (Adapted from Jou).[182]

application, duration of sun exposure, and substantivity (i.e., resistance to removal by sweat, water, and toweling). The recommended SPF for patients with type I and II (i.e., easily burned) is SPF 15–20, whereas patients tanning more easily may use a product with SPF ~10. Sunscreens above SPF >25–30 do not add protection from UVB because the solar radiation dose is not sufficient even at the equator to produce erythema during the day assuming the sunscreen is properly applied.[184] Sunscreens that contain zinc oxide or titanium dioxide pastes are more effective at blocking visible light than UV-absorbing sunscreens that contain oxybenzone or cinnamates. Measurement of UVA protection is complicated by the 1,000-fold less erythrogenic property of UVA than UVB; hence, the minimal persistent pigment darkening (PPD) at 2–24 hours is the recommended measure of UVA protection.[162] A sunscreen with a PPD of 10 provides adequate protection from UVA radiation.

Broad-spectrum sunscreens with an SPF factor ~15–20 should be applied uniformly on sun-exposed skin daily by individuals with type I or II skin; the effectiveness of the sunscreen depends on several preconditions.[53] These sunscreens should be used to reduce total UV radiation exposure rather than increase the time spent in the sun; under-applying the sunscreen reduces its efficacy. The SPF value assumes the application of the sunscreen to a thickness of 2 mg/cm^2. Generous amounts of sunscreen should be applied 15–30 minutes prior to sun exposure to allow time for the chemicals to bind to the stratum corneum.[185] Re-application of sunscreen is necessary after swimming, contact with clothes, toweling, or heavy sweating. Children should be protected with sunscreen and develop the habit of using sunscreen early.

Although potential adverse effects include allergic contact dermatitis (e.g., methoxycinnamate, oxybenzone), irritant contact dermatitis, photoallergic reactions (e.g., benzophenone-3, PABA), and phototoxic reactions, the incidence of these effects is probably relatively low.[186] UVB radiation is a potent stimulus for the activation of *Herpes simplex labialis*; sunscreens reduce the incidence of recurrent infections on sun-exposed skin;[187] however, not all *H. simplex labialis* lesions associated with UV radiation are responsive to acyclovir.[188]

Sun Protection

The use of a hat and protective clothing along with the avoidance of outdoor activities between 10 AM–2 PM reduces exposure to UV radiation. Reflective surfaces (e.g., white sand, concrete, ice, snow) substantially increase exposure to solar radiation. Additionally, the relative dose of UV radiation increases with altitude, proximity to the equator, and exposure to the midday sun. Window glass absorbs most UVB radiation; therefore, the driver's window should be kept closed during travel. Most sunglasses filter UVB radiation well, but the transmission of UVA radiation is much more variable.

Tanning is not sufficient protection from the sun because even the darkest tan on a Caucasian is only equivalent to an SPF of 4.[1] People with type I skin and those with solar keratoses or previous skin cancer should avoid the use of tanning devices. Individuals with well-tanning skin should limit their exposure to tanning machines to 30–50-minute sessions per year **or** less.[53] Current research into improving skin protection from solar radiation includes enhancement of skin pigmentation (synthetic melanins, L-tyrosine, thymidine dinucleotides), self-tanning agents (e.g., dihydroxyacetone), antioxidant enzymes, nonenzymatic antioxidants (e.g., vitamin supplementation), DNA repair enzymes (e.g., T4 endonuclease V, photolyases), and phytochemicals (e.g., plant secondary phenolic metabolites).[186]

Biological Monitoring

For research purposes, intrinsic biomarkers [e.g., cyclobutane pyrimidines, (6-4) pyrimidine-pyrimidone adducts, p53 mutations, matrix proteinases] and extrinsic biological dosimeters (i.e., measures of biological effective dose, H_{eff}, in $J_{\text{eff}}/\text{m}^2$) are available to monitor biological effects of UV radiation.[189]

Medical Surveillance

Medical surveillance is not usually recommended for workers exposed to UV radiation, in part because of the long latency periods for skin cancers and cataracts. Although the US Preventive Services Task Force found insufficient evidence to recommend skin examinations for the early detection of skin cancer in adults, high-risk individuals may benefit from these examinations. Periodic examinations may be appropriate for high-risk workers, including those exposed to other skin carcinogens (e.g., coal tar), with strong family or personal histories (e.g., multiple skin cancers, family history of melanoma), and solid-organ transplant recipients.[190] The skin and eye are the primary target organs for excessive UV radiation. Skin examination should focus on signs of excessive UV exposure, including spotty pigmentation, actinic keratoses, nevi, and evidence of photoaging (e.g., solar lentigines; wrinkles; dry, rough, leathery, furrowed, and/or poor elastic skin, telangiectasia).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Signs of excessive ocular UV radiation include pterygiums, pingueculas, corneal opacities, and cataracts. The history should include recorded episodes of keratoconjuctivitis.

TREATMENT

Based on a mathematical model, the use of sunscreen with a sunscreen protection factor (SPF) of 15 during the first 18 years of life would reduce the incidence of basal and squamous cell carcinomas of the skin by 78%.[191] Methods to prevent sunburn include sun avoidance during peak UV radiation (e.g., 10 AM–4 PM or at least 11 AM–2 PM), wearing protective clothing (wide-brim hats, UV protective fabrics, well-shielding sunglasses with broad UV blocking properties), and the use of broad-spectrum sunscreens (UVA/UVB blocking properties). The most important aspect of treating sunburn is avoiding further sun exposure. Treatment of mild sunburn includes emollients, topical anesthetics, cool soaks with evaporative cooling (wet T-shirt and fan), topical steroids, and analgesics (aspirin, nonsteroidal anti-inflammatory).[1] Topical anesthetics with pramoxine hydrochloride produce less sensitizing effects than topical preparations with benzocaine. Emollients with small concentrations of menthol, camphor, or phenol may contribute to the soothing effect of these preparations. Aspirin or nonsteroidal anti-inflammatory medication should be taken early to blunt the effects of sunburn mediators. A short course of prednisone (60 mg daily tapered over 1 week) may reduce the clinical effects of severe sunburn. Cleansing and covering the area of blistering is similar to the treatment of partial thickness of thermal burns. Intact vesicles should not be drained. Topical tretinoin (vitamin A acid) promotes the formation of new collagen in UV-damaged and photo-aged skin.[192]

MEDICAL TOXICOLOGY OF OCCUPATIONAL AND ENVIRONMENTAL EXPOSURES

Volume 3

Carcinogens: Risk Factors, Pathophysiology, Susceptibility, and Clinical Abnormalities

DONALD G. BARCELOUX, MD, FAACT, FACMT, FACEP

Consultant, Medical Toxicology
Donald G. Barceloux, M.D., Inc.

Emeritus Physician
Department of Emergency Medicine
Pomona Valley Hospital Medical Center
Pomona, California

Emeritus Partner, Vituity
Emeryville, California

Clinical Professor of Medicine, 2002–2023
Department of Emergency Medicine
Olive View/University of California at Los Angeles Medical Center
Sylmar, California

Edited by

ROBERT B. PALMER, PhD, DABAT, FAACT

Rocky Mountain Poison and Drug Safety
Denver, Colorado

Section of Medical Toxicology
Department of Emergency Medicine
University of Colorado School of Medicine
Aurora, Colorado

Toxicology Associates, PLLC
Littleton, Colorado

To Murali Janakiram, MD

Your friendship, wisdom, compassion, and medical expertise made the completion of this book possible.
Donald G. Barceloux, MD

To my parents, Robert L. Palmer, MD, and Linda J. (Addison) Palmer, RN; my wife, Karen E. Simone, PharmD; and my dear friend and colleague, Donald G. Barceloux, MD

You all taught me more than I could ever recount about cancer and the truly important things in life.
Rob

Oncogenes 27
Tumor Suppression 29
Nonprotein Coding RNAs 31
Cellular Alterations 32
Cell Proliferation 32
Invasion and Metastasis 35
Immune System 36
Tumor Microenvironment 38
CARCINOGEN CATEGORIES 38
Classic Carcinogen Stages 38
Genotoxic Carcinogens 39
Epigenetics Effects 40
Gene Expression 41
DNA Methylation 42
Histone Modifications 43
Chromatin Accessibility and Nucleosome Positioning 43
Noncoding RNAs 45
References 46

B CHEMICAL CARCINOGENICITY 57

48 GENERAL PRINCIPLES 59
Statistics 59
Overall 59
Tissue Sites 62
Etiology 63
Occupation 64
Environment 65
Lifestyle 66
Infection 67
In Utero 67
General Causation 67
Strength 68
Consistency 69
Specificity 69
Temporal Relationship 69
Dose-Response (Biological Gradient) 69
Biological Plausibility 70
Coherence of Evidence 70
Experimental Evidence 70
Analogy 70
Causation and Individual Exposures 70
References 71

49 EVALUATING CARCINOGENICITY 75
Chemical Structure and Metabolism 75
Experimental Cell Studies 77
Mutations 78
Short-Term Assays 79
System Biology Framework 81
Animal Studies 82
Design 83
Interpretation 86

FOREWORD

The multivolume *Medical Toxicology of Occupational and Environmental Exposures* covering metals, radiation, and cancer is the eagerly awaited third instalment in the seminal series of medical toxicology textbooks written by Dr. Donald Barceloux. The first two books focused on natural substances and drugs of abuse, respectively, and have quickly established themselves as reference works in their respective fields. The comprehensive coverage of topics coupled with a consistent and easy-to-follow organization of content have made them indispensable companions of physicians and researchers alike.

The newest volumes in the series, created by Dr. Barceloux and edited by Dr. Robert Palmer, is a worthy successor to the first two books. Once again, the focus is on naturally occurring and man-made toxic threats that all medical toxicologists will have heard of but few will have had first-hand experience with. This is precisely what makes this work so valuable. The first volume literally comprises an A–Z of all there is to know about the clinical toxicology of metals and metalloids, from aluminum to zirconium. Chapters on well-known toxic metals such as arsenic, lead, and mercury are almost textbooks in their own right covering their subjects in a breadth and depth rarely seen in other publications. But who would know where to look for information on the toxicokinetics of rare earths, or whether tellurium is a human teratogen?

There is an ongoing debate on whether radiation is a subject that toxicologists should concern themselves with, or whether it would best be left to physicists, radiologists, and oncologists. The second volume takes a pragmatic view: if it induces a toxic response, then it is of relevance to anyone involved in the prevention, diagnosis, and treatment of human exposures. Consequently, the chapters in the section on radiation provide a comprehensive summary on what is known about potential health effects of all forms of radiation, and what may be done to prevent them.

The final volume on cancer departs from the familiar substance-based approach of the rest of the book in that it starts from the point of view of the risk assessor, looking at the mechanism of chemical carcinogenesis and then providing an organ-centered overview. This is a useful approach since carcinogenicity is as much governed by the cascade of molecular events elicited by carcinogens as it is by human physiology, biokinetics, and organ response.

In contrast to standard textbooks on clinical toxicology, *Medical Toxicology of Occupational and Environmental Exposures* is not only aimed at those working in the treatment of the poisoned patient. As the most comprehensive source of information in its field, it will equally be an invaluable reference for occupational physicians and hygienists, those working in environmental health and indeed anyone concerned with the human health risk assessment of exposure to metals, radiation, and chemical carcinogens. It is a truly interdisciplinary work that will stand the test of time.

PREFACE

This volume, *Cancer*, along with *Radiation* and *Metals and Metalloids* in the three-volume *Medical Toxicology of Occupational and Environmental Exposures* is a continuation of the *Medical Toxicology Series* that began with *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals* and *Medical Toxicology of Drug Abuse: Synthesized Chemicals and Psychoactive Plants*. The *Medical Toxicology Series* provides in-depth, evidence-based coverage of the most important human toxins. Similar to the rest of the *Medical Toxicology Series*, the goal of this volume is the creation of a comprehensive and convenient reference to answer questions regarding the etiology and presentation of cancer by presenting the basic and clinical science associated with various organs.

The reader will recognize the similarities between the template in this volume and the templates in the first two books of the *Medical Toxicology* series. This organizational consistency allows easy location of the appropriate information necessary for decisions regarding the sources, effects, and regulation of occupational and environmental carcinogens. The focus on understanding the current basic science, clinical consequences, and etiology of cancer resulted in an adjustment of the standardized template by using an organ-based approach. The template in this volume emphasizes carcinogenesis (cancer pathophysiology, molecular biology, carcinogen categories), chemical carcinogenicity (chemical carcinogen classifications, risk assessment, evaluation of carcinogens, cancer surveillance), and individual tumor sites (carcinogenesis/genetics, risk factors, histology, host susceptibility, clinical features).

Medical toxicology is a field often dependent on relatively weak scientific evidence (case reports, case series, retrospective analyses), resulting in the increased risk of perpetuating equivocal statements and even folklore. This volume provides the relevant evidence necessary to understand the clinical consequences and safety measures important for the prevention of cancer in the workplace and the environment. References are documented to validate the information and provide sources for further inquiry. Although this unique volume presents a medical toxicologist's perspective on exposures to carcinogens, the coverage contains input from a variety of disciplines including other clinical specialties, public health physicians, and basic scientists.

The choice of topics in this volume reflects our desire to expand communication between medical toxicologists and related fields. Our hope remains that this interdisciplinary, evidence-based approach will increase communication between traditional clinical settings and fields aligned with medical toxicology including those in laboratories, academic settings, and regulatory agencies. We anticipate this approach will encourage more inquiry into the pathophysiology, clinical effects, biomarkers, and origins of cancer in this rapidly expanding field and will improve our efforts to decrease the incidence of cancer.

ACKNOWLEDGMENTS

I thank the following colleagues for their contributions to the quality, depth, and accuracy of *Medical Toxicology of Occupation and Environmental Exposures: Cancer*.

John Wiley & Sons' Staff

Dr. Andreas Sendtko, Senior Managing Editor, Physical Sciences Books, whose dedication and patient guidance guaranteed the accuracy of the printing process and the quality of these books.

Bob Esposito, former Senior Editor, made our *Medical Toxicology Series* a reality by believing in the importance of a highly detailed, structured series covering the expanding field of Medical Toxicology.

Michael Leventhal, Associate Editor, helped smooth the production process from submission to printing.

Summers Scholl, Executive Editor, whose contributions were essential to informing our medical audience of the key constituents of the *Medical Toxicology Series*.

Pomona Valley Hospital Medical Center

I admire the dedication and perseverance of the physicians, nurses, and the Emergency Department staff in times complicated by COVID-19 and variants, difficult medical problems, and complex social issues. In particular, I appreciate the support of the physician staff including Howard Friedman; Ivan Schatz; Richard Dorosh; Ken Nakamoto, past Vice President of Medical Affairs; Ken Moore, former Medical Director Emergency Department; and James Kim, Medical Director, Emergency Department.

UCLA Emergency Department Colleagues

I appreciate all our colleagues who shared their expertise and clinical experience at UCLA Conferences, especially Gregory W. Hendey, MD, Department Chair; Steven Lai, MD, Assistant Program Director, Olive View-UCLA; Richelle J. Cooper, MD, UCLA Emergency Department Research Director; Lynne B. McCullough, MD, UCLA ED Medical Director; Pamela Dyne, MD, Associate Program Director, Olive View-UCLA; Cynthia Koh, MD; Eric A. Savitsky, MD; Luis Lovato, MD, Informatics; David A. Talan, MD, former Chairman, Department of Emergency Medicine, Olive View-UCLA Medical Center, and Matthew Waxman, MD.

UCLA Librarians

Writing this book series was not possible without the support of the UCLA Biomedical Library, especially Juan Jaime, Access Services Manager, UCLA Science Libraries.

DONALD G. BARCELOUX, MD

Chapter 47

CARCINOGENESIS

MOLECULAR BIOLOGY

HISTORY

Although the existence of chromosomal alterations in cells that contribute to tumor formation was hypothesized by Theodor Boveri in 1914,[1] the first chromosomal marker was not identified until 1960 when Nowell and Hungerford discovered the Philadelphia chromosome in the genomes of patients with chronic myelogenous leukemia.[2] Although hematological malignancies often have signature chromosomal abnormalities, most solid tumors display numerous clonal and nonclonal chromosomal changes. In the mid-1970s, Peter Nowell proposed a model of cancer as a sequential evolutionary process beginning with an initiating event that converts a normal cell into a potential cancer cell; then, a progressive accumulation of genetic changes endowing the cancer cells with selective growth and invasive properties to form cancer clones.[3] Before complete mapping of the human genome, oncovirus studies discovered several genes (e.g., *APC*, *KRAS*, *TP53*) with cancer-forming mutations. Avian sarcoma virus studies in the late 1970s identified the presence of the first normal cellular genes (proto-oncogenes) in the Rous sarcoma virus capable of transforming into altered versions (oncogenes) that induce sarcomas in chickens.[4] The importance of proto-oncogenes to the development of cancer became apparent in 1982 with the discovery of a point mutation as the transforming event causing the oncogenic activation of *H-RAS* in human bladder carcinoma cells. High-resolution chromosome banding techniques also revealed the other genetic alterations contributing to oncogene activation in human cancers, including gene amplification, rearrangement, and expression.[5] In 1987, the first tumor suppressor gene (retinoblastoma, *RB1*) was cloned; tumor suppressor gene inactivation resulted from a variety of genetic alterations producing gene silencing, including gene deletions, point mutations, and epigenetic alterations. Specific chromosomal locations were identified for 13 tumor suppressor genes by 1993.[6] These studies revealed over 100 oncogenes by 2002, with most of these oncogenes encoding protein tyrosine kinases that modulate signal transduction pathways involving cell division, which is important to the later development of chemotherapeutic agents.[7] During the pregenomic era (1960–2003), inefficient sequencing technologies and the enormous complexity of tumor genomes limited early attempts to identify and separate protein-encoding cancer genes (driver genes) from other genetic alterations (passenger genes) uninvolved with the cancer process. The discovery of cyclin-dependent kinases in 2001 was a very significant advance in the understanding of cell cycle regulation prior to the genomic era.[8]

The lack of a sequence-based map of the normal human genome impeded the identification of cancer genes involved with cancer and the cell cycle until the completion and publication of the Human Genome Project in 2003, which initiated the postgenomic era.[9] In 2004, the Wellcome Trust Sanger Institute established the Cancer Gene Census to catalog mutated

human genes present in cancers at a higher frequency than predicted by chance.[10] The International Cancer Genome Consortium (http://www.icgc-argo.org) was formed in 2008 to standardize the approaches to the gene alterations identified in human cancers. Sequence-based mapping of the human genome and high-throughput Sanger sequencing allowed rapid, extensive cataloging of somatic mutations in candidate and causal cancer genes.[11] The targeting of specific biochemical pathways and large numbers of candidate genes with high-throughput resequencing resulted in the development of genotype-directed therapy initially involving primarily protein kinase-encoding genes.[12] This approach allowed specific pathway-directed therapy for genotype-defined cancer subgroups [e.g., HER2 (also known as erb-b2 receptor tyrosine kinase 2) mutation-positive breast cancer with trastuzumab]. Following the completion of the Human Genome Project, a map of non-cancerous human genomic variation (HapMap) was constructed that identified single nucleotide polymorphisms (SNPs) and underlying genomic structure. The associated development of high-density SNP genotyping arrays facilitated the classification of cancer subtypes and prediction of clinical phenotypes; however, the genetic complexity of human cancers limited systematic sequencing of tumor genomes.[11]

In 2006, a systematic analysis of coding exons involving 13,023 protein-encoding genes from 11 breast cancers and 11 colorectal cancers revealed individual tumors accumulate an average of ~90 mutant genes.[13] Considerable inter-tumor variability occurred, resulting in altered genes with a relatively small number of frequently mutated genes, many infrequently mutated genes, and a substantial subset of mutated genes uninvolved in the neoplastic process. All somatic mutations are not functionally equivalent. Hence, identification of a somatic mutation indicates the presence of a candidate gene and not necessarily a causal gene because somatic alterations can confer a selective growth advantage to a tumor cell ("driver" mutation) or produce no effect on tumor formation ("passenger" mutation). Thus, reducing the complexity of genetic diversity in human cancers required a focus on genetically induced alteration of specific biological pathways and processes rather than the altered genes.[14]

Since the postgenomic era began, multiple domestic and international multi-institutional consortia have formed to identify and rapidly distribute data on genomic and epigenomic alterations in normal and cancerous tissues, including the Encyclopedia of DNA Elements (ENCODE), Human Epigenome Project (HEP), International Cancer Genomics Consortium (ICGC), International Human Epigenome Consortium (IHEC),[15] NIH Roadmap Epigenomics Initiative (NREI), Stand Up to Cancer (SU2C), Structural Genomics Consortium (SGC), The Cancer Genome Atlas (TCGA), and Therapeutically Applicable Research to Generate Effective Treatments (TARGET).[16] Although the resequencing of cancer exons identified protein-encoding gene mutations, this method did not assess noncoding regions (i.e., introns) of the genome that contain noncoding RNA (ncRNA) and ultraconserved elements. The National Human Genome Research Institute launched a public research consortium, the Encyclopedia of DNA Elements (ENCODE), in September 2003 to identify all functional elements in the human genome sequence including ncRNA. By the mid-2000s, recognized influences of ncRNAs on the function of RNA and proteins in cell division included regulation of chromosome structure and transcription, modification and processing of RNA, translation and stability of mRNA, and transport and stability of proteins.[17] Subsequently, a subset of ncRNAs, micro-RNAs (miRNAs), was recognized as an inhibitor of abnormal gene expression; dysregulation of miRNAs contributed to the development of oncogenic and tumor suppressive properties.[18] Another of the subsets (long noncoding RNAs, Inc-RNAs) are transcripts longer than ~200 nucleotides with little or no protein-coding capacity. Transcribed ultraconserved region transcripts are a subset of lncRNAs transcribed from ultraconserved regions of the genome; studies of alterations of these transcripts in the late 2000s and 2010s associated the altered expression of these transcripts with human leukemias and carcinomas.[19,20]

In 2008, the US National Institutes of Health launched the NIH Roadmap Epigenomics Mapping Consortium (https://egg2.wustl.edu/roadmap/web_portal/) to provide a public resource of human epigenomic data with the goal of using basic biology to improve disease-oriented research. The consortium uses experimental data from next-generation sequencing technologies to map DNA methylation, histone modifications, chromatin accessibility including nucleosome positioning, and RNA transcripts in stem cells and primary *ex vivo* tissues representative of tissues and organ systems frequently involved in human disease including cancer.[21] By 2015, the Consortium reported the integrative analysis of 111 reference human epigenomes from primary human cells and tissues using a diverse set of high-throughput molecular assays including methylated DNA immunoprecipitation, methylation-sensitive restriction enzyme digestion, DNA digestion by deoxyribonuclease I, bisulfite treatment, chromatin immunoprecipitation, and RNA profiling.[22] A major advance in studying genome-wide

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. DNA methylation was the separation of methylated and unmethylated DNA by sodium bisulfite conversion of unmethylated cytosines to uracil (unmethylated cytosines remained unaffected), followed by PCR amplification and analysis of PCR products.[23] Expanded knowledge of the genetic and epigenetic basis of cancer added comprehensive data to classical pathology-based tumor classification as well as to the development of personalized medicine designed to predict individual cancer risk and drug response.

DNA REPLICATION

Developing after conception, somatic cells are the cells in the body (i.e., skin, connective tissues, bone, blood, internal organs) other than undifferentiated stem cells and germline cells (i.e., sperm, ovum, gametocytes that produce sperm or ovum). Each somatic cell contains all the organism's genetic information within the deoxyribonucleic acid (DNA) sequences in the genome of the cell nucleus, whereas reproductive cells contain ½ the chromosomal material (i.e., one set of chromosomes, haploid) present in somatic cells. The genome in a human somatic cell includes ~80,000–100,000 genes arranged linearly in 2 sets of 23 chromosomes with histone proteins (i.e., diploid). These genes contain a sequence of ~3 billion base pairs. Microscopically, chromosomes are visible as dark clumps (chromatin) in the nucleus. A gene represents the whole sequence of DNA bases necessary to determine the amino acid sequence of a single polypeptide chain in a protein. The four types of nucleotide bases (adenine, guanine, thymine, cytosine) produce a unique amino acid sequence because each base triplet (i.e., codon) specifies a particular amino acid. Thus, each human cell possesses the potential to synthesize 50,000–100,000 polypeptide chains; however, the differential expression of the genes depends on genetic and epigenetic factors, with the subsequent production of proteins determining cell function. In the cell nucleus, messenger ribonucleic acid (mRNA) copies the information in a gene (i.e., the DNA) during transcription. Transcription factors bind to specific DNA sequences (enhancer, promoter sequences) and recruit RNA polymerase to an appropriate transcription site. The transcript terminates when the selected DNA strand in the exons is copied; then, during translation, the newly formed mRNA copies move to the extra-nuclear ribosomes, where protein synthesis occurs from the information contained in the mRNA.

At a grossly microscopic level, most genes contain discrete protein-coding regions (exons) separated by noncoding regions (intervening sequences, introns), as displayed in Figure 47.1. The introns represent a much greater portion of the gene than the actual

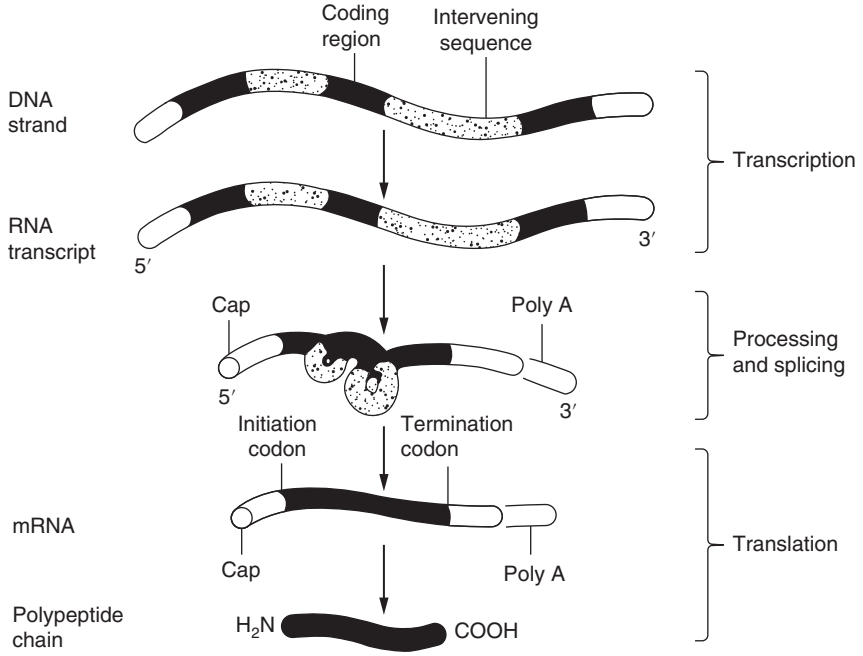

FIGURE 47.1. Schematic diagram of the genetic control of protein synthesis. Somatic cells contain activated and inactivated genes. mRNA copies the DNA information during transcription. The mature mRNA carries the protein-coding information to the cytoplasm, where protein synthesis occurs during translation in RNA-protein structures (ribosomes). (The Protein, Harrisons, p. 286).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. protein-coding sequences, with intron regions able to increase gene expression (e.g., increased steady-state concentrations of cytosolic mRNA) without functioning as a binding site for transcription factors; this intron-mediated enhancement of gene expression also increases mRNA translation efficiency and changes transcript concentrations by altering transcript stability, nuclear export, and/or transcription rates.[24] The effect of introns on gene expression is highly variable, despite similar locations on the same gene.[25]

Beginning at the promoter initiation site present ahead of the protein-coding sequence, the enzyme RNA polymerase II translates the DNA sequence of the gene into a duplicate mRNA copy. The DNA code consists of a series of three-letter combinations of nucleotides (codons), with each codon corresponding to a specific amino acid or stop signal. The promoter region upstream of the protein-coding sequence initiates transcription and influences the frequency of translation. Additionally, there are specific DNA sequences (enhancers) existing upstream and downstream of the transcribed DNA sequence. These enhancers either promote or suppress transcription. The newly transcribed mRNA contains an untranslated leader (i.e., sequence that does not code for an amino acid) in the initial 5′ portion, followed by alternating sequences of exons (coding) and introns (noncoding) regions. During the maturation process in the nucleus, the introns are deleted, the initial (5′) portion is capped or methylated, and a sequence of adenylic ribonucleotides (termed poly A tail) is added to the terminal 3′-portion of the mRNA.

Translation of mRNA by the ribosome in the cytoplasm occurs in three stages: initiation, elongation, and termination. During initiation, the small ribosomal subunit binds the beginning of the mRNA sequence, followed by the binding of methionine to the start codon by a transfer RNA (tRNA) molecule. The start codon (AUG) codes for methionine. The binding of the large ribosomal subunit forms the complete initiation complex. The elongation stage involves the linking of amino acids with peptide bonds based on the translation of each codon until every codon in the mRNA sequence is read. Termination occurs when the ribosome reaches a stop codon that tRNA does not recognize (i.e., UAA, UAG, and UGA).

CELL DIVISION

At any one time, most human cells are not cycling with most functional cells withdrawn from cell division into a reversibly quiescent (G0) state (e.g., hepatocytes, thyroid follicular cells) or permanently into a differentiated state (e.g., myocytes, neurons). Only a minority of the cells are actively proliferating, primarily stem and transit cells. Stem cells may divide without maturation, whereas mature cells approaching functional competence may not divide. In contrast, transit cells divide and mature while demonstrating intermediate properties between stem cells and mature functional cells.[26]

The goal of cell division is the generation of two genetically identical daughter cells from the precursor cell. A complex regulatory network controls DNA replication (S-phase) and the orderly segregation of cellular contents (M-phase) to preserve the fidelity of the process.[27] Changes in phosphorylation and cell cycle protein concentrations determine the progression through different cell cycle stages. Cyclin-dependent serine/threonine kinases (CDKs) initiate S- and M-phases, whereas protein phosphatases (PPs) reset the cell cycle by dephosphorylating the CDKs. The mutually exclusive activities of CDKs and PPs maintain cell regulation. The ubiquitin-proteasome system provides additional regulatory control by selective protein destruction.

Cell Cycle

Mitosis (M-phase) and interphase are the two fundamental parts of somatic cell division; the former includes various stages of nuclear and cytoplasmic division as recognized by the condensation of replicated chromosomes seen through light microscopy and outlined in Table 47.1.[28] Interphase consists of the DNA synthesis phase (S-phase), the two gap phases (G1, G2), and the reversible quiescent phase (G0) occurring in response to mitogen deprivation or high cell density. Mitosis involves cell division (cytokinesis) consisting of separation of the daughter DNA, segregation of sister chromatids, and formation of daughter nuclei. Cyclin-dependent kinases (CDKs) initiate the G1/S-phase and G2/mitosis transitions by phosphorylating various substrates. Cyclin-dependent kinase1 (CDK1) and cyclin-dependent kinase2 (CDK2) can bind several different cyclin types (A, B, D, E), whereas CDK4 and CDK6 bind only D-type cyclins. Figure 47.2 displays the essential cyclins and CDKs in the classical model of cell cycle controls.

Interphase

Most cells reside in the resting or quiescent (nonproliferative) phase (G0) with cell division interspersed at discrete intervals rather than occurring continuously. Interphase is the portion of the cell cycle other than mitosis consisting of the folllowing: 1) the nonproliferative phase (G0); 2) the phase (G1) between the end of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 47.1. Phases of the cell cycle with key events and major regulators. Substantial redundancy of cyclin-dependent kinases (CDKs) occurs throughout the cell cycle; however, CDK1 (also known as cell division cycle protein 2, CDC2) is the only CDK essential for cell division. High cyclin B/CDK1 activity and inactivation of antagonizing protein phosphatases triggers cell entry into mitosis. Key events during mitosis include nuclear envelope breakdown, chromatin condensation, and bipolar spindle assembly. Exit from mitosis requires reactivation of protein phosphatases, inactivation of maturation-promoting factor (MPF), and degradation of cyclin B by the ubiquitin-proteasome pathway.

G0 and the initiation of DNA replication; 3) the S-phase of DNA replication with the formation of intranuclear daughter DNA; and 4) the phase (G2) between the end of DNA replication and the beginning of mitosis. Entry past the S-phase and into mitosis depends on the progression of the cell past the restriction point, spindle assembly checkpoint, replication checkpoint, and, to ensure DNA fidelity, the DNA damage response network.

G1 and the Restriction Point

Maintenance of the quiescent phase is an active process requiring transcriptional repression of DNA replication and mitosis along with the expression of antisenescence, antidifferentiation, and antiapoptotic genes.[30] Commitment to cell cycle progression or quiescence is mutually exclusive with the onset of DNA replication, an irreversible process. Passage through the restriction point at the end of mid-G1 phase commits the cell to entering the S-phase and progressing through the remaining phases of the cell cycle, whereas a state of quiescence persists when the cell does not progress past the restriction point.[31] Pocket proteins from the retinoblastoma family (RB/p105, p107, RB2/p120) block entry into the S-phase at the mid-G1 checkpoint (i.e., restriction point), as displayed in Figure 47.3.[32] The pRb protein represses gene transcription necessary for transition from G1 to S-phase by binding to the transactivation domain of E2F and forming a complex with the promoter of these genes. E2F controls the expression of genes required for DNA replication, S-phase progression, and mitosis. The retinoblastoma protein interacts with the E2F family of DNA-binding transcription factors rather than binding directly to DNA. Cell division cycle 6 (CDC6) is an essential regulator of DNA replication that assembles prereplicative complexes at replication origins during late M-phase and early G1.[33]

Multiple, redundant pathways tightly control the transition from G1 to the S-phase. External mitogens activate signal transduction activities including RAS GTPase, RAS signaling, downstream mitogen-activated protein kinases (extracellular-signal-regulated kinases, ERKs; Jun amino-terminal kinases, JNKs; stress-activated protein kinases, p38/SAPKs); and ultimately cyclin D transcription. Classically, cyclin D-CDK4,

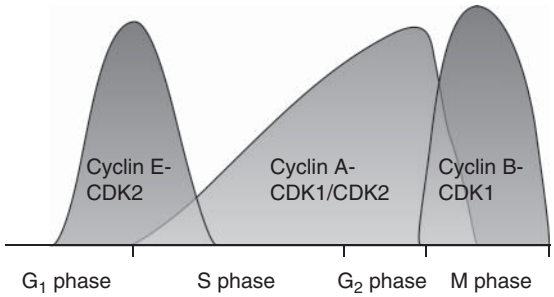

FIGURE 47.2. Classical model of relative activity of kinases and cyclins during the cell cycle. Cyclin-dependent kinases (CDKs) initiate the G1/S-phase and G2/mitosis transitions by phosphorylating various substrates, whereas anaphase-promoting complex/cyclosome (APC/C) E3 ubiquitin ligase initiates the metaphase-to-anaphase transition by ubiquitylation and proteasome-mediated degradation of B-type cyclins and other proteins. Cyclin E-CDK2 initiates DNA replication (S-phase), cyclin A-CDK1 and/or cyclin A-CDK2 control the completion of S-phase, and cyclin B-CDK1 sustains mitosis. (Adapted from Hochegger et al.).[29]

cyclin D-CDK6, and cyclin E-CDK2 drive G1 progression through the restriction point by phosphorylating and inactivating the RB protein, as displayed in Figure 47.3. RAS-driven MYC accumulation interacts with E2F transcription activity to control multiple proliferation-related genes.[34] Progressive E2F activation by cyclin D-induced RB phosphorylation in early- and mid-G1 and the positive feedback loop of progressively rising cyclin E concentrations producing RB hyperphosphorylation result in increased cyclin E transcription and entry into the S-phase; however, the gradually progressive RB phosphorylation during G1 is not easily reconciled with the binary decision to proliferate. Cyclin D-mediated RB phosphorylation may not be the only late G1 event that initiates passage through the restriction point; high CDK2 concentrations are associated with commitment to entering S-phase (threshold model).[35] This model suggests either CDK1- or CDK2-cyclin A complex controls interphase, while CDK1-cyclin B complex is essential for entry into mitosis.[29] In early and mid-G1, CDK2 activity is low, whereas it increases abruptly in later G1 and remains elevated until later in the early S-phase. The G1/S transition is a bistable switch for the steady-state distribution of two populations of cells that demonstrate different discrete CDK2 activities and interconvert in a rapid manner. The G1 restriction point is the primary passage point for quiescent cells re-entering G1, whereas the G2 decision window is more important for continuously cycling cells.[36] Actively replicating cells have the following two distinct proliferation decision points: 1) the G1 restriction point; and 2) the G2 window decision.

Synthesis Phase

Origins are sites on the chromosomal DNA where a bidirectional pair of replication forks begin. A replication licensing system coordinates the initiation of DNA replication on the chromosomes by a complex of initiator proteins (prereplication complex) that bind and unwind the DNA helix at origins prior to the formation of bidirectional replication forks.[37] During the late M- and early G1-phases, the licensing proteins assemble prereplicative complexes to prepare the chromosomes for DNA synthesis during the S-phase. These licensing proteins include the origin and recognition complex (ORC1–6), CDC6, CDT1, and the six minichromosome maintenance proteins (MCM2–7). The latter replicative helicases unwind the template DNA, whereas CDC6 and CDT1 function as clamp-loaders for the ring-shaped hetero-hexameric complex. The ORC first binds to each replication origin and then recruits CDC6 and CDT1. Down-regulation of CDC6 during the proliferation-differentiation switch in late G1 triggers loss of proliferative capacity and migration of the cell from the transit-amplifying compartment to the functionally differentiated compartment.

Figure 47.4 displays the progression of cell differentiation/maturation and expression of initiation proteins (CDC6, CDT1) and replicative helicases (MCM2–7) in the compartments of rapidly renewing tissues. Following inactivation of the replication licensing system during late G1 phase, no further MCM2–7 binding to the origins occurs during the remaining portion of the normal cell cycle (i.e., S-phase, G2, and early mitosis). A more gradual down-regulation of MCM2–7 occurs as the cell differentiates, whereas proliferating cells express high concentrations of these MCM proteins; consequently, MCM2–7 proteins are biomarkers of cell proliferation that reflect growth in diverse tumor cell populations (e.g., bladder, breast, lung, ovary, prostate).[37] The prereplication complex is functional only during late mitosis and G1 when CDK activity is low.

The S-phase-specific cyclin-dependent protein kinases (S-CDKs) and the DBF4 regulatory subunit–CDC7 kinase (DDK, Dbf4-dependent protein kinase) are essential activators for initiation of DNA replication in S-phase, with the generation of a single-stranded DNA template necessary for the recruitment of DNA synthesis machinery (replication protein A, RPA; DNA polymerase α-primase; proliferating cell nuclear antigen, PCNA).[38,39] Increased CDC7-DBF4 abundance

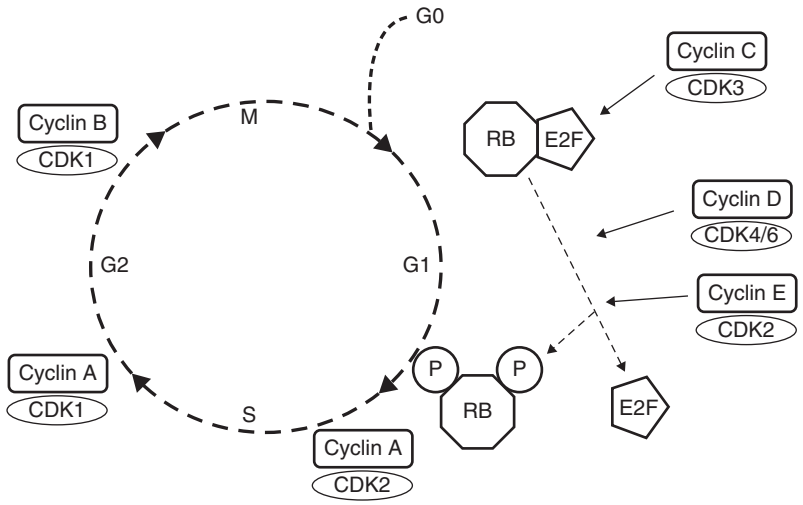

FIGURE 47.3. Retinoblastoma protein (RB) and G1 restriction point. The unphosphorylated RB protein binds to transactivation domain of E2F factors to repress gene transcription in G0 and early G1. Phosphorylation and inactivation of the RB protein (RP-P) by cyclin/cyclin-dependent kinases (cyclin D/CDK4/6, cyclin E/CDK2) release E2F factors in later G1 allowing the expression of genes necessary for S-phase progression. The mitotic cyclins A and B facilitate progression through S-phase, G2, and mitosis. (Adapted from Giacinti and Giordano).[32]

occurs in human malignancies, particularly breast cancer.[40] The binding of the regulatory protein, geminin, to CDT1 and cell cycle-dependent proteolysis of CDT1 suppress relicensing of origins after initiation of DNA synthesis.[41] High CDK activity does not displace MCM2–7 binding to origins, resulting in normal progression through the S-phase in the presence of S-phase induction by CDKs.

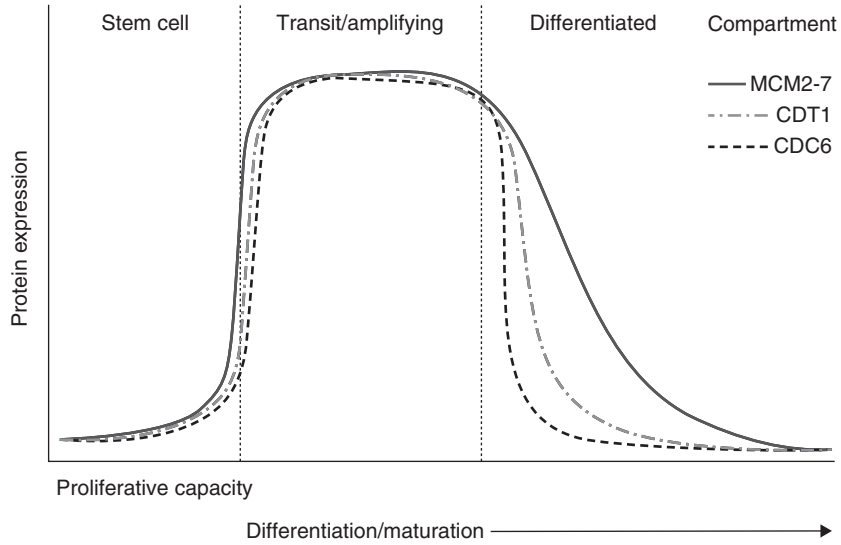

FIGURE 47.4. Progression of cell differentiation/maturation and expression of initiation proteins (CDC6, CDT1) and replicative helicases (MCM2–7) in the compartments of rapidly renewing tissues. New cells are supplied by the stem cell compartment; these cells have low expression of initiation proteins. Rapid increases in initiation proteins and MCM2–7 concentrations occur as the cells enter the transit/amplifying compartment. Gradual downregulation of MCM2–7 ensues as the cell matures and differentiates into a functional phenotype. The loss of proliferative capacity occurs with downregulation of initiation proteins (CDC6, CDT1) as the cells exit the transit/amplifying compartment. (Adapted from Williams and Stoeber).[37]

Deregulation of the licensing system is probably an important driver of oncogenesis in some tumor types. Only licensed origins loaded with MCM2–7 can initiate a pair of replication forks with the bound MCM2–7 displaced during initiation of the origins as a fail-safe mechanism to prevent duplicate DNA replication.[42] Arrested differentiation associated with cancer results from the failure to down-regulate the replication initiation proteins.[43]

Dysplasia is associated with a failure to down-regulate the licensing system producing high MCM protein concentrations. Most premalignant lesions fail to progress through the cell cycle expressing little geminin; consequently, most neoplastic cells remain in the G1 extended or arrested state.[37] Geminin appears only in cells progressing through S, G2, and M phases. CDC6 participates in the activation and maintenance of S-phase and mitotic checkpoints; overexpression of CDC6 promotes DNA hyper-replication and senescence similar to oncogene activation along with interfering with the expression of *INK4/ARF* tumor suppressor genes.[33]

Spindle Assembly Checkpoint

The spindle assembly checkpoint controls cell cycle progression before the onset of anaphase and monitors fidelity of the spindle and proper attachment of chromosomes to spindle microtubules during prometaphase or metaphase of mitosis. Thus, spindle assembly checkpoint signaling ensures accurate chromosome segregation during mitosis. Equal segregation of sister chromatids requires the establishment of proper attachment to microtubules at opposite poles of the mitotic spindle by pairs of kinetochores. This checkpoint ensures the complete separation of chromatids into two daughter cells with a full complement of chromosomes. The chromosomal kinetochores are essential sensors for detecting spindle and/or chromosomal defects via proteins residing on the outer plate of the kinetochores at the spindle microtubule attachments (i.e., NDC80 complex and other components of the microtubule-binding interface).[44] The kinetochore is the primary location of the attachment of microtubules to mitotic chromosomes, with their scaffold proteins creating a solid link between chromatin and the mitotic spindle; kinetochores generate the spindle assembly checkpoint signal.[45,46] Structurally, kinetochores probably contain an inner plate consisting of a 15-subunit constitutive centromere-associated network (CCAN) and specialized centromeric chromatin along with a 10-subunit outer plate involved with microtubule binding through the KMN network. The major binding site for spindle assembly checkpoint proteins at the outer plate of the kinetochore is the interaction of the KMN network (KNL1, MIS12, NDC80 subunits) and microtubule binding activity.[47]

Checkpoint protein kinases include the catalytic proteins budding uninhibited by benzimidazole 1 (BUB1 or BUBR1 in humans) and monopolar spindle 1 kinase (MPS1) as well as noncatalytic proteins including mitotic-arrest deficient 1 (MAD1), mitotic-arrest deficient 2 (MAD2), and Rod-Zwilch-ZW10 complex (RZZ complex). These regulatory proteins interact to form the checkpoint effector (mitotic checkpoint complex, MCC). This complex maintains the mitotic state by protecting cyclin B and securin from ubiquitination and proteasome-induced destruction until the completion of the attachment of chromosomes to the spindle.[48] Abnormally attached kinetochores inhibit the anaphase-promoting complex/cyclosome (APC/C) cofactor, cell division cycle 20 (CDC20), following binding to MAD2 and BUBR1-BUB3 subunits of the MCC complex.[49] The subsequent inhibition of ubiquitylation and degradation of anaphase inhibitors (cyclin B, securin) prevent the initiation of anaphase until proper attachment of kinetochores to a bipolar spindle. Cyclin B is an activator of the major mitotic kinase, CDK1, whereas securin is the inhibitor of a protease that cleaves cohesin and allows sister chromatid separation. Following the correct attachment of kinetochores to microtubules, the MCC disassembles; activation of the APC/C-CDC20 complex triggers entry into anaphase, as displayed in Figure 47.5.

G_2 and the Replication Checkpoint

Actively proliferating cell populations have a decision point in G_2 (i.e., G_2 decision window) to commit to cell division or quiescence in the next cell cycle using increasing and self-reinforcing CDK activity (e.g., CDK1/CDK2) as the switch. Although the G1 restriction point and G_2 decision window require mitogen signaling through the RAS GTPase pathway,[50] the CDK- and RB-E2F-regulated networks in this decision point are similar but not identical.[36] RAS-driven MYC accumulation regulates E2F transcription during the G_2 decision window to control proliferation-related genes, particularly cyclin E transcription,[51] whereas the G1 restriction point depends primarily on the RB-E2F control pathway. Actively proliferating G_2-committed cells usually pass quickly through a subsequently shortened G1 phase.

Figure 47.6 displays the multiple molecular events in the two proliferating decision points for actively proliferating cells. The replication checkpoint prevents progression to mitosis when chromosomes remain incompletely separated. Although the signaling pathways are not identical, G2 DNA damage and replication

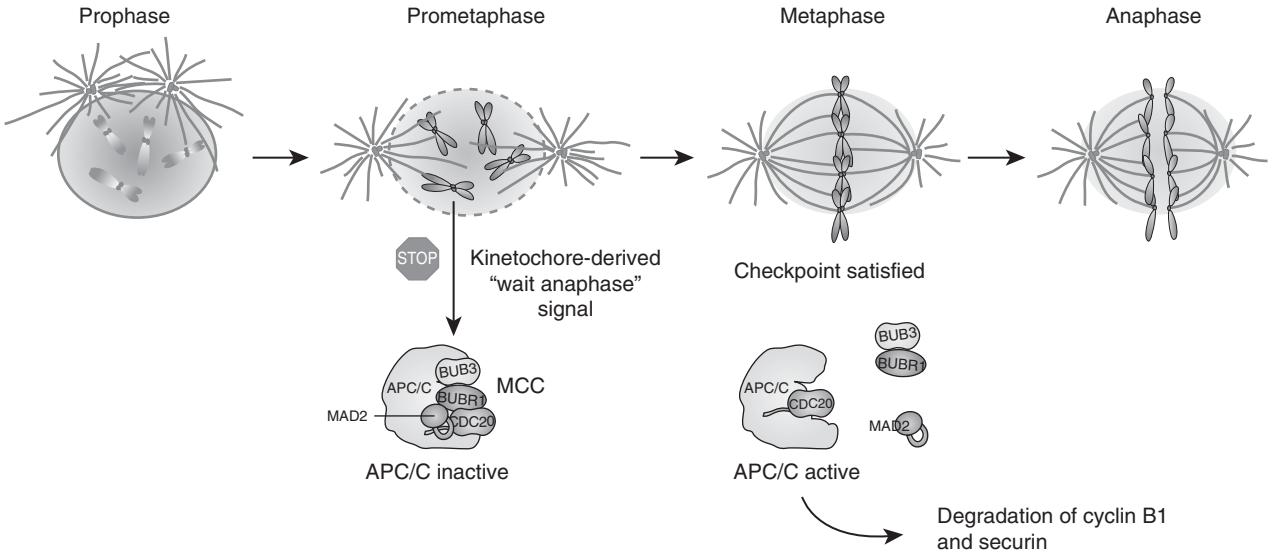

FIGURE 47.5. Spindle assembly checkpoint regulation. Nuclear envelope degradation marks the beginning of mitosis (prophase), followed by the activation of the spindle assembly checkpoint (SAC) by the presence of unattached kinetochores (prometaphase). Formation of the mitotic checkpoint complex (MCC) results from the recruitment of SAC proteins by unattached kinetochores. The mitotic checkpoint complex binds and inhibits the anaphase promoting complex (APC/C). The SAC deactivates when all the kinetochores are properly attached during metaphase; the mitotic checkpoint complex disassembles allowing the freed CDC20 to activate APC/C. The APC/C-CDC20 complex triggers entry into anaphase by degrading cyclin B1 and securin. (Adapted from Lischetti and Nilsson).[49]

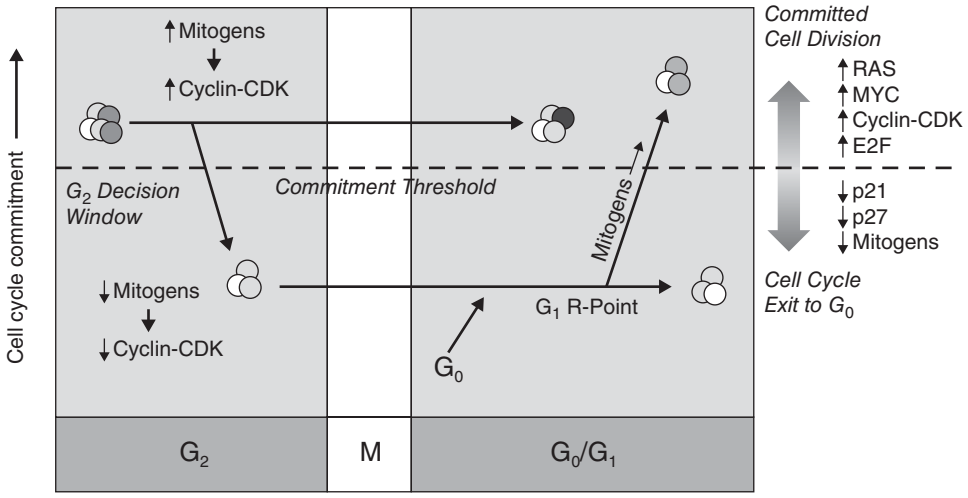

FIGURE 47.6. The G_1 restriction point and G_2 decision window proliferation decision points for actively proliferating cell populations. In G_2, cells with CDK activity above a critical threshold concentration commit the cells to completing the next cell cycle with a short G_1, whereas a subpopulation of G_2 cells with low cyclin-CDK activity and/or reduced mitogen signaling do not commit to the next cell cycle. The latter cells have a long G_0/G_1 phase with a second proliferation decision at the G_1 restriction point. Multiple molecular events noted in the figure determine the commitment to cell division and the exit to G_0. (Adapted from Matson and Cook).[36]

checkpoints function similarly by the CHK1-induced inhibition of CDC25A and subsequent inactivation of cyclin-dependent kinase1 (CDK1).

Mitosis

Phases of mitosis include prophase, prometaphase, metaphase, anaphase, and telophase, as outlined in Table 47.2 and displayed in Figure 47.7. The process of mitosis involves nuclear division and reorganization of almost all cellular elements; during this process, chromosomes condense, the nuclear envelope breaks, mitotic spindles reform the cytoskeleton with chromosomes moving to opposite poles, and finally cell division (cytokinesis) occurs following segregation of sister chromatids and formation of daughter nuclei. The condensation of chromatin reduces the chromatin almost 1000-fold with transcription of highly dense chromatin ceasing.

A single replicated chromosome has two sister chromatids that contain identical chains of double-stranded DNA and a protein support structure (histones) held together by the centromere. The latter has a protein-binding site (kinetochore) for the eventual binding of spindle microtubules. The interruption of the nuclear envelope allows spindle microtubules to bind chromosomes at their kinetochores, beginning chromosome movement during prometaphase. Proteins at the kinetochore direct chromosomes toward the centrosome, resulting in the shuffling of chromosomes between centrosomes and the center of the spindle. Ultimately, the chromosomes align on the metaphase plate in the center of the spindle. Three mitotic engine kinases (PLK1, Aurora A, Aurora B) control most mitotic events, including centrosome maturation/separation and chromosome orientation/segregation at the spindle assembly checkpoint.[52] Histone H3 is a substrate for Aurora kinases; therefore, phosphorylated H3 (H3S10ph) is a biomarker of the M phase. Cells exit mitosis with residual CDK2 activity acquired in the G2 decision window; the amount of CDK activity determines subsequent cell cycle progression. Multiple redundant feedback loops and protein inhibitors (e.g., p21) control CDK2 activity.[53]

TABLE 47.2. Five phases of mitosis.

Mitotic Phase	Actions
Prophase	Newly replicated daughter DNA molecules formed during S-phase unwind during chromatin condensation and attach to a centromere. Centrosomes formed during interphase separate and move to opposite poles in the nucleus, where mitotic spindle formation begins during late prophase along with dissolution of the nuclear envelope.
Prometaphase	Mitotic spindle microtubules shuffle the condensed chromosomes back and forth between the spindle center and the centrosomes. Microtubules from opposite poles of the spindle bind the two sister chromatid kinetochores on opposite sides of the replicated chromosome, leading to alignment on the metaphase plate in the center of the spindle.
Metaphase	Completion of the alignment of chromosomes on the metaphase plate in the center of the spindle. Metaphase is brief compared with other phases of mitosis.
Anaphase	Breakage of the link between sister chromatids and movement of the two sister chromatids to opposite poles of the spindle.
Telophase	Reformation of the nuclei, decondensation of the chromosomes, and formation of two interphase daughter cells.

Control of Cell Division

Cell division is a highly regulated process involving multiple, redundant processes involving transcriptional, posttranscriptional, and posttranslational events. A study of cell cycle regulation by transcription factors and miRNAs identified 3,028 genes associated with the cell cycle, transcription factors regulated cell cycle-associated genes, and miRNAs targeted cell cycle-associated genes.[54] Most regulation of the cell cycle occurs during the two "gap" phases (G1, G2). Integration of information from the cell and the external environment determines if and when the cell cycle progresses to the synthesis and mitosis phases, respectively. The cyclin-dependent kinase (CDK) family of serine/threonine kinases and their regulatory units (cyclins) drive the progression of the cell cycle by altering the phosphorylation state and cell cycle protein concentrations (e.g., cyclin-dependent kinases, CDKs; maturation-promoting factor, MPF).[55] These kinases phosphorylate proteins by catalyzing the transfer of phosphates from high-energy ATP molecules to the oxygen atom of serine or threonine sidechain on the protein. Normal cell division requires the mutually exclusive regulation of mitotic kinases and antagonizing phosphatases, as displayed in Figure 47.8.

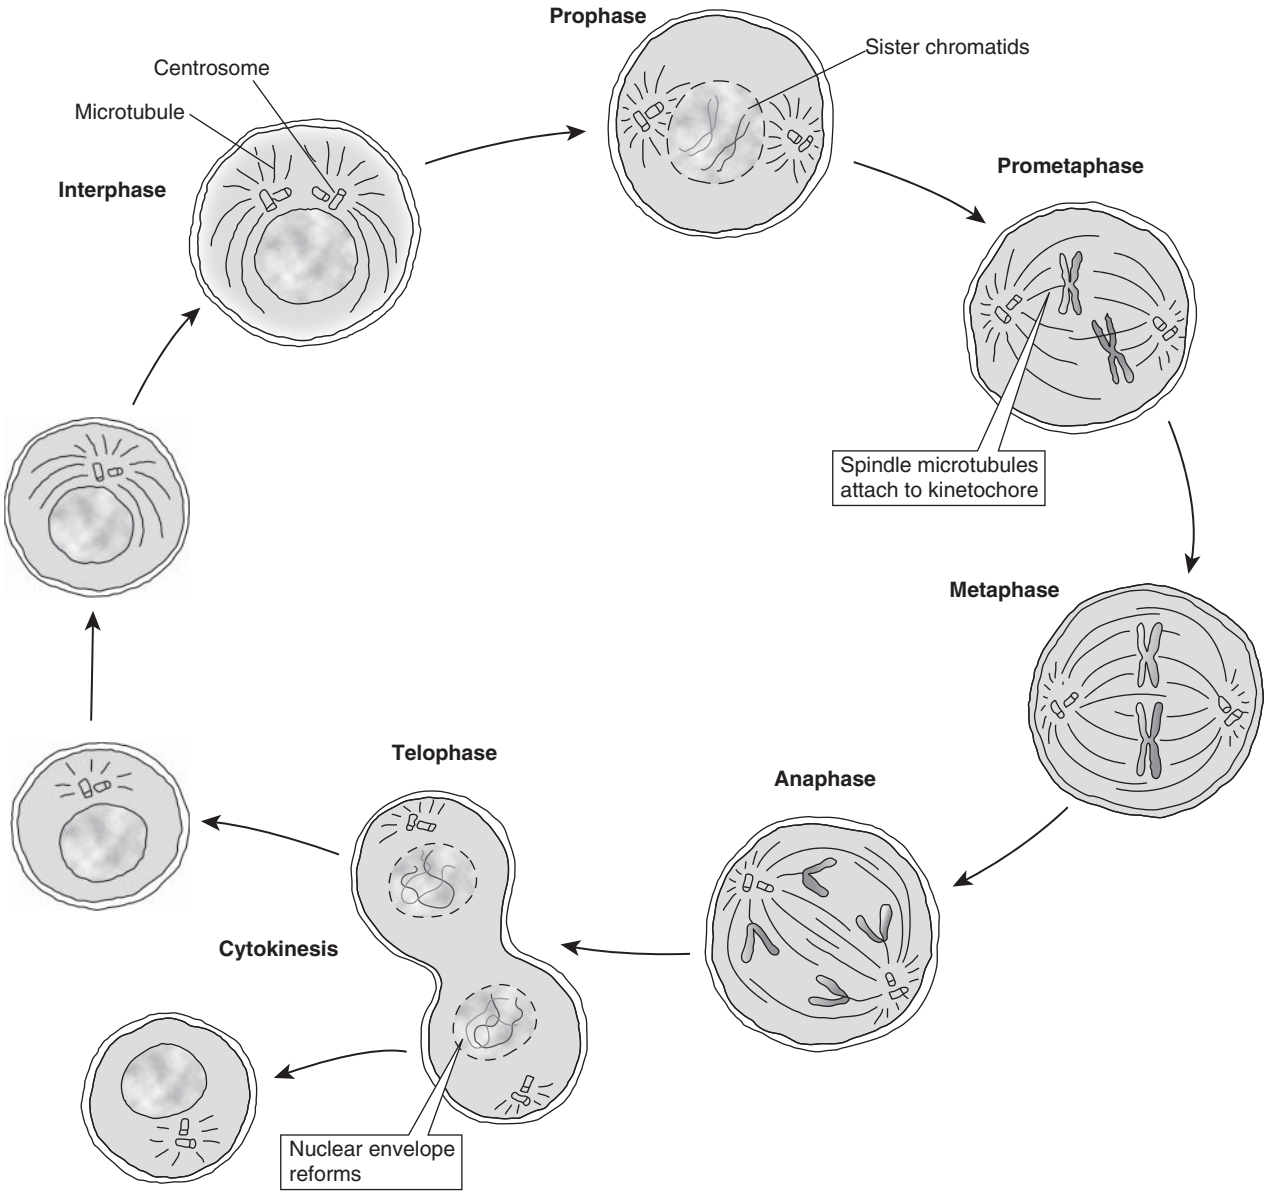

FIGURE 47.7. Stages of mitosis. Chromosomes condense and centrosomes move to opposite sides of the nucleus during prophase, starting the formation of the mitotic spindle. Dissolution of the nuclear envelope allows spindle microtubules to bind to the kinetochores on the chromosomes. Prometaphase involves chromosomes shuffling back and forth between the centrosomes and the center of the cell until alignment of the chromosomes in the center of the spindle initiates metaphase. The sister chromatids separate and move to opposite poles of the spindle during anaphase. Mitosis then ends with restoration of the nuclear envelopes, and chromosome decondensation during telophase marks the end of mitosis with cytokinesis yielding two duplicate daughter cells. Each daughter cell receives one centrosome that reproduces before the next mitosis. (Adapted from Cooper).[27]

During the G0/G1 transition, activation of immediate early genes increasingly sensitizes the cell to growth factors, while the cell progresses through G1 to the synthesis phase. D-type cyclins (D1, D2, D3) activate cyclin-dependent kinases (CDK4, CDK6) for functions from the middle G1 to G1/S transition. Cells not committed to DNA replication during G1 may differentiate and enter the resting phase (G0) or may undergo apoptosis (programmed cell death) when factors (e.g., p53) block progression. Germline cells (sperm, ovum, gametes) divide by meiosis producing four daughter cells, each with one set of chromosomes (haploid) compared with two sets of chromosomes (diploid) in each of the two daughter cells from somatic cell division

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 47.8. Phosphorylation maturation-promoting factor (MPF) and regulatory cell cycle proteins (substrates-P) during interphase (G0–G2) and mitosis. Both of these processes initiate important cell cycle events (e.g., DNA replication, chromosome decondensation). Mitotic kinases and phosphorylation are regulated as mutually exclusive processes, with dephosphorylation reversing processes enhanced by mitotic phosphoproteins. (Adapted from Heim et al.).[55]

during mitosis Table 47.2 describes the five phases of mitosis.

The cycle of cells deprived of growth factors or essential nutrients stops in mid-G1 at the restriction point.[36] Most malignant cells do not have a restriction point; this deficit helps the malignant cell evade normal growth control signals. Cells passing the restriction point progress to late G1, when the cell either enters the S-phase and divides or the G0 phase and differentiates. Progression of cell division then depends on the complicated interaction of numerous factors, including numerous cell receptors, the amount of binding of hormones and growth factors to the receptors, and the presence of specific regulatory proteins within the nucleus.[56]

Changes in the phosphorylation state of structural and regulatory components of the cell cycle by serine/threonine-directed protein kinases trigger critical mitotic events, including nuclear envelope breakdown, chromatin condensation, and bipolar spindle assembly.[57] Maturation-promoting factor (CDK1 (CDC2)/cyclin B complex, MPF) is the main regulator of mitosis; cyclin B1 is predominantly cytoplasmic during interphase, although p21 (*CDKN1A*) can induce nuclear translocation of cyclin B1 when degradation occurs.[58] MPF factor promotes entry of the cell cycle into mitosis and its own degradation by inducing anaphase-promoting complex at the beginning of mitosis. This p21-dependent process sequesters cyclin B1 in the nucleus of untransformed cells, marking the G2 restriction point for terminal cell cycle exit, whereas transformed cells exclude cyclin B1 from the nucleus and accumulate high, cytoplasmic cyclin B1 concentrations during ongoing DNA damage.[59]

MPF (G2 checkpoint) controls the expression of genes that regulate the passage of the cell from the G2 growth phase to the M phase. Activation of the *MSLN* gene produces CDK1/cyclin-B, inhibitory kinases (WEE1-like protein kinase, WEE1; membrane-associated tyrosine and threonine kinase 1, MYT1), and an activating phosphatase, CDC25.[55] Protein phosphatase 1 (PP1) contributes to the activation of CDC25 by directly dephosphorylating S287 and enhancing the activation of CDC25 by CDK1/cyclin-B.[60] Exit from mitosis depends on the inactivation of CDK1/cyclin-B, mediated primarily by the destruction of cyclin-B via the ubiquitin-proteasome pathway.[61] Control of mitosis involves multiple phosphatases. Protein phosphatase type 2A is the major CDK1 antagonizing phosphatase that dephosphorylates mitotic phosphorylations and initiates the exit from mitosis.[62]

Following passage of the metaphase checkpoint, activation of anaphase-promoting complex (a ubiquitin ligase) by MPF degrades two key regulatory proteins (PDS1, ESP1) that result in the degradation of the cohesin, SCC1; the latter protein maintains the link between sister chromatids on the metaphase plate, as displayed in Figure 47.9. Cleavage of SCC1 and the link allows sister chromatids to move to opposite poles on the spindle. All normal human somatic cells undergo a finite number of cell divisions during their lifespan; at the end of their proliferative capacity, these cells enter the programed state of replicative senescence determined by the topology of telomeres, progressive

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 47.9. Anaphase and telophase regulatory controls. After passage of the metaphase checkpoint, activation of anaphase-promoting complex begins the transition from metaphase to anaphase by initiating the degradation of cohesin Scc1 and breaking the link between sister chromatids. The anaphase-promoting complex also degrades cyclin B, resulting in inactivation of MPF and the completion of mitosis (cytokinesis). (Adapted from Cooper).[27]

telomere shortening, and partly the expression of the $p16^{INK4a}$ cell cycle inhibitor.[63] Ultimately, these cells remain in permanent G1 arrest. Malignant transformation of cells overcomes replicative senescence to provide the cancer cell with unlimited proliferative capacity.

CELL SIGNALING

Cell signaling pathways inside cells involve the binding of a signaling molecule (ligand) with a receiving molecule (receptor). The ligand binds only to a specific or a few specific receptors, transmitting a signal that produces a change in shape or activity inside the cell. Kinases are enzymes that transfer phosphate groups to a protein or other targets; receptor tyrosine kinases transfer phosphate groups specifically to the amino acid tyrosine. A signaling molecule binds to the extracellular domains of two adjacent cell-surface tyrosine kinase receptors, phosphorylating each other and then transmitting the signal to intracellular molecules.

Cellular Communication

The four phases of DNA replication that produce cell division are: 1) signal generation; 2) signal recognition; 3) signal transduction; and 4) cell response (e.g., DNA replication, cell division).[64] Initiation of cell division (i.e., signal generation) results from an external signal (e.g., cytokines, growth factors, peptides/steroid hormones) that may be humoral or local. Generally, growth factors are either steroid hormones or polypeptides. Signal recognition requires the presence of receptors located on the plasma membrane, cytoplasm, or nucleus. The interaction of growth factors or hormones with the appropriate receptors results in a sequence of events (signal transduction). Events occurring during transduction that result from binding growth factor to the plasma membrane include dimerization of the receptor, activation of the phosphatidylinositol pathway, release of calcium stores, and stimulation of the serine/threonine-specific protein kinase C. Steroid hormones bind to receptors in the cytoplasm rather than plasma membranes. Gene activation results from the migration of the hormone-receptor complex to the nucleus, where the hormone-receptor complex binds to DNA. The responses to signal transduction include cell replication, protein synthesis, or programmed cell death (i.e., apoptosis). Consequently, the interaction of growth factors or hormones with their receptors is insufficient alone to initiate cell division.

Cytokines

Cytokines are critical components of signaling pathways that control cell growth and development, DNA replication and repair, differentiation, cell death, and cell migration; these proteins include inflammatory cytokines (e.g., interferons, interleukins), chemokines (e.g., macrophage inflammatory proteins, MIP-1α/1β), and growth factors (e.g., hepatocyte and epidermal growth factor).[65] Chemokines are cytokines that specifically influence cell migration. These proteins have short half-lives and interact locally with specific receptors on the cell membranes of their target cells. Plasma contains inadequate cytokine concentrations to measure in blood. Peptide and steroid hormones are not considered cytokines. In response to signal transduction, cytokines typically are released from activated cells rather than storage vesicles. Most cytokines elicit multiple biological responses in different cell types; in a specific cell type, functional overlap (i.e., cross-talk) occurs with different cytokines producing the same response in a specific cell type. Multiple factors (e.g., neighboring cells, other

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cytokines, cytokine concentrations, chemical reactions) affect the duration and type of cytokine response. Many protein products of oncogene expression are cytokine growth factors.

Kinases

Cyclin-dependent kinases (CDKs) are serine/threonine-specific, protein-directed protein kinases composed of a positive regulatory subunit (cyclins) and catalytic subunits (CDKs) with little intrinsic enzymatic activity; the kinase activity depends on the association of the CDK with a regulatory subunit. Mammal cells have several different CDKs (1, 2, 3, 4, 6) and cyclin types (A, B, D, E) performing similar functions during different phases of cell division; each cyclin type also has several variations (e.g., A1, A2) that perform the same functions. Unlike other kinases, CDK2 remains inactive without binding to cyclin; only CDK2 is essential for cell division. Although CDK concentrations are relatively constant during the cell cycle, the concentrations of various cyclins vary dramatically during the regulation of biosynthesis and degradation. Cyclin B/CDK1 phosphorylates core anaphase-promoting complex/cyclosome (APC/C) subunits, enhancing the affinity of APC/C for coactivator CDC20. Subsequently, APC/C targets cyclin-B for proteasomal destruction, resulting in the end of anaphase. Thus, APC/C helps regulate DNA replication and transcription by targeting proteins for proteasomal destruction.[55]

DNA Damage Response Network

In addition to repair of endogenous misreads by DNA polymerase (i.e., $\sim 1/10^9$ replications), proper function of organisms requires the maintenance of genome integrity, particularly against numerous endogenous and exogenous destructive agents, including reactive oxygen species, ionizing radiation, and organic/inorganic chemical substances. The DNA damage response network is the signaling pathway that senses DNA damage, halts cell cycle progression, modulates cell metabolism, and initiates DNA repair mechanisms or apoptosis depending on the severity of DNA damage.[66] This pathway ensures genome stability by regulating the transition of cell cycle phases and coordinating various DNA damage repair processes to prevent error-prone DNA replication and the loss of genetic material. The DNA damage checkpoint pathway functions as a tumor suppressor with disruption of the pathway associated with increased tumorigenesis.[67] In addition to regulating DNA damage repair, checkpoint genes are essential to cellular survival.[68] The pathogenesis of most common human cancers involves dysfunction in the DNA damage response network.[69]

Regulation of the DNA damage response involves very complex, redundant pathways expressing post-translational, protein-modifying enzymes (kinases, phosphatases, ubiquitin ligases, deubiquitinase, sumoylation, de-sumoylation, methylation, acetylation) and epigenetic regulators (mRNAs, lncRNAs).[66] Post-translational, enzyme-catalyzed alterations of proteins allow rapid conformational changes in target proteins without *de novo* synthesis, primarily by changing one or more amino acid residues on the protein. Usually, these alterations are reversible. In the presence of damaged DNA, cell cycle checkpoints sense DNA damage and delay progression of cell division until repairs are complete using signaling effector proteins (e.g., INK4 and CIP/KIP families). The INK4 family (INK4A, p16; INK4B, p15; INK4C, p18; INK4D, p19) inhibits CDK4 and CDK6, whereas the CIP/KIP family (p21, p27, p57) suppresses CDK2 activity.[70] Inactivation of tumor suppressor genes that encode INK4 and CIP/KIP family genes commonly occurs in diverse tumor types. Several checkpoints contribute to DNA fidelity, including DNA damage, replication, and spindle integrity checkpoints. These checkpoints are barriers to DNA over-replication and perpetuation of aberrant DNA; DNA damage response and oncogene-induced senescence are diminished as precancerous lesions progress to advanced cancers.[71]

DNA Damage and Cell Cycle Checkpoints

The major DNA damage checkpoints during cell division are: 1) G1 (pre-S phase); 2) intra-S phase; 3) G2 (before M-phase); and 4) mitotic (mid-mitosis), as displayed in Figure 47.10. Large DNA-bound protein kinases (phosphatidyl-inosol-3-kinase-like kinases, ATM and ATR) detect damaged DNA at these checkpoints along with activating the DNA damage signaling pathways via checkpoint mediators, Chk1 and Chk2. Activation of ATM precedes ATR activation because the latter requires processing of double-stranded breaks. The complex pathways activated by ATM include: 1) sensory proteins [e.g., Mre11-Rad50-Nbs1 (MRN) complex, RAD17 protein] that sense DNA strand breaks; 2) mediator or adaptor proteins that attract multiprotein complexes to damaged DNA and enhance phosphorylation (e.g., BRCA1, 53BP1, MDC1, H2AX variant H2A histone near the DNA break); and 3) protein components of intra-S phase checkpoint pathway (e.g., FANCD2, SMC1).[72] Additionally, ATM targets

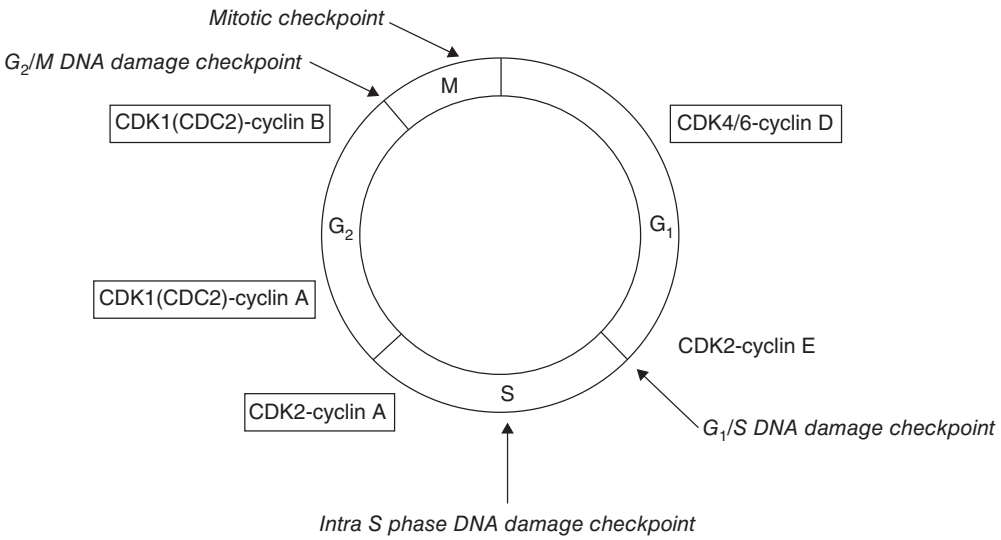

FIGURE 47.10. Cell cycle checkpoints in the DNA damage response network and the main regulatory cyclins and cyclin-dependent kinases (CDK1, CDK2). CDK1 is also known as cell division control protein 2. The DNA damage response network provides DNA repair processes and cell cycle checkpoints to ensure the fidelity of DNA replication. Regulation of cell cycle checkpoints involves ATR/ATM-Chk1/Chk2 and mitogen-activated protein kinase (MAPK) pathways as detailed in the text. Malignant tumors frequently contain mutations in cell cycle checkpoint and DNA repair genes (e.g., *BRCA1* and *BRCA2*). (Adapted from Poehlmann and Roessner).[68]

downstream substances that contribute to genomic stability, including transcription factors involved in the cell cycle and programmed cell death (e.g., E2F1, p53) and effector kinases (Chk1 and Chk2) that signal DNA damage to the CDC25 family of cell cycle regulatory phosphatases (e.g., p53, E2F1, BRCA1). These phosphatases remove critical inhibitory phosphorylations on CDK/cyclin complexes at the G1/S and G2/M checkpoints. Mutations of checkpoint components substantially increase the risk of cancer, particularly mutations in the ATM/Chk2-p53 pathway during the early stage of tumorigenesis before genomic instability and malignant conversion.[73] Mutations in the ATM pathway (e.g., *BRCA1*, *BRCA2*, *CHK2*) substantially increase the risk of breast and ovarian cancers.[74,75] Several substrates of ATM/ATR kinases (Chk1, Chk2, p53, NBS1, BRCA1, 53BP1) are tumor suppressors, whereas *CDC25A* is a proto-oncogene.[68]

An important effector at the G1 and G2 checkpoints is the transcription factor p53. High p53 concentrations ultimately reduce cyclin-dependent kinase activity via inhibition of the CIP/KIP inhibitor p21, leading to G1 and G2 arrest by depression of transcription. Although p53-dependent processes are necessary for G1 checkpoint function and long-term cell arrest, the immediate G2 and intra-S phase DNA damage checkpoints are checkpoint protein kinase Chk1/Chk2-dependent and p53-independent. A variety of DNA repair mechanisms exist, including base excision and nucleotide excision repair, mismatch repair, homologous recombination repair, and nonhomologous end joining. Until completion of DNA repair, the presence of DNA damage promotes the phosphorylation of CDK1-activating phosphatase (CDC25A) by Chk1 or Chk2, resulting in destabilization of the CDK2 complexes required for DNA synthesis.

CLASSIC PATHOLOGICAL STAGES

Normal cell replication and cancer represent opposite ends of the continuum of cell growth. In healthy tissue cells, replication replaces cells lost through normal turnover; the replication ceases following regeneration of the normal structure. Cancerous cells lack normal growth controls, invade surrounding tissues, and ultimately metastasize to distant sites. Somatic mutations are alterations of DNA that occur after conception in cells other than germ cells (i.e., not in sperm or eggs); these changes are not inherited by the children. Although most human cancers are sporadic tumors that arise from a series of somatic mutations producing genetic/epigenetic alterations and abnormal (i.e., cancerous) cell growth, every somatic mutation does not cause cancer. The acquired attributes of cancer cells (e.g., uncontrolled proliferation, resistance to exogenous growth-inhibitory signals, metastasis) result from the accumulation of multiple genetic and epigenetic alterations leading to dysregulation of protein-encoding

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. genes and noncoding RNA (ncRNAs). During the formation of cancer cells, these sequential alterations result in the production of oncogenes, tumor suppressor genes, and microRNA genes that transform a single cell into a clinically detectable clone of fully invasive cells. This multifactorial, multistep process in solid tumors usually develops over 1–2 or more decades.

The tumors typically contain many infrequently mutated genes and a few frequently mutated genes, resulting in substantial genetic heterogeneity and cytogenetically different clones produced by secondary and tertiary genetic alterations of the original initiating cell.[11] This heterogeneity results in different clinical and therapeutic responses in diagnostically similar tumors due to several altered biological processes and biochemical pathways.[76] Understanding the genetic basis of individual tumors allows personalized chemotherapy.

Many human carcinogens act via multiple mechanisms that cause various pathological changes during the multistage cancer process. Before the development of a better understanding of key mechanistic data, genotoxic alterations, and epigenetic pathways, the natural history of these clones was divided into three classic stages (initiation, promotion, and progression), as displayed in Figure 47.11.[77] Chemical carcinogenesis in mammals usually involves chronic exposure to a carcinogen prior to the development of cancer, resulting in a prolonged latent period between exposure and clinical presentation. Under experimental conditions, a single high dose of a potent chemical carcinogen may cause malignant tumors after a sufficient latent period.[78]

Initiation

The progression to malignancy is a multistage process that involves loss of control over cell proliferation, alteration of the balance between cell survival and apoptosis, reduced communication with neighboring cells and the extracellular matrix, induction of tumor neovascularization (angiogenesis), and tumor migration and invasion. The first steps in the neoplastic conversion of a cell are the metabolic activation of the procarcinogen (if needed) and the covalent interaction of the ultimate carcinogen with cellular DNA and other macromolecules.[79] Tumor initiators (e.g., benzo[*a*]pyrene or other high-molecular-weight polycyclic aromatic hydrocarbons) induce heritable intracellular changes that produce dividing cells capable

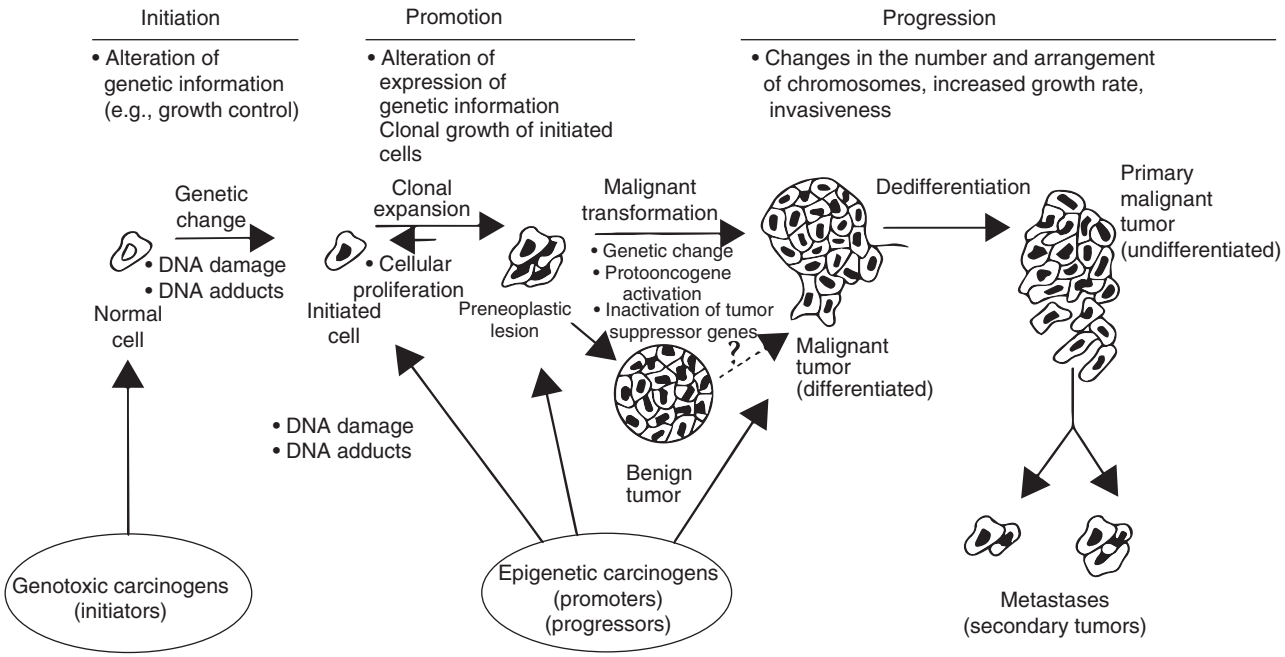

FIGURE 47.11. The three classic pathological stages of carcinogenesis, based on the multistage model developed from studies of hepatocellular carcinoma in rats. An initiator alters the genetic information of a normal cell irreversibly with subsequent prolonged exposure to a promoter, resulting in cellular proliferation, clonal expansion, and formation of preneoplastic foci. Under the influence of progressor agents, irreversible karyotypic changes occur along with increased proliferation and invasiveness that result in metastasis. Although benign and malignant tumors appear during this process, the presence of localized *in situ* malignant cells in pathologically benign tumors cannot be excluded. (Adapted from Derelanko).[77]

TABLE 47.3. Biological characteristics of the stages of carcinogenesis. (Adapted from Pitot and Dragan).[80]

Initiation	Promotion	Progression
Irreversible	Reversible	Irreversible
Initiators are usually genotoxic	Promoters are not usually mutagenic	Progressors may not be initiators
Subtle, pathologically unobservable change in critical genes without morphological changes. Early cellular changes have not been identified	No discernible chromosomal abnormalities, but changes in gene expression	Discernible alteration in the genetic structure of cells (aneuploidy) with both benign and malignant tumors present
Spontaneous initiation occurs. Initiation requires cell division for "fixation"	Depends on continued administration of a promoting agent to expand progeny of initiated cell population	Spontaneous progression to benign and/or malignant neoplasms occurs
Lack of readily defined threshold dose with no measurable maximum response	Measurable thresholds and maximal effects depend on the total dose of initiating agent	
Efficacy of initiators sensitive to chemicals	Efficacy is sensitive to dietary and hormonal factors	Growth of altered cells sensitive to environmental factors during early progression
Single exposure may be sufficient, but usually multiple exposures	Prolonged, repeated exposure is necessary	Environmental factors influence early progression

of evolving into clones of neoplastic cells. Characteristics of initiation include irreversibility, additivity, and the absence of an easily measured threshold dose.[80] Table 47.3 compares the biological characteristics of initiation, promotion, and progression. Mutations in single cells frequently initiate carcinogenesis; these mutations can occur spontaneously in the absence of external carcinogens.[81] Although initiation may be a relatively common event, progression of an initiated cell to a neoplasm is relatively uncommon, with most initiated cells remaining dormant and failing to progress to a malignant tumor.[82] Few xenobiotics act only as initiators. Most carcinogens are complete carcinogens that act at all three cancer stages including initiation; however, many carcinogens act as initiators at low doses and complete carcinogens at high doses.[83] Initiation produces genotypic (i.e., preclinical) changes in the cell that are not visible histologically.

Initiation involves the following events: 1) absorption and distribution of the carcinogen; 2) metabolic activation of the procarcinogen, if necessary; 3) covalent interaction with the cell genome; 4) fixation of DNA damage including activation of proto-oncogenes; and 5) proliferation of the altered cells. Prime targets for initiation include proto-oncogenes and tumor suppressor genes. Under normal circumstances, these genes produce proteins that affect cell division and regulation of cell growth (e.g., genetic alterations promote cell proliferation by converting normal proto-oncogenes to oncogenes). This genetically transmissible activation occurs primarily during DNA repair processes before repair of damaged DNA sequences or after severe DNA damage occurs at multiple sites. This activation provides the cell with a growth advantage. In contrast to the deletion of genetic materials that often occurs following ionizing radiation exposure, chemical carcinogens usually produce either transversion mutations (i.e., replacement of pyrimidine with purine or purine with pyrimidine) or transitional mutations (i.e., replacement of purine with another purine or pyrimidine with another pyrimidine).[84]

Animal cancer models indicate initiation requires some cell proliferation to form heritable, preneoplastic lesions capable of responding to promoting agents.[85] Although genetic damage at various stages of oncogenesis is necessary for the development of cancer, mutations alone are not sufficient to induce cancer. Mammalian cells possess DNA repair mechanisms that remove most DNA adducts and mutations; however, further enhancement of these preneoplastic cells occurs through error-prone DNA repair mechanisms that create permanent alteration of the genome. Initiation may arise as a spontaneous event in response to naturally occurring carcinogens, radiation, or viruses; therefore, this step does not require the presence of chemical carcinogens. Nevertheless, chemical carcinogens can promote the clinical appearance of a spontaneous, initiated preneoplastic event.

Metabolic Activation

Most procarcinogens do not produce cancer on direct contact with skin; many procarcinogens require biotransformation via CYP isoenzymes to induce cancer.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Variation in the distribution of multiple CYP isoenzymes among organs, individuals, and species explains most, but not all, differences in the response to carcinogens between animals and humans. Substantial interindividual variation in the ability to metabolize carcinogens results from a number of factors, including the presence of xenobiotic metabolizing isoenzymes with different substrates and inhibitor preferences, genetic factors (polymorphism),[86] exposure to environmental chemicals, and host factors (age, sex, health).[87] Individuals exhibiting slow acetylation have a higher risk of developing bladder cancer because these individuals inactivate the carcinogenic arylamines (e.g., 4-aminobiphenyl) more slowly compared with rapid acetylators.[88]

In animal models, oxidation by CYP1 and CYP2 enzymes activates most known procarcinogens; however, other phase I reactions (hydrolases, dehydrogenases, flavin monooxygenases) may also stimulate procarcinogens. These pathways form electrophilic (i.e., positive ions, uncharged molecules with electron-deficient regions) intermediate metabolites (ultimate carcinogens) that react with nucleophilic (electron rich) sites on the DNA in the presence of sufficient concentrations of these metabolites. Nucleophiles include some amino acids of proteins along with purine and pyrimidine bases of the nucleic acids. Phase II conjugation reactions usually inactivate chemical compounds; thus, some genes controlling phase II reactions may contribute to individual susceptibility to specific cancers.[89] The *N*-acetyltransferase 2 gene (*NAT2*) is associated with the biotransformation of aromatic amines, and the glutathione S-transferase M1 gene (*GSTM1*) is involved with detoxifying polycyclic aromatic hydrocarbons in smoke using phase II reactions. The metabolic intermediates of some chemical carcinogens (e.g., low and high molecular weight polycyclic aromatic hydrocarbons) act as promoters and cocarcinogens by activating the aryl hydrocarbon receptor complex; this pathway controls the expression of a diverse set of genes, including some CYP isoenzymes, and a broad spectrum of cellular responses (cell proliferation, cell cycle regulation, apoptosis).[90]

Mutations

The progression of neoplasia involves three broad categories of gene mutations: 1) oncogenes (e.g., *HER2*) that are growth stimulators capable of inducing the malignant transformation of cells; 2) tumor suppressor genes (e.g., *TP53*) that inhibit growth regulators; and 3) mutator genes (e.g., *HNCC*) that control the fidelity of the DNA replication process. Oncogenes are altered versions of normal genes (proto-oncogenes) that regulate cell growth and differentiation. Oncogenes produce proteins that affect every level of growth regulation.[91] The alterations of the proto-oncogenes by chemical carcinogens (e.g., point mutation, gene amplification, chromosomal translocation) confer malignant transforming potential to that gene.[92] No specific type or sequence of alterations necessarily causes cancer. Oncogenes promote cell division, whereas mutations in oncogenes result in the inappropriate stimulation of cell division. Oncogene mutations occur in a dominant fashion, resulting from alterations of a single allele altering the phenotype. These mutations are classified as gain-of-function mutations.

In contrast to oncogenes, tumor suppressor gene mutations require changes in both alleles; hence, these loss of function mutations are inherited as recessive changes that inhibit suppression of cell proliferation. Tumor suppressor genes normally block cell division either by preventing cell replication or repairing a defect in DNA replication. The inhibition of tumor suppressor genes contributes to the malignant transformation of these cells.[93] Unlike oncogene mutations, tumor suppressor gene mutations are inherited in the heterozygous state, resulting in a predisposition to human cancer.[94]

Mutator genes control the purity of the DNA replication process by eliminating endogenous mutations formed from the spontaneous deamination of 5-methylcytosine (C/T transition) and defective repair of DNA by DNA polymerase during replication. The genetic alterations include deregulation of gene expression, allelic losses, amplifications, point mutations, deletions, and translocations. Alterations of these mutator genes reduce the effectiveness of the editing process during DNA replication; consequently, the mutation rate increases. Like tumor suppressor gene mutations, these loss of function mutations contribute to the inherited predisposition to cancer.

Promotion

Initiation is the initial process that produces genetic changes to form the first clone of mutated cells; however, the development of cancer requires further epigenetic stimuli before the cellular expression of cancer appears. Early animal studies on the development of epidermal carcinogenesis in mice and later liver cancer in rats demonstrated the necessity of applying an initiating agent followed by a promoting agent.[82,95] Neither the application of benzo(a)pyrene nor croton oil to the skin of mice produced cancer; however, the application

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of benzo(a)pyrene followed by croton oil did cause cancer of the skin. Reversing the application of the chemicals (i.e., croton oil followed by benzo(a)pyrene) did not induce skin cancer. This observation indicates the action of promoting agents is reversible, whereas the effects of initiating agents are irreversible. Promotion involves alterations in gene expression rather than molecular changes in DNA; promoting agents increase cell replication only in a specific subset of the initiated cell population. Tumor promoters may be difficult to separate from mutagens because the epigenetic effects of promoters on cell and tissue homeostasis may secondarily produce mutagens.[96]

Stages

The promotion process confers a selective growth advantage to the initiated cell population and decreases the rate of cell division of uninitiated cells;[97] selective blockage of gap junctional intercellular communication limits growth control from normal adjacent cells, resulting in clonal expansion.[78] Within the multistage process of chemical carcinogenesis promotion, there is at least a two-stage process.[98] Stage I promotion is the transformation of the initiated cell; stage II is the propagation of the transformed cell into a premalignant tumor. Tumor promotion produces primarily benign foci of preneoplastic cells that must undergo one or more additional heritable changes during progression to form a malignant neoplasm.[99] The spontaneous development of a malignant lesion within the preneoplastic lesions formed during promotion is a rare event.

Course

Promotion is a slow process that represents the longest stage in cancer development.[78] During this stage, exposure to promoting agents converts dormant, initiated cells into a growing, premalignant clone by altering the expression of portions of the genes that control cell proliferation and morphology. These preneoplastic cells are more susceptible than normal cells to proteins affecting cell replication and less susceptible to apoptosis. Apoptosis (i.e., active cell death) serves at least two functions: homeostasis of cell numbers in tissues and elimination of damaged cells. Tumor promoters confer a growth advantage to the initiated cells by shifting the balance from apoptosis to cell replication.[100] This stage probably accounts for the long latent period between initiation and the clinical detection of cancer; prolonged exposure to the promoter is necessary for tumor development.

Many, if not all, initiated cells in the stage of promotion depend on the continual presence of the promoting agent to survive.[101] Consequently, promotion is the *reversible* stage of cancer development (i.e., in the early stages of promotion), involving replication of the initiated cell and alteration of gene expression. The development of nodular hyperplasia and hepatic adenomas in premenopausal women following the administration of some synthetic estrogen preparations may regress after drug cessation.[102]

Intermittent exposure and cessation of exposure reduce the carcinogenic potential of a promoting agent in experimental settings.[78,103] Epidemiology studies indicate lung cancer risk decreases exponentially with time after cessation of smoking; after 15–20 years of nonsmoking, the lung cancer risks of prior smokers and never-smokers are similar.[104] The laryngeal cancer risk also decreases in intermittent smokers compared with continuous smokers.[105]

Characteristics

Although promoting agents do not directly induce structural changes in genes, they can produce metabolic changes (e.g., free oxygen radicals) that cause chromosomal alterations, strand breaks in the deoxyribosyl DNA backbone, and base modifications.[106] Characteristics of promoting agents include the requirement of prolonged exposure, the absence of an additive effect in the early phase, a lack of mutagenicity, the insignificance of metabolic activation, the probable presence of a threshold effect, and the importance of mitogenic properties (i.e., enhanced DNA synthesis), as noted in Table 47.3.[107]

Like initiating agents, promoting agents are structurally dissimilar and represent a wide variety of compounds (drugs, synthetic chemicals, hormones, and natural products). Metabolic activation probably is not a significant part of the process of promotion. Promoting agents include phenobarbital, phorbol esters (croton oil), butylated hydroxytoluene (BHT), cigarette smoke, viral infections, hormones, bile salts, and 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). These compounds often display tissue specificity.

Site of Action

Tumor promoters (e.g., the phorbol ester, phorbol 12-myristate 13-acetate) are nongenotoxic carcinogens that enhance the clonal expansion of initiated cells by preventing apoptotic loss of initiated cells. In contrast to an initiator and a progressor, phorbol ester receptors

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

bind protein kinase C-α (PKCα), members of the protein kinase C (PKC) family of serine/threonine-specific protein kinases involved in phosphorylating a wide variety of cell functions and protein targets including activating protein-1 and nuclear factor kappa B depending on cell types and conditions.[108] Activation of PKCα produces lipid hydrolysis and interactions with various adapter proteins affecting cellular transformation, differentiation, proliferation, apoptosis, motility, and adhesion including the ability of preneoplastic and malignant cells to resist apoptosis-based tumor surveillance. Consequently, promotion is an epigenetic phenomenon that involves changes in the expression of the genetic information in the genome rather than alterations of DNA structure.

Modulating Factors

Environmental factors (hormones, age, diet, sex) modulate the effect of promoting agents. Although these compounds cannot initiate cells, promoting agents may produce spontaneous mutations in the environment by causing chronic inflammation and free-radical formation. Benzoyl peroxide is an example of a compound that acts as a promoter during the induction of epidermal cancer in the mouse.[109] In cell cultures, these agents modulate aspects of gene expression through discrete effects on differentiation (e.g., inhibition, stimulation, recovery, terminal phase). The mechanism of action is not known, but the inhibition of intercellular communication[110] and alteration of cell membranes are plausible effects. Protein kinase C is an enzyme formed from the receptor-mediated hydrolysis of inositol phospholipids that regulates intracellular processes by relaying information across the cell membrane to the interior of the cell.[111] Presumably, this family of enzymes plays an integral part in the response (e.g., activation of transcription, alteration of membrane functions) of the cell to external signals. Studies in cells suggest that the primary site of action of the strong promoting agent of croton oil (phorbol esters) is the cell membrane and the principal target is protein kinase C.[112]

Progression

Progression is the irreversible, genetic process in the natural history of cancer when the malignant morphological changes in the cell genome become clinically evident; consequently, a tumor progressor allows premalignant, mutated cells to irreversibly acquire the phenotype of a fully malignant cell.[113] This stage is the final step in the transition from preneoplastic foci to malignant cells. Malignant conversion frequently involves multifocal changes in the premalignant lesions. During progression, marked changes in cellular morphology and biochemistry develop, the growth rate of the premalignant cells increases, the cells become increasingly invasive, and metastasis occurs. In human hepatocellular carcinomas, progression involves the transition from an early to a more advanced tumor manifesting histologically as a nodule-in-nodule lesion (i.e., a moderately to poorly differentiated cancerous nodule growing inside a well-differentiated cancer nodule).[114]

In contrast to the subtle alterations in the cell genome during initiation (e.g., single base changes including transitions and transversions), progression produces major chromosomal abnormalities (e.g., gene amplification, karyotypic instability, loss of heterozygosity, translocations, duplications, insertions, and deletions) in the genetic structure of the nucleus.[115] At the cellular level in experimental models, malignant conversion is associated with gene amplification, upregulation of AP-1 transcriptional activity, and overexpression of cell cycle regulatory genes and secreted proteases. During the stage of progression, the cell clone continually expands and displays gradually increasing malignant properties (i.e., undifferentiated/dedifferentiated and uncontrolled growth, invasion of surrounding tissue, metastasis). Angiogenic switches and increased hypervascularity are important processes in the development of malignant tumors during progression.

CANCER PATHOPHYSIOLOGY

Abnormal cell proliferation from deregulation of the cell cycle characterizes the development of malignant lesions with loss of cell cycle checkpoint controls, promoting genetic instability. Important factors in the pathogenesis of cancer include oncogene and tumor suppressor gene mutations and dysfunction of the DNA damage response network, particularly control of cell cycle checkpoints and DNA repair systems. Oncogene proliferation results from mutation-induced activation of growth signaling networks coupled with loss of tumor suppressor protein function.[37]

DNA DAMAGE RESPONSE NETWORK

The DNA damage response network is a complex signal transduction pathway of interacting molecules that activates DNA repair mechanisms, regulates cell cycle arrest, adjusts telomere length, and activates transcription for viable cells or apoptosis for unrepairable DNA. The major parts of this pathway are DNA damage sensors (e.g., MRN protein complex,[116] DNA-binding protein replication protein A, RPA), signal transducers (e.g., ataxia-telangiectasia mutated, ATM; ataxia-telangiectasia and RAD3-related, ATR), and downstream signal effectors that suppress kinases or phosphatases (e.g., cell division cycle 25A, CDC25A; p53). ATM and DNA-dependent protein kinase catalytic subunit (DNA-PKcs) respond primarily to double-strand DNA breaks, whereas single-stranded DNA and stalled DNA replication forks activate ATR.[117] ATM and ATR signal transducers frequently act together with the related kinase (DNA-PK) because of the common occurrence of both types of DNA damage.[118]

ATM/ATR-Chk1/2 Signaling Pathways

ATM activates the downstream protein kinase Chk2 and the tumor suppressor gene *TP53*, whereas ATR-mediated phosphorylation activates Chk1; however, a substantial amount of redundancy occurs in these two pathways.[119] Important targets of Chk1/2 are the CDC25 phosphatases that control mitotic entry (CDC25B/C) and S-phase progression (CDC25A). The ATR-Chk1 pathway is the essential direct effector of DNA damage and replication checkpoints necessary for the survival of most cell types. Although organisms survive with mutations in *ATM* (e.g., BRCA1, BRCA2), the presence of these mutations increases genomic instability and cancer risk.

The G1/S checkpoint involves Chk1- and Chk2-induced degradation of CDC25A phosphatase in response to DNA damage, resulting in the inactivation of CDK2-cyclin E complex and G1/S arrest. Activation and accumulation of p53 also occur after DNA damage catalyzed by multiple protein kinase pathways (ATM, ATR, DNA-PK, Chk1/Chk2). Upregulation of p53 enhances transcription and upregulates several genes involved with DNA damage response (e.g., *GADD45A*, $p21^{WAF1/CIP1}$). Accumulation of $p21^{WAF1}$ protein suppresses CDK2-cyclin E, producing G1 arrest. The G2M checkpoint involves Chk1-induced phosphorylation of CDC25C phosphatase; increased phosphorylation of CDK1 by WEE1/MYT1 inactivates the CDK1-cyclin B1 complex, resulting in G2/M arrest. DNA damage also activates p53 via Chk1/Chk2, resulting in the induction of $p21^{WAF1/CIP1}$, blockage of CDK1-cyclin B1 formation, and G2/M arrest.

MAPK Pathways

The DNA damage response network contains a third effector kinase complex that operates parallel to Chk1 and downstream of ATM and ATR; the p38 mitogen-activated protein kinase pathway (p38MAPK) targets the downstream effector kinase, MAPK activated protein kinase 2 (MK2).[120] In response to DNA damage, this pathway regulates G1/S and G2/M cell cycle checkpoints by multiple mechanisms, including p53 phosphorylation, stabilization of the transcriptional repressor (HBP1), and degrading CDC25A. Other members of the MAPK family (e.g., ERK, JNK) respond primarily to stress and inflammatory stimuli rather than mitogens; the JNK MAPK pathway responds to DNA damage by phosphorylation of CDC25C, resulting in G2/M arrest.[121] $p21^{WAF1}$ is a cyclin-dependent kinase inhibitor for all cyclin/CDK complexes, particularly in the G1 phase; ERK MAPK enhances $p21^{WAF1}$ accumulation and G1 arrest.[122] In response to a variety of extrinsic (ionizing radiation, osmotic stress) and intrinsic (reactive oxygen species, cytokines, DNA damage) stimuli, the p38 MAPK pathway alters transcription, protein synthesis, cytoskeletal structure, cell surface receptors, and cell survival.[123] JNK, ERK, and p38 MARK pathways participate in the activation of activating protein-1 (AP-1) transcription factor that is a component of the c-Jun proto-oncoprotein. MAPK signaling pathways regulate many aspects associated with malignant cell behavior, including proliferation, longevity, migration, and invasion with the ERK pathway deregulated in $\sim^1/_3$ of human cancers.[68]

GENE MUTATIONS

Mutations following exposure to chemical carcinogens are DNA alterations inherited by subsequent cell progeny and occurring in <1% of the general population, whereas mutations occurring at a higher frequency are polymorphisms. These DNA alterations appear as visible changes (i.e., gene translocation, inversion, amplification, rearrangement) in the chromosome or changes in the nucleotide bases of the DNA structure (e.g., insertions, deletions, point transpositions, frameshifts).[98] Single nucleotide polymorphisms (SNPs) are the most common DNA variations in the human genome (i.e., 1/300–1,000 bp).

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Malignant tumors typically contain multiple mutations that alter many cell control functions and allow the tumor to acquire malignant characteristics. On a molecular level, mediators of cell growth suppression (e.g., p53, pRb, TGF-β signaling pathway) affect multiple cancer hallmarks, including metabolism, angiogenesis, genetic instability, cell death, invasion/metastasis, inflammation, and tumor microenvironment maintenance.[124] Similarly, multiple molecular targets regulate each cancer hallmark.

The number of cells in a tissue is a balance between cell proliferation and cell death. Proto-oncogenes and tumor suppressor genes regulate the former, whereas apoptosis and anti-apoptosis genes regulate the latter. The human genome contains ~20,000 protein-coding genes; however, the number of tumor suppressor genes and oncogenes is very small (~70 and 50, respectively).[125] Other natural mechanisms limiting tumor progression include growth inhibition and senescence. Somatic mutations occur only in somatic cells from changes in cellular DNA, environmental factors, and/or DNA replication errors with the number of somatic mutations correlating strongly to the number of stem cell divisions and age; germline mutations occur in germ cells inherited from parents. Although the rate of point mutations in tumors and normal cells is similar, the rate of chromosomal changes (e.g., deletions, inversions, translocations, chromosome number) in tumors is relatively greater. Cancer genome sequencing and epidemiological data suggest DNA replication errors account for up to $\sim^2/_3$ of somatic mutations.[126]

Sequencing of common human cancers indicates tumors typically contain a few frequently mutated and many infrequently mutated genes. Driver gene mutations confer a selective growth advantage to the altered cell, whereas passenger gene mutations provide no direct or indirect growth advantages. The total number of driver genes is unknown; however, at least 140 genes can promote (i.e., drive) carcinogenesis, with typical solid tumors containing 2–8 driver gene mutations and many passenger gene mutations (i.e., ~30–60).[125] Some tumors have substantially more somatic gene mutations (i.e., ~200), particularly with exposure to potent carcinogens (e.g., cigarette smoke, UV light). Most of these mutations are single-base substitutions (e.g., C > G) resulting in missense changes; deletions or insertions of up to a few bases occur much less frequently. Driver genes usually involve mutations in 12 signaling pathways that regulate cell survival, cell fate, and/or genome maintenance, as displayed in Figure 47.12. Although metastatic cancer usually requires decades to develop,

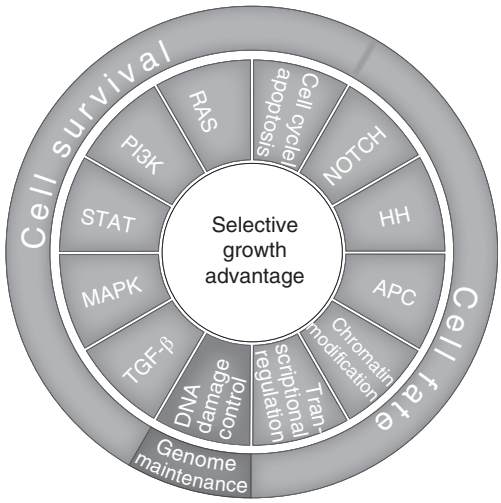

FIGURE 47.12. Cell processes and cancer cell signaling pathways are typically involved in driver gene mutations. In colon cancer, gatekeeper mutations often occur in the *APC* gene with increased clonal expansion developing after a second mutation in *K-RAS* proto-oncogene. Somatic mutations in *PIK3CA*, *SMAD4*, and *TP53* eventually confer malignant properties (e.g., invasiveness, metastasis) to the clone. (Adapted from Vogelstein et al.).[125]

almost all somatic mutations in metastatic tumors are present in the primary tumor.

Adducts

The electrophilic metabolites of known carcinogens covalently bind DNA, forming DNA-carcinogen complexes (adducts). Almost all adducts cause mutations rather than inaccurate replications.[127] Different classes of carcinogenic chemicals form adducts with different portions of the DNA molecule; however, these adducts are specific for a given chemical because the DNA-chemical adduct is the same in different animal species.[128]

An increase in adduct concentrations associated with bulk DNA usually increases the probably of mutations in critical genes. Sensitive measures (e.g., enzyme-linked immunosorbent assay, radioimmunoassay, ^{33}P-postlabeling, gas chromatography/mass spectrometry) can determine the presence of specific DNA-chemical adducts. This type of test allows monitoring of individuals exposed to chemicals capable of causing cancer; however, positive tests do not necessarily indicate the presence of mutagenesis or carcinogenesis.[129] The persistence of these adducts depends on the susceptibility of the tissue to neoplastic changes and particularly on DNA repair mechanisms.[130]

During various cellular processes (transcription, recombination, replication, and apoptosis), these mechanisms repair DNA abnormalities including single-strand and double-strand breaks. Gene translocations, deletions, amplifications, and rearrangements occur during the repair of double-strand DNA breaks that may contribute to the initiation of a cell and subsequent tumor development.[131] Studies of the autosomal recessive disease, xeroderma pigmentosum, provide evidence for the importance of DNA repair mechanisms in carcinogenesis. Homozygotes demonstrate hypersensitivity to sunlight and marked increases in the incidence of skin cancer.[132] The fibroblasts from these patients possess defective DNA repair mechanisms for ultraviolet radiation-induced damage.

Proto-oncogenes

Proto-oncogenes are normal genes that produce proteins affecting all phases of cell signaling involved in the control of processes associated with normal cell growth, differentiation, and division.[133] These genes are essential regulators of cell proliferation, differentiation, apoptosis, and genome stability. Proto-oncogenes include genes that produce growth factors tyrosine kinases, growth factor receptors, nuclear regulatory proteins, and small membrane-associated GTPases (G proteins) that help regulate signal transduction.[134] Oncogene- and proto-oncogene-encoded proteins are structurally similar; however, the abnormal, oncogene-encoded proteins do not respond to normal regulatory limits. During carcinogenesis, mutations of proto-oncogenes (e.g., *MYC*) and tumor suppressor genes (e.g., *TP53*, RB family) alter the control of cell proliferation by altering the relationship of these regulatory proteins to growth factors.

Oncogenes

The discovery of oncogenes resulted from the isolation of a small set of cellular genes from retroviruses that produce tumors.[135] The progenitors of these oncogenes are altered versions of normal cellular genes (proto-oncogenes) acquired by retroviruses during evolution. Oncogenes produce oncoproteins that alter signal transduction pathways at the cell surface, cytosol, and nucleus. Mutations (point mutations, inversions, translocations), chromosomal rearrangement, gene fusion, and gene amplification convert proto-oncogenes to oncogenes that alter cell regulation and growth by producing oncoproteins. These oncoproteins contribute to the malignant transformation of cells by activating signaling pathways to preserve initiated cells through cell proliferation, deregulation of the cell cycle, and inhibition of apoptosis. Translocations and mutations occur during initiation and progression, whereas amplification usually occurs during progression. Over 1% of the genes in the human genome are associated with human cancers.[10,136]

Most oncogenes are positive growth signals that enhance growth factors, growth factor receptors, intracellular signaling molecules, and/or nuclear transcription factors. The six broad classes of oncogenes include: 1) transcription factors; 2) apoptosis regulators; 3) chromatin remodelers; 4) growth factors; 5) growth factor receptors (tyrosine kinases involving integral membrane proteins, receptors without protein kinase activity); and 6) signal transducers (cytoplasmic tyrosine kinases, membrane-associated G proteins, GTPase exchange factor, cytoplasmic serine/threonine kinases, cytoplasmic regulators).[76,137] The site of action for oncogenes includes the cytoplasm (e.g., growth factor, growth factor receptors, signal transducers) and nucleus (e.g., chromatin remodelers). Alterations in oncogenes affect the signal transduction process by altering cellular proteins involved in growth signal transduction pathways, including proteins in the extracellular environment (growth factors), cell membrane (growth factor receptors), cytoplasm (G proteins), and nucleus (DNA-binding proteins).[138] All tumors do not display alterations in proto-oncogene expression;[28] spontaneous translocations may create fusion (chimeric) proteins with functions similar to transcription factors produced by oncogenes.[139] The latent period between oncogene formation and progression to a malignant cell indicates that alteration of other genes in addition to a particular oncogene is necessary to produce cancer. Table 47.4 is a partial list of the six classes of oncogenes associated with specific neoplasms, protein function, and mechanism of activation.

The *RAS* oncogene family was the first oncogene family discovered; the RAS oncoprotein (p21) was the first oncogene protein identified. RAS encodes a family of membrane-bound, small GTPases including Harvey-Ras (H-RAS), neuroblastoma-Ras (N-RAS), and Kirsten-Ras (K-RAS). *RAS* oncogenes occur in ~30% of all human tumors, including lung, pancreatic, and colon cancers.[140,141] *RAS* oncogenes are downstream signal transducers of many receptor tyrosine kinases; activation of these pathways ultimately promotes cell survival and proliferation.[142] Oncogenes act on a variety of sites on cell constituents, including tyrosine kinase receptors, growth factors, serine/threonine kinases, nuclear proteins, transcription factors,[143] and

Oncogene	Neoplasms	Mechanism of Activation	Protein Function
		Transcription Factors	
L-MYC	Lung	Deregulated activity	Transcription factor
N-MYC	Neuroblastoma: lung cancer	Deregulated activity	Transcription factor
V-ERBA1	Erythroblastosis	Deregulated activity	T3 Transcription factor
V-ERBA2	Erythroblastosis	Deregulated activity	T3 Transcription factor
V-ETS-1	Erythroblastosis	Deregulated activity	Transcription factor
V-ETS-2	Erythroblastosis	Deregulated activity	Transcription factor
V-FOS	Osteosarcoma	Deregulated activity	AP1 Transcription factor
V-JUN	Sarcoma	Deregulated activity	AP1 Transcription factor
V-MYB	Myeloblastosis	Deregulated activity	Transcription factor
V-MYC	Myelocytomatosis	Deregulated activity	Transcription factor
V-REL	Lymphatic leukemia	Deregulated activity	Transcription factor
V-SKI	Carcinoma	Deregulated activity	Transcription factor
		Apoptosis Regulators	
BCL2	B cell lymphomas	Deregulated activity, ↑ gene amplification	Antiapoptotic protein
MDM2	Sarcomas	Protein	Complexes with p53
		Chromatin Remodelers	
ALL1 (MLL)	Acute lymphocytic leukemia, acute myelogenous leukemia	Gene fusion	Chromatin modifier
		Growth Factors	
HST	Stomach	Constitutive production	FGF family
INT2	Mammary carcinoma	Constitutive production	FGF family
KS3	Kaposi's sarcoma	Constitutive production	FGF family
V-SIS	Glioma, fibrosarcoma	Constitutive production	B chain PDGF
		Growth Factor Receptors–Tyrosine Kinases: Integral Membrane Proteins	
EGFR	Squamous cell	Gene amplification-protein-point	EGF receptor
	Non-small cell lung cancer	Mutation	
MET	MNNG-treated human osteocarcinoma cell line	DNA rearrangement/ligand-independent constitutive activation (fusion proteins)	HGF/SF receptor
HER2/NEU	Neuroblastoma, non-small cell lung cancer, breast, ovary	Constitutive activation-point mutation	Mitogen-activated protein kinase (MAPK) and phosphoinositid-3 kinase/protein kinase B signaling pathways, BCL-2 family suppression of pro-apoptotic functions of BAX and BAK
RET	Medullary thyroid carcinomas, MEN 2A-B, Hirschsprung disease	DNA rearrangement/ligand-independent, constitutive activation (fusion proteins)	Cadherin superfamily, cell-surface molecules transduce signals for cell growth and differentiation
TRK	Colon, thyroid	DNA rearrangement/ligand-independent, constitutive activation (fusion proteins)	NGF receptor
V-FMS	Sarcoma	Constitutive activation	CSF1 receptor
V-KIT	Sarcoma, GIST	Constitutive activation-point mutation	Stem cell factor
V-ROS	Sarcoma	Constitutive activation	Tyrosine kinase activity

TABLE 47.4. (Continued)

Oncogene	Neoplasms	Mechanism of Activation	Protein Function
		Signal Transducers–Cytoplasmic Tyrosine Kinases	
ABL	Chronic myelogenous leukemia	DNA rearrangement (constitutive activation, fusion proteins)	Protein tyrosine kinase
SRC	Colon	Constitutive activation	Protein tyrosine kinase
V-FES	Sarcoma	Constitutive activation	Protein tyrosine kinase
V-FGR	Sarcoma	Constitutive activation	Protein tyrosine kinase
V-YES	Sarcoma	Constitutive activation	Protein tyrosine kinase
		Signal Transducers–Membrane-Associated G Proteins	
BRAF	Melanoma, thyroid, colon, ovary	Point mutation	Serine/threonine kinase
GIP	Ovary, adrenal	Point mutation	Inhibitory G protein α-subunit
GSP	Thyroid adenoma	Point mutation	Stimulatory G protein α-subunit
H-RAS	Colon, lung, pancreas	Point mutation	GTPase
K-RAS	Acute myelogenous leukemia, melanoma, thyroid, colon, lung	Point mutation	GTPase
N-RAS	Melanoma	Point mutation	GTPase
		Signal Transducers–GTPase Exchange Factor	
DBL	Diffuse B cell lymphoma	DNA rearrangement	Guanine nucleotide exchange factor for RHO subfamily of RAS-like GTP-binding proteins
VAV	Hematopoietic cells	DNA rearrangement	Guanosine nucleotide exchange factors for RHO GTPases and signaling adaptors downstream of protein tyrosine kinases involved with actin cytoskeletal rearrangements
		Signal Transducers–Cytoplasmic Serine/Threonine Kinases	
PIM-1	T cell lymphoma	Constitutive activation	Serine/threonine kinase
V-MOS	Sarcoma	Constitutive activation	Serine/threonine kinase
V-RAF	Sarcoma	Constitutive activation	Serine/threonine kinase
		Signal Transducers–Cytoplasmic Regulators	
V-CRK	—	Constitutive tyrosine phosphorylation cellular substrates	SH2/SH3 domain adaptor activity

Abbreviations: AP1 = activator protein-1; B chain PDGF = platelet-derived growth factor B chain; BAK = BCL2 antagonist/killer 1; BAX = BCL2 associated X; CSF1 = colony stimulating factor 1; EGF = epidermal growth factor; FGF = fibroblast growth factor; GIST = gastrointestinal stromal tumor; GTPase = guanosine triphosphatase; HGF/SF = hepatocyte growth factor/scatter factor; MNNG = *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine; NGF = nerve growth factor; T3 = 3,5,3′-triiodo-L-thyronine (Triiodothyronine). The prefix v refers to vial oncogenes, whereas the prefix c refers to their cellular counterpart. Oncogene names are abbreviations that reflect the history of their isolation and the types of tumors involved.

DNA, as outlined in Table 47.4. Most neoplastic transformations probably require several oncogenes and perhaps the inhibition of tumor suppressor genes or the interaction of oncogenes and promoters.[93] Cancer therapies targeting oncogenic proteins include small molecules (Gefitinib, Erlotinib) that affect intracellular processes or monoclonal antibodies (Cetuximab, Trastuzumab) that affect oncogenic proteins on the cell surface.[76]

Tumor Suppression

Most cancers demonstrate multiple genetic changes that produce enhanced proliferation (oncogenes) and loss of inhibition of cell growth (tumor suppressor genes) rather than a single mutation type.[144] The ability of cancer cells to evade cell growth-inhibitory signals is one of the hallmarks of cancer; this characteristic involves alterations in multiple cell processes, including tumor

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. suppressor genes (e.g., *TP53*, *RB1*), TGF-β signaling pathway, gap junction, and contact inhibition. Point mutations in the p53 tumor suppressor gene are the most common genetic alterations detected in human cancers, with ~50–60% of tumors containing the TP53 gene mutation depending on the tumor type.[145,146] Conceptually, these genes are involved in the "checkpoint" controls of cell division that stop progression of the cell cycle when mutations occur. Loss of function of tumor suppressor genes allows the duplication of damaged DNA and increases the risk of neoplasia. The concentration of p53 proteins is frequently elevated in workers exposed to carcinogens (e.g., hexavalent chromium,[147] vinyl chloride).[148] Although ~30–40% of patients with p53 gene mutations develop antibodies against this mutation, the presence of these antibodies is not a good diagnostic marker of cancer because other methods are more sensitive.[149] The biological significance and the predictive value of high concentrations of serum p53 proteins remain unclear.

p53 Pathway

The p53 pathway maintains a normal genome by regulating cell cycle checkpoints, activating DNA damage repair, inducing apoptosis (programmed cell death), and altering angiogenesis and cellular stress response. The normal *TP53* gene produces a tetrameric nuclear transcription factor that suppresses tumor formation by detecting DNA damage and preventing cell replication until the damage is repaired. Two homologous negative proto-oncogenes (*MDM2*, *MDM4*) control p53 activity by producing proteins that degrade p53 via ubiquitination.[150] Other signaling pathways also influence p53 function including Ataxia-Telangiectasia-related (ATR)-Checkpoint kinase 1 (Chk1), Ataxia-Telangiectasia-mutated (ATM)-Checkpoint kinase 2 (Chk2), and liver kinase B1 (LKB1).[124]

The *TP53* tumor suppressor gene limits cell replication by inducing the transcription of *CDKN1A* gene, which produces an inhibitory protein that binds to the regulatory protein, cyclin and the cyclin-dependent kinase complex. The restriction of kinase activity limits cell replication and allows time for the repair of DNA. Inactivation of these genes accelerates neoplastic changes by limiting the inhibitory effect of these genes on mutated cells. This gene participates in the cell cycle checkpoint signal transduction pathway responsible for causing arrest of the cell in the G1 phase or apoptosis after the detection of DNA damage. C-to-T transitions at CpG dinucleotides account for the majority of human tumor mutations in the p53 gene, particularly in brain, colon, and blood cancers.[151] The p53 tumor suppressor gene is located on the short arm of chromosome 17; mutations of tumor suppressor genes require inherited changes in both alleles.

Retinoblastoma Protein (pRb)

First identified in a malignant retinal tumor (retinoblastoma), the nuclear RB protein is a tumor suppressor protein encoded by the retinoblastoma susceptibility gene (*RB1*); this protein is an integral part of the restriction point in mid-G1 that blocks S-phase entry (G1/S transition) and limits cell growth. The retinoblastoma family includes three "pocket proteins" (RB/p105, p107, RB2/p130) that repress gene transcription required for the G1/S transition by binding to the promoter of E2F family of transcription factors and interacting with proteins involved with nucleosome remodeling, histone acetylation/deacetylation, and methylation.[32] The pRb pathway includes cyclin D, cyclin-dependent kinases 4/6, and CDK inhibitor 2a (p16/INK4a); this pathway integrates mitogenic and antimitogenic signals including growth factor receptors, RAS, and p53 as well as affecting DNA replication, differentiation, cellular senescence, and apoptosis.[152] Many human neoplasms (e.g., osteosarcoma, retinoblastoma, small cell lung carcinoma) contain direct mutations or deletions of the *RB1* gene or alterations in the activation or expression of upstream regulators.[153]

Transforming Growth Factor-β (TGF-β)

The TGF-β inhibits cell growth by producing the downstream effector transcription factors, SMAD2 and SMAD3;[154] these proteins reduce transcription of *TGF-β* genes, including the growth inhibitors, $p15^{INK4B}$ (*CDKN2B*) and $p21^{WAF1}$ (*CDKN1A*).[155] A major upstream regulator of TGF-β is epidermal growth factor receptor (EGFR) that activates SMAD2 and SMAD3 as well as other pathways and effectors (MAPK/ERK, CDKs, glycogen synthetase kinase 3β, JNK, p38).[156] Inactivation of TGF-β-mediated growth inhibition is an important prerequisite for tumor development that allows cancer cells to resist TGF-β tumor suppression activities and utilize TGF-β as a prooncogenic factor.[157]

Gap Junctions

The large connexin family of transmembrane proteins assembles tightly packed intercellular channels (gap junctions) that allow intercellular communication for a variety of metabolites, ions (ATP, cAMP, Ca^{2+}), and small signaling molecules. Individual cells may express

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

different connexins, resulting in many different subtypes of gap junctions. Thus, these channels provide communication channels between cytoplasm and the extracellular environment; these channels also dock with each other to form gap junction plaques that limit communication. Connexins are tumor suppressors in normal cells that reduce tumor cell growth and partially redifferentiate transformed cells; however, connexins promote tissue invasion and metastasis in advanced stages of some tumors.[158]

Contact Inhibition

Normal cells respond to increased cell density by undergoing G1 arrest and/or decreased cell division. Contact growth inhibition results from signal transduction events mediated by a large family of transmembrane proteins (cadherins) that alter calcium-dependent adhesive interactions between adjacent cells. Cytoplasmic proteins (e.g., β-catenin, p120) interact with the intracellular domain of cadherins. Nontransformed cells express E-cadherin to maintain intercellular contact between cells and form epithelial monolayers. This process involves CDK inhibitors (p16, p21, p27) that block cyclin D-CDK4 and cyclin E-CDK2, resulting in G1 arrest; additionally, contact growth inhibition recruits tumor suppressors (pRb, p53, p27).[159] Mutations of tumor suppressors in cancer cells allow transformed cells to evade contact inhibition and limit cell cycle progression.[160]

Nonprotein Coding RNAs

Approximately 10% of the RNA in human cells is mRNA that provides templates for protein expression, whereas the remaining 90% of RNA is nonprotein coding RNA (ncRNA). Long noncoding RNA (lncRNA) consists of transcripts of >200 nucleotides in length located in overlapping antisense transcripts of protein-coding genes or intergenic stretches. Epigenetic processes affected by lncRNAs involve chromatin remodeling, histone modification, and DNA methylation. The main functions of these lncRNAs include molecular guides for localizing mRNA to their binding sites, scaffold molecules for chromatin modification, regulation of DNA looping, alteration of RNA transcription, translation, splicing, and stability, and coactivator of transcription factors.

MicroRNA (miRNA) genes produce single RNA strands of ~21–23 nucleotides rather than oncoproteins; these RNA strands alter gene expression by degrading mRNA and blocking protein translation. Some miRNAs and lncRNAs are potential biomarkers for determining clinical typing, diagnosis, and prognosis of specific tumors (e.g., leukemia subtypes).[161,162] Deletion or downregulation of miR-15a and miR-16-1 occurs in most indolent cases of chronic lymphocytic leukemia.[163] MicroRNA genes can function as oncogenes (i.e., downregulating tumor suppressor genes) or tumor suppressor genes (downregulating oncogenes), depending on their specific tissue targets (i.e., suppressor gene or oncogene). Both genetic (deletions, amplifications) and epigenetic (demethylation, epigenetic silencing) factors affect the expression of microRNA genes. Table 47.5 displays the key cellular proteins targeted by specific miRNAs.

TABLE 47.5. Key targets of microRNA during DNA damage response. (Adapted from Liu et al.).[66]

Key Target	Function	MicroRNA Number
CDK2	Cell cycle	124a, 372, 376a, 385-5p
Cyclin D	Cell cycle	15, 16, 195
p21	Cell cycle	17, 20a/b, 93, 106a/b, 192, 215, 663
CDC25a	Cell cycle checkpoint	21, 424, 449a/b, 503
Chk1	Cell cycle checkpoint	15 family, 26a
WIP1	Cell cycle checkpoint	16
MDM2	Cell cycle checkpoint, apoptosis	192, 194, 215, 605
p53	Cell cycle checkpoint, apoptosis	125b, 504
H2AX	Sensor	24, 136
ATM	Transducer	18a, 100, 101, 181a/b, 421
BRCA1	DNA repair	146a, 146-5p, 182
BCL1	Apoptosis	15a, 16-1, 34a, 195

MiRNAs participate in most DNA damage repair processes, including sensing DNA damage, transducing DNA damage signals, repairing DNA damage, stimulating cell cycle checkpoints, and initiating apoptosis when DNA damage persists. MiRNAs regulate gene expression by degrading or inhibiting transcription of target mRNAs after attachment to complementary sequences in the mRNAs.[66] A dense network of miRNAs controls the activity and expression of p53, ensuring the rapid accumulation of p53 following DNA damage. DNA damage activates multiple transcriptional factors (e.g., C-JUN, C-MYC, E2F1, nuclear factor-kappa B, p53) that alter miRNA expression by regulating essential steps in miRNA processing and maturation. Additionally, phosphoinositide 3-kinase (pI3K)-like protein kinases (ATM, ATR, DNA-PKcs) also regulate miRNA expression following DNA damage.[164] MiRNA

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. regulates gene expression by binding to the 3′ untranslated gene region, resulting in the induction of RNA degradation or blocking gene translation.[165]

CELLULAR ALTERATIONS

Conceptually, cancer is a disruption of the normal control processes that regulate cell division and differentiation. Most cancers begin as an alteration of a single cell that develops into a clone of malignant cells capable of spreading throughout the body.[166] This clone demonstrates several characteristics, including: 1) autonomy (i.e., unregulated growth independent of normal biochemical and physical control factors); 2) anaplasia (i.e., abnormal cell differentiation); and 3) metastasis (i.e., dissemination of the clone to distant sites in the body). Chemical carcinogens may exert their effect by permanently altering the DNA of the cell genome (i.e., initiation); however, DNA is not the only critical target of chemical carcinogens. Chemical carcinogens also act at other cancer stages (e.g., promotion, progression), including interactions with proteins important in the regulation of gene expression or changes in enzymatic methylation of DNA.[167,168] These epigenetic mechanisms involve inactivation of specific control points by hypermethylation of gene promoters and reactivation of suppressed genes by hypomethylation.[169] As the normal cell evolves into the malignant state, the cells acquire a succession of hallmark capabilities listed in Table 47.6.

Two enabling characteristics enhance the multistep transition from a normal cell to an invasive tumor. The most prominent characteristic in a large majority of human tumors is genome instability with the generation of random mutations.[170] Normally, DNA replication and chromosomal segregation are impressively accurate processes, with somatic cell cultures displaying overall mutation rates of $\sim 2 \times 10^{-7}$ mutation/gene/cell division and $\sim 1.4 \times 10^{-10}$ single base substitutions/nucleotide/cell division.[171] Based on the presence of ~70,000 genes/cell, each cell accumulates an estimated one mutant gene during the life span of an individual; however, cancer cells often increase spontaneous mutation rates by increased sensitivity to mutagenic agents and/or impairment of genome maintenance systems that detect and repair mutations. Almost all human tumor cells contain immune cells with infiltrates ranging from a few cell type-specific antibodies to gross inflammation.[172] Tumor-associated inflammation is the other enabling characteristic that enhances tumorigenesis and progression by supplying bioactive molecules to the tumor microenvironment. Uncontrolled release of prostaglandins, cytokines, chemokines, and reactive oxygen species enhances genomic instability, alterations in vasculature, and disruption of local immune processes.

Emerging hallmarks include: 1) reprogramming energy metabolism to glycolysis that normal cells use primarily under anaerobic conditions; and 2) the evasion of immune destruction by unclear mechanisms.[170] Immune cells within the tumor microenvironment produce conflicting effects including tumor-inhibiting and tumor promoting actions.[173] Tumors arise from a small population of cells (cancer stem cells or tumor initiating cells) that produce histopathologically diverse neoplastic lesions with various degrees of differentiation, vascularity, inflammation, proliferation, and invasiveness. Based on animal studies, the stroma and parenchyma of these tumors contain distinct cell types that enable tumor progression and the seeding of new tumors by cancer stem cells.[174] Hallmark-targeting cancer drugs direct their activity at specific molecular targets involved in enabling particular capabilities; however, the common occurrence of relapses following the use of these drugs suggests these hallmark capabilities are regulated by partially redundant signaling pathways.

Cell Proliferation

Telomeres

The telomere is a nucleoprotein complex located at the ends of linear eukaryotic chromosomes; in contrast to most plasmids and viruses with circular genomes, the linear chromosomes of eucaryotes require mechanisms to protect and replicate DNA ends. These short, dysfunctional repetitive nucleotide sequences help maintain chromosomal stability by forming a specialized complex (shelterin) that protects telomeres from the DNA damage response. This complex conceals chromosomal ends from DNA repair mechanisms and represses ATM/ATR signaling pathways.[175] Cells count the number of cell divisions based on telomere length with each cell division shortening the telomere as a result of incomplete replication of linear DNA molecules by conventional DNA polymerases. These heterochromatic DNA-protein structures (shelterin) reduce the loss of nuclear material, stabilizing chromosomes, and avoiding fusion between adjacent chromosomes during cell replication.[176]

Telomeres progressively shorten throughout the life of an individual.[177] Telomerase is the enzyme responsible for maintaining proper telomere length by compensating for telomere attrition by adding TTAGGG repeats in regenerating cells (e.g., pluripotent stem cells).[178] Telomeres shorten with every cell

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 47.6. Hallmark characteristics of cancer. The hallmarks of cancer are acquired functional capabilities that allow cancer cells to survive, proliferate, and metastasize via genetic and epigenetic changes during the multistep process of carcinogenesis. Two emerging hallmarks that enhance carcinogenesis are reprogramming energy metabolism and evading immune destruction. Enabling hallmarks include genome instability and inflammation along with the formation of a tumor microenvironment to enhance the growth of the tumor. (Adapted from Hanahan and Weinberg).[170]

Characteristic	Primary Target	Example
	Classic Hallmarks	
Sustaining proliferative signaling	Growth factors binding cell-surface receptors containing intracellular tyrosine kinase domains	RAS oncoprotein-induced disruption of negative-feedback mechanisms attenuating proliferative signaling (membrane-associated G protein signal transducers) or activation of epidermal growth factor receptor (EGFR) signaling pathway by epidermal growth factor and/or transforming growth factor-α resulting in tumor proliferation.
Evading growth suppressors	Control nodes in complementary pathways to regulate cell proliferation and activate senescence/apoptotic programs	RB (retinoblastoma-associated) and TP53 (tumor protein p53) oncoproteins inhibit tumor suppressor genes and reduce tumor senescence/apoptosis in lung tumors.
Resisting cell death	Intrinsic and extrinsic apoptotic pathways	BCL-2 family of regulatory proteins inhibits apoptosis by binding to proapoptotic triggering proteins (BAX, BAK).
Enabling replicative immortality	Telomeres protect the ends of chromosomes from progressive shortening from successive cell generations	Enhanced telomerase activity reduces telomere erosion and increases resistance to senescence and apoptosis. Telomerase reverse transcriptase and DNA methyltransferases control telomere length, producing successive generations.
Inducing angiogenesis	Neovascularization generated by angiogenesis supplies nutrients and oxygen along with eliminating CO_2 and waste	Production of aberrant vessels with erratic blood flow by activation of stimulatory angiogenic regulators (vascular endothelial growth factor-A) and downregulation of inhibitors (thrombospondin-1).
Activating invasion and metastasis	Alteration of shape and attachment of other cells and extracellular matrix via epithelial-to-mesenchymal transition	Downregulation of cell-to-cell adhesion molecules (E-cadherin) and alteration of the developmental regulatory program (epithelial-mesenchymal transition) by pleiotropically acting transcription factors (SLUG, SNAIL, TWIST, ZEB1/2).
	Emerging Hallmarks	
Reprograming energy metabolism	Cytosolic aerobic glycolysis via reprogrammed metabolic pathways in cancer cells	Upregulated glucose transporters and multiple glycolytic pathway enzymes along with hypoxia-inducible 1-α factors (HIF1α, HIF2α).
Evading immune destruction	Immune cells lose their ability to eradicate cancer cells in tumor microclimates via alteration of programmed death-ligand 1, then help support tumor survival	Unclear exact mechanism, possibly involving altered function of cytotoxic T cells, T_h1 helper T cells, and natural killer cells.
	Enabling Characteristics	
Genome instability (↑ genome alteration during cell division from changes in DNA damage checkpoints, DNA repair machinery, and mitotic checkpoints)	Chromosomal and telomere abnormalities cause ↑mutations and carcinogenic changes to genome	A succession of clonal expansions triggered by chance acquisitions of mutant genotypes by alteration of genome maintenance and repair. Some epigenetic mechanisms (DNA methylation, histone modifications) also contribute to progression.
Inflammation	Immune cell infiltration of tumors	Supply of bioactive molecules to tumor environment (growth factors, extracellular matrix-modifying enzymes) that limit cell death, facilitate angiogenesis, and activate epithelial-mesenchymal transition.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

division, particularly in aging patients with chronic diseases. In mice, the percentage of shortened telomeres is associated with shorter lifespans rather than the monthly rate of telomere shortening.[179] Shortened telomeres induce the DNA damage response that causes cell cycle arrest and replicative senescence when DNA repair is not possible. Insufficient telomerase and loss of telomeric DNA expose vulnerable chromosomal ends to subsequent amplification/deletion of chromosomal segments.[180]

Telomere shortening induces chromosomal instability and enhances tumor development in the absence of functional tumor suppressor genes. Short telomeres block stem cell proliferation and tissue regeneration; hence, telomere shorting is a potential physiological marker of aging.[181] Telomere syndromes include aplastic anemia, liver and pulmonary fibrosis, dyskeratosis congenita (nail dysplasia, skin pigmentation, and oral leukoplakia with very high risk of bone marrow failure), and Hoyeraal-Hreidarsson syndrome (multisystemic genetic disorder with very short telomeres).[182] In nonmalignant cells, the maximum number of cell divisions is ~60–70.[183] Cells enter a state of senescence when cell division stops. Normal DNA damage-sensing systems recognize erosion of telomeres, resulting in the activation of mechanisms to limit further somatic cell division. Germline cells (sperm, ova, gametes) undergo meiosis to produce haploid daughters with a single set of chromosomes. The Mendelian randomized study of genome-wide association reports associated increased telomere length in germline genetic variants with increased risk of some cancers (glioma, low-malignant-potential ovarian cancer, lung adenocarcinoma, neuroblastoma, bladder cancer, melanoma, testicular cancer, kidney cancer, endometrial cancer) and a lower risk of some nonmalignant diseases (cardiovascular diseases, abdominal aortic aneurysm, celiac disease, interstitial lung disease).[184]

Angiogenesis

The development of new blood vessels in tumors (angiogenesis) is a prerequisite for the growth, maintenance, and progression of malignant tumors. Tumor angiogenesis is a complex process involving the interaction of tumor cells, endothelial cells, phagocytes, and inflammatory cytokines. Mechanisms for tumor angiogenesis include endothelial sprouting (i.e., formation of new vessels from preexisting blood vessels) and intussusceptive vascular growth (i.e., splitting of preexisting blood vessel into two new blood vessels by formation of transvascular pillars). The sprouting process involves endothelial cell migration, proliferation, and tube formation, whereas the splitting process involves the formation and insertion of interstitial tissues into the lumen or walls of preexisting vessels. There is a large, diverse range of angiogenesis mediators, including stimulators and inhibitors of angiogenesis. Positive regulators of these two mechanisms of angiogenesis include PDGF/VEGF growth factor family. and its receptors FLK-1 (KDR) and FLT-1 for the sprouting process; factors mediating the splitting process include the angiopoietin/tie-2 and ephrin-B/EpH-B signaling pathways.[185] In some malignant tumors (e.g., glioblastomas, breast and ovarian cancer, hepatocellular carcinomas), cancer stem cells can form nonendothelium-lined blood vessels (vasculogenic mimicry).[186] This process involves several families of growth (angiogenic) factors, including vascular endothelial (VE)-cadherin, vascular endothelial growth factor receptor (VEGFR1), phosphatidyl inositol 3-kinase (PI3K), matrix metalloproteinases (MMPs), erythropoietin-producing hepatocellular receptor A2 (EPHA2), and hypoxia inducible factor-1α (HIF1α). Some of these angiogenic factors are direct-acting, binding primarily to activated epithelial cells (e.g., VE-cadherin, VEGFR1). Others are indirect-acting and express pro-angiogenic growth factors or recruit endothelial cells to the tumor, including transforming growth factor beta (TGF-β), cytokines (IL-6, IL-8, Stromal-derived factor-1, G-CSF), and sex hormones (androgens, estrogens).[187] Tumor angiogenesis produces qualitatively different blood vessels. Overexpression of pro-angiogenic factors allows for higher density along with greater permeability from the cytoplasmic projections penetrating the lumen and creating small, intercellular gaps in the vessel walls.

The body also contains a variety of endogenous angiogenesis inhibitors including the large glycoprotein thrombospondin-1 (TSP-1a), which is upregulated by p53; loss of p53 downregulates TSP-1 expression.[188] The development of angiogenesis and malignant tumors requires the downregulation of neovascularization inhibitors present in most normal cells. VEGF-induced angiogenesis upregulates the NOTCH/DLL4 signaling pathway that is essential as a stimulator of embryonic, wound, and *in utero* angiogenesis; however, in adults, activation of this pathway inhibits tumor angiogenesis by producing abnormal, poorly functioning blood vessels that inhibit tumor growth. Consequently, delta-like four Notch ligands (DLL4) produce a negative feedback system to prevent functional tumor angiogenesis.[189] The first successful randomized phase 3 clinical trial of an antiangiogenic agent involved the use of bevacizumab, a monoclonal antibody to VEGF, in metastatic colon cancer; however, the success of the drug depended on

the coadministration of radiation or chemotherapeutic agents to alter other pathways.[190]

Apoptosis and Necroptosis

Apoptosis (programmed cell death) and necroptosis (RIPK3/RIPK1-mediated necrosis) are the phenotypic expression of energy-dependent events that cause cell death by two different pathways. The cascade of apoptotic events results from the presence of certain stimuli that produce morphological changes (DNA fragmentation, nuclear condensation, cell shrinkage) characteristic of cell death.[191] In normal adult tissue, apoptosis is an active physiological process that maintains homeostasis by eliminating damaged DNA or pathogens in defective cells (e.g., over-expressed oncogenes, infected cells) resulting from spontaneous/induced mutations from invasion by a pathogen. Apoptosis packages dying cells into fragments easily eliminated by phagocytes without disturbing normal cell function.[192] This biological process differs from necrosis because apoptosis does not produce a secondary inflammatory response and potentially the formation of additional mutations; apoptosis requires activation and inactivation of certain regulatory genes, primarily a family of cysteine-dependent, aspartate-directed proteases (caspases). The two apoptosis pathways are: 1) intrinsic or mitochondrial pathway (caspase-9 mediated); and 2) extrinsic or death receptor pathway (caspase-8- or caspase-10-mediated); both pathways utilize caspases as downstream effectors.[193]

Multiple upstream signal pathways (e.g., DNA damage, oncogenic stress) activate initiator caspases (caspases-2/-8/-9/-10) that cleave effector caspases (caspase-3/-6/-7); subsequently, the latter caspases mediate the proteolytic destruction of cells via cell death cascades.[194] Proapoptotic and antiapoptotic members of the BCL-2 family of apoptotic regulator proteins (e.g., BAX, BAK) control the disruption of mitochondrial membranes, activation of caspase-9, and intrinsic cell death.[195] Proapoptotic and antiapoptotic genes influence cell death; therefore, mutations of these genes also affect tumor growth. Some oncogenes proteins (C-MYC, p53, pRb) affect both cell proliferation and apoptosis. In mice, antiapoptotic BCL-2 proteins enhance the expression of the *MYC* oncogene;[196] overexpression of BCL-2 family proteins occurs in breast, colorectal, gastric, hepatocellular, lung, and pancreatic cancers.[193]

A protein family of death receptors activates the extrinsic apoptosis pathway (caspase-10 in humans, caspase-8 in rodents), primarily by members of the tumor necrosis factor receptor (TNFR) superfamily, including CD95, DR4, DR5, and TNFR. The role of caspase-8 in cancer varies with tumor type; frequent deletions of caspase-8 occur in small cell lung carcinomas, hepatocellular carcinomas, medulloblastomas, and gliomas, whereas decreased incidence of esophageal, colorectal, cervical, and breast cancer occurs with reduced caspase-8 expression. This variable response may be related to the variable effect (i.e., stimulation or inhibition) of caspase-8 on necroptosis, the programmed form of necrotic cell death.[193] The proinflammatory effects of necroptosis differ from the lack of inflammation in apoptosis.

Invasion and Metastasis

The invasion-metastasis cascade is a late, multistep process in malignant tumorigenesis involving: 1) invasion of local tissue parenchyma reflecting diminished cell adhesion and increased motility; 2) intravasation into neighboring microvesicles followed by survival during hematogenous dissemination via lymphatics and blood; 3) cell arrest and extravasation into distant host tissues; and 4) survival in the distant microenvironment and formation of macroscopic metastases (colonization) that successfully adapt to the new microenvironment.[197] The traditional model of progressive metastasis suggests cancer cells gradually acquire metastatic functions through progressive mutations that ultimately form macrometastatic-colonization genes with macrometastatic-colonization functions. Consequently, altered expression of these genes would be absent or rare in the primary tumor and present in the metastatic tumor. An alternative model suggests metastasis is a preprogramed event from the initiation of cells in the primary tumor that execute metastasis initiation functions. Thus, both primary and metastatic tumors share similar predetermined mutated genes and initiated cells. Some experimental evidence suggests an integrated model indicating the presence of mutated genes with dual metastasis-progression functions;[198,199] however, the exact role of each model in the development of metastatic tumors remains unclear.

Tumor-derived VEGF-A, TGF-β, and TNF-α induce premetastatic changes in distant host tissues that recruit CD11b* myeloid cells in a VEGFR1-dependent process enhanced by extracellular matrix-remodeling metalloproteinase (MMP9).[200,201] This process creates a premetastatic niche for the subsequent deposition of disseminated cancer cells. The success of the metastatic cells depends on the remodeling of the extracellular microenvironment, accessing local growth factors, resisting the host immune response, acquiring a blood supply, and forming a supportive microenvironment.

TABLE 47.7. Metastatic cancer sites from some common primary malignant tumors. Susceptibility of tissues to metastasis depends on the tissue type and tumor characteristics. Estrogen-positive breast cancer commonly spreads to bone, whereas estrogen-negative breast tumors prefer visceral organs. The metastatic bone lesion from breast carcinomas and myeloma typically are osteolytic compared with the dense, osteoblastic lesions associated with prostate cancer. Although neuroblastomas occasionally regress, most metastatic lesions are progressive. (Adapted from Minn and Massague).[197]

Tissue Type	Metastatic Sites
Breast	Commonly to bone, liver, lung, and pleura; less frequently to brain and bone
Colon	Spread through portal system, favoring peritoneal cavity and liver with dissemination to lungs
Glioma	Metastasis outside the central nervous system is unusual
Lung	Small cell lung cancer typically spreads widely to adrenals, bones, brain, lungs, and pancreas, whereas nonsmall cell lung cancer spreads to adrenals, bones, brain, liver, and lungs
Myeloma	Primarily osteolytic bone lesions with occasional spread to other organs
Neuroblastoma	These pediatric tumors of adrenal nervous tissues usually metastasize to bones, liver, and lungs
Ovarian	Primarily local spread in peritoneal cavity
Pancreas	This aggressive tumor metastasizes to surrounding organs, particularly liver and lungs
Prostate	Almost exclusively to local bones (spine, pelvis)

The metastatic process is inherently inefficient.[202] Most extravasated tumor cells (i.e., >99%) disappear after failing to complete this process.[203] In mouse studies, only a small subset of injected B16F1 melanoma cells (i.e., ~0.02%) survive hematological spread, implant in distant tissues, and form fatal macroscopic tumors.[204] Some primary tumors can suppress distant metastases by secreting antiangiogenic factors (e.g., angiostatin, endostatin).[205] Additionally, systemic signals released by aggressive tumors can promote a supportive microenvironment in distant indolent tumor cells by enhancing the formation of growth factors (e.g., epidermal growth factor, EGF, insulin-like growth factor-1, IGF-1).[206] Pathological characteristics increasing the risk of metastasis by malignant tumors include large tumor size (i.e., increased cancer cell population), poorly differentiated tumor tissue, invasion beyond the normal tissue boundaries, and lymphatic spread. Table 47.7 lists the frequent metastatic sites of common primary malignant tumors.

Immune System

Many types of cancer activate inflammatory signaling pathways (e.g., proinflammatory signaling CXC-chemokine CXCR1/2 and their ligand CXCL8) through a complex network of inflammatory mediators. Subsequently, chronic inflammation contributes to all stages of tumorigenesis by generating genotoxic stress, producing mutations and oncogene activation, disrupting cell cycle controls and DNA repair, inducing cell initiation and proliferation, enhancing angiogenesis, remodeling tissues, and promoting tissue invasion.[207,208] Although the immune system initially protects against tumor formation, selection pressure from multiple generations of tumor cells favors the development of less immunogenic tumor cells until the tumor cells escape detection by the immune system.[209] This process (i.e., immunoediting) is a dynamic process with the three phases of elimination, equilibrium, and escape.[210] At first, tumor cell alterations and tissue necrosis activate the immune system with bone marrow-derived cells (dendritic cells, eosinophils, lymphocytes, macrophages, natural killer cells) invading the tumor during the elimination phase. The cells release various proinflammatory cytokines (IL-1β, IL-8, TNF-α), reactive oxygen species, proteases, and activated fibroblasts. Subsequently, adaptive immunity maintains an equilibrium phase while the continuous eradiation of tumor cells and the emergence of increasing resistant tumor cell variants interact to select tumor cells with reduced immunogenicity. Table 47.8 lists the normal functions of major cytokines and alterations in their function in tumor microenvironments.

The immunosuppressive environment of tumors contains immunomodulating factors (e.g., cyclooxygenase-2, COX-2; macrophage growth factor or colony stimulating factor-1, CSF-1; IL-6; IL-10; TGF-β).[212] Many immune cell types and cytokines (e.g., tissue necrosis factor family) display tumor suppressive and tumor-promoting properties.[213] During premalignant phases, TGF-β suppresses tumor proliferation in the local microenvironment; however, as tumor cells evade the immune system, TGF-β promotes the progression, invasion, and metastasis of tumor cells. The tumor cells enter the escape phase when most intrinsic and extrinsic tumor suppressor mechanisms fail as tumor cells acquire resistance to cytotoxic functions of immune cells. A complex immunosuppressive network develops in the tumor microenvironment that protects tumor cells against the host-protective antitumor response by altering the expression of inflammatory mediators, including chemokines, cytokines (e.g., interleukin 10,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 47.8. Major cytokine function in the tumor microenvironment. Although cytokines and chemokines preserve normal cellular homeostasis by helping regulate cell growth and differentiation, chronic inflammation alters critical signaling pathways (e.g., NF-κB, STAT3 or signal transducers and activators of transcription-3), inhibits immune surveillance of preneoplastic cells, inhibits apoptosis, and promotes angiogenesis and tumor invasion. (Adapted from Fernandes et al.).[211]

Cytokine	Abbreviation	Cancer Function
Interleukin-1β	IL-1β	Suppresses p53 expression allowing stromal fibroblast proliferation.
Interleukin-6	IL-6	Stimulation of cell proliferation, angiogenesis, and survival of malignant cells while inhibiting apoptosis of cancer cells.
Interleukin-10	IL-10	Enhances interferon-γ, TNF-α, IL-6, and IL-12 production inhibiting tumor development; however, in tumor microenvironment, IL-10 promotes tumorigenesis by inhibiting T-helper cell 1 (Th1)-induced interferon-γ production.
Interleukin-12	IL-12	Protective function against cancer by stimulating cytotoxic activity of interferon-γ, TNF-α, Th1 response, and antiangiogenic activity. Tumor microenvironment inhibits IL-12 protective function by altering IL-12/IL-23 (Th17 promoter).
Interleukin-17	IL-17	Induces proinflammatory mediators (IL-1β, IL-6, TNF-α). The tumor microenvironment alters IL-17 expression and increases Th17 cell production.
Interleukin-18	IL-18	Acts with IL-12 to induce Th1 immune response and inhibit tumorigenesis. Overexpression of IL-18 occurs in several tumors (e.g., skin squamous cell carcinoma).
Tumor necrosis factor-α	TNF-α	The NF-κB pathway regulates numerous cytokines and adhesion molecules involved in the regulation of immune responses. Alteration of this pathway in tumors expresses NF-κB-dependent anti-apoptosis proteins, promotes angiogenesis, suppresses cytotoxic T cells and activated macrophages, enhances cancer cell migration/invasion, stimulates nitric oxide production and genetic stress.
Transforming growth factor-β	TGF-β	An anti-inflammatory/immunosuppressive cytokine that stimulates regulatory T cells. Attenuation of TGF-β inhibits tumor suppression, promotes tumor progression, and enhances tissue invasion/metastasis.

IL-10), growth and transcription factors (e.g., transforming growth factor-β, TGF-β); vascular endothelial growth factor, VEGF), soluble phosphatidylserines, free radicals, prostaglandin E2, and enzymes (e.g., cyclooxygenase, matrix metalloproteinase).[211]

Immunological tolerance that separates "self" from foreign material depends on immune checkpoint pathways, subsets of regulatory immune cells, and suppression of cytokines. The checkpoints are natural inhibitory feedback loops that avoid inflammation of normal tissues by reducing inflammation; tumor tissues protect themselves by aberrantly expressing ligands that interact with inhibitory immune receptors (e.g., cytotoxic T cell antigen 4, CTLA-4; programmed death 1, PD-1) and ligands (programmed death-1 ligand, PD-L1) that usually protects normal host tissues. CTLA-4 modulates the early activation of T cell immunity, whereas PD-1 modulates activated killer T cells present in the tumor.[214] The development of drugs to interrupt immune checkpoints (e.g., anti-CTLA-4, anti-PD-1, anti-PD-L1) and enhance antitumor immunity results in durable cancer regressions in a significant number of solid tumors that contain high mutational burdens (microsatellite instability).[215]

Additionally, tumors develop mechanisms to coopt immune cell functions and perpetuate tumor growth, including recruiting bone marrow-derived cells and myeloid-derived suppressor cells to enhance tumor invasion. The zinc-dependent proteolytic enzymes (matrix metalloproteinases, MMPs) regulate the destruction of various components in the extracellular matrix and basement membranes. In the tumor microenvironment, MMPs degrade matrix proteins and signaling molecules, promote angiogenesis, facilitate recruitment of stem cells, and reduce cell adhesion. MiRNAs help regulate the development of inflammatory cell subpopulations (e.g., Th1, Th17) and enhance immune cell function by controlling cytokine concentrations. Modulation of toll-like receptors (TLRs), cytokines, and signaling pathways in the tumor microenvironment promotes initiation and progression of tumors, particularly those associated with infectious agents.[216]

Tumor Microenvironment

Solid tumors contain a heterogeneous population of neoplastic cells and tumor-associated stroma containing mesenchymal and inflammatory cells (e.g., extra-cellular matrix, endothelial cells, fibroblasts, leukocytes, pericytes) recruited from the host; together, this mass is called the tumor microenvironment.[217] The interplay in the tumor microenvironment between cancer and stromal cells is a crucial determinant of cancer growth along with tumor homeostasis and growth progression.[218] Tumor cells secrete chemokines that recruit various peripheral blood cells from the host circulation and tissues (e.g., bone marrow, spleen) to the tumor, including the tumor-derived cytokine granulocyte-colony stimulating factor (G-CSF). Alterations in certain hematopoietic progenitor cells (e.g., CD11b*/Gr1+ myeloid cells) involved in the regulation of myeloid cell mobilization and angiogenesis facilitate tumor-associated angiogenesis and protect the tumor against the inhibiting effects of anti-VEGF (vascular endothelial growth factor).[219] A variety of tumor-derived factors act systemically to promote angiogenesis, proliferation, invasion, and metastasis, including osteopontin (OPN), placental growth factor (PLGF), vascular endothelial growth factor-A (VEGF-A), angiotensin-II (ANG-II), GDF15 (growth/differentiation factor 15 or macrophage inhibitory cytokine-1), and IGF-II (insulin-like factor-II).[218] The tumor microenvironment also communicates with distant host tissues by secreting membrane-bound particles (microvesicles, exosomes, microparticles) that contain proteins, mRNAs, miRNAs, and lipids.[220]

CARCINOGEN CATEGORIES

Exogenous chemical carcinogenesis is an extremely complex, multifactorial process involving promotion, mutations, and genetic/epigenetic interactions of polymorphisms in multiple, cancer-susceptible genes and chemical carcinogen-induced cocarcinogenesis. These polymorphisms include beneficial and harmful polymorphic allelic variants (e.g., genes controlling phase I and phase II metabolic enzymes, the cell cycle, and DNA repair proteins).[221] Additionally, chemical carcinogens may produce mutagenesis indirectly by epigenetic alterations and free-radical production.

The ability of the cell to adapt to the presence of carcinogens depends on a complex interaction between individual host variations, gene mutations, and epigenetic factors. Reduction of cancer risks results from processes (detoxification, excretion, binding to noncritical sites) that decrease the carcinogen concentration at the cell genome and mechanisms (DNA repair, terminal differentiation) that inhibit the effect of the carcinogen. Numerous environmental and host factors affect cancer development by altering the action of carcinogens and cocarcinogens. Genetic factors alone are insufficient to explain the effect of chemical carcinogens on the many processes that influence cancer development, as reflected by differences in cancer incidence between genetically identical monozygotic twins;[222] hence the two broad categories of processes (genotoxic, epigenetic) affecting tumorigenesis.[223] Although some carcinogens act via both types of mechanisms, most chemical carcinogens affect cancer development predominately by a single type of mechanism. Genetic contributions associated with benzene-induced acute myelogenous leukemia include polymorphisms in microsomal epoxide hydrolase, glutathione-*S*-transferase subfamily *GSTT1* and *CYP2E1* genes involved with benzene metabolism along with alteration of genes involved with DNA repair (multifunctional DNA repair enzyme, APEX nuclease; excision repair cross-complementation group 1, ERCC1), whereas epigenetic contributions include DNA methylation and microRNA deregulation.[223] Although some epigenetic agents are genotoxic, all nongenotoxic agents are not epigenetic carcinogens (e.g., dioxin acts via a receptor-mediated, nongenotoxic, nonepigenetic mechanism). Genetic changes typically are irreversible, whereas epigenetic modifications are usually reversible.[224]

CLASSIC CARCINOGEN STAGES

Based on animal experiments, a chemical carcinogen initiates heritable, preneoplastic changes in a susceptible cell, followed by promotion of the initiated clone and progression to a visible, malignant tumor. Complete carcinogens (e.g., cigarette smoke) enhance cancer development at all three classical stages, whereas incomplete carcinogens (e.g., asbestos) act only at one stage (i.e., promotion). At low doses, some complete carcinogens may mimic the actions of incomplete carcinogens by affecting only the initiation stage. Most chemical carcinogens require metabolic activation from procarcinogens (e.g., nitrosamines, vinyl chloride, ethylene dibromide) to the intermediate form (proximate

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

carcinogens) and subsequently to the biologically active form (ultimate carcinogens). CYP450 enzymes (e.g., CYP1A1) oxidize the carbon atoms in the "bay region" of benzo(a)pyrene to the dihydrodiol epoxide (proximate carcinogen) and then to the electrophilic reactant, (+)-anti-benzo[*a*]pyrene-7,8-dihydro-9,10-epoxide (ultimate carcinogen).[225] The final product irreversibly interacts with the cell genome.

Approximately 75% of chemical carcinogens (e.g., benzene, benzo[*a*]pyrene, and other high molecular weight polycyclic aromatic hydrocarbons) are procarcinogens that require metabolic activation to electrophilic (electron-deficient) metabolites primarily by phase I enzymes (e.g., CYP1/CYP2 enzyme families). About 25% of chemical carcinogens are direct (ultimate) carcinogens (e.g., 2,3,7,8-tetrachlorodibenzo-*p*-dioxin).[226] Ultimate carcinogens covalently bind to cellular macromolecules (DNA, RNA, proteins, sulfhydryl groups). Most known human carcinogens alter DNA structure (i.e., genotoxic), whereas ~½ known animal carcinogens demonstrate epigenetic properties without demonstrating mutagenic properties. Some chemicals (e.g., nitrates, nitrites) require more than one enzymatic step to produce a carcinogen; these procarcinogens are converted to an intermediate metabolite (proximate carcinogen) before final conversion to the direct (ultimate) carcinogen. DNA bases, phosphate groups, and three-dimensional DNA structure represent molecular targets for these carcinogenic metabolites, as reflected by the presence of heritable cellular changes, chromosomal abnormalities, aberrant gene expression, and activated oncogenes in cancer cells.[79] Several factors affect the induction of enzymes required for the metabolic detoxification or activation of procarcinogens, including environmental exposures, diet, and hormone concentrations; these factors add to the complexity of assessing the outcome of exposure to chemical carcinogens.

Direct-acting carcinogens [e.g., nitrogen mustard, ethylene imine, bis(chloromethyl)ether] do not require metabolic activation; hence, the procarcinogen, proximate carcinogen, and ultimate carcinogen in this class of carcinogens are structurally similar. During initiation, cocarcinogens enhance DNA damage caused by the administration of genotoxic carcinogens. Cocarcinogens are not carcinogenic agents; however, these agents activate and/or enhance the carcinogenic potential of genotoxic carcinogens. The effects of cocarcinogens include increased proliferation of initiated cells with DNA damage, enhanced metabolic activation or reduced detoxification of the carcinogen, increased delivery (i.e., absorption, transport) of the carcinogen to the cell genome, and reduced cellular repair processes.[227] Mechanisms of action include depletion of endogenous detoxifying proteins (e.g., glutathione), inhibition of phase I and/or phase II metabolic enzymes, inhibition of DNA repair mechanisms, and induction of CYP enzymes that convert procarcinogens to carcinogens.

GENOTOXIC CARCINOGENS

Genotoxic carcinogens produce heritable changes in DNA sequences and other cellular macromolecules; therefore, these carcinogens demonstrate mutagenic activity.[228] Genotoxic carcinogens include a variety of structurally diverse compounds [e.g., halogenated compounds (benzyl chloride), nitrogen mustards, dimethyl sulfate, lactones, alkylene epoxides, ethylene imine, polycyclic aromatic hydrocarbons, aromatic amines, quinolines, azo compounds including dyes (e.g., direct blue 6), dialkylhydrazines, *N*-nitroso compounds, carbamates (urethane), natural compounds (aflatoxins, daunomycin), and metals (hexavalent chromium, nickel)]. These exogenous chemical carcinogens induce bulky, stable DNA adducts that covalently bind to macromolecules, alter cell cycle control signaling pathways, and impair various repair systems in the body. Many of these chemicals require aryl hydrocarbon receptor activation and CYP enzyme induction to develop chemical carcinogenesis.[221]

In the mid-1970s, the International Agency for Research on Cancer (IARC) began including short-term mutagenicity tests in IARC Monographs on the carcinogenic risk of chemicals to humans based on the observation that most carcinogens were also mutagens, despite not all mutagens being carcinogens.[229] With the exception of asbestos and conjugated estrogens, most initially recognized human carcinogens were genotoxic (i.e., react with DNA) as defined by these short-term mutagenicity tests (Salmonella mutagenicity assay, Ames test) or the rodent bone marrow cytogenetics assay.[230] Most of these human carcinogens displayed a common tumor site in animal studies and epidemiology studies. Genotoxic carcinogens with similar affinity for a specific tissue or organ produce cumulative effects on carcinogenesis when administered together. Occasionally, genotoxic chemicals are effective after a single dose in animal studies of cancer.[95] The strength of the correlation between carcinogenicity and short-term mutagenicity tests diminished over subsequent years with identification of putative epigenetic carcinogens; however, these tests helped identify potential human carcinogens and understand carcinogenic mechanisms.[231]

EPIGENETICS EFFECTS

Epigenetic effects describe heritable changes in gene expression without altering the DNA sequences involved in several biological (e.g., embryonic development, X-chromosome inactivation) and pathological (autoimmune diseases, cancer) processes.[232] Epigenetic mechanisms provide an interface between the genome and environment, with aberrant epigenomic changes contributing to carcinogenesis by affecting initiation, promotion, invasion, and metastasis.[233] These changes usually occur during an early stage of carcinogenesis typically preceding genetic alterations. Unlike the virtually identical composition of the genome in an organism's cells, different tissues and cell types have distinct epigenomes that undergo substantial changes in response to cellular development and maturation.[234] The plasticity produced by epigenome modifications is essential to adaptation of the cell to the environment, which occurs normally at different times in different cell types, particularly during cell differentiation, embryogenesis, and aging. Over many cell cycles, epigenetic mechanisms maintain heritable changes in gene expression and chromatin organization that are transmitted to future cell generations. Deregulation of epigenetic mechanisms disrupts key cellular processes that may cause oncogenic transformation and malignant tumor growth. DNA methylation, histone modifications (covalent alteration in core histones), nucleosome positioning (physical changes), and noncoding RNA (posttranslational gene regulation) refer to heritable, epigenetic changes in gene expression without mutation in DNA sequences. These changes may occur independently or concomitantly with genotoxic alterations, as displayed in Figure 47.13. Consequently, both epigenetic and genetic mechanisms determine the response, susceptibility, and adaptation to environmental carcinogens (e.g., tobacco smoke, radon, UV light, arsenic).

Almost all functions associated with DNA involve nongenotoxic modifications of chromatin and DNA proteins, including chromosome stability, transcriptional control, DNA replication, and DNA repair. The complex interaction between chromatin modification and DNA encodes information (i.e., epigenetic) in addition to the information provided by the genetic code; this information can also be preserved during cell replication and potentially inherited by subsequent cell generations.[236]

Epigenetic modifications are typically more abundant in malignant cells than DNA changes;[237] however, previous studies of these changes have shown that they are much less common for epigenetic than genotoxic carcinogens. Some of these epigenetic alterations are

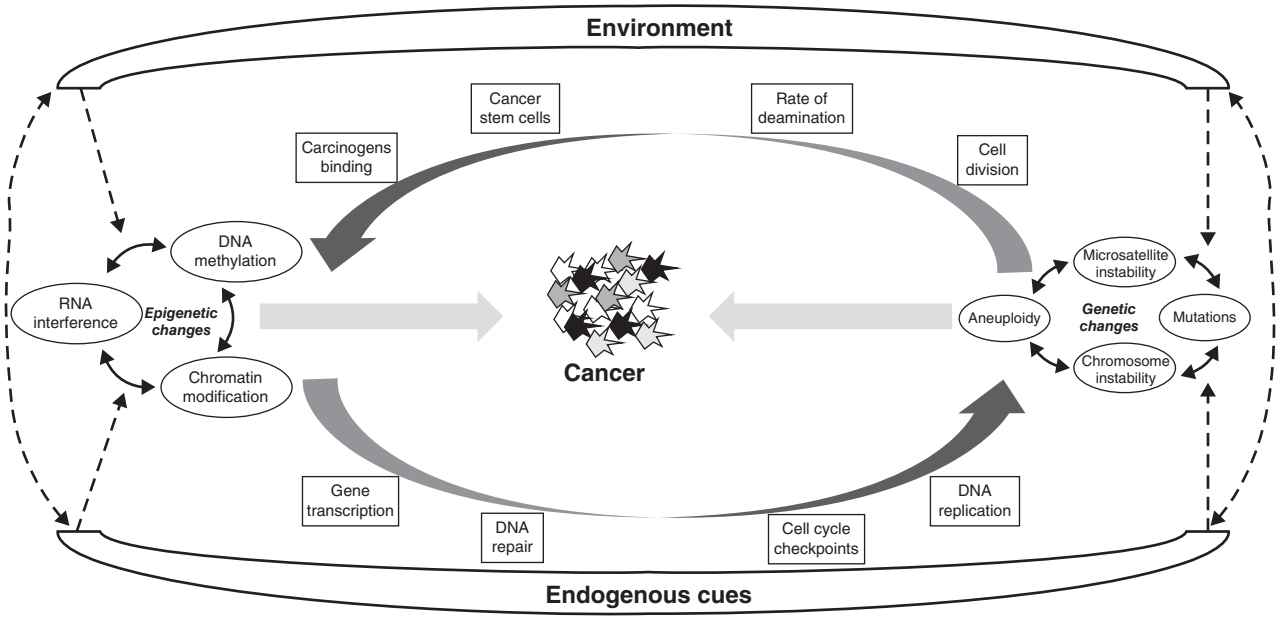

FIGURE 47.13. Epigenetic alterations, genetic changes, environmental exposures, and endogenous stimuli. Disruption of epigenetic mechanisms may cause abnormal phenotypes and cancer. Substantial cross-talk occurs between genetic and epigenetic alterations during the development and progression of cancer. The coexistence of genetic/epigenetic changes in all cancers and the complexity of the cross-talk between the two processes complicate the determination of primary and secondary events in tumorigenesis. (Adapted from Herceg et al.).[235]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. relatively nonspecific (e.g., global DNA hypomethylation) and common in many cancers, whereas other epigenetic changes involve more specific signaling pathways (e.g., increased potency of DNA binding at methylated CpG sites in certain codons).[238] Epigenetic mechanisms primarily involve the following three processes: 1) DNA methylation; 2) histone modifications; and 3) expression of noncoding RNA (microRNA, miRNA; long noncoding RNA, lncRNA), as displayed in Figure 47.14. The three common epigenetic pathways do not always act independently, similar to many cellular signaling pathways that influence other signaling pathways by "cross-talk."[239] Structurally diverse substances associated with epigenetic mechanisms include aflatoxins, 4-aminobiphenyl, asbestos, benzene, benzidine, benzo[α]pyrene, 1,3-butadiene, formaldehyde, metals (arsenic, beryllium, cadmium, hexavalent chromium, nickel), ionizing radiation, sulfur mustard, tobacco smoke, vinyl chloride, and biological organisms (human hepatitis B/C viruses, human papillomavirus, *Helicobacter pylori*).[235,240] In general, the extent of cancer promotion through epigenetic mechanisms depends on the amount and duration of exposure.[235] Although some epigenetic agents are also genotoxic, not all nongenotoxic agents are epigenetic carcinogens (e.g., dioxin acts on receptor-mediated pathways rather than epigenetic mechanisms). Furthermore, epigenetic pathways may be secondary mechanisms in tumors formed from some genotoxic epigenetic carcinogens (e.g., diethylstilbestrol, HBV, hexavalent chromium, ionizing radiation).[235]

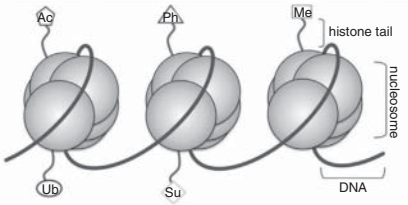
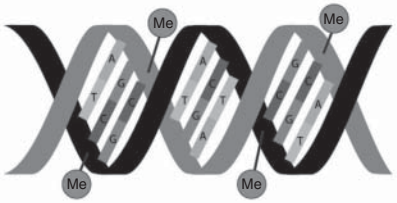
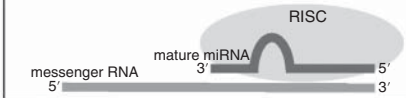
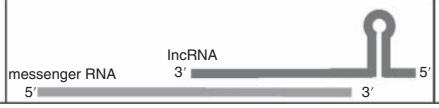
Gene Expression

Epigenetic carcinogens produce changes in the regulation of gene expression (e.g., alterations in DNA methylation, translational control, posttranslational modifications, transcriptional activation).[28] These changes occur during normal development as well as during carcinogenesis. Epigenetic carcinogens increase the incidence of cancer in animal studies, usually because of prolonged, high-dose exposure that produces histological and biochemical changes in the animal.[241] Pathological signs of tissue damage include hydropic degeneration, cell necrosis, and fatty changes. In contrast to these abnormal pathological signs, evidence of more adaptive alterations includes organ enlargement, proliferation of cellular organelles (peroxisomes), and enzyme induction (e.g., mixed function oxidases).[242] Cell division is essential to the conversion of DNA









Epigenetic modifications			Commonly used evaluation methods
Histone modifications			• Western blot • Mass spectrometry • Chromatin immunoprecipitation (ChIP) - ChIP on chip (microarray) - ChIP sequencing
DNA methylation			• Methylation-specific PCR (MSP) whole-genome bisulfite sequencing (WGBS) • Reduced representation bisulfite sequencing (RRBS) • Bisulfite pyrosequencing • Combined bisulfite restriction analysis (COBRA) • Methylation DNA immunoprecipitation (MeDIP) • Mass spectrometry
Noncoding RNA	miRNA		• Single miRNA quantitative RT-PCR • smallRNA sequencing • miRNA microarray
	lncRNA		• Single lncRNA quantitative RT-PCR • RNA sequencing

FIGURE 47.14. Overview of main types of epigenetic mechanisms with simplified illustrations and commonly used methods to evaluate these mechanisms. (Adapted from Chappell et al.).[240]
Abbreviations: Ac = acetylation; Me = methylation; Ph = phosphorylation; Su = sumoylation; Ub = ubiquitination; IncRNA = long non-coding RNA; miRNA = microRNA; RISC = RNA-induced silencing complex; PCR = polymerase chain reaction.

damage into inheritable mutations and the selection of altered phenotypes.

Epigenetic carcinogens represent a large, diverse category of compounds; these chemicals are not always easily distinguished from genotoxic chemicals. Animal studies identified a variety of epigenetic compounds, including mitogenic liver carcinogens (phenobarbital, polybrominated biphenyls), cytotoxic liver carcinogens (carbon tetrachloride), peroxisomal proliferators (clofibrate, di[2-ethylhexyl]phthalate, fenofibrate), cytotoxic stomach carcinogens (butylated hydroxyanisole), cytotoxic bladder promoters (saccharin, butylated hydroxytoluene), cytotoxic kidney carcinogens (chloroform, unleaded gasoline), hormones (diethylstilbestrol), solid-state carcinogens (asbestos), progressors (arsenic salts, benzene, hydroxyurea), and thyroid carcinogens (dietary deficiency of iodine).[243]

In animal studies, sustained tissue damage is an important mechanism for the induction of cancer by epigenetic chemicals; however, the action of epigenetic carcinogens probably results from both cytotoxicity and receptor-mediated cell proliferation, as demonstrated in Table 47.9. The former mechanism occurs at high doses, whereas the latter effect operates at high and low doses.[244]

Cytotoxic kidney carcinogens (unleaded gasoline, tetrachloroethylene, chloroform) produce cancer by the cytotoxic effects caused by the accumulation of a protein (alpha 2μ globulin) that is specific to male rats; however, humans do not produce this protein. Therefore, extrapolation of animal data to humans requires evaluation of the mechanisms associated with carcinogenesis and the use of different risk models.[245] The acceptance of the assumption that persistent cell damage produces tumors in rodents exposed to epigenetic carcinogens suggests the possibility of threshold doses for the carcinogenic effects and the establishment of safety margins;[242,243] however, this issue of threshold doses for certain carcinogens remains highly controversial.

DNA Methylation

DNA methylation involves the covalent modification of the CpG dinucleotide on the cytosine ring by adding methyl groups from the universal donor *S*-adenosyl-L-methionine to the DNA cytosine residues; the family of DNA methyltransferases catalyzes the covalent addition of a methyl group to the 5′ position of cytosine to form the fifth DNA base, 5-methylcytosine in cytosine-phosphate-guanosine (CpG) dinucleotide sequences (dyads). DNA methylation is a dynamic, well-balanced epigenetic process that occurs throughout the genome only at cytosine residues (CpG dinucleotides) in vertebrates; this process represses gene expression and helps regulate transcription, chromatin structure, chromosome integrity, and genomic imprinting (inheriting a gene from only 1 of 2 parents), resulting in gene silencing, histone modifications, and chromatin compaction.[246] The latter results from topological changes in chromatin confirmation. Regulatory processes are typically unmethylated when active.[247] Aberrant DNA methylation can disrupt any or all of these processes, causing gene activation and/or silencing with genomic instability contributing to carcinogenesis.[235] In tumor cells, DNA demethylation in genome-wide regions (global hypomethylation) is associated with genomic instability and cancer progression, whereas hypermethylation at localized promoter-associated CpG islands causes functional loss and transcriptional silencing of tumor suppressor genes as well as oncogene upregulation.[248]

TABLE 47.9. Pathological changes associated with chronic exposure of rodents to epigenetic carcinogens. (Adapted from Grasso et al.).[242]

Agent	Early Changes	Tumor Site	Threshold Dose
Solid implants (subcutaneous)	Fibrosis	Connective tissue	Yes (size)
Food coloring (subcutaneous)	Fibrosis	Connective tissue	Yes[a]
CCl_4, $CHCl_3$	Necrosis, regenerative hyperplasia	Liver	Yes
DEHP, fenofibrate	Hepatic hypertrophy, peroxisomal proliferation	Liver	Yes
Diethylene glycol	Hyperplasia, stones	Bladder	Yes
ESNS	Hyperplasia, stones	Bladder	Yes
H_2-antagonists	Hypergastrinemia/hyperplasia of ECL cells	Glandular stomach	Yes

Abbreviations: ECL = enterochromaffin-like; ESNS = 4-ethylsulfonylnaphthalene-1-sulfonamide.
[a] Related to the injected concentration.

Although DNA methylation has some involvement in genome compartmentalization and chromosome stability, its primary supportive role is transcriptional regulation. Via the recognition of transcription factors, the DNA sequence accounts for a substantial part of the observed DNA methylation and chromatin patterns and, thus, the variation between cell types and individuals.[249] Typically, DNA hypermethylation represses gene expression (e.g., tumor suppressor genes in malignant tumors) by interfering with DNA binding of transcriptional activators and recruiting methyl CpG-binding transcriptional repressors, whereas DNA hypomethylation enhances gene expression and oncogene activation. There are short sequences of highly enriched CpG dinucleotides (CpG islands) near the 5′ regions of the genes that are resistant to methylation in normal tissues; most non-5′ regions outside the CpG islands are methylated. Typically, this methylation pattern is reversed in cancer cells. In contrast to histone modifications and noncoding RNAs, DNA methylation is the only epigenetic process that covalently binds to DNA. Global hypomethylation commonly occurs in cancerous cells along with locus-specific hypermethylation.[250] Methods to measure DNA methylation include whole-genome bisulfite treatment with sequencing (WGBS), combined bisulfite restriction analysis (COBRA) for gene-specific DNA methylation, mass spectrometry for global DNA methylation levels, and methylated DNA immunoprecipitation (MeDIP).[23]

Histone Modifications

In the chromatin of the human cell nucleus, special proteins (histones) package the DNA double helix into nucleosomes (i.e., chromatin structural units) that consist of DNA wrapped around repeated structural octamers of four core histone proteins (H2A, H2B, H3, H4) with 15–30 amino acid N-terminal tails protruding from the core assembly; most histone modifications occur in the tails. Posttranscriptional histone tail modifications can alter the access of chemicals and transcription factors to DNA, resulting in transcriptional changes that affect DNA damage/repair processes. Covalent modification of specific amino acid residues (e.g., lysine) on the histone tail involves a variety of processes (e.g., acetylation, methylation, phosphorylation, sumoylation, ubiquitination).[251] The integration of these processes either activates or silences the histones affecting events downstream (e.g., transcriptional activation or gene repression).

Chromatin Accessibility and Nucleosome Positioning

Higher-order chromatin is a complex spatial structure containing CpG-islands along with cis-regulatory regions or elements (e.g., proximal promoter, enhancer, insulator, silencer) that interact to control transcription and gene expression during the course of cell differentiation.[252,253] Mammalian cells have a large core (proximal) promoter region overlapping the first exon and upstream promoter elements, as displayed in Figure 47.15. In the core promoter region, hexagonal-shaped regulatory proteins help position RNA polymerase I adjacent to the transcription start site. Activated enhancers bind to pre-(transcriptional) initiation complexes or tethering elements in the proximal promoter region to upregulate transcription, whereas upstream silencers downregulate transcription by actively interfering with the preinitiation complexes.[254] Enhancers and silencers interact with multiple genes; however, another level of regulation and complexity results from special cis-regulatory DNA insulator regions that block those interactions.

In the nucleus, a compact nucleoprotein complex (chromatin) surrounds the DNA. The basic building block of the chromatin complex is a nucleosome comprised of 147 base DNA pairs wrapped around a histone octamer core and tail. Multiple nucleosomes assemble in a unidimensional shape resembling a string of

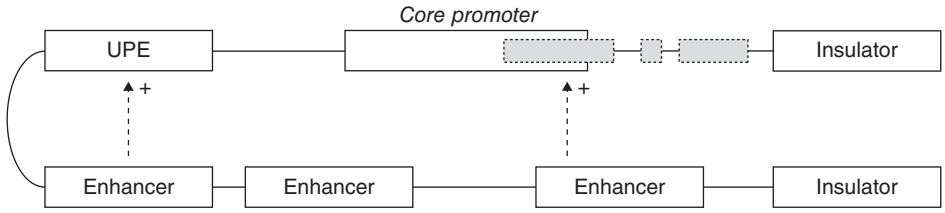

FIGURE 47.15. Mammalian transcription unit. The large core (proximal) promoter surrounds the transcription start site, overlapping the first exon and upstream promoter elements (UPE). Enhancers adjacent to the core promoter or upstream promoter elements brought close to the core promoter by the DNA loop can upregulate the gene transcription process. Silencers downregulate gene transcription, whereas insulators can block the actions of enhancers and/or silencers. (Adapted from Riethoven).[254]

beads that fold into intragenic loops; the nucleosomes typically cover over 80% of the DNA-suppressing contact between DNA-binding proteins (e.g., DNA repair enzymes, transcription factors, polymerases) and the DNA.[255] In eukaryotic cell nuclei, chromatin folds multiple times into higher-order, 10 nm-chromatin fibers that form enhancer-promoter loops, insulated neighborhoods, and ultimately three-dimensional topologically associating domains (TADs), as displayed in Figure 47.16. Chromatin looping brings enhancers and promoters into close spatial proximity, stabilizing the loop and allowing communication between these two regulatory regions.[256] The folding of DNA into chromatin fibers and TADs compacts the genome and contributes to regulation of gene function.[257] These domains ultimately determine physical interactions (i.e., chromatin accessibility) between genomic regions and their regulatory elements (e.g., transcription factors, repair enzymes, polymerases). Some chromatin (heterochromatin) is highly condensed limiting chromatin access to regulatory elements, whereas other chromatin (euchromatin) has a loosely packaged, "beads on a string" shape that allows easier binding of regulatory proteins (e.g., transcription factors).[258,259] Nucleosome positioning along the DNA, methylation of cytosines within CpG dinucleotides, covalent histone modifications, and DNA-binding regulatory proteins (e.g., transcription factors) synergistically regulate chromatin conformation and DNA accessibility. Alterations in DNA accessibility and gene expression from cancer correlate to histone modifications and nucleosome positioning, particularly at transcription start sites or transcribed regions.[260] The TADs form nuclear compartments that vary in histone modifications and nuclear positions, resulting in either active or silent transcriptional sites on the chromosome.[261]

Functional sequence elements (e.g., transcription factor binding sites) in a genome are often associated with specific DNA sequence patterns called motifs. Different types of functional elements can have different motifs. CTCF binds a well-defined motif that forms specific loops and subsequently TAD boundaries with cohesin stabilizing the interactions of CTCF on enhancer- and promoter-bound transcription factors.[262] Cohesin is a multi-subunit, ring-shaped protein complex that binds DNA strands; normal chromosome segregation from the S-phase to cell division requires cohesin to mediate sister chromatid cohesion.[263]

A single genome can produce several hundred distinct cell types with identical genomes, but different epigenetic marks at regulatory elements, producing dissimilar gene expression. The two main types of regulatory elements in transcriptional activation

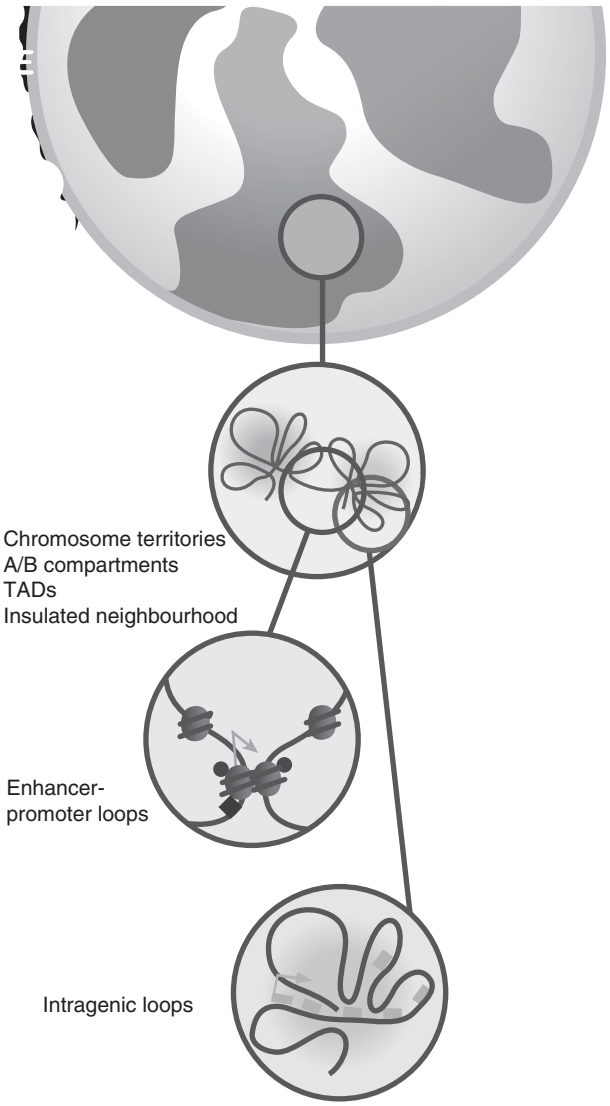

FIGURE 47.16. Schematic display of chromosomal structure. The smallest level of organization is the chromatin architecture in a single gene represented by intragenic loops of chromatin fibers at the functional level of transcriptional regulation. The intermediate level of organization involves enhancer-promoter loops and intra-TAD (topologically associated domains) that affect gene expression *via* distal regulatory networks. Large-scale chromatin organization in three dimensions divides the chromosome into megabase-sized active (open, A compartment) and repressed (closed, B compartment) territories that progressively subdivide into smaller and smaller subdomains (TADs). Physical interactions occur within the TADs with little contact outside the TAD boundary (isolated neighborhood). Histone modifications and nucleosome positioning are critical to chromatin accessibility and gene expression with alterations common in tumors. (Adapted from Ruiz-Velasco et al.).[262]

are enhancers and promoters, with the prediction of carcinogenic changes in gene expression better for enhancers than promoters.[264,265,266] The latter regulatory element is a relatively small region surrounding a transcription start site necessary for initiating gene transcription, whereas enhancer elements contain multiple transcription factor-binding sites distant from the gene they regulate.[267] Enhancers do not always regulate the nearest gene; one enhancer may regulate many genes, or one gene may be regulated by multiple enhancers. Consequently, enhancers are numerous, with a given cell line sometimes containing thousands of enhancers. Using tumor profiling of breast, kidney, and prostate tumor tissues with DNA methylation data, Rhie et al. identified over 25,000 differentially activated enhancers, 1,200 transcription factors in the tumor-specific enhancer networks, and over 800,000 genome-wide links between genes and enhancers.[268] Genome-wide association studies indicate multiple single nucleotide polymorphisms (SNPs) are associated with increased cancer risks (i.e., susceptibility);[269] these SNPs exist within enhancers, DNase hypersensitive sites, and transcription factor-binding sites, primarily in noncoding regions of the genome.

CCCTC-binding factor (CTCF) is a master regulatory protein that bridges the gap between genome architecture and gene expression.[270] Arrangement of chromosomal architecture results from CTCF binding to various sites, including nuclear matrix and numerous genomic sites within active and inactive domain boundaries. CTCF helps control gene expression via insulation of enhancers, activation or repression of promoters, and regulation of distant chromatin interactions. CTCF can block the transcription of gene promoters or enhancers by binding to an insulator sequence, creating insulated neighborhoods.[271] A variety of factors affect CTCF activity including binding proteins and DNA methylation. CTCF alters higher-order chromatin structure, thereby controlling the inter- and intra-chromosomal distances between TADs. Figure 47.17 displays a schematic representation of CTCF and cohesion effect on gene expression.

Noncoding RNAs

Noncoding RNAs (ncRNAs) modulate chromatin regulation and gene expression in normal and cancerous cells, primarily involving transcriptional and posttranscriptional gene silencing. DNA damage from a variety of exogenous and endogenous sources produces several DNA lesions including base adducts, DNA mismatches, deletions/insertions, interstrand DNA cross-linking, and single-/double-strand breaks. The DNA damage response system responds to these abnormalities by initiating repair mechanisms before the damaged genes replicate. In addition to DNA damage response-activated gene transcription programs for protein-coding genes, DNA repair requires a subset of regulatory RNAs that do not produce proteins (noncoding RNAs).[272] The genome contains >60% RNA molecules transcribed into small ncRNAs of <200 nucleotides) and large ncRNAs (>200 nucleotides).[273] Various types of ncRNAs include DNA damage response RNAs (DDRNAs), double-stranded break-induced RNAs (diRNAs), promoter-associated RNAs (PARs), enhancer RNAs (eRNAs), long noncoding RNAs (>200 nucleotides, lncRNAs), and small ncRNAs. The latter includes microRNAs (miRNAs), PIWI-interacting RNAs (piRNAs), small nucleolar (snoRNA), small interfering RNA (siRNAs), and short hairpin RNAs (shRNAs).[274] Silencing (knockdown) of target gene expression involves the latter two double-stranded RNAs that degrade target mRNA during the process of RNA interference.[275] Over 1,000 miRNAs help regulate cellular processes, primarily via RNA polymerase-II by targeting multiple protein-coding transcripts that regulate the translation of an estimated 60% of the protein-coding genes in the human genome.[276,277]

LncRNAs are promoter- or enhancer-associated regulatory ncRNAs rather than housekeeping ncRNAs; the primary function of lncRNAs is the regulation of the expression of protein-coding genes in response to environmental factors. The lncRNAs can function as oncogenes or tumor suppressors, with significant numbers of these ncRNAs changing in cancer tissues.[278] Noncoding RNAs enhance genomic stability through extensive cross-talk with the DNA damage response signaling pathways, resulting in the expression of ncRNAs and posttranslational regulation of the DNA damage response genes. The ncRNA-regulated DNA damage response connects the fast phase of DNA damage response mediated by protein-induced translational modifications (acetylation, methylation, phosphorylation, sumoylation, ubiquitination) and the slow phase of the DNA damage response mediated at the transcriptional level of gene expression.[164]

Control of the DNA damage response genes occurs at multiple levels (transcriptional, posttranscriptional, RNA degradation). The small, double-stranded, non-(protein)-coding RNAs influence gene expression by posttranslational changes in chromatin confirmation or through posttranscriptional gene silencing by the formation of complementary (antisense-oriented),

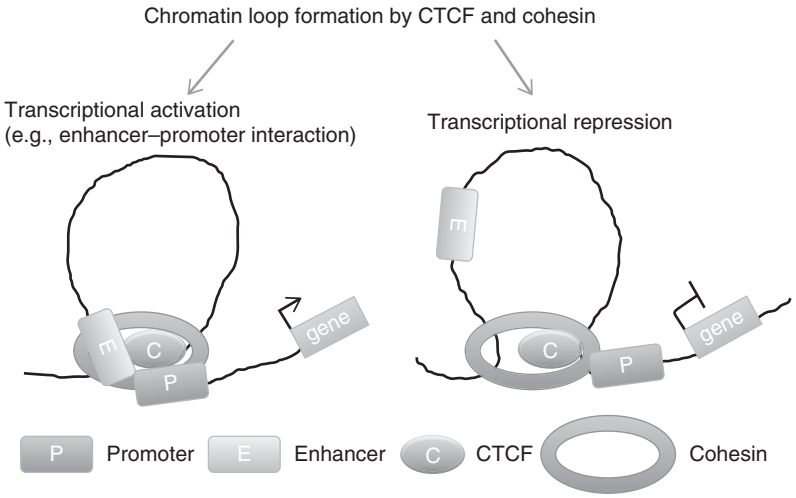

FIGURE 47.17. Chromatin loop function mediated by CTCF (CCCTC-binding factor) and the cohesin complex that produces transcriptional activation or repression depending on the binding site. CTCF and cohesin create a chromatin loop that encompasses the enhancer and promoter, resulting in transcriptional activation. Conversely, formation of a chromatin loop by CTCF and cohesin that blocks the enhancer from reaching the promoter represses gene expression. (Adapted from Kim et al.).[271]

small interfering RNAs (siRNAs).[279,280] Exogenous small ncRNA includes the endogenous 18–24 nucleotide microRNA (miRNA) and small interfering RNA (siRNA). Many small ncRNAs regulate gene expression, and ~60% of all coding protein genes use several mechanisms, including translational repression (miRNA) and mRNA degradation (siRNA). Some miRNAs function as oncogenes, whereas others act as tumor suppressor genes; human malignant tumors often contain many miRNA modifications.[281]

The classes of lncRNA include bidirectional, intronic, intergenic, sense, and antisense based on adjacent protein-coding genes. LncRNAs regulate gene expression through transcriptional regulation, mRNA processing, and chromatin modification, with RNA polymerase II transcribing most lncRNAs. Many lncRNAs are involved in epigenetic regulation of target genes by interacting with chromatin-remodeling or histone-modifying protein complexes (e.g., polycomb repressive complex 1/2, PCR1/2). In addition to providing molecular scaffolding to facilitate chromatin regulation, some lncRNAs (e.g., p21-associated ncRNA DNA damage activated, PANDA; long intergenic noncoding RNA-p21, linc-p21) are direct transcriptional targets of tumor suppressor proteins (i.e., p53) following initiation of the DNA damage response network.[282]

Chapter 48

GENERAL PRINCIPLES

STATISTICS

The contribution of chemicals to cancer incidence remains controversial because of limitations in detecting the effect of chemical carcinogens on the multifactorial etiology of cancer, inconsistencies in the diagnosis and coding of cancer statistics, and confounding from associated risk factors. The latter includes the simultaneous exposure to multiple carcinogens. In general, exposure to carcinogens within the same class based on toxicological and physiochemical properties exerts additive effects on cancer risks, whereas carcinogenic mixtures of different carcinogen classes produce multiplicative effects on cancer risks.[1]

Overall

The lifetime probability of being diagnosed with invasive cancer is 45% in men compared with 38% in women; cancer causes ~1 of 4 deaths in the United States.[2] Although several thousand chemicals were synthesized annually from 1965–1985, the overall age-standardized mortality rates from cancer remained stable excluding lung cancer until 1991.[2,3] Since then, mortality rates have declined >30% from decreased smoking, improved treatment, and effective cancer screening; however, in high-income countries, cancer is the most common cause of disease-related death in adolescence and young adulthood.[4] Individuals with a previously diagnosed tumor are particularly vulnerable to developing a different tumor type. Based on population-based data from the Surveillance, Epidemiology, and End Results (SEER) program of cancer registries, ~25% of adults ≥65 years of age and 11% of younger adults will develop a new malignant tumor after their initial diagnosis with the prevalence rate ranging from ~4–37%, depending on the initial cancer type and age.[5] The SEER data exclude metastatic and recurrent tumors. Substantial geographical variation occurs in all cancer rates between various counties within the United States and between the United States and other countries.

Incidence

During the 1980s, the incidence rates for most cancers increased;[6] factors associated with this increase include improved detection (prostate, breast), increased smoking among women (lung cancer), increased rate of acquired immunodeficiency syndrome (non-Hodgkin lymphoma, Kaposi's sarcoma), and excessive exposure to sunlight (melanoma).[7] Data from the Surveillance, Epidemiology, and End Results (SEER) survey indicate the overall cancer incidence rate in the United States peaked in 1992.[8] By 1996, statistically significant decreases in cancer incident rates in males occurred for lung cancer, leukemia, colorectal cancer and cancer of the bladder, oral cavity and pharynx.[8] Similar decreases in cancer rates occurred for women except for lung cancer incidence. In the United States during 2009, the annual incidence rate of all invasive cancers was 459 cases/100,000 persons for a total of 1,476,504 cases.[9] Overall cancer incidence rates continued to decline in men in 2008–2014 at 2.2%/year, while the cancer incidence rates in women remained stable based on data from the Annual Report to the Nation on the Status of Cancer (American Cancer Society, Centers for Disease Control and Prevention,

National Cancer Institute, North American Association of Central Cancer Registries).[10] Recently, the incidence of some cancers have begun increasing including breast, cervical, colorectal, HPV-associated oral, kidney, female liver, melanoma, and prostate cancers. In the Global Burden of Disease 2017 study, reported cancer incidence cases increased by 33% between 2007 and 2017 globally with the most developed countries accounting for the smallest increases.[11] Countries with the highest sociodemographic index reported 51% of the incident cancer cases but substantially fewer cancer deaths. Globally, there were 16.8 million reported incident cancer cases excluding nonmelanoma skin cancer; nonmelanoma skin cancers accounted for 7.7 million additional cancer cases. The highest 5-year survival rates (>90%) remain for melanoma and cancers of thyroid, prostate, and testis, whereas cancers of the esophagus, lung and pancreas produce the lowest 5-year survival rates (<25%).

Cancer Mortality

For the last 40 years, heart disease and cancer remained the top 2 leading causes of death with overall death rates similar for the last few years; mortality from cancer is slightly lower than that from cardiovascular disease as displayed in Figure 48.1.[12] In the United States, mortality from cardiovascular disease declined significantly as death from cancer rose, particularly from brain cancer and non-Hodgkin's lymphoma.[13] Death rates from cancer peaked in 1990 for men and 1991 for women. In contrast to cancer incidence rates in the 1980s, cancer mortality rates either stabilized or declined. By the late 1980s, cancer was the second leading cause of death in the United States, accounting for ~22% (i.e., ~550,000) of all reported annual US deaths.[14] During the late 1980s, the incidence cancer rate for people >54 years of age increased for most cancer types except for stomach and liver cancers; the latter two cancers began declining in the 1930s.[15] Worldwide, an estimated 10 million cancer-related deaths occur annually.

Figures 48.2 and 48.3 demonstrate the trends in the overall US death rates from selected cancers in men and women, respectively. Overall, cancer mortality decreased ~20% 1980–2014 with the cancer mortality rate decreasing annually by 1.8% for men, 1.4% for women, and 1.6% for children 2010–2014 as displayed in Figures 48.2 and 48.3.[10,16] During 2004–2008, cancer mortality decreased by 1.8%/year in men and 1.6%/year in women.[2] The mortality rates for the two sexes are slightly different; in 2014, the mortality rate for heart

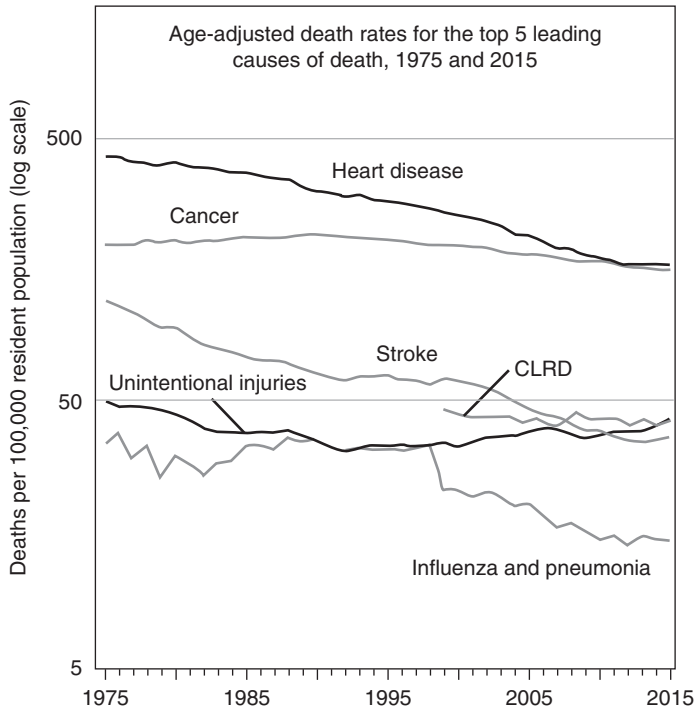

FIGURE 48.1. Leading causes of overall deaths in the United States per 100,000 residents, from 1975–2015. The five leading causes of death in 2015 were heart disease, cancer, chronic lower respiratory diseases (CLRD), unintentional injuries, and stroke. The age-adjusted death rate for heart disease stabilized from 2011–2015, whereas the rate for cancer steadily declined from 2000–2015. (Adapted from National Center for Health Statistics).[12]

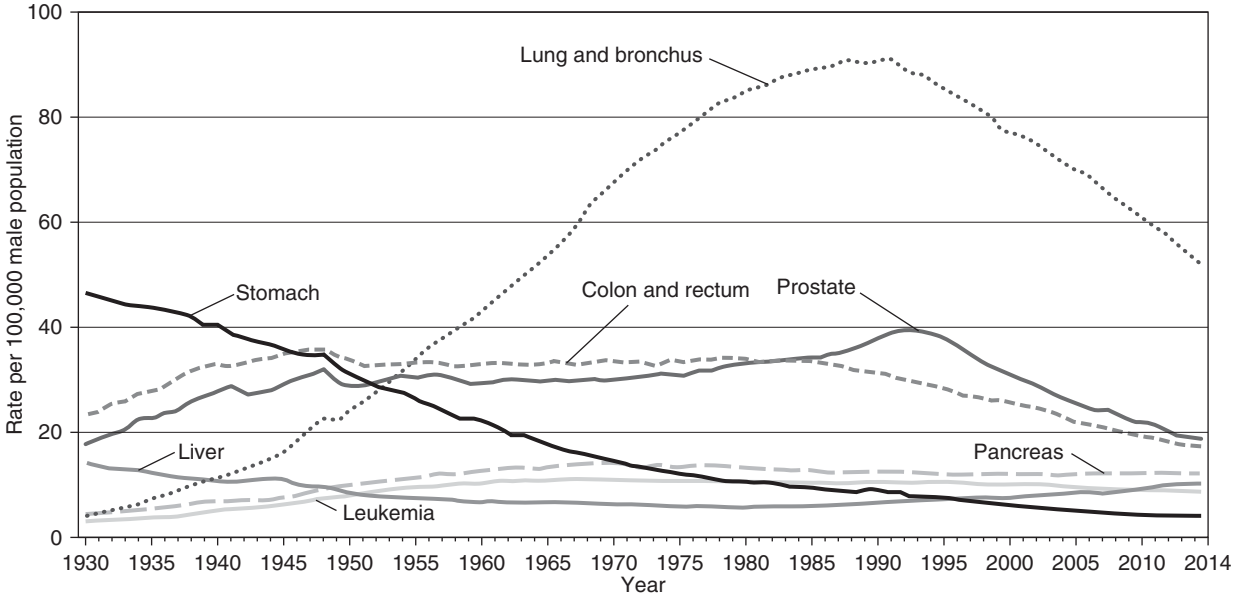

FIGURE 48.2. Annual 1930–2014 age-adjusted, cancer mortality rates per 100,000 men by common malignant tumor type. Currently, mortality for cancers of the liver and pancreas is increasing, whereas the other cancers noted in the figure are decreasing. SEER data indicate the overall age-adjusted death rates for pancreatic cancer increased annually ~0.1% from 2011 to 2020. From 2016 to 2020, the age-adjusted mortality rate for pancreatic cancer in men was 12.7/100,000 compared with 9.6/100,000 for women (https://seer.cancer.gov/statfacts/html/pancreas.html). ICD coding changes affect the mortality rates for cancers of the colon, liver, lung/bronchus, and rectum. (Adapted from American Cancer Society).[6]

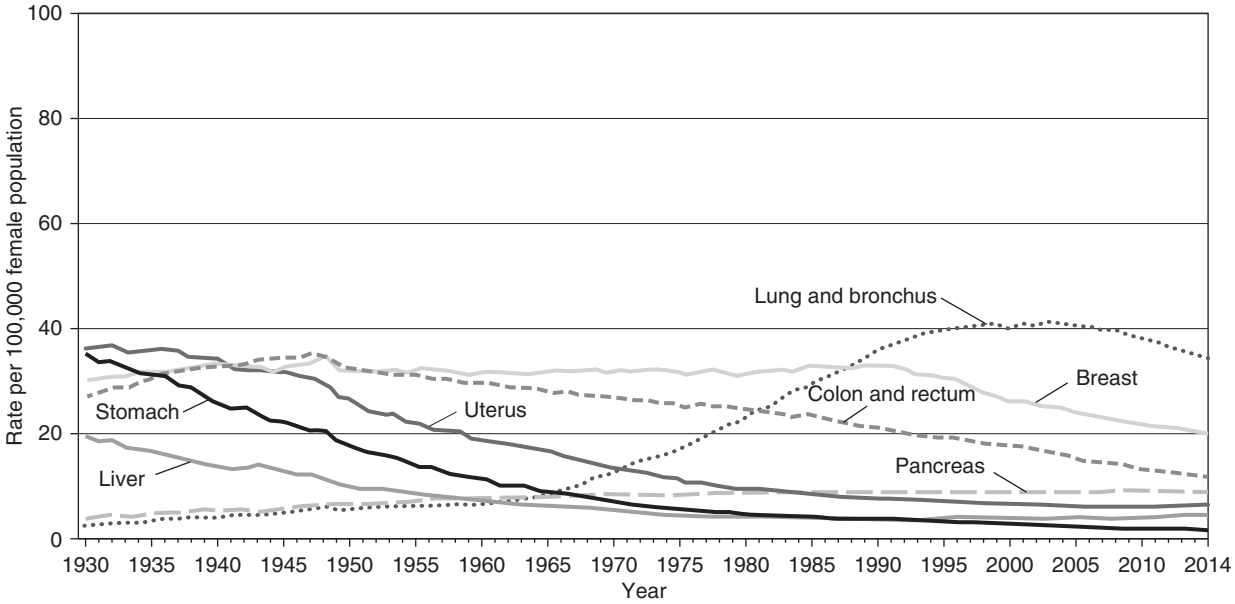

FIGURE 48.3. Annual 1930–2014 age-adjusted, cancer mortality rates per 100,000 women by common malignant tumor type. Currently, mortality for liver cancer is increasing, whereas the other cancers noted in the figure are decreasing. SEER data indicate the overall age-adjusted death rates from liver and intrahepatic bile duct cancer increased ~0.7% annually from 2011 to 2020. From 2016 to 2020, the age-adjusted mortality rate for liver and intrahepatic bile duct cancer was 5.2/100,000 in women compared with 14.1/100,000 in men (https://seer.cancer.gov/statfacts/html/livibd.html). ICD coding changes affect the mortality rates for cancers of the colon, liver, lung/bronchus, rectum, and uterus. Data on uterine cancer include cervical and corpus cancers. (Adapted from American Cancer Society).[6]

disease in men was 24.5% compared with 22.3% for women.[17] Cancer accounted for 23.4% of deaths in men and 21.6% in women. Reductions in lung, prostate, and colorectal cancer deaths accounted for ~78% of the total decrease in men, whereas reductions in breast and colorectal cancer deaths accounted for ~56% of the total decrease in women. During this same period, the overall cancer incidence rate declined slightly (0.6%/year) in men, while remaining stable in women. Currently, almost ½ of all cancer survivors live ≥10 years after their initial cancer diagnosis with ~$^2/_3$ surviving at least 5 years.[18] In 2017, the Global Burden of Disease Study reported 9.6 million cancer-related deaths.[11] The vast majority of these deaths resulted in years of life lost (97%) rather than years lived with disability (3%). Countries with the highest sociodemographic index accounted for 30% of the cancer-related deaths but 51% of the reported incident cancer cases. The highest 5-year survival rates (>90%) remain for melanoma and cancers of thyroid, prostate, and testis, whereas cancers of the esophagus, lung and pancreas produce the lowest 5-year survival rates (<25%).

Tissue Sites

Incidence

In the United States over the last decade, the cancer incidence rate remained stable in women and declined annually by ~2% in men with the most common male cancers being prostate (19%), lung/bronchus (14%), and colorectum (9%) in men and breast (30%), lung/bronchus (13%), and colorectum (7%) in women.[19] The decline in cancer incidence in men results from continuing declines in lung and colorectum cancers along with sharp declines in prostate cancer incidence. The latter partially reflects changes in prostate cancer screening guidelines. Overall, during this period, cancer incidence rates declined for 11 of the 18 most common cancer sites in men and 7 of the 17 of the most common cancer types in women.[10] Cancer incidence increases progressively from childhood (≤14 years) to adolescence (15–19 years) and young adulthood (beginning at 20 years).[4] Embryonal tumors (medulloblastoma, hepatoblastoma, nephroblastoma, neuroblastoma, retinoblastoma) predominate in childhood, whereas sarcomas, Hodgkin and non-Hodgkin lymphomas are prevalent in adolescence and young adults.

The highest US cancer incidence rates involve the prostate (137.7/100,000 men), female breast cancer (123.1/100,000 women), and colorectal cancer (42.5/100,000 persons). Together, these three cancer types accounted for about ½ of all cancers diagnosed each year. Approximately ½ of newly diagnosed cancers in men are prostate, lung/bronchus, and colorectum cancers compared with breast, lung/bronchus, and colorectal cancers in women. Overall lung cancer incidence rates peaked in 1984.[8] In contrast to these major cancers, the overall incidence rates of human papillomavirus-related oropharyngeal cancers, esophageal adenocarcinoma, pancreatic cancer, melanoma, and cancers of the liver, intrahepatic bile duct, thyroid, kidney, and renal pelvis have increased over the last 10 years with some racial variation in the actual rates.[20] The incidence of thyroid cancer increased 3.6% annually from 1974–2013, driven largely by papillary thyroid cancer with annual mortality rates increasing 1.1% from 1994–2013.[21] Reductions in smoking prevalence (lung), increased screening and removal of premalignant lesions (colon, cervix), improved hygiene (stomach), and prostate-specific antigen testing have contributed to the decline in overall cancer incidence and death rates. Excluding nonmelanoma skin cancers (4.3 million incident cases), the most common global incident cancers in men during 2017 were tracheal-bronchus-lung cancer (1.5 million incident cases) and prostate cancer (1.3 million incident cases).[11] Globally, the most common cancers, excluding nonmelanoma skin cancers (3.3 million incident cases), in women were breast cancer (1.9 million incident cases) and colorectal cancer (0.819 million incident cases).

Cancer Mortality

Significant declines in cancer death rates continue for men and women; however, progress in reducing cancer mortality varies with specific tissue types. A review of cancer statistics in 15 industrialized countries between 1969–1986 indicates that cancer mortality in persons aged 45 years and older increased for lung, breast, and prostate cancers, while the mortality rate for stomach cancer decreased substantially.[22] Overall, the risk of dying from cancer has decreased by 32% since 1991. Cancer death rates continue to decline in the United States, including female breast, colorectal (men/women), lung/bronchus (men/women), and prostate. Although overall cancer mortality rates declined between 2010 and 2014, death rates for liver (men/women), pancreas (men/women), oral cavity/pharynx (men), soft tissue (men), uterus, and brain/nervous system (men/women) cancers have increased.[10,16]

Overall lung cancer mortality rates peaked in 1990;[8] however, lung/bronchus/tracheal cancer remains the leading causes of cancer mortality in men and women, accounting for ~29% of US cancer-related deaths.[23,24]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 48.1. Five-year US cancer survival rates for four common tissue types, depending on stage I and IV diagnosed during the late 2000s and early 2010s, based on data from the Annual Report to the Nation on the Status of Cancer data.[10] Survival rates include men and women combined unless otherwise specified. The survival rates for lung/bronchus cancers remain higher for men than women. Newer treatment options (e.g., immunotherapy) have improved the survival rates for melanoma significantly.

Tissue Type	5-year Survival Stage I (%)	5-year Survival Stage IV (%)
Breast, female	100	26.5
Colorectal	88.1	12.6
Lung/bronchus	55.1	4.2
Melanoma	99.5	16

Although lung cancer mortality rates have fallen by 56% in men and 32% in women since 1990, lung cancer remains the leading cause of cancer-related deaths in the United States. Breast cancer and prostate cancer are the second-most common causes of cancer mortality in women and men, respectively. Overall, lung/bronchus (28%), colon/rectum (10%), prostate (6%), and female breast (8%) cancers account for the major portion of all cancer-related deaths.[23] Although there is little difference in the age-adjusted lung cancer mortality rates between white women and black women, these rates are much higher for black men compared with white men.[25]

Between 1980 and 2014, 5-year survival rates for stage I of six cancers (breast, Hodgkin lymphoma, melanoma, testicular, thyroid) exceeded 85%; however, cancer clusters of many cancers occur in individual US counties with especially high mortality including breast, liver, and kidney cancers.[23] Cancers with the lowest 5-year survival rates include brain, esophagus, liver, lung, pancreas, and stomach, with particular slow progress in treating lung and pancreatic cancers. During this period, pancreatic cancer and non-Hodgkin lymphoma mortality rates remained relatively constant, whereas liver cancer mortality increased by ~87%. For cancers diagnosed in the late 2000s and early 2010s, 5-year survival rates varied with tissue type and stage at diagnosis, as displayed in Table 48.1. Globally, the leading causes of cancer-related deaths in women during 2017 were breast cancer (0.601 million deaths), tracheal-bronchus-lung cancers (0.596 million deaths), and colorectal cancer (0.404 million deaths).[11] For men during 2017 globally, the most common causes of cancer-related deaths were tracheal-bronchus-lung cancers (1.3 million deaths), liver cancer (0.572 million deaths), and stomach cancer (0.542 million deaths).

ETIOLOGY

Chemical carcinogenesis is a multifactorial, multistep process that results from the complex interactions of endogenous/exogenous mutations (oncogenes, tumor suppressors, microRNAs) with genetic/epigenetic carcinogens. This process involves cellular control and repair pathways and cellular alterations of cell proliferation, adhesion, invasion, metastasis, and immune surveillance.

Interindividual variation in the response to carcinogens results from variation in several processes including metabolic activation (e.g., CYP2E1, *N*-acetyl transferase), detoxification (e.g., glutathione *S*-transferase 1), DNA repair, proto-oncogene types (e.g., *HRAS*, *c-MYC*), tumor suppressor genes (e.g., *TP53*), and immune function.[26] The lifetime risk of many cancer subtypes strongly correlates to the total number of divisions in normal, replicating stem cells that maintain tissue homeostasis; random DNA replication errors occurring during cell turnover account for the chance (i.e., "bad luck") events that increase organ-specific cancer risks.[27] A substantial percentage of these cancer-related deaths result from exposure to carcinogens associated with lifestyles (e.g., tobacco, alcohol) and environmental factors (e.g., viruses, radiation, natural and synthetic chemicals).[28] The exact portion of cancers attributable to the environment, heredity, and lifestyle factors compared with chance mutations of normal cells ("bad luck") remains unclear because of interactions between environmental and lifestyle carcinogens, variation in inter-country exposure patterns, and inadequate exposure data.

The cancer incidence rises sharply with advancing age; the cumulative cancer risks increase with ~4th power of age. At the end of our natural life span (i.e., typically 85 years), the cumulative risk (i.e., 30%) of acquiring cancer is similar to that of short-lived rodents at the end of their life span (i.e., 2–3 years).[29] The relationship between most cancers and advancing age reflects several factors, including the long latent period associated with solid tumors, cumulative effects of prolonged exposure to carcinogens,[30] and/or the procarcinogenic effect of aging (e.g., oxidative DNA damage).[29]

The population attributable fraction (PAF) quantifies the total effects of a cancer risk factor by providing a percentage or portion of avoidable cancers; however, the PAF does not necessarily indicate the percentage of cancers that can be prevented. The latter depends on the practicality of the preventive strategies and the uncertainties in the estimates Table 48.2 displays the PAF of cancer associated with 14 non-genetic risk

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 48.2. Estimates of the population-attributable fraction (PAF) of cancer associated with 14 major lifestyle, dietary, and environmental risk factors based on the 2010 UK study excluding nonmelanoma skin cancers. The optimum exposure levels indicate the ideal but not necessarily practical efforts to prevent cancer. The PAF for diet was 9.2% reflecting the interaction of multiple dietary factors in the overall impact of suboptimal diets on cancer rates. The dietary estimates do not specifically include the effects of early nutrition on cancer rate estimates. (Adapted from Parkin et al.).[31]

Exposure	Optimum Exposure Level	Estimated PAF (%)
Tobacco	None	19.4
Diet, total		9.2
Deficient fruit/vegetables	≥5 servings (400 g)/day	4.7
Red/processed meat	None	2.7
Deficit fiber	≥23 g/day	1.5
Excess salt	≤6 g/day	0.5
Overweight/obesity	≤25 kg/m^2 BMI	5.5
Alcohol	None	4.0
Occupation	None	3.7
Solar (UV) radiation	1903 birth cohort	3.5
Ionizing radiation	None	1.8
Infections	None	3.1
Physical exercise	≥30 minutes 5 times/week	1.0
Breastfeeding	6 months minimum	0.9
Postmenopausal hormones	None	0.5

factors). In a UK study of 14 major lifestyle, dietary, and environmental risk factors, the four most important cancer risk factors excluding nonmelanoma skin cancers were tobacco smoking, dietary factors, alcohol drinking, and body weight accounting for 34% of cancer cases occurring during 2010.[31] Because of the multifactorial causes of cancer, the same cancer may be attributed to several factors; thus, summing the PAF of individual factors overestimates the total burden of cancer attributable to the 14 risk factors. The overall estimate of the impact of the 14 factors on the overall cancer burden was 18% compared with 26% (range, 6–42%) for the 2009 American Institute for Cancer Research/World Cancer Research Fund study.

Occupation

Approximately 40% of the human carcinogens classified by the International Agency for Research on Cancer (IARC Group 1) are workplace chemicals or employed in specific occupations/industries. The proportion of cancer attributable to occupational exposure at a particular work site depends on carcinogenic potency, exposure duration, and the portion of the work force exposed to the carcinogen as well as study design (e.g., prevalence of exposed individuals within the general population, cancer type studied, proper classification of individuals within the exposed study group). Estimates of the overall proportion of cancer attributable to the work site typically range from ~2–8%[32,33] with a generally accepted level of ~4–5%.[28,34,35] The estimated population attributable fraction for men is ~3–14% compared with ~1–2% for women.[36] In a 2010 French study using a 1994 survey and other data along with relative risks for 23 exposure–cancer combinations derived from meta-analyses and pooled analyses, the estimated portion of cancers attributable to occupational exposures was 2.7% in men and 0.3% in women, whereas the cancer deaths attributable were 4.0% in men and 0.6% in women.[37] In certain cases of hazardous work sites (e.g., asbestos mining), the estimated proportion of cancers attributed to work site exposure ranges up to 40%.[38]

Most industrial-related cancers occurring among male workers develop in the lung and bladder. Of the total number of workers with these cancers, the estimated percentage of workers with industrial-related cancers ranges from ~10–20% and 21–27%, respectively.[39] In a French study of 4335 cancer cases in men and 403 cancer cases in women, lung cancer accounted

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for 75% of the overall cancer deaths.[37] The main occupational carcinogens were asbestos, polycyclic aromatic hydrocarbons, and hexavalent chromium in men and asbestos and involuntary smoking in women. Other important occupationally related cancers in men include nonmelanoma skin, mesothelioma, and sinonasal, whereas the main occupationally related cancers in women include lung, sinonasal, nasopharyngeal, and mesothelioma. In a study of six cancers (bladder, leukemia, lung, mesothelioma, nonmelanoma skin, sinonasal) in the United Kingdom, the estimated contribution of asbestos exposure to these cancers accounted for > ½ occupationally attributable deaths.[40]

The association between occupation-associated chemical exposure and cancers of the breast (except estrogens), ovary, prostate, and colorectal is not as strong as that between lung and bladder cancers.[41] The contribution of occupational exposures to female breast cancer remains unclear, depending on assumptions related to the effect of epigenetic factors (shift work, hormones, endocrine disruptors) on these estimates. A follow-up study on occupational cancer in 15 million inhabitants in 5 Nordic countries did not detect strong associations between occupational chemicals and breast cancer based on self-administered occupation questionnaires; the largest variation in breast cancer incidence occurred in women with their first children at an older age and women with a large average number of children.[42] Women in occupations requiring high educational level often have a higher age at first childbirth and an elevated breast cancer incidence. Prostate cancer in men is typically not associated with occupational exposures.

Environment

Evidence supporting the importance of environmental factors in cancer epidemiology includes the following: 1) the similar cancer risk in native and migrant populations (e.g., Japanese immigrants in California) adopting the habits of the host population over a generation; 2) larger differences in cancer incidence rates between countries than within different regions of the same country; and 3) substantial ethnic and racial differences in cancer incidence within countries (e.g., United States). Cancer rates vary by ~5-fold between industrialized countries and up to 30-fold between all countries.[15] Increasing cancer incidence or mortality rates do not necessarily imply environmental carcinogens are responsible for the increase because many factors influence cancer rates (e.g., aging, biological and epigenetic carcinogens).[43] Arsenic, asbestos, UV radiation, radon, and silica are common environmental carcinogens.

Air

Air pollution is a complex mixture of compounds, including multiple carcinogens from natural and anthropogenic sources (e.g., nitrosamines, benzene, vinyl chloride, asbestos, carcinogenic metals, formaldehyde, polychlorinated dibenzodioxins, polycyclic aromatic hydrocarbons) that varies substantially over time and space reflecting atmospheric processes (weather, oxidative reactions, pollutant interactions). The International Agency for Research on Cancer considers outdoor mixtures of air pollution and particulate matter human carcinogens (Group 1) based on sufficient evidence of increased risks of lung cancer in humans, sufficient evidence in animals, and strong mechanistic evidence (altered gene expression for DNA repair, epigenetic changes including altered DNA methylation, inflammation, oxidative stress).[44] For most pollutants, urban air contains pollutant concentrations several times greater than rural areas; however, concentrations of certain pollutants of concern near industrial sources may be several magnitudes higher than rural areas (e.g., arsenic, benzene, cadmium).[45]

Epidemiological evidence suggests urban air pollution near industrial sources (e.g., nonferrous smelters) increases the relative risk of lung cancer (i.e., 1.2–2.0);[46] however, the relatively low relative risks suggest uncontrolled confounding variables may significantly alter the determination of the contribution of air pollution to lung cancer. These findings are consistent with pooled analyses of European data and cohort studies in the United States.[47] In a prospective analysis of data obtained by the European Study of Cohorts for Air Pollution Effects using data from 17 cohort studies based in 9 European countries (4,013,131 person-years at risk), the meta-analyses demonstrated a statistically significant association between lung cancer and PM_{10} (hazard ratio = 1.22, 95% CI: 1.03–1.45)/10 μg/m^3.[48] There was no association between nitrous oxide and lung cancer. Quantitative risk estimates of airborne carcinogens suggest polycyclic organic matter forming during incomplete combustion is the major contributor in outdoor air to the increased human cancer risks.[49] Indoor air pollution is a significant risk factor for the development of cancer because of the presence of cigarette smoke, radon, benzene, and formaldehyde. Reviews indicate the relative risk of lung cancer is approximately 1.3 for nonsmokers living with smokers compared with nonsmokers living with nonsmokers.[50]

Cancer risks from pollution lie near the detection limit of epidemiological studies (i.e., RR = 1.5–2); below these levels, imprecise exposure data and confounding variables are potentially important sources of error.[46]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Although suggestive of possible associations in the ESCAPE study with the exception of bladder cancer,[51] the hazard ratios for PM_{10} and nonpulmonary cancers (brain,[52] breast,[53] kidney,[53] liver[54]) were weak and statistically nonsignificant. Current analytical technology allows the detection of many trace pollutants in the air and water; however, few of these contaminants are routinely monitored. Estimates of human exposure to these pollutants frequently do not consider the wide geographical, individual, and economic variation in exposures.[55] Compared with the higher chemical concentrations at the work site, the lower exposure levels present in the environment create a greater probability of detecting an association generated by a confounding variable rather than an association with the variable under study.[56]

Drinking Water

Ecological studies suggest an increased risk of certain cancers from contamination of drinking water with hexavalent chromium (IARC Group 1), inorganic arsenic (Group 1), and nitrates (Group 2A), with some support from individual-based studies.[57] High inorganic arsenic concentrations in drinking water (i.e., >200 μg/L) are associated with elevated risks of skin, bladder, and lung cancers, whereas these associations are weaker at lower inorganic arsenic concentrations of <100–200 μg/L.[58] Although limited epidemiological evidence for ingestion of Cr^6 in drinking water suggests an increased risk for stomach and possibly lung cancers in Chinese and Greek ecological studies,[59,60] the quality of exposure information and lack of a dose-response relationship limit conclusions regarding causation.[61] A meta-analysis of highly Cr^6-exposed workers did not detect an elevated risk of gastrointestinal cancers, including stomach cancer (meta-standardized mortality ratio for stomach cancer = 1.09, 95% CI: 0.93–1.28) compared with the general population.[62] The primary issues regarding nitrates in drinking water result from the formation of *N*-nitroso compounds that potentially produce adverse effects from the complex interaction of nitrate concentrations and concomitant ingestion of nitrosation precursors/cofactors in susceptible subpopulations. Although the IARC lists ingested nitrates and nitrites as probable human carcinogens (Group 2A) under conditions of endogenous nitrosation based primarily on animal data and mechanistic considerations,[63] the causal role for nitrates and nitrites in the development of cancer remains controversial [inadequate epidemiology evidence for nitrates in food and drinking water, limited evidence for carcinogenicity in humans (i.e., stomach cancer) for nitrites in food].[64] Chlorination by-products form from the interaction of chlorine with naturally occurring fulvic and humic acids along with other organic chemicals. Chloroform (Group 2B) and other trihalomethanes are the most important organic chemical carcinogens found in chlorinated water; however, chlorination by-products are difficult to study because the chemical concentrations in this complex mixture of hundreds of halogenated chemical species vary significantly over time, source waters, and treatment practices.[65] Evidence of carcinogenicity is suggestive for bladder cancer and possibly colorectal cancer; overall, the evidence is inadequate to determine carcinogenicity because of inconsistent results and generally poor exposure data.

Lifestyle

The histological type of most cancers (i.e., >80%) is epithelial (i.e., uterus, rectum, colon, lung), typically in organs with exposure to environmental carcinogens and high cell proliferation/spontaneous mutation rates.[66] Determination of the contribution of diet to the overall cancer rate is the most uncertain of lifestyle factors because of the difficulty in obtaining accurate measures of dietary components, the long latency between dietary intake and clinical appearance of solid tumors (10–20 years), and the complex interaction of various dietary components. Tobacco smoking is clearly the most important lifestyle carcinogen; however, changes in smoking patterns and aging do not account for all the earlier increases in cancer rates. Since the 1960s, the prevalence of smoking in the general population has declined by ~½ to 23% in men and 19% in women aged 35–64 years by the early 2010s.[67] Despite the reduction in tobacco smoking prevalence, the overall cancer incidence attributable to smoking remains high at 29% (35% in men and 24% in women); the estimates for lung cancer attributed to smoking remain high at 84% among men and 81% among women, as more tumor types are associated with smoking (e.g., cervix, colon, acute myeloid leukemia, liver, stomach).

In an analysis of data from the Nurses' Health Study, the Health Professionals Follow-up Study, and US national cancer statistics, the population-attributable risk (PAR) was calculated for a low-risk group with a healthy lifestyle pattern (16,531 women, 11,731 men) and all other members of the cohorts (73,040 women, 34,608 men).[68] A healthy lifestyle included never or past smoking (<5 pack-years), no or moderate alcohol consumption (≤1 drink/day for women; ≤2 drinks/day for men), BMI 18.5–27.5, and at least 75 vigorously intense

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

or 150 moderately intense minutes of aerobic physical activity/week. The estimated PAR for the overall incidence of total carcinomas attributable to unhealthy lifestyle factors studied was 41% for women and 63% for men; however, the relative reduction in cancer between the highest and lowest quintiles of the Nurses' Health and Health Professionals follow-up studies was relatively small (6–10%), indicating the attributable fractions specifically for diet were smaller, consistent with the 2010 UK estimates.[31,69] A meta-analysis of 314 observational and randomized clinical trials evaluated dietary risk factors for the five most common cancers (breast, colorectal, lung, prostate, stomach) based on predetermined guidelines to assess the strength of the evidence.[70] The authors reported convincing evidence for an association between alcohol/whole grains and colorectal cancer, whereas evidence was highly suggestive for heavy alcohol intake/breast cancer, fruit intake/lung cancer, and calcium/colorectal cancer. Large cohort studies have not detected overall protective effects of fruits/vegetables or vitamin A/β-carotene/retinol on lung or overall cancer rates.[71]

Additionally, the diet of an individual may contain a number of natural carcinogens (e.g., aflatoxin B_1, cycasin, safrole, pyrrolizidine alkaloids, natural pesticides). However, the contribution of synthetic pesticide residues to the overall incidence of cancer appears small, including in occupational settings where the evidence is weak and inconsistent due to the difficulty of study designs (bias, confounding, sample size, heterogeneous exposures).[55] The cooking of food generates a number of mutagens (nitropyrenes) and carcinogens (heterocyclic amines).

Infection

At least 10 infectious agents are established human carcinogens. These causal associations include *Helicobacter pylori*/stomach cancer, hepatitis B and C virus/liver cancer, Epstein–Barr virus/Burkitt's lymphoma, human herpesvirus type 8/Kaposi's sarcoma, human T cell lymphotropic virus/adult T cell leukemia and lymphoma, human papillomaviruses/cervix, penile, anal, and oropharyngeal carcinomas, *Schistosoma hematobium*/bladder carcinoma, *Clonorchiasis sinensis*/cholangiosarcoma of the bile duct, and AIDS/HIV-associated tumors. The attributable fraction varies with location, development status, and specific infectious rates. In a study of background infections with carcinogenic infectious agents and associated cancers using cancer incidence estimates from GLOBOCAN 2012, the attributable fraction varied from <5% in highly developed countries (the United States, Canada, Australia, New Zealand) to >50% in sub-Saharan African countries.[72] The overall global attributable fraction for infectious agents was 15.4% with the most important infectious agents globally being *H. pylori*, human papillomaviruses, hepatitis B virus, hepatitis C virus, and Epstein–Barr virus.

In Utero

Established human carcinogens following *in utero* exposure to diethylstilbestrol are vaginal adenocarcinoma in female offspring and squamous cell carcinoma of the cervix and testis.[73] The major childhood cancers are leukemia, lymphomas, Wilms' tumor, neuroblastoma, and brain tumors; almost all studies of parental exposures and childhood cancers use case-control designs because of the rarity of these cancers. A review of 24 case-control studies suggested an association between childhood brain cancer and hydrocarbon-associated occupations and between childhood leukemia and parental occupation in the paint industries; however, the limited study size and inaccurate exposure assessment in this study limit conclusions regarding causation.[74] Although reviews of other case-control studies also suggest the possibility of an association between childhood leukemia and several paternal exposures (paints, solvents, motor vehicle exhaust) and childhood nervous system cancers and paternal paint exposure,[75] significant limitations prevent definite conclusions regarding associations and/or causation.[76] These limitations include poor exposure assessments (self-reporting, interviews, birth certificates), recall bias, selective reporting bias, multiple comparisons, limited follow-up, little maternal data, and small sample size of cases.[77,78] Adequate exposure data from parents is a major limitation of these retrospective studies; the rarity of childhood cancers restricts the use of more definitive prospective studies.

GENERAL CAUSATION

Population data do not provide information on the etiology of disease in an individual. Although Japanese inhabitants have a higher stomach cancer incidence and eat more fish than Americans, this does not prove that fish in Japan causes stomach cancer. A large relative cancer risk in the study population may not significantly alter the cancer risk in the general population when the specific cancer rate is rare.

The multifactorial causes of cancer, the high prevalence of cancer in the general population, and the prolonged latency period between exposure and the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. clinical onset of cancer complicate the determination of causation in cancer patients with chemical exposures. Simple one-to-one correspondence between a specific factor and disease rarely, if ever, occurs so that the presence of the factor is necessary and sufficient; hence, even strong exogenous factors (e.g., long-term smoking, dominant breast cancer genes) do not always cause cancer when present.[79] Factors suggesting the possibility of an occupational cancer include the development of a cancer unique to the industry where the individual works (e.g., angiosarcoma/vinyl chloride exposure, mesothelioma/asbestos), an appropriate latency period between exposure and diagnosis of the specific type of cancer, and clinical evidence of exposure to a toxic dose of the carcinogen. Establishing contributory cause requires that the chemical exposure precedes the disease and that alteration of the chemical exposure changes the disease (rate). Contributory cause is neither sufficient nor necessary. Therefore, all subjects with a chemical exposure do not necessarily develop the disease and not every subject with the disease must be exposed to the compound. Determining a cause-effect relationship requires an experimental approach; thus, the use of epidemiological (observational) and animal data necessitates an evaluation of the *probability* of a causal relationship.[80] Observational human and experimental animal studies can demonstrate an association between a chemical and the increased incidence of cancer; however, the determination of a true cause-and-effect relationship requires a careful evaluation of the association.

There is no generally accepted consensus on the criteria for distinguishing positive from negative studies. The presence or absence of a statistically significant endpoint does not guarantee a causal relationship because the presence of certain factors (e.g., bias, confounding, inadequate sample size) may complicate the interpretation of the results. Reportedly negative studies should be evaluated for misclassification, dilution of the exposure group with unexposed subjects, omissions, adequate statistical power, and inadequate latent periods.[81] Factors favoring the validity of a positive result include dose-response relationship, strong association, lack of positive bias and confounding, and adequate exclusion of chance effects. Sir Austin Bradford Hill postulated nine characteristics of an association that suggest true causation.[82,83] None of the nine criteria of causation provide irrefutable evidence of a causal role, except for the presence of the disease before the exposure. However, the fewer criteria satisfied, the greater the probability that chance, bias, or confounding variables account for the association. The use of studies in this evaluation of chemical carcinogenicity assumes the studies are valid.

Other methods of determining causality include the Epidemiology-Toxicology ("Epid-Tox") framework involving: 1) collection of all relevant studies, 2) assessment of the study quality, 3) weight of evidence evaluation, 4) assignment of a scalable conclusion, and 5) placement of the conclusion regarding causal relationship on a grid that reflects the likelihood of a positive connection.[84] This approach reflects causality as an inference with varying degrees of certainty rather than absolute proof of a causal relationship. Epidemiological studies using a null hypothesis can fail to reject the null hypothesis as false; however, this type of postulate cannot establish that the variable has no effect on a health outcome. Ultimately, the determination of the presence or absence of a causal relationship between an exposure and a disease is a subjective process that evaluates the strength or likelihood that the exposure causes the effect of interest. A conclusion of a likely causal relationship between the environmental factor and the disease means the epidemiology and animal data provide consistent, reliable evidence of a causal inference (e.g., asbestos and mesothelioma; tobacco smoke and lung cancer). The causal relationship is uncertain when the epidemiology and animal data are inconsistent; in this situation, the weight of evidence from epidemiological studies demonstrates little or no evidence of any effect, although toxicological studies may suggest the plausibility of an effect in humans. The strength and primacy of epidemiology data may suggest a causal relationship in the absence of evidence supporting biological plausibility (Kaposi's sarcoma and HIV), particularly in the early phases of epidemiology studies and animal experiments. A causal relationship between the environmental factor and the disease condition is unlikely when epidemiological and toxicological evidence is compatible with the absence of effect (e.g., D-limonene and kidney cancer in male rats or phenobarbital and rodent liver cancers after negative epidemiology studies). The following is a list of characteristics for evaluating causal relationship of chemical exposures to a disease process in order of importance.[83]

Strength

A higher relative risk (rate ratio) indicates a stronger likelihood of a causal relationship. The studies should contain adequate sample sizes and substantial numbers of observed/expected cases to reduce random fluctuations due to chance. A relative risk of <2 may result from unrecognized bias or confounding variables, whereas a relative risk of >5 is unlikely to result from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

these factors.[85] A small relative risk does not necessarily imply lack of causality, particularly if the disease under study is common. Statistical significance implies the lack of an association is probably not missed rather than indicating a causal relationship exists; the size of the *P* value reflects the confidence to dismiss the null hypothesis. The *P* value is **not** a measure of the strength of the relative risk. Typically, the significance of the *P* value relates to one comparison, whereas multiple comparisons or tests weaken the significance of the *P* value. The ratio of a disease in two groups (exposed/unexposed) is probably more important in understanding a causal relationship than the absolute difference in the disease rate between the two groups.

Consistency

The similarity of results between studies of different designs, places, times, and populations supports a causal association; however, the occurrence of publication bias (i.e., nonpublication of negative studies) complicates the evaluation of consistency. The larger the number and type of studies reproducing the same results, the stronger the causal link and the less likely a constant error or fallacy accounts for the positive results. Consistency requires similar observations by multiple investigators using different methods at different times in different locations. Prospective studies provide more persuasive evidence of causation than retrospective or mortality studies. When discrepancies occur between studies, the studies with better methodology and exposure data should receive greater weight.

Specificity

Specificity is a measure of the uniqueness of the type of disease or the magnitude of the response. The latter implies causation when the magnitude of the disease is much higher for one disease (e.g., lung disease in smokers) than for other diseases (e.g., cardiovascular disease in smokers). Specificity is less common in chronic diseases with multifactorial etiologies than in infectious diseases. The development of hepatic angiosarcomas and mesotheliomas strongly suggests chemical exposure (vinyl chloride and asbestos, respectively) because of the single cause attributed to these diseases; however, the etiology of many diseases is multifactorial; each contributing cause adds a small portion to the risk of developing the disease. Hence, the demonstration of specificity strongly supports causation, but the absence of specificity does not negate a theory of causation.

Temporal Relationship

The cause or exposure *must* precede the development of the disease. When studying cancer with long latent periods, the exposure must occur earlier than one-half of the mean latent period. The latent period represents the time from initiation of the cancer cell to the presence of a clinically detectable tumor. Most of the latent period represents the promotion stage, when the initiated cell grows into a premalignant lesion. Consequently, disease induction and latent periods are important factors in the determination of cancer etiology in cohort studies that use exposure data to define exposure-response gradients.[86] Although minimum latent periods are necessary to establish a true causal link, the long latent period from induction of cancer to clinically apparent disease probably does vary substantially after similar exposure periods. Based on cancer data from atomic bombing victims, leukemia has the shortest latent period with the first evidence of excess leukemia cases appearing about 5–7 years postirradiation.[87] These studies indicate solid tumors have a longer latent period than leukemia with excess incidence of solid cancers persisting for 40 years and mean latency periods ranging from 5–30 years.[88] For analysis of data from radiation victims, the Committee on the Biological Effects of Ionizing Radiations assumes a minimum latent period of 2 years for leukemia and 10 years for tumors other than leukemia and breast cancer.[87] The latent period is age-dependent because the latent period is longer when exposure occurs at a young age.

Dose-Response (Biological Gradient)

The incidence of disease should increase with increasing exposure levels documenting the presence of a biological gradient. The demonstration of a true dose-response relationship and reduction in disease incidence following cessation of exposure strongly support a causal relationship. The presence of other carcinogens, poor exposure data, or the addition of confounding variables may obscure the dose-response relationship. Hence, the lack of a dose-response relationship does not exclude a causal link to the exposure.

Typically, exposure to genotoxic carcinogens demonstrates a dose-response effect; higher carcinogen concentrations produce: 1) an increased incidence and multiplicity of tumors; and 2) a reduction in the latent period. Genotoxic carcinogens exhibit a wide range of potencies. Strain A mice studies indicate a 30,000-fold difference in carcinogen potency for the development of pulmonary tumors.[89] Biotransformation frequently explains species- and dose-dependent

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. differences in cancer rates as manifested by the shape of the dose-response curve. Furthermore, many chemicals may induce cancer following chronic exposure to near-toxic doses based on increased mitogenesis.[90] The issue of whether a threshold exists below which exposure to a carcinogen does not produce cancer remains controversial. Theoretically, the requirement for metabolic activation, the presence of saturated DNA repair processes, and dose-related latent periods may produce a no-observable-effect level.

Biological Plausibility

Biologically plausible depends on the extent of knowledge concerning the biological mechanisms of action; consequently, this characteristic involves toxicological corroboration of epidemiological evidence. The greater the biochemical data on the basis of the disease and the more extensive the pharmacokinetic information on the exposure, the more persuasive the evidence is for a causal role. Experimental animal data helps improve our understanding of the relationship between exposure and disease. The proposed causal relationship should not seriously conflict with data on the pharmacodynamics and toxicology of the substance. The use of frameworks for evaluating the human relevance of modes of action in the production of cancer in experimental animals improves the relevance of animal data to human cancer.[91,92]

Coherence of Evidence

The establishment of a cause-effect relationship should not conflict with apparent truths about the natural history or biology of the disease. Variation in the presence of a suspected environmental or occupational carcinogen should coincide with statistics on the prevalence of cancer in patients exposed to the carcinogen. The association of a carcinogen with a specific type of cancer should be consistent with known latent periods and the natural history of the type of cancer involved. Sound judgment requires the careful evaluation of unexpected associations; 1 in 20 associations will be statistically significant by definition. The incidences of most diseases are too low and the latencies too long to enroll a realistically large number of compliant volunteers for long periods of time. Confounding and bias complicate the interpretation of epidemiology studies.

Experimental Evidence

Although human carcinogens typically produce positive results in animal studies,[93] positive rodent studies do not always predict the carcinogenic potential of the chemical in humans, in part because high experimental doses do not reflect typical human exposures.[94] Interventional studies demonstrating an alteration in the disease corresponding to a change in the exposure strongly suggest a cause-effect relationship. Retrospective or prospective evaluation of changes in the concentration of a chemical that result from improved work practices provides important evidence to support causation, if the corresponding confounding variables are also controlled.

Analogy

If similar compounds produce the disease, the chemical exposure in question by analogy would cause the disease. Although the structure of chemical carcinogens diverges widely, the lack of an increased incidence of cancer in similar compounds argues against a causal role for the development of cancer.

CAUSATION AND INDIVIDUAL EXPOSURES

Establishment of a link between an individual exposure and a particular disease is very difficult to prove conclusively; however, several criteria establish a link between exposure and disease at the more likely than not degree. These criteria include: 1) the exposure is an established cause of the disease, 2) the exposure of the individual is similar (i.e., latency, intensity, duration) to the exposures of persons developing the disease, 3) the individual has a similar disease to persons etiologically linked to the exposure, 4) the individual was not exposed to another established cause of the disease, and 5) the adjusted relative risk of the disease among exposed individuals exceeds two. The latter value indicates the diseased individual is more likely than not to have developed the disease as a result of the specified exposure based on an excess risk being greater than the background risk (i.e., 1).[79] An odds ratio exceeding two suggests the results are quantitatively significant rather than simply statistically significant.[95] The development of cancer at a specific site should be consistent with known exposures and compatible latency periods.

Chapter 49

EVALUATING CARCINOGENICITY

Chemical carcinogenesis is the induction or enhancement of neoplastic disease (benign or malignant) by xenobiotics. These substances are usually genotoxic, affecting specific organs and tissues (e.g., epithelial or other susceptible cells). Classification of the carcinogenic potential of specific xenobiotics involves evaluation of animal experiments, mechanisms of toxicity, and epidemiological studies. Signs of carcinogenicity in animal studies include increased frequency and types of tumors, decreased latency periods, and increased total tumors per animal. Experimental animal studies are the primary screening method for detecting environmental and occupational carcinogens; however, the use of maximum tolerated doses and interspecies variations require confirmation of carcinogenic effects in epidemiology studies. Chemical doses close to the maximum tolerated dose can induce mitogenesis, favoring mutagenesis and suggesting evidence of carcinogenesis when none exists. Each regulatory agency develops somewhat different methods for the assessment of cancer risks from xenobiotic exposures. Cocarcinogens (e.g., ethanol) may act at each stage of carcinogenesis; therefore, these xenobiotics increase the carcinogenic potential of other agents.[1] Cocarcinogens increase the effective concentration of the ultimate carcinogen through alterations of their kinetics; however, cocarcinogens are not genotoxic. These chemicals deplete the organism of endogenous detoxifying processes, including glutathione, induce oxidative and conjugating enzymes, inhibit DNA repair enzymes, and activate procarcinogens.[2,3] Cocarcinogens may be difficult to separate experimentally from tumor promoters that act through epigenetic mechanisms.

CHEMICAL STRUCTURE AND METABOLISM

A chemical carcinogen is a compound capable of producing a statistically increased incidence, type, onset, or multiplicity of neoplasms in *animals* when compared with animal controls. The issue of whether or not an animal carcinogen causes cancer in humans depends on a scientific evaluation of the appropriateness of extrapolating the animal data to humans (i.e., mechanism of action, route of exposure, interspecies variations, pharmacokinetics, dose, potency) and epidemiology data on human exposures.[4] Most chemical carcinogens are procarcinogens that undergo metabolic activation by the cytochrome P450 (CYP450) system or other metabolic pathways before these chemicals react with DNA or alter epigenetic mechanisms.[5] This process generates reactive intermediate metabolites that bind to nuclear and/or mitochondrial DNA and form DNA adducts (e.g., CYP2E1, CYP2A6, and CYP2D6 activation of *N*-nitrosamines; CYP2E1 activation of benzene to reactive benzoquinones). The latter is necessary but probably not sufficient for the development of cancer. Each class of genotoxic carcinogens reacts selectively with pyrimidine and purine bases to form DNA adducts. Aflatoxins, aliphatic epoxides, mustards, *N*-nitroso compounds, and polycyclic aromatic hydrocarbons (PAHs) transfer simple alkyl or aryl-alkyl groups to specific DNA bases, whereas azoamino dyes, aryl aromatic amines, and heterocyclic aromatic amines transfer arylamine residues to DNA. These genotoxic carcinogens are powerful mutagens that can produce nonsense or missense mutation by base pair mismatches or small

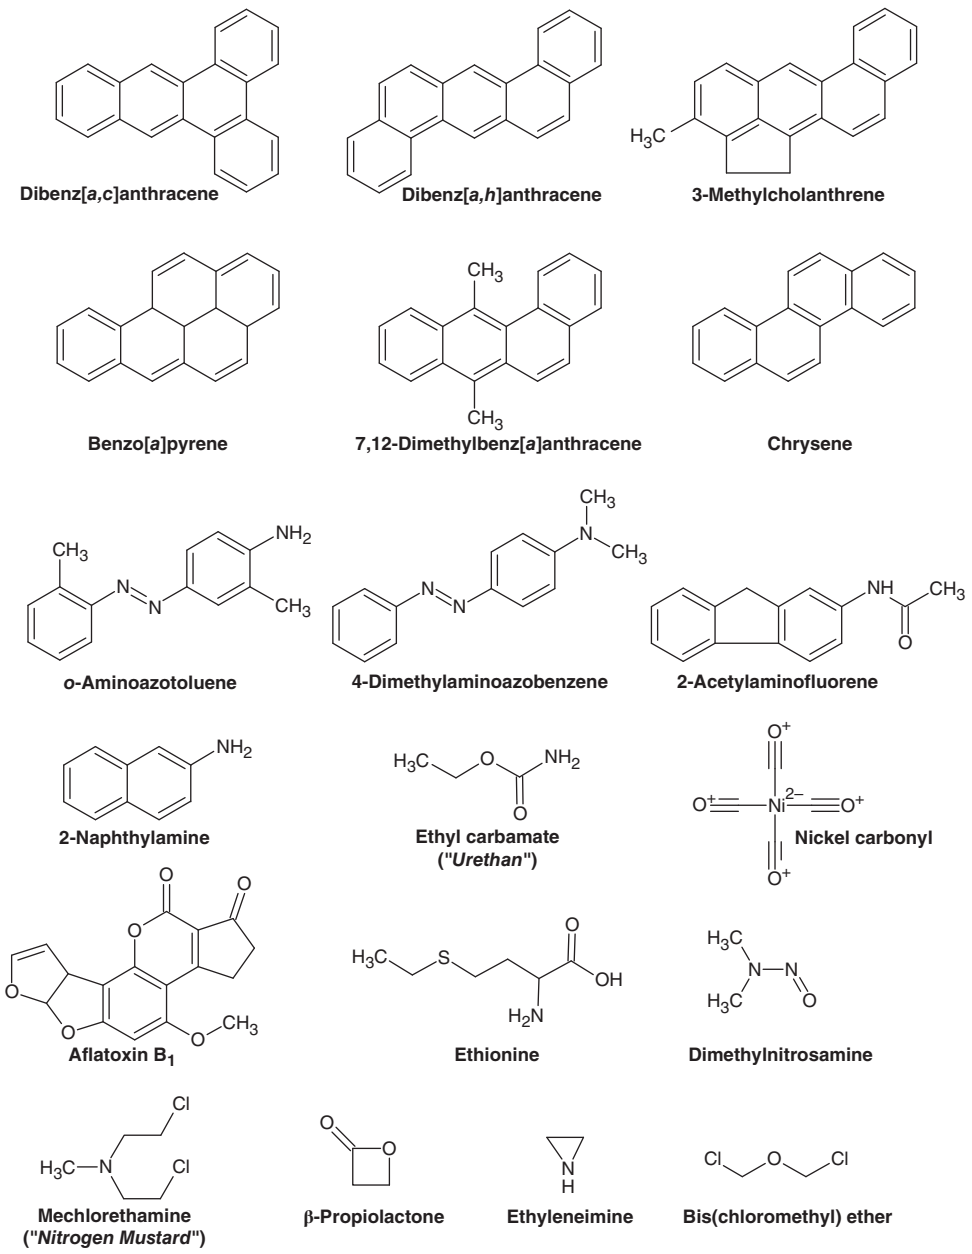

FIGURE 49.1. Diverse chemical structures of selected known and suspected chemical carcinogens.

deletions; other genotoxic chemical carcinogens can cause large deletions or chromosomal breaks. Many organic exogenous chemical carcinogens (e.g., PAHs and polyhalogenated aromatic hydrocarbons) accumulate in lipid stores that slowly release these chemicals into the blood; subsequently, following metabolic activation, these carcinogens travel to carcinogenic targets in peripheral tissues where the metabolic intermediates form DNA adducts.[6]

Some chemical carcinogens are not genotoxic; these carcinogens act at epigenetic sites usually at high doses and following prolonged exposure as detected in rodent studies via multiple mechanisms (e.g., DNA/histone methylation, DNA oxyradical damage, deamination of 5-methylcytosine, depurination, alteration of hormones, regenerative hyperplasia). Known and suspected chemical carcinogens display diverse chemical structures and divergent origins, as displayed in Figure 49.1.

Aromatic hydrocarbons were the first chemical group associated with cancer when Percival Pott linked the soot from the combustion of coal with scrotal skin cancer

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. in chimney sweeps; however, the actual carcinogenic compounds (polycyclic aromatic hydrocarbons) were not identified until 150 years later. The pyrolysis of fossil fuels produces polycyclic aromatic hydrocarbons in automobile exhaust, factory emissions, and cigarette smoke. In 1935, Sasaki and Yoshida discovered the first carcinogen to act at a site remote from its application when they produced liver tumors in rats by feeding them the aminoazo dye, *o*-aminoazotoluene.[7] Rehn associated exposure to aniline dyes with the development of bladder cancer in 1895; subsequent[8] studies over the next 50 years revealed aromatic amines (e.g., benzidine [*p*-diaminodiphenyl], 1-naphthylamine, 2-naphthyhlamine) were the primary carcinogens in aniline dyes.

Highly reactive nitroso compounds (e.g., dialkylnitrosamine, dimethylnitrosamine) are potent liver carcinogens in animal studies; however, evidence for a causal link between dietary amines and an increased risk of stomach, brain, esophageal, or nasopharyngeal cancers is inconclusive.[9,10] Some chemotherapeutic agents are associated with increased cancer risks. An increased incidence of carcinomas of the bladder and acute nonlymphocytic leukemia occurs following chemotherapy with MOPP (nitrogen mustard, vincristine, procarbazine, prednisone) and other alkylating agents (melphalan, cyclophosphamide).[11] Carcinogens of natural origin represent a significant source of exposure to known human carcinogens. Based on studies of the incidence of carcinomas in rodents exposed to various chemicals, 58% of the synthetic chemicals and 45% of the natural chemicals tested positive in at least one species.[12,13] Recognized human carcinogens of natural origin include both organic (e.g., aflatoxins, asbestos, mineral oils, shale oils, soot) and inorganic (e.g., arsenic, hexavalent chromium, nickel) compounds. The carcinogenic risk in the latter group depends on the metal species. The valence of the metal affects the compound's bioavailability; hence, the species determines the amount (i.e., absorbed dose) of the compound reaching the critical target organ.

EXPERIMENTAL CELL STUDIES

The Chemical Abstract Services Registry contains over 100 million unique chemical numbers (CAS RN). Over 100,000 chemicals are used in sufficient quantities to raise concern about their toxic effects. The purpose of animal studies and *in vitro* experiments with suspected chemical carcinogens is the identification of those chemicals producing significant risks of inducing human cancer. Human carcinogens predicted by experimental testing include vinyl chloride, 4-aminobiphenyl, *bis*(chloromethyl)ether, diethylstilbestrol, mustard gas, melphalan, and the combination of 8-methoxypsoralen and ultraviolet light.

There is no simple way to identify which environmental chemicals pose the greatest cancer hazard. Screening for suspected human carcinogenicity typically begins with short-term predictive tests (e.g., Ames test), followed by long-term bioassays in rodents and then epidemiology studies if the screening tests indicate the chemical is a potent carcinogen.

Table 49.1 lists the advantages and disadvantages of important methods for testing chemical carcinogenicity. The congruence of carcinogenicity testing and human epidemiology studies indicates these tests are sensitive; however, extrapolation of animal data to humans as a means to establish quantitative data rather than priorities for concern and regulation remains complicated and controversial.[14,15] Chemicals demonstrating potent or multiorgan effects in carcinogenicity studies signal the need for epidemiology studies; however, carcinogen potency in animal studies (e.g., dioxins) does not necessarily correlate with the induction of human

TABLE 49.1. Classical carcinogenicity testing. (Adapted from Shields and Harris).[14]

Method	Advantages	Disadvantages
In vitro testing	Economical, short-term with rapid results, human cells	Uncertain extrapolation to humans, frequent false positives/negatives, substantial inter-laboratory variation, mutagenicity does not imply carcinogenicity
Animal bioassay	Better predictive value than *in vitro* assay, elucidates species differences	Uncertain quantitative extrapolation to humans, higher doses than human exposure, species differences in DNA repair and metabolism
Molecular epidemiology	Measures internal dose, identifies individual risk and molecular pathways	Highly complex in a rapidly changing field
Classical epidemiology	Direct evaluation of human experience, examines confounders, provides dose-response data	Insensitive with unknown confounders limiting predictive value. Positive results suggest, but do not prove, carcinogenicity

cancer. Issues surrounding animal studies include: 1) consequences of the study on environmental and economic matters, 2) appropriateness of using animals, 3) validity of the animal model, and 4) interpretation of the data.[16]

Mutations

Genotoxins are a broad spectrum of chemical or physical agents that disrupt cellular genetic material involving DNA; these agents can be mutagens, carcinogens, and/or teratogens. Genotoxic agents cause DNA damage including alterations in DNA structure from inaccurate replication of a portion of the genome that is not necessarily transmitted to the next generation of cells. Mutagens are chemical or physical agents that produce *transmissible* genetic alterations that are not necessarily carcinogenic, whereas carcinogens cause heritable genetic and/or epigenetic alterations resulting in autonomous tissue growth (neoplasia) and metastasis. Mutagenic chemicals may be direct mutagens or indirect mutagens that require metabolic activation. Most chemicals classified as human carcinogens or probable human carcinogens are mutagenic in mammalian cells *in vivo* and/or *in vitro*. Determination of mutagenicity or nonmutagenicity usually involves a minimal set of data, including gene mutations in bacteria and/or mammalian cells and *in vitro* and *in vivo* cytogenetics.[17] Mutagenic events result from: 1) carcinogen- or activated metabolite-induced DNA or chromatin modification or interference with other processes (spindle function, gene transcription); and/or 2) disruption of tissue homeostatic mechanisms (cell turnover, tissue necrosis, apoptosis, inflammation). The agreement between mutagenic activity and carcinogenic potential depends on the choice of databases. For the US National Toxicology Program (USNTP), the correlation between genotoxicity and carcinogenicity is ~60%, with the database containing many single-species or single tissue carcinogens.[18] Most chemicals in the IARC classification of carcinogens are multispecies or multitissue carcinogens. Compared with the USNTP, the correlation between carcinogenicity and genotoxicity is higher in the IARC database (e.g., Group 1, 80–93%; Group 2A, 84–90%; Group 2B, 50–90%).[19]

Most chemicals causing mutation in somatic or germ cells are positive in *in vitro* tests, including bacterial gene mutation (Ames test), mouse lymphoma assay, chromosomal aberration in cultured mammalian cells, hypoxanthine phosphorybosyl transferase (HPRT) gene mutation testing, and transgenic rodent studies (e.g., heterozygous p53-deficient, Tg.AC, Tg-Hras2 models).[20,21] Induction of micronuclei and chromosomal aberrations in rodent bone marrow supplements these tests. These tests primarily detect events causing cell initiation (i.e., mutation or clastogenicity) rather than mimicking all cancer stages. Although large differences may occur between mutagenic and carcinogenic potencies of a specific chemical, these assays are good screening tests for potential genotoxic carcinogens. The correlation between DNA reactivity, evidence of mutagenicity on the Ames test, and structural similarities to other known animal carcinogens is typically good.[22] Negative assays for mutagenicity in the presence of positive long-term bioassays in rodents suggest the chemical acts at a stage of carcinogenesis (e.g., promotion) other than initiation and displays epigenetic characteristics. Current standard genotoxicity test batteries are not highly sensitive to nongenotoxic (i.e., epigenetic) carcinogens.[23]

Table 49.2 lists some examples of chemicals recognized by the IARC as causes of human or animal tumors that are inactive in a variety of short-term genotoxic tests. These chemicals tend to produce tumors in susceptible tissue (e.g., mouse liver, rodent leukemogens, rodent thyroid gland, male rat kidney) and display diverse, unpredictable chemical structures.

Since the 1970s,[25] the most studied and best validated *in vitro* mutation assay has been the Ames test (*Salmonella* mammalian microsome mutagenicity assay);[26] this test uses special tester strains of *Salmonella typhimurium* requiring histidine for growth to detect the mutagenicity of physical agents, drugs, foods, natural substances, body fluids, and environmental chemicals/mixtures.[27] Newer approaches to carcinogenic testing based on emerging technologies in molecular biology, genomic sciences, and computer modeling include techniques based on computational methods, statistics-based (Q)SAR (Quantitative

Structure-Activity Relationship), toxicogenomics and pharmacogenomics, *in vitro* assays, and high-throughput screening assays (e.g., US EPA ToxCast; US government regulatory/research entity, Tox21).[28,29]

The *Salmonella* assay (Ames test) detects the presence of either base substitution or frame shift reversion mutations by measuring the number of revertant bacteria capable of synthesizing histidine. Chemicals first recognized as animal carcinogens by screening with this test include the flame-retardant Tris, furylfuramide (a Japanese food additive), and hair dyes. The test uses the subcellular S-9 microsomal fraction of the rat liver that contains enzymes capable of activating procarcinogens; however, the conditions of the *Salmonella* assay may not exactly duplicate the milieu in an intact animal. A false positive test may occur in a *Salmonella* assay because of a lack of type II conjugation systems that allow the formation of DNA-reactive metabolites.[30] Prediction models based on the *Salmonella* assay with structural information provide information to determine the potential genotoxicity of industrial and pharmaceutical chemicals.[31,32] Chemicals producing tumors in more than one rodent species or more than one tissue site are more likely to test positive in the Ames test than single-species or single-site carcinogens.[33]

The utilization of mammalian cells in cell cultures is a complementary assay to the *Salmonella* assay, although the former test is more sensitive, expensive, and technically difficult than the latter. Completion times for mammalian mutation assays average 1–2 weeks. These tests detect forward mutations at one of several loci (e.g., thymidine kinase, hypoxanthine guanine, and phosphoribosyltransferase) by screening for loss of enzyme activity. Cell lines used in mammalian mutation assays include mouse lymphoma L5178Y, Chinese hamster ovary (CHO), and Chinese hamster V79. In cell cultures, the ability to interfere with the inhibitory effects of the gap junction and disrupt intracellular communication provides a test for the promoting activity of a suspected chemical carcinogen.

Short-Term Assays

Rapid *in vitro* assays provide a means to identify potential carcinogens from the plethora of chemicals involved with human exposure. Traditionally, the 2-year rodent bioassay was the primary vehicle for determining carcinogenicity; however, cost, time, and limited resources reduced emphasis on this type of experimental study in favor of short- and medium-term assays with endpoints of neoplasia or precursor lesions of neoplasia, particularly with advances in understanding chemical carcinogenesis and nongenotoxic mechanisms (e.g., inflammation, gap-junction intercellular communication inhibition, receptor-medicated effects). Short-term tests reflect underlying carcinogenic mechanisms; consistently, positive test results for mutations (point mutations, chromosomal rearrangements) usually indicate cancer potential.[34] The categories of tests include mutational assays in bacteria and cell lines, cell transformation assays, and cytogenetic assays.[35] These assays measure changes in the genome (e.g., mutations, chromosome damage, aneuploidy, DNA-adducts, sister chromatid exchange); however, these assays do not detect all genetic damage (e.g., gene amplification, insertion mutations, DNA methylation).[36] No single assay detects all carcinogens; therefore, carcinogen screening often uses assay panels with sequential *in vitro* and *in vivo* testing.[37] However, some studies indicate comparable results between *in vitro* assays (e.g., *Salmonella* and mouse lymphoma cell assays, chromosome aberrations and sister chromatid exchanges in Chinese hamster ovary cells).[18] In comparison to rodent bioassays, short-term assays lack similar pharmacokinetics (i.e., metabolic activation and detoxification), involve short-term exposure, and fail to detect potent initiators specific to individual organs. These assays identify genotoxic chemicals rather than epigenetic carcinogens. Table 49.3 lists types of short-term assays based on the differences in the endpoint and source of genetic changes; regulatory agencies typically use a battery of tests to screen a chemical for genotoxicity, mutagenicity, and carcinogenicity.

Cell Transformation

Cell transformation assays involve the induction of certain phenotypic alterations related to neoplasms in cultured cells; these tests (e.g., Syrian hamster embryo cells, BALB/c3T3 mouse cell system) screen for potential carcinogens. The morphological transformation of mammalian cell lines (e.g., rodent 3T3 or 10T1/2) or human epithelial cell lines produces dense foci in cell cultures. These transformed cells lose the suppressive effects of contact inhibition and continue to divide. The injection of transformed cells into the appropriate strain of rodent will produce tumors. The procedures are technically difficult and require six weeks to complete; some chemical carcinogens (e.g., asbestos) are positive in cell transformation assays and negative in mutation assays.

Cytogenetic

All tumors contain chromosomal alterations (e.g., translocations, deletions, aneuploidy) with errors in

DNA replication and/or repair resulting in genomic instability. Clastogens are chemicals that induce structural chromosomal aberrations; chemicals producing DNA replication errors typically form DNA adducts, whereas ionizing radiation and chemicals disrupting DNA-enzyme complexes (e.g., topoisomerases) are associated with DNA repair errors.[17] Tests for genotoxicity include measures of chromosomal aberrations and changes in chromosomal structure with classification of chromosomal aberrations based on breaks (deletion, fragment) or rearrangements (translocation/inversion, exchange between chromatids/chromosomes). These assays use human lymphocytes, human fibroblasts, or rodent fibroblasts to detect abnormalities in chromosome numbers (polyploidy, aneuploidy) or chromosomal structure (translocations, fragmentation, rearrangement). The endpoint is the number of cells arrested in metaphase by colchicine.[35]

Sister chromatid exchange involves the detection of the reversal of loci from a sister chromatid that results from the breakage and symmetric rejoining of the sister chromatids within a single chromosome. These alterations are the end products of homologous recombination, necessitating differentiation of the sister chromatids. Although this exchange produces no alteration in morphology, florescent dye and Giemsa's stain allow documentation of the exchange.[38] Many chemicals that produce sister chromatid exchanges also

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. cause DNA/chromosomal damage and gene mutations. This test is sensitive to genotoxic and epigenetic (e.g., saccharin, asbestos, phorbol esters) carcinogens; however, sister chromosome exchange is an indicator of exposure and not necessarily a mutagenic response. Sister chromatid exchange can be performed as an *in vivo* test in urine or blood from workers exposed to carcinogens; however, the results of testing in workers must be interpreted cautiously because of the lack of specificity of this test for carcinogens. Highly sensitive immunoassays for specific DNA-carcinogen adducts are available to test human exposure to genotoxic carcinogens, but these tests also should be interpreted with caution because of the presence of DNA adducts as part of natural DNA repair mechanisms.

Standard Genotoxicity Testing

Assessment of the genotoxicity of chemical and physical agents involves various *in vitro* and *in vivo* assays, with the former providing information regarding primary genotoxicity, whereas the latter assesses secondary genotoxic effects resulting from oxidative stress and inflammation.[39] No single screening test identifies all the chemicals that produce the most serious risk of human cancer; therefore, regulatory agencies require a battery or tier system to evaluate the carcinogenic potential of a chemical. Typically, the standard genotoxicity testing battery involves: 1) a bacterial gene mutation assay, 2) an *in vitro* mammalian mutation and/or chromosome (DNA) damage assay, and 3) an *in vivo* chromosome (DNA) damage assay.[40] The International Collaborative Programme for the Evaluation of Short-Term Tests for Carcinogens (IPESTTC) concluded that the Ames test was the most valuable *in vitro* screening test for genotoxicity.[41] The Ames test typically uses the presence and absence of an exogenous metabolic activation system to improve sensitivity. However, the test has limited sensitivity for inorganic metals and halogenated organic carcinogens along with relatively poor specificity for nitrogen- and sulfur-containing organic chemicals.[42] Overall, the Ames bacterial mutagenicity assay detects ~90% of known human carcinogens and predicts ~60% of rodent carcinogens.[43] A subsequent study (Collaborative Study on Short-Term Tests for Genotoxicity and Carcinogenicity) identified four *in vitro* assays (chromosomal aberrations, gene mutations, neoplastic transformation in cultured mammalian cells, and aneuploidy initiation in yeast) that improved the screening potential of the Ames test. This international study concluded that the combination of the Ames test and the chromosomal aberrations assay (i.e., microscopically visible alterations in chromosomal structure) was the most appropriate *in vitro* primary screen for the carcinogenic potential of new chemicals.[44] The second phase of this study confirmed the importance of *in vivo* assays as a means of identifying which *in vitro* genotoxic chemicals are active *in vivo* with the greatest potential human hazards. Based on this study, the mouse bone marrow micronucleus test was the best *in vivo* test of *in vitro* genotoxic compounds.[45] The latter detects genotoxicity but not mutagenicity, similar to DNA adduct or strand break analysis, chromosome aberration (abnormal chromosomes, chromosome/chromatid breaks, and translocations), Comet (single cell gel or micro-gel electrophoresis for DNA base damage, single/double-strand breaks), unscheduled DNA synthesis, and sister chromatid exchange assays. The uses of the latter two assays are very limited currently.[39]

The micronucleus assay detects genotoxicity including aneuploidy and clastogenicity *in vitro* and *in vivo*. Most clastogens produce lesions during G1 and S cell phases, with the formation of the micronuclei in the subsequent cell cycles, primarily during anaphase. The micronuclei are acentric chromosomal fragments and lagging chromosomes extruded from the nucleus during mitosis; the micronuclei are visible in cells from rodent bone marrow or mouse erythrocytes. These micronuclei represent chromosomal breakages, and their presence indicates genetic damage suggestive of carcinogenicity. The micronucleus assay is the only standard genotoxicity method for detecting aneuploidy (production of daughter cells with abnormal number of chromosomes) in somatic cells.[46] In germ cells, the dominant lethal assay can also detect aneuploidy as well as clastogenicity (mutations that break or rearrange genetic material in chromosomes).[47] Results from transgene mutation induction studies help differentiate initiating agents, tumor promoters, and complete carcinogens (e.g., Tg.AC mouse).[48] Chromatid aberrations and sister chromatid exchanges occur during the S phase in culture; consequently, their frequency reflects DNA damage remaining after *in vitro* replication and thus recent chemical exposure. Because the *in vivo* tests are somewhat insensitive, concluding a genotoxic chemical is inactive *in vivo* requires negative data from at least two *in vivo* assays in different tissues. Limited *in vivo* bioassays in rodents allow the testing of a promoter when the exposure to the chemical follows the administration of a carcinogen that is genotoxic for a specific target organ.

System Biology Framework

Classic genetic testing involving standard *in vitro* genotoxicity assays frequently generates false positive results

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. that are not relevant to human cancer risk assessment and lead to expensive, 2-year animal studies. Other limitations include: 1) difficulty extrapolating *in vivo* experimental models with complex human systems; and 2) classifying genotoxic and nongenotoxic carcinogens based on pathological mechanisms. The system biology framework integrates the latest scientific data on genomics, including toxicogenomics, proteomics, metabolomics, computer modeling (*in silico* approaches), single cell genomics, and epigenomics to predict carcinogenicity.[39] Advances in techniques for gene expression analysis (e.g., high-throughput methods, 3-D culture systems, flow cytometric analysis) allow measurement of the multiplicity of chemical effects on the genome that cause mutations and cancer. Toxicogenomics uses global genomic technology and gene expression analysis in a single experiment to analyze the whole genome and identify genes responding to groups or categories of chemicals. The analysis of gene expression profiles (i.e., mRNA transcription) provides insights into the common molecular actions of different chemical carcinogens, identifies useful biomarkers of disease/cancer, and elucidates the relationship between human susceptibility and environmental factors.[49,50] Agent-specific gene expression profiles display both distinct and common features. Studies on ionizing radiation and genotoxic chemicals indicate genes susceptible to carcinogens involve cell growth arrest, cellular signaling DNA repair, and apoptosis via multiple pathways (e.g., p53 tumor suppressor pathway, NF-κB-dependent *AP1*, *GADD45G*, Cyclin E, *XPC* complex).[51] The gene expression profiles for DNA repair demonstrate relatively modest alteration of relatively few DNA repair genes compared with cell cycle control, inflammation, senescence, and apoptosis.[52] Information obtained from toxicogenomics helps predict the presence of carcinogenic mechanisms between carcinogens with similar structures. Proteomics and metabolomics are downstream events in the processes of genotoxicity and carcinogenicity. Proteomics focuses on the protein interactions in stem cell differentiation into various cell types and molecular mechanisms of carcinogen-induced DNA damage response to determine direct and indirect protein biomarkers for genetic damage. Metabolomics provides information on metabolic processes in the biological system that determine carcinogenic potential and individual susceptibility. *In silico* approaches involve the development of computer models to predict the carcinogenicity of chemicals based on molecular structure or structure-activity relationships (SARs). Quantitative SAR (QSAR) uses a variety of physicochemical parameters to identify the genotoxicity of a range of chemicals based on information from a variety of databases, including the US Tox21 Project, the National Institutes of Health Chemical Genomic Center, and the US EPA National Center for Computational Toxicology. The US FDA Center for Drug Evaluation and Research uses QSAR-based computational toxicology approaches to help evaluate drugs and drug-related genotoxic contaminants.[23]

The epigenome is the exceedingly complex physiological connection between the genome, transcriptional regulation, and the cellular environment. Processing large numbers of gene expression profiles by high-throughput, rapid techniques helps understand cell differentiation and the various signaling pathways activated by DNA damage during carcinogenesis; however, there currently is no clear, direct *in vitro*/*in vivo* relationship similar to DNA-reactive chemical carcinogens. Gene expression profiles indicating a strong DNA damage response suggest direct DNA modification, whereas increased expression of genes involved with cell cycle progression characterizes indirect-acting agents.[53] The latter indirect agents produce oxidative stress, aneuploidy, impaired DNA repair, or alteration of DNA methylation, whereas nongenotoxic (i.e., epigenetic) mechanisms involve changes in signal transduction pathways, disruption of gap junction intercellular communication, and inhibition of tubulin polymerization or topoisomerase activity as well as cell cycle progression that produce cell proliferation, differentiation, and metastasis.[54] Most epigenetic profiling studies focus on the identification of epigenetic changes associated with annotated genes (Gene Ontology Consortium, http://www.geneontology.org; Encyclopedia of DNA Elements, ENCODE, https://www.encodeproject.org).[55]

ANIMAL STUDIES

Although short-term assays for genotoxicity and carcinogenicity are efficient, inexpensive, and supplement animal bioassays, the long-term mammalian bioassay remains the gold standard for detecting chemical carcinogens. Most human cancers can be produced in animal models following chronic exposure to the carcinogen, even though the specific organ or exposure pathway may differ. Genetically modified mice enhance the understanding and sensitivity of rodent models by expressing human drug-metabolizing enzymes, specific human cancer syndromes, and models of preneoplastic/precancerous lesions.[56] Statistical considerations limit the sensitivity of these assays. These studies typically involve 50 control animals and groups of 50

animals given different chemical doses. Even with the rare occurrence of no spontaneous tumors in the control group, a statistically significant result requires a 10% incidence of neoplasms in the treated animals.[57] To overcome these statistical limitations without using thousands of laboratory animals, these assays use the highest dose (i.e., maximum tolerated dose, MTD) of the chemical that will produce minimal toxicity (e.g., small reduction in body weight) with no increased mortality in the exposed group. Consequently, interpretation of the results and extrapolation of these results to humans require a careful evaluation of the experimental design and a cautious interpretation of the significance of the results. Long-term animal studies are usually sensitive, but not necessarily specific, indicators of human carcinogens. Most, if not all, human carcinogens produce tumors in laboratory animals; these studies usually demonstrate at least one common site of cancer in humans and animals.[58] Analysis of databases on 536 rodent carcinogens by computer information systems suggests there is no obvious association between chemical structure (i.e., chemical class), mode of action, and tumor profile.[59] A specific class of carcinogen typically produces tumors at a wide range of sites rather than a unique tumor pattern.

Design

Chemical carcinogenicity studies typically consist of four separate experiments involving one to two rodent strains of both sexes divided into three different exposure concentrations, including the maximum tolerated dose (MTD) and unexposed controls. Frequently, the goals of these studies are both detection of chronic toxicity and evaluation of chemical carcinogenic potential. The National Toxicology Program (NTP) uses Fischer 344 rats and B6C3F$_1$ mice exposed to the chemical for 2 years. Most carcinogenicity studies start with weanling animals to allow a sufficient latent period for neoplasm development. When determining the carcinogenicity of a chemical, the spontaneous rate of neoplasm formation in rodents is not usually considered; however, the production of benign neoplasms is evidence of carcinogenicity in these studies because no chemical to date has caused only benign neoplasms when administered to animals. In an evaluation of 471 NTP studies, the most common sites associated with carcinogenic effects in long-term rodent studies were the following: liver, 30%; kidney, 12.5%; lung, 10%; mammary gland, 7.4%; hematopoietic system, 7.2%; and forestomach, 6.4%.[60]

The spontaneous tumor incidences for ~100 tumor types examined in 2-year rodent studies are typically relatively low (i.e., <1–3%), with a few exceptions noted in Table 49.4.[61] Approximately 96% of untreated (control) male and female F344 rats developed a benign or malignant tumor during these long-term studies, whereas the presence of at least one malignant neoplasm occurred in 64% of male rats and 43% of female rats. About $^2/_3$ of the B6C3F$_1$ mice developed a benign or malignant tumor, whereas ~39% developed at least one malignant tumor. The tumor rates in the control rat groups from feeding studies and chamber (inhalation) studies were usually similar.

TABLE 49.5. Design factors for animal studies. (Adapted from Goodman).[65]

Animal Data	Chemical Data
Animal models	Dose
Controls	Duration of test
Number of animals	Statistical tests
Age at onset of testing	Route of administration
Pathology protocols	Toxicity of chemical
Clinical observations/pathology	

For chronic (2-year) rodent studies, the US National Toxicology Program typically uses 50 male/50 female F344 rats and the same number of male/female $B6C3F_1$ mice; the most common tumors in the former control (untreated) are leukemias and tumors of the adrenal gland, pituitary gland, and testicle (males), whereas the most frequent tumors in the latter are hematopoietic, liver, and lung tumors. Several doses are administered with the highest dose being the maximum tolerated dose. Preneoplastic lesions in rodent livers are precursor lesions that progress to benign and malignant liver cell tumors; these lesions are endpoints in carcinogenicity testing when identified as hepatic foci by H&E (hematoxylin and eosin) stained sections.

The NTP considered replacing the $B6C3F_1$ mouse with a strain that produced a lower and less variable incidence of spontaneous tumors, but the extensive experience with good husbandry practices and the substantial amount of data on the incidences of natural diseases persuaded the group to retain this mouse strain.[62] Nutritional status is an important variable in these studies because excessive nutrients and subsequent endocrine dysfunction in some rodent strains produce high spontaneous tumor incidences in control animals.[63] A review of data from 53 rat studies and 55 mouse studies indicates a positive relationship between body weight and the incidence of the following tumors: liver in both sexes of mice, pituitary gland in both sexes of rats, and mammary gland tumors in female rats.[64] When the mean body weight of treated animals was 10% higher than that of control animals, the rates of false positive studies increased by up to 20–30%.

Table 49.5 lists the important design considerations for long-term carcinogenicity studies in animals. The sensitivity of long-term carcinogenicity tests in rodents depends on the background tumor incidence. The sensitivity improves as the incidence of spontaneous tumors approaches zero and the sample size increases.[66] The sample size should be large enough to reduce the likelihood of chance to a rarity while limiting excessive exposure of the subjects and avoiding the waste of resources. Power of a hypothesis test is the probability of obtaining a statistically significant result when there is a true difference between groups; thus, power is the complement of type II error.[67] For a 20% type II error and a difference in rates of size d (e.g., $P = 0.05$), there is a 20% chance a difference in size d will not be detected. The statistical power is the complement (e.g., 1–0.2) and indicates an 80% likelihood that the test will detect the difference. This analysis is specific to the parameters used. A power analysis helps interpret study findings when the results are not statistically significant.

Table 49.6 lists the sample size needed to detect a specific increase above background concentrations of the chemical, assuming the test has a power of 80% and a significance level of $P = 0.05$. These calculations assume the variation in tumor frequency is small.

Selection of Chemicals

The choice of which chemical to test depends on indications that the chemical might be carcinogenic based on structural similarities to known carcinogens and evidence of genotoxicity in short-term tests. Equally important are the extent of human exposure and the needs of government regulatory agencies. International cooperation in standardizing protocols, sharing

TABLE 49.7. Major selection criteria for the determination of the route of chemical administration. (Adapted from Chabra et al.).[62]

Route	Major Criteria
Feed	Oral major route of human exposure, chemical easily absorbed by all routes, and least labor-intensive administration
Gavage	Limitations to use in feed (mucosal irritant, unpalatable, volatile, unstable, or non-uniform distribution in feed), limited amount of chemical, and containment of toxic chemical
Drinking water	Water-soluble and drinking water are major sources of human exposure
Inhalation	Inhalation is a major source of human exposure, and the lungs are the primary target organ
Dermal	Skin is the major source of human (occupational) exposure; skin is the primary target organ; and there are 2-stage initiation-promotion studies
Multiple routes	Major human exposure involves more than one route

information, and reducing costs by the elimination of duplicate studies helps to improve the amount and quality of data on carcinogenicity studies.[68]

Route of Exposure

The route of administration should be consistent with the most common route of exposure to the chemical in humans. Differences in pharmacokinetics and toxicokinetics between alternate exposure routes support studies that demonstrate up to a 10-fold variance in carcinogenic potency for compounds (e.g., asbestos, vinyl chloride, hydrazine).[69] Oral administration by gavage is an alternative method when the physical characteristics of the chemical preclude the use of more common exposure routes. In an evaluation of 400 carcinogenicity studies by the NTP, the administration of the chemical in feed accounted for 60% of the studies, whereas oral gavage accounted for ~27% of the studies.[16] Microencapsulation is a method for administering unstable, reactive, or unpalatable chemicals in the feed; this method avoids the complications of the gavage method.[70] Table 49.7 lists the criteria used for the selection of the route of administration.

Physiochemical Properties

The dose of the chemical at the critical target site in the animal depends partly on the physicochemical properties of the chemical. The stability and reactivity of the chemical during administration or storage may alter the amount of the chemical absorbed by the animal. Impurities may confound the results of long-term studies, particularly if commercial grades contain substances (e.g., dioxins) known to cause cancer in animals. Volatility of the chemical may change the dose absorbed by both the exposed and control groups, including chemicals administered in the diet or drinking water.

Dose

A major area of controversy is the selection of exposure concentrations that allow a reasonably normal life span while ensuring the emergence of obvious signs of chronic toxicity distinguishable from aging. Most long-term studies screen for chronic toxicity and carcinogenicity. Prechronic (14-day and 90-day) studies improve chronic study design by demonstrating frank toxicity concentrations and no observable adverse effect levels (NOAELs). Previously, most chronic carcinogenicity studies used a control group and two doses including: 1) the highest dose or maximum tolerated dose (MTD) capable of producing the greatest yield of tumors; and 2) one-half of the highest dose.

The selection of the MTD is an area of intense discussion because of the necessity to extrapolate the results to human exposures at much lower levels, particularly when the pharmacokinetics of the ultimate carcinogen may differ in humans. More recent long-term studies incorporate at least three dosage levels to delineate the dose-response curve. These studies include both interim sacrifices and autopsies of all deaths to determine the clinical effects at a particular dose.

Endpoints for selecting the proper dose include body weights, metabolism and disposition, organ weights, biochemical parameters, food/water consumption, pharmacological signs, gross pathology, clinical chemistry, histopathological changes, hematological changes, mortality, clinical signs, and toxicity. The guidelines of the National Cancer Institute indicate the MTD should not cause increased mortality or signs of clinical toxicity that would shorten the life span of the exposed group compared with the control group. Additionally, the MTD should not exceed 5% of the diet or cause more than a 10% reduction in weight in the exposed group compared with the control group. Clinical observation of food consumption, body weight, toxicity (diarrhea, coughing, convulsions), behavior, and mortality provides monitoring for chronic toxicity and intercurrent illness.[65] Special studies on metabolism, pharmacokinetics, biochemical abnormalities, interim necropsy, stop exposure groups, and immunotoxicology enhance the study design by improving the ability to extrapolate the results to different species.

TABLE 49.8. US National Toxicology Program (NTP) criteria favoring positive results in animal bioassays for carcinogenicity. (Adapted from Huff et al.).[16]

Criteria Favoring Carcinogenicity
Occurrence of rare neoplasms
Progression toward more malignant lesions
Lack of regression of tumor
Mixture of benign and malignant lesions
Shorter latent period in tumor formation
Multiple tumors in the same tissue
Metastatic lesions
Few similar tumors in control animals
Statistically significant increase in the incidence of tumors
Similar tumors in other sites or experiments
Presence of dose-response effect
Similar mortality and morbidity between control and test animals
Adequate experimental design
Supportive evidence from structure–activity correlation
Positive genotoxicity studies

Interpretation

The determination of chemical carcinogenicity depends on the appearance of different histological tumor types at different pathological sites or on an increased incidence of neoplasms in exposed animals compared with control animals. Many factors (e.g., housing conditions, diet, duration of study) affect the rate of spontaneous tumor development in animals; therefore, the tumor incidence data must be compared carefully to concurrent and historical controls. The four major determinants providing evidence of carcinogenicity include: 1) increased neoplasm incidence consisting of a specific cell type at a specific site, 2) multiple neoplasms of the same cell type at a specific site, 3) reduction in the latent period, and 4) progression of benign lesions to malignant lesions.

Table 49.8 lists factors used in the determination of the carcinogenic potential of a chemical by the US National Toxicology Program. For statistical analysis, the occurrence of benign and malignant neoplasms of the same cell type at the same site is considered a group and an individual lesion because of the belief that benign neoplasms are an important indicator of rodent carcinogenicity.[71] The appearance of rare tumors at a specific site is a more important determinant of carcinogenicity than the same incidence of a common, spontaneous tumor at the same site. Chemicals causing tumors in several species and particularly tumors at the same site are greater cancer hazards than chemicals producing tumors in one tissue of one species.[33]

An unequivocally positive result on the animal bioassay demonstrates a clear, dose-related increase in tumor incidence at one or more sites in the exposed group compared with the control group. This dose-related increase should be linear and statistically significant. An equivocal result arises in the following circumstances: 1) the increased tumor incidence occurs in one strain or sex, 2) there is no obvious dose-response, or 3) the tumors develop at the same site as spontaneous tumors appear in the control group. Such circumstances are common following the development of tumors of the breast, pituitary, and thyroid in Fischer 344 rats and lymphomas, hepatomas, and lung tumors in $B6C3F_1$ mice.[72] Wide variation in the incidence and onset of tumors between species, sexes, strains, and ages raises concern about the validity of the results. A negative result in the bioassay means the chemical did not cause an increased incidence of neoplasms under the conditions of the experiment; this result does not exclude the potential for inducing cancer under other conditions. The lack of an effective dose, species, and/or strain resistance, excess mortality, or acute toxicity may limit the sensitivity of the bioassay.

Extrapolation

Compared with epidemiological studies, animal models of carcinogenesis have several advantages, including: 1) more precise exposure data; 2) adequate latent periods; and 3) early detection of potential carcinogens.[73] A positive bioassay in the carcinogenicity study indicates the chemical is carcinogenic in animals under the conditions of the study and the criteria used for positive tests (i.e., the number of positives required in different sexes and species); therefore, the chemical *may* represent a carcinogenic hazard to humans.[16] Typically, in the past, ~50% of chemicals tested in 2-year rodent bioassays in most databases were positive in one or both rodent species, including naturally occurring chemicals and pesticides.[74,75] As the criteria for a positive animal study strengthened and the testing selection criteria changed from an emphasis on highly suspicious carcinogenic chemicals to high-volume chemicals, the percentage of positive animal tests decreased significantly.[76] In a review of chemical carcinogenesis studies in nonhuman primates performed by the US National Cancer Institute at doses 10–40 times estimated human exposures, a variety of chemicals were tested, including 7 "classical" rodent carcinogens, 3 heterocyclic amines, 5 *N*-nitroso compounds, 6 chemotherapeutic agents, and 13 food-related compounds.[77] Most studies were inconclusive, except for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

2-amino-3-methylimidazo[4,5-f]-quinoxaline, diethylnitrosamine, methylnitrosourea, and procarbazine. Cyclamate and saccharine were not carcinogenic in these nonhuman studies.

Concerns for extrapolating animal testing to human exposures include the potential for testing at the maximum tolerated dose to screen for potent cytotoxins near the MTD rather than human carcinogenicity (i.e., false positives rather than false negatives), whereas almost all human chemical carcinogens produce positive results when tested in sufficient animal species.[78,79] This high positivity rate reflects selection toward suspected carcinogens, the use of rodents displaying high tumor rates (e.g., liver), and exposure to high doses of chemicals that promote rapid cell division. Consequently, rodent studies are subject to false positive results from the induction of mitogenesis and mutagenesis, when compared with epidemiology studies on the chemical concentrations present in the environment and workplace. Additional limitations to extrapolating positive rodent studies to human exposures include: 1) discordance in rodent bioassay results between species, strains, and genders of rodent and human exposures, 2) variable stresses in rodent studies involving restraint, handling, and administration of the chemical, 3) differences in toxicokinetics and routes of exposure between rodents and humans, and 4) variable responses of human and rodent organs to chemicals;[80] however, cancer bioassays remain a valuable and unique source of data to determine chemical carcinogenicity along with epidemiological and mechanistic information.

Animal carcinogens demonstrate a wide range of potencies. Based on the median daily dose (TD_{50}) as measured by the dose required to induce tumors in ½ of the animals that would normally remain tumor-free over their lifetime, the potency of animal carcinogens varies over 6–7 orders of magnitude.[74] The estimated TD_{50} usually ranges within a 30-fold factor of the MTD (i.e., the maximum dose used in the long-term studies).[81] Although gavage is somewhat more likely to produce cancer in rodents following exposure to chemicals with a low rather than high MTD, the absolute amount of the MTD is not usually a reliable predictor of rodent carcinogenicity.[82]

Evaluation of a potential hazard to humans from animal carcinogens requires extrapolation *down* the dose-response curve to concentrations encountered in environmental or occupational settings, as well as extrapolation *across* species from rodents to humans. Controversy remains regarding which animal carcinogens with high MTDs are human carcinogens at concentrations currently present in the workplace or the environment. For almost all known human cancers produced by chemicals, at least one common organ site of cancer occurs both in animals and humans following exposure to the chemical carcinogen; however, every animal carcinogen will not necessarily become a proven human carcinogen because the concordance from animal to human experience is variable.[58] Some animal tumors (e.g., Leydig cell adenomas) are not relevant in humans because of their unique hormonal effects in rodents and the rarity of these tumors in humans.[83] Although chemicals producing tumors in multiple species and multiple sites are more likely to cause human cancer,[33] some animal carcinogens produce multiple tumors in rodents, despite little evidence that the chemical causes human carcinogenicity when administered at doses sufficient to cause toxicity.[84]

Mathematical models aid extrapolation from high to low doses, depending on the validity of these models. Assessing human risks involves an analysis of the weight of the evidence of carcinogenicity in animal studies, human exposure data, epidemiology studies, and short-term tests. Table 49.9 lists the factors used for risk assessment; this analysis is discussed in the chapter on risk assessment.

TABLE 49.9. Factors used to assess risk in humans. (Adapted from Goodman).[65]

Risk Assessment Factors
Epidemiological data in humans
Positive animal studies (weight of evidence)
Number species/strains positive
Number of tumor sites
Dosage
Consistency of positive results between studies
Malignant potential of tumors
Time from first exposure to tumor (latent period)
Rarity of tumor type
Short-term tests
In vivo
In vitro (genotoxicity)
Supporting biological data
Extent of human exposure to chemicals

OBSERVATIONAL STUDY DESIGN

Because the development of cancer both in humans and in animals is a multistage process that is modulated by numerous environmental factors, the detection of a carcinogen by an epidemiological study requires prolonged exposure of a reasonably large sample to a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 49.10. Comparison of epidemiological data. (Adapted from Derelanko).[86]

Study	Alternate Terms	Use
Cross-sectional	Prevalence, survey	Random sample of the prevalence of disease in population at one specific time. Best for studying common chronic diseases. Does not measure incidence, causal association, or temporal relationships.
Case-control	Retrospective, dose or case-referent	Compares exposure in subjects with and without a disease. Although selection of cases with and without disease is controlled, exposures are not controlled. Allows estimation of the relative risk of cases with and without exposure, but not absolute risk. Retrospective evaluation (recall bias, estimation of exposure) limits precision.
Cohort	Prospective, longitudinal, incidence	Observation of exposed subjects over time for onset of disease. Allows estimation of relative and absolute risk. Difficult to detect rare diseases. Prospective design reduces biases. Dose-response evaluation possible if data available.
Experimental studies		Controlled human exposures usually involve low doses. Useful for hazard identification, risk characterization, dose-response near threshold levels.
Case reports		Suggests association, but not proof or refutation of hazard.

potent carcinogen. No single study design or criterion establishes the link between exposure to a chemical and the development of cancer, and most governmental organizations use a subjective evaluation of the strength of the evidence to classify chemical carcinogens. A long latent period between exposure and the clinical occurrence of cancer, the high background incidence of cancer in the study population, and difficulty determining exact exposure data currently limit the sensitivity of the best-designed epidemiology studies to a risk ratio of approximately 1.5 and above.[57,85] Despite the limitations of epidemiology studies, proof that an animal carcinogen causes an increased incidence of cancer in humans requires epidemiological data (e.g., primarily mortality, cohort, and case-control studies). Randomized, controlled clinical trials are rarely feasible when studying potential chemical carcinogens; consequently, epidemiology studies on environmental factors are usually nonrandomized observational studies (i.e., ecological, case-control, cross-sectional, cohort designs).

Well-designed cohort or case-control studies easily detect relative risks of >10, whereas careful clinical observation can identify relative risks of >100, especially an association with a rare tumor. Table 49.10 outlines the differences between the types of epidemiology studies.

Exposure Assessment

The evaluation of the potential risk of cancer from environmental or occupational sources begins with a complete history and physical examination.

Table 49.11 lists important items to discuss in the medical history. Further information on potential carcinogens is available from sources listed in the appendix. The presence of a known or suspected carcinogen in the environment requires an evaluation of the dose of the chemical absorbed because the proximity of a carcinogen does not establish a causal link between the chemical and an increased risk of cancer. Table 49.12 records variables that affect the amount of chemical absorbed by a worker.

Chemical analysis of the blood and urine is available for the detection of some of the known and suspected carcinogens. However, the results must be carefully interpreted for biological half-lives, accurate population norms, potential contamination of the samples or containers, and confounding variables (e.g., cross-reacting metabolites and alternate sources of contamination such as food).

The risk of cancer depends on the intensity and duration of exposure as well as the natural history (e.g., induction time) of the disease and host factors. The chemical form of the substance, especially metals, affects bioavailability and the concentration of the carcinogen at the target site.[87] The solubility of a chemical (e.g., mercury, selenium, and arsenic) varies between the various forms (e.g., organic, inorganic, elemental); consequently, the medical effects of different forms of a chemical vary at divergent sites in the body. The ability of a chemical to damage the lungs will depend on particle size and density, water solubility, and inhaled concentration of the chemical. Compounds entering the gastrointestinal tract pass through the liver; therefore, other sites in the body may be exposed to an altered chemical (e.g., methylation of arsenic, binding of cadmium to metallothionein).

TABLE 49.11. Medical history for environmental exposures. (Adapted from Shields and Harris).[14]

Category	History
Medical	Present illness, hospitalizations, radiation treatments, medical disorders associated with secondary malignancies, past chronic medications, disability, pre-employment physical exams
Family	Cancer, hereditary disorders associated with malignancy, household smokers, household occupations
Social	Tobacco and smokeless tobacco use, alcohol and substance use, hobbies, diet and nutrition (fads, special diets), foreign travel
Occupational	Job history, job hazards (chemicals, fumes, dusts, gases, odors), cancer clusters
Chemical hazards	Chemical name/CAS number, size of the work area, ventilation (engineering controls, natural flow (windows, doors, breezes, seasonal variations, location of work site in relation to chemical use), protective equipment, work practice (mechanism and duration of chemical exposure, accidental spills, daily amount used, storage of chemicals, changes in work practice during employment), industrial hygiene evaluations and measurements
Environmental	All residences and types of construction (building material, insecticide use), local point sources of pollution (industry, waste sites, agriculture), water source, cancer clusters

TABLE 49.12. Variables affecting the amount of the absorbed dose.

Variable	Covariable
Route of exposure	Skin, lungs, gastrointestinal tract
Duration of exposure	
Coworker exposure/effects	
Acute symptoms of overexposure	Sensory irritation, odors
Personal work habits	Protective equipment, personal hygiene, personal habits
Physical properties of chemicals	Volatility, evaporation rate, vapor density, odor threshold, particle size/type

For epidemiology studies, individual assessment of exposure usually is neither practical nor possible. Traditionally, job titles are used as a surrogate for exposure to chemicals. Job-exposure matrices (JEM) are alternatives to job titles as a means of improving the assessment of exposure. The JEM are cross-classification of job titles and/or industries based on the estimation of relative risk of exposure to chemicals. These estimates include probability of the use of the chemical, identification of exposure by decade, and correlating occupational codes with specific chemicals.[88]

Ecological Studies

Ecological studies compare the incidence of disease (e.g., over time) in geographically different populations or subpopulations with the presence or amount of exposure to an environmental factor. These studies ascertain exposure and disease for groups or whole populations rather than individuals. The validity of the exposure-disease relationships depends on several factors including: 1) large differences in exposure, 2) reliable assessment of environmental exposures, 3) minimal differences in confounding factors of the disease, and 4) reliable measures of the disease incidence. Limitations of ecological studies are substantial involving difficulty retrospectively evaluating exposures over time and among different population subgroups as well as complete ascertainment of the disease over time and place. The weaker the association, the more likely the association results from confounding and/or chance, particularly when comparing disparate geographical populations; however, ecological studies should detect the effects of common exposures (e.g., smoking and lung cancer). A statistically significant association does not necessarily indicate causation, depending on the presence of confounding, biases, or chance; however, causation is unlikely when the results are not statistically significant.

Mortality Studies

Mortality studies describe the pattern of death or cancer incidence in categories of workers exposed to specific chemicals. By demonstrating variations in risk between groups with different chemical exposures, these studies suggest, but do not determine, whether an association between a chemical and the occurrence of cancer is causal. Mortality statistics must be interpreted with caution as a result of concern over the validity of the following: 1) cause of death recorded on the death

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Selection bias
Confounding (e.g., smoking, diet, alcohol)
Aggregation of job classifications dilutes exposure data

certificate, 2) limited number of deaths in specific categories, and 3) relevance of the listed occupation to actual chemical exposure.[89] Table 49.13 lists limitations associated with the interpretation of data from mortality statistics.

Establishing databases improves the ascertainment of work histories; these databases prospectively gather information on present, past jobs, and exposure data. Although most occupational cancer studies rely on death certificates, the development of some tumors remains undetected because the worker dies of other causes. The incidence of cancer is a preferable measure of outcome compared with mortality.[90]

Proportional Mortality Ratio

Crude rates of incidence (i.e., the number of new cases per population per unit time) or prevalence (i.e., the number of existing cases per population at risk per unit time) are calculated irrespective of properties (e.g., age, sex) that differ within the populations. Incidence provides information about the risk of the disease in the defined population, whereas prevalence signifies the extent of the disease in the defined population. All measures of mortality require some adjustment to compare statistics from two populations. When the cancer incidence in a specific population is unknown, national figures determine if the percentage of cancer deaths from exposed workers exceeds the percentage in the larger population. The proportional mortality ratio (PMR) compares the proportion of deaths in a group of interest with the distribution of cancer deaths expected in the general population, as determined by Equation 49.1.

$$\text{PMR} = \frac{\text{Proportional mortality of exposed group}}{\text{Proportional mortality of unexposed group}}$$

$$= \frac{a/(a+b)}{c/(c+d)} \qquad \text{(Equation 49.1)}$$

where

a = deaths *observed* in exposed group from cause of interest,

b = deaths *observed* in exposed group from all other causes,

c = deaths in unexposed group from cause of interest from *statistical* data,

d = deaths in unexposed group from all causes determined by *statistical* data.

The PMR is adjusted for age and calendar year. If the cause of interest is common, local data help eliminate biases based on local factors (e.g., social class, environment). The use of the PMR has several limitations. Potentially, excess deaths from a major cause may mask the occurrence of excess cancer deaths. Furthermore, the PMR depends on the consistency of age-specific data between each category; therefore, the PMR is less reliable than the standardized mortality ratio (SMR).

Standardized Mortality Ratio

Standardization is the method used to produce an index that adjusts data from two populations for important variables such as age and sex. Equation 49.2 defines the standardized mortality ratio (SMR), which measures the number of deaths in the population of interest, with *expected* deaths obtained from mortality tables of the general population corrected for age and sex.

$$\text{SMR} = \frac{\text{Observed deaths (O)}}{\text{Expected deaths (E)}} \times 100$$

$$= \text{O/E} \times 100 \qquad \text{(Equation 49.2)}$$

where direct observation of a specific population provides O and mortality statistics from the general population determine E.

Because of the large number of statistics generated by mortality studies, some statistically significant increases will occur by chance only. A simple estimation of statistical significance of observed deaths in a small population is the determination of the number of expected deaths (E) within the 95% confidence limit (CI) of the observed deaths (O), as calculated by Equation 49.3.

$$\text{CI} = \text{O} \pm 2\sqrt{\text{O}} \qquad \text{(Equation 49.3)}$$

For example, if O = 16

$$\text{CI} = 16 \pm 2 \times 4 = 8 \text{ to } 24$$

Small sample size often complicates the evaluation of mortality data for statistical significance.

Table 49.14 lists the minimum number of deaths required to achieve statistical significance for an SMR of 100 at 2 probability levels (i.e., <0.05, <0.01). A SMR

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 49.14. Minimum number of deaths necessary to reach statistical significance from SMR 100 at $P < 0.05$ and $P < 0.01$. (Adapted from Alderson).[89]

SMR	$P < 0.05$	$P < 0.01$
105	1,614	2,796
110	423	732
115	197	340
120	116	200
125	77	133
130	56	96
135	43	73
140	34	58
145	28	48
150	23	40

of <100 indicates the selection of more fit workers compared with the general population; the presence of this SMR complicates the interpretation of the impact of the exposure on mortality.

Cross-Sectional (Prevalence)

These observational studies are identical to retrospective studies, except that study characteristics (e.g., disease) and the outcome (e.g., exposure categories) are evaluated at the same time. In contrast to the usual (termed inception) cohort studies that follow workers over a stipulated period, cross-sectional cohorts register only workers employed at a particular date without regard to the previous exposure concentration. Hence, cross-sectional studies enroll subjects with various exposure concentrations; these subjects are compared with one another in terms of an outcome. Like retrospective (case-control) studies, cross-sectional studies can investigate rare diseases that affect small numbers of individuals because the study *starts* with patients who have the disease; then, the study design analyzes differences in exposure (i.e., the study characteristic). Cross-sectional studies can easily estimate the prevalence of a disease in the population. Interpretation of the results from cross-sectional studies is difficult because selection factors may strongly influence the observed dose-response relationships. These types of studies traditionally help generate hypotheses and search for the etiology of a disease in an epidemic; however, cross-sectional studies do not definitively determine causation because disease incidence is not the outcome measure. Therefore, this type of study cannot determine whether the exposure preceded the disease.

The cross-sectional study is not a good design for cancer research because it requires a high prevalence of disease to separate exposure levels and sensitive laboratory methods to detect cancer early. Cross-sectional cohorts encounter chronology and selection biases. The former bias results from decreasing exposure concentrations over time. The latter bias produces problems interpreting the data because the cohort contains subsets of workers with different employment periods that may not reflect the exposure of the original cohort.[91] Cross-sectional studies are most effective when the following occurs: 1) exposure is continuous and steady up to the time of evaluation, 2) effects develop soon after exposure, and 3) the effect persists but does not cause loss of employment.[92]

Cross-sectional studies only suggest a cause–effect relationship because selection bias often masks true etiological factors and observation bias produces positive bias. Chronology and selection biases also overestimate risk in cross-sectional studies. Furthermore, poor exposure data and misclassification create negative bias by diluting broad categories. Longitudinal studies (cohort, case-referent, intervention) provide a better basis for establishing the etiology of cancer compared with cross-sectional studies.

Case-Control (Case-Referent) Studies

Case-control and cohort studies are analytical epidemiological studies that ascertain exposure and disease outcome in individuals. The former study design separates populations into groups based on the presence (case) or absence (control, referent) of *disease* and then retrospectively assesses the exposure rate to chemicals in each group. Among persons with a disease (cases), these studies ascertain the proportion of persons *previously* exposed to a chemical compared with a sample of persons in a group (controls) similar to the cases except for the exposure. Hence, exposure ascertainment is a potential source of bias because of the retrospective evaluation of the exposure. Nested case-control studies identify cases in a large cohort and a specified number of controls matching the cases for all characteristics except exposure; increasing the number of controls beyond the cases (e.g., 2:1, 3:1) improves precision.

The odds ratio (OR) measures the association between exposure and outcome, reflecting the occurrence of the disease in the two populations (i.e., exposed vs. nonexposed). The larger the OR, the stronger the association between exposure and disease, with an

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 49.2. Calculation of odds ratio in case-control studies. Exposures in the cases are evaluated retrospectively, whereas the disease (e.g., cancer) may be defined retrospectively or concurrently. (Adapted from Hernberg).[92] *Abbreviations:* a = cases with exposure; b = cases without exposure; c = controls with exposure; d = controls without exposure.

OR of 1.5 indicating a modest association. Figure 49.2 outlines the method of calculating the odds ratio in case-control (case-referent) studies. These study designs investigate the etiology of diseases; therefore, validity of these studies depends on the ability to quantify the amount of exposure to a chemical and the influence of confounding factors on exposure. As defined in Figure 49.2, Equation 49.4 defines the odds ratio.

$$\text{Odds Ratio (OR)} = a/b \div c/d = ad/bc \quad \text{(Equation 49.4)}$$

An odds ratio of >1 indicates exposure is more common in persons with the disease (cases) than in the nonexposed group (controls), whereas an odds ratio of <1 indicates a less frequent exposure in the cases with the disease. The odds ratio is an *estimate* of the absolute disease risk in the exposed population because the cases are not representative samples of the exposed and unexposed populations. When the outcome of interest is common (i.e., >20% of subjects in any group), the odds ratio does not approximate the relative risk (risk ratio); however, the relative risks and odds ratios are similar when the absolute risk is low (e.g., mortality rate for most cancers) reflecting a rare outcome of interest. Because case-control studies estimate relative risk and not absolute risk, the interpretation of the importance of an elevated relative risk depends on the absolute risk as determined by other sources. Consequently, a relative risk of 10 may not be valid if the absolute mortality risk is very low (e.g., 10^{-7}).

Advantages

Case-control studies provide clues about the etiology of the disease studied and help quantify the risk of developing the disease after exposure to the chemical under study. This type of study provides circumstantial evidence of an association between exposure and disease (e.g., cancer); however, these studies do not infer temporal or causal relationships. The case-control study is the preferred type of study when the disease is rare because of the usual ease of accumulating a large number of cases quickly with relatively low expenses, particularly when follow-up is difficult. In this situation, the study characteristic is the disease; therefore, the study begins when enough persons with the disease are located. Additionally, the cost of the study is low, and the design is simple. Nested case-control studies are less expensive than full cohort studies because exposure assessment involves only the cases and selected controls. Relatively few subjects are necessary for the study compared with the number required for cohort studies. This type of study provides data about the etiology of disease; case-control studies can investigate multiple exposures as possible causal factors in the development of the disease.

Disadvantages

This type of observational study is useful only for a single endpoint that does not involve rare exposures; weaknesses include the inability to calculate absolute risks,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

incidences, or prevalence. Consequently, case-control studies cannot establish causality because of their inability to control unmeasured confounders.[93] Additionally, case-control studies are susceptible to unidentified and unpredictable biases including information bias from ascertainment of exposure data after disease occurrence and selection bias from suboptimal processes for controlling selection; however, both case-control and cohort studies are susceptible to chance and confounding. The disadvantages of case-control studies are similar to those of any retrospective study that relies on indirect measures of exposure and on the similarity of the control and case groups. Observer bias is the most common cause of positive bias when persons with the disease remember more about their exposure status than persons without the disease. Inaccurate or incomplete exposure data produces misclassification.

Ascertainment of exposure data almost always involves reported job history or recall of specific exposure rather than direct measurements; questionnaire-based methods of estimating exposure frequently do not produce valid or reliable results. Direct blood or tissue measurements of the chemical obtained after the diagnosis may not reflect prediagnosis values because the illness or treatment may alter these measurements. Increasing complexity of the occupational history, short duration of employment, and longer periods of recall reduce the validity and precision of exposure data.[94] The incorporation of industrial hygiene measurements from administrative exposure databases and expert assessment of direct measurement of study subjects (i.e., assuming a reasonable latency and biological half-life of the substance) improves the validity of the exposure data. Selection bias may arise when the exposed group contains individuals with multiple exposures and is not representative of the general population. Validation of information is difficult because of the retrospective nature of the study. Other sources of bias include diagnostic suspicion bias in case determination, exclusion bias in choosing controls, bias in the selection of cases and exposure ascertainment, and recall bias in the determination of exposure.

Cohort (Follow-Up) Studies

In this type of study, individuals are assigned to cohorts based on exposure (i.e., exposed, unexposed) and the outcome is mortality or incidence of the disease (e.g., cancer) in each group. Selection of subjects should proceed without knowledge of individual disease status; objective exposure criteria should be obtained. Options for objective exposure assessment include job category, environmental monitoring (exposure), and biological monitoring (dose). Exposure and dose should be considered separately because dose reflects intensity, duration of exposure, and personal factors (protective equipment, personal hygiene, activity, work schedule, and conditions). The cohort study may be either retrospective (historical) or prospective (concurrent), depending on whether the disease incidence is followed from some distant time in the past to the present (i.e., retrospectively) or traced from the present to a future time (i.e., prospectively). Prospective studies require highly reproducible and specific outcome measures to avoid a high rate of "false positive" tests. These tests should detect biologically significant differences.

Figure 49.3 outlines the configuration of a cohort study and the calculation of the rate ratio and rate difference. The cohort study is similar to an experimental study in which the investigator separates animals into exposed and unexposed groups and then measures the disease incidence. However, the environment, exposure intensity, and number of chemical exposures are less controlled in cohort studies than in experimental studies. Relative risk (RR) is a measure of the strength of an association and frequently refers to the rate ratio and the risk ratio. The rate ratio is a comparison of the rates of disease in the exposed and unexposed cohorts, as defined in Figure 49.3 by

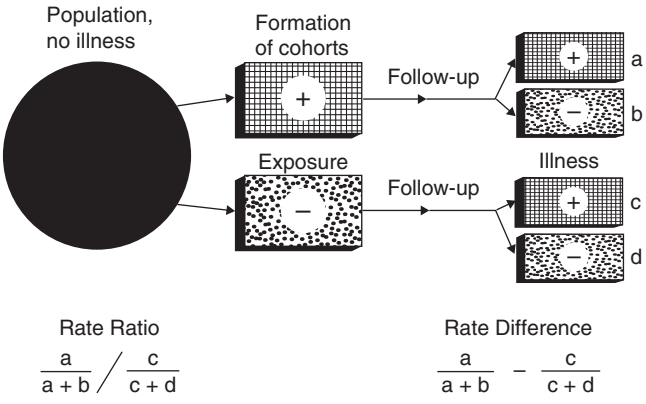

FIGURE 49.3. Calculation of rate ratio and rate difference in cohort studies. The cohort is divided based on exposure (exposed/unexposed groups) and then followed for a period of time. Only one exposure is usually studied, whereas several disease outcomes can be evaluated simultaneously. In contrast to experimental studies, confounding exposures may occur and exposures are not adjustable. (Adapted from Hernberg).[92] *Abbreviations:* a = exposed cohort with disease; b = exposed cohort without disease; c = unexposed cohort with disease; d = unexposed cohort without disease.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Equation 49.5.

$$RR = a/(a+b) \div c/(c+d) \qquad \text{(Equation 49.5)}$$

An RR of >1 indicates a higher incidence of disease (i.e., times the risk) in the exposed group than the nonexposed group, whereas an RR of <1 demonstrates a lower disease incidence in the exposed group than the nonexposed group. If an unexposed cohort is not available for economic reasons and the standardized rates for age, sex, and calendar year from national statistics are used for the denominator, then the rate ratio for cancer mortality becomes the standardized mortality ratio (SMR). The rate ratio and risk ratio are closely related. The former is the ratio of the incidence rates in an exposed and unexposed comparison group, whereas the latter is a simple ratio that reflects the higher or lower probability of the risk occurring in the exposed group compared with the unexposed group.

Retrospective (inception) cohort studies help identify the potential etiology of various diseases, but these studies do not definitively establish causation because of the imprecise nature of the data on exposure. This type of study must be evaluated cautiously because of the following potential complicating factors: confounding of exposure between cohorts, dilution of the results from imprecise job classification, inadequate length of follow-up to detect the disease, and biases in the cohort over time. These biases include observation bias, loss by death in some categories, age at entry, entry of new workers, percent of original sample followed, and condition of cohort at the start of study. Inception cohort studies tend to underestimate the relative risk because of the presence of selection bias as a result of the healthy worker at hire and healthy worker survivor effects.

Prospective studies produce the best epidemiological data on the etiology of diseases such as cancer, but this type of study is less likely to uncover **new** causes of the disease compared with mortality or case-referent studies. These longitudinal studies eliminate the problem of interindividual and intraindividual variation because the members of the cohort act as their own controls. Because of the ability of this type of study to quantify exposure and study multiple medical factors, a prospective study can provide definitive answers about etiology and dose-response relationships. These studies are costly, require a stable industry, and need a high disease incidence in the population.

Advantages

The exposure-based design is most suitable for studies of rare exposures; the purpose of the study is to determine which disease results from exposure to a specific chemical with this study design allowing multiple endpoints. The advantages of a retrospective cohort study are the relative promptness of the results and the low cost of the project compared with concurrent prospective and intervention studies. Prospective studies offer the advantage that exposures are directly measured, confounding variables are more easily controlled, and the indicators of disease are better defined. Unlike cross-sectional studies that compare participants with various levels of exposure, prospective studies allow each participant to act as a control. Hence, prospective studies eliminate the normal variation between participants, allowing easier detection of small decrements in function over time. Several types of diseases can be evaluated in a cohort study at the same time, resulting in the examination of multiple effects from a given exposure. This study design allows the calculation of absolute risks, incidences, and prevalence.

Disadvantages

Retrospective cohort studies depend on the quality of prior exposure data and the ability to link that exposure with the development of a disease or diseases. Often, data on exposure, medical risk factors, and measures of disease are limited or unreliable. The presence of multiple chemical exposures, ascertainment of reliable prior work history, and other disease-causing exposures (e.g., smoking) complicate the interpretation of study results. Retrospective studies on cancer usually focus on mortality because little data are available on the medical conditions of the cohorts. The potentially long duration of follow-up increases the difficulty and cost of the project. A thorough study of the etiology of the disease is usually not possible, especially when the etiology is multifactorial.

Prospective studies provide more accurate data on exposure and disease, but this type of study requires large sample size, high cost, and prolonged follow-up for the long latent periods of cancer. The cohort design is not a good design for studying rare diseases.

Table 49.15 outlines the size of a cohort necessary to detect a specific relative risk given the incidence of the disease in the control population. This table demonstrates the difficulty of using the cohort design for rare diseases. The follow-up period for a cohort typically should be at least one-half the length of the latent period.[95] Because cohorts are divided on the basis of exposure, only one exposure can be studied at a time; however, by studying a large number of diseases potentially related to the exposure, some associations may occur solely on the basis of chance.

TABLE 49.15. Approximate number of subjects required for detection of various relative risks of disease in a cohort study. (Adapted from Griffin and Weber).[95]

Prevalence of Disease in Controls	1.2:1[a]	1.5:1[a]	2:1[a]	3:1[a]	20:1[a]
1/100	57,000	10,000	3,000	1,000	50
1/500	288,000	52,000	16,000	5,000	300
1/1,000	577,000	105,000	31,000	10,000	600

[a] Relative risk of disease in exposed subjects and control subjects.

Interventional Studies

In contrast to the previous observational studies, an intervention study measures the effect of a *change* in the exposure of the exposed cohort; these studies are considered extensions of the cohort study. This type of study design is different from the clinical research trial, which is a true experimental study that randomizes subjects *before* exposure. Documented changes in the disease process following changes in exposure provide strong evidence of a causal link between the disease and the exposure; however, intervention study designs are rare.

Cancer Clusters

A cancer cluster involves a greater than expected number of cancer cases over a defined period of time, when compared with the same type of cancer in a similarly sized population (e.g., age, gender, race/ethnicity) over the same time. Historically, examination of cancer clusters resulted in the detection of several carcinogens including scrotal cancers in chimney sweeps (1775), osteosarcomas in radium dial painters (1929), lung cancers in asbestos workers (1965), hepatic angiosarcomas in vinyl chloride workers (1974), and vaginal clear cell carcinomas in daughters exposed to diethylstilbestrol *in utero* (1971). However, many perceived cancer clusters are not confirmed; chance remains a plausible explanation for most nonconfirmed cancer clusters, even though the cancer cluster meets statistical criteria.[96,97] Both the number of cancer cases in the cluster and the calculation of expected cases depend on the definition of the boundary of the geographical area; changing the boundaries may enhance or obscure the significance of the cancer cluster. Increasing public awareness of potential carcinogens in the environment contributes to an expansion in the number of anecdotal reports on cancer clusters. While improved health surveillance results in important discoveries of environmental causes of disease, intense surveillance produces many false alarms, and most investigations of clusters do not establish the presence of environmental carcinogens.[98,99] Multiple factors complicate the investigations of cancer clusters including: 1) the long latent period before the clinical appearance of cancer, 2) the limited number of cases available for study in a given situation, 3) the poorly understood etiology of most cancers with multiple multifactorial causes and few known risk factors, 4) the high incidence of cancer in the population, 5) migration producing alteration of the cumulative exposure profile of the population under study, and 6) the difficulty applying statistical analysis to the small size of most cancer clusters, particularly with rare cancers.[100]

In a random distribution of cancer cases over a geographical area, some cases will appear in close proximity based only on random statistical variation. The *post hoc* definition of the study population and a time frame including the initial cancer cluster cases may result in spuriously high rates of cancer types in that population. This approach is similar to the "Texas sharpshooter," who shoots at his object and then draws his target. Besides chance and exposure to a carcinogen, an excess cancer incidence may result from the presence of confounding variables (e.g., smoking, radiation, hereditary traits, infections). The determination of the cause of a cancer cluster is frequently difficult because of the intense emotional atmosphere surrounding these investigations and the presence of many design problems (small sample size, ascertainment bias, confounding variables, limited exposure data). Cancer is many different diseases with different causal mechanisms, contrary to the popular misconception that a single environmental contaminant causes any or many types of cancer. Investigation of these observations requires a multistage response to determine the extent of research necessary to establish causation.[101] Statistical methods (e.g., cluster analysis studies) are available to evaluate the spatial clustering of diseases based on Poisson distribution of cases.[102]

Table 49.16 outlines an approach to cancer cluster investigations. The Centers for Disease Control and Prevention (CDC) published guidelines focused specifically on cancer clusters in residential or community settings (https://www.cdc.gov/mmwr/pdf/rr/rr6208.pdf). The four-step approach for managing a reported cluster included: 1) initial contact and response, 2) assessment, 3) determining the feasibility of conducting an epidemiological study, and 4) conducting an epidemiological investigation. The CDC noted that only a small fraction of cancer cluster inquiries met the statistical and etiological criteria to support a cluster investigation as

TABLE 49.16. Approach to the investigation of cancer clusters. (Adapted from Sullivan and Keiger).[103]

1. Identify and confirm each cancer case, including cancer type, with medical records and histopathology.
2. Document temporal relationship between diagnosis and exposure.
3. Compare observed overall number of cancer cases with expected rates based on cancer registries standardized for age. Calculate SMR.
4. Compare cancer types (organ, cell type) with expected rates. All cases must involve the same cancer type or types with the same cause.
5. Evaluate latency period (period of time between first exposure and clinical diagnosis) of each cancer. Typical latency period for hemological tumors is 5–10 years and for solid tumors, 15–20 years. The association of the exposure with a tumor is equivocal if the latency period is too short.
6. Evaluate confounding and contribution factors (smoking, substance abuse, familial history of cancer, other potential carcinogens, occupations associated with cancer).
7. Examine epidemiological data for elevated cancer rates for specific jobs or sites.
8. An excess of histologically similar cancer cases suggests the possibility of a causal relationship. Overrepresentation by a particular job, environment, or chemical exposure supports a causal relationship. The lack of a common exposure or excess of different histological types of cancer indicates a true cancer cluster is unlikely.
9. Environmental assessment and industrial hygiene review of area, with elevated cancer rates for the presence of potential carcinogens.
10. Conclusions include: a) absence of cancer cluster, b) possible presence of cancer cluster, but occupational or environmental source unlikely, c) cancer cluster is present and possibly related to occupational or environmental exposure, and d) cancer cluster is related to a specific chemical exposure.

outlined in these guidelines. Despite ascertainment bias (i.e., inclusion of index cases) and the lack of statistical power, the use of statistical significance is a useful tool to determine the preliminary probability of any health hazard.[104] Statistical methods indicate how unusual the cancer incidence is in a particular population; however, these methods do not determine the likely cause of the cancer cluster. A study of malaria would find a statistically significant association between marshy swampland and malaria. In fact, Hippocrates wrote that a poisonous cloud lifting up from marshy land caused malaria. Consequently, the establishment of a chemical as the cause of the cancer cluster requires careful evaluation of the exposure to determine the following: 1) the identified chemical causes human cancer, 2) an adequate exposure pathway existed, and 3) the dose of the chemical was sufficient to cause cancer.

After the preliminary investigation, the decision to continue the cancer investigation depends on an evaluation of the following three criteria: 1) high disease rate compared with age-adjusted cancer incidence in a similar (e.g., working) population and a sufficient latent period (i.e., 15–20 years for solid tumors, 5–10 years for hematological malignancies), 2) excessive, prolonged exposure (e.g., similar job classification, close proximity) to suspected carcinogens that correlates with the development of the cancer, and 3) biological plausibility.[105] The presence of two or three of these criteria indicates the need for further research. The predominance of a particular cancer type favors a chemical carcinogen as the etiology of the cancer cluster, particularly those cancers associated with well-recognized chemical carcinogens.[106] The discovery of several cases of hepatic angiosarcoma or malignant mesothelioma suggests the presence of excessive exposure to vinyl chloride and asbestos, respectively. The index cases should not be used in a study to test the hypothesis that a cancer cluster resulted from a chemical carcinogen because the addition of these cases will bias the results toward a positive result.[107]

OBSERVATIONAL STUDY INTERPRETATION

Time Dependency and Age

Latency describes the change in relative or excess disease rates with the time since exposure began. Determination of latency depends on several factors, including variation of exposure over time within the study group, the size of the group developing the disease of interest, the quality of the biomarkers of exposure, and the accuracy of exposure information. For most cancers, the cancer rates increase dramatically with age in any study group; therefore, age-related normalization of the cancer rates in the unexposed is necessary to assure the appropriate comparison of disease rates between the exposed groups and the aging control group with no exposure. Frequently, various timing factors (e.g., initial exposure time, duration, age at initial exposure,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

magnitude) are correlated to each other, requiring stratification or modeling to determine the effect of each factor depending on the quality of the exposure data. When investigating latency, changes in relative risks with time since exposure occurs later in mortality studies than incidence studies by approximately the average time from cancer detection to death. Exposure misclassification tends to bias the results of observational studies toward the null hypothesis (i.e., no association between exposure and disease) when a true association exists; however, the effect of misclassification on time-related factors is difficult to predict.

The appearance of excess cancer rates following exposure to chemical or physical carcinogens probably varies with the specific chemical agent and mechanism of action; some chemicals produce cancer rates resembling a unimodal pattern (e.g., leukemia in atomic bomb survivors), initially increasing after a latent period, then decreasing over time. In these situations, the mean or median latency period reflects the temporal relationship between the exposure and carcinogen; however, other chemical exposure-cancer relationships demonstrate a variable risk rate and latency reflecting the multicausal, multistep process of cancer development. Part of the difference in cancer risk with time results from study design, including time-related changes in exposure, short follow-up periods relative to the true latency period, and inclusion of subjects with variable *a priori* exposure (i.e., selected survivors).[108] The latter biases the observed latency period toward longer time intervals, whereas short follow-up periods bias the observed latency period to shorter intervals. The latency period also varies with the choice of outcome (e.g., symptoms onset, diagnosis, death).

Validity

The detection of an association between a disease and an exposure does not necessarily imply a true cause–effect relationship. Bias is a consistent error that causes either the overestimation (positive bias) or the underestimation (negative bias) of the true value of the outcome measure. The potential for systematic error (i.e., bias) is usually greater for observational than experimental studies. If proper statistical methods eliminate the likelihood of a chance association, the presence of a false positive association may result from: 1) selection bias, 2) information bias, and/or 3) confounding by a variable of the study characteristic that affects the outcome. The validity of a study is determined by the degree to which it accurately measures the true outcome; therefore, a valid study lacks bias. Statistical methods do not exclude the presence of bias. Precision (reliability) is a measure of the proximity of repeat samples to each other rather than a measure of the proximity of the samples to the true value; hence, a study may be reliable but not valid (i.e., not close to the true value of the observation) because of systematic bias.

Bias

Selection Bias

Selection bias occurs when the control (reference) group in case-control studies is not representative of the same population as the index subjects (e.g., when employed workers and members of the general population are matched for age and sex).[109] In practice, the effects of selection bias and confounding are similar, with the former usually referring to the lack of comparability of workers to the general population. The presence of selection bias indicates systematic error that results in the referral of subjects into the two study groups, depending on exposure or the disease studied, particularly when the participation rates between the two groups significantly differ. The first question is whether all employees were included in the study. Exclusion of workers may bias the results if the excluded workers are atypical of the workers in the study with respect to exposure, diseases, or associated risk factors for the development of the disease. Bias results may occur from several elements of study design, including selective referral patterns, use of volunteers, excessive dropout of workers during the study, uneven distribution of job skills (e.g., low psychomotor skills) that affect outcome measures (neuropsychological testing), and different methods of detecting disease in the two study groups.

Selection bias usually arises in case-control studies when different criteria of exposure separate cases and controls or in cohort studies when disease outcome influences the selection of exposed and unexposed subjects. Examples of selection bias include: 1) hospital admission bias or Berkson's bias, 2) prevalence or incidence bias, 3) detection bias, 4) volunteer bias, 5) healthy worker at hire and healthy worker survivor effects, 6) excessive losses to follow-up, and 7) membership bias.[110] Berkson's bias occurs when studies occur in the hospital setting and a spurious association between disease and exposure results from the different probability of admission between subjects with and without exposure. Mild or brief episodes of illness may be missed if the study focuses on the later period in the disease process, resulting in prevalence/incidence bias.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Detection bias occurs when a nonspecific sign or symptom of disease is attributed to an innocuous exposure, resulting in a false association between exposure and disease. Volunteer and/or nonrespondent bias develops when these subjects are systematically different from other subjects in the study regarding health or exposure. Similarly, bias may result when group members have different health or exposure characteristics (membership bias, healthy worker at hire, healthy worker survivor effects) compared with the general population. Loss of follow-up may bias a study when those subjects lost to follow up differ from the study population.

Table 49.17 demonstrates the direction of selection and information biases. The physical requirements of a job may determine the disease pattern rather than any exposure in the occupational environment. Cancer is a disease with a long subclinical period; therefore, selection bias is seldom present. True selection bias occurs only when the disease under study affects the distribution of workers into groups. The issues of selection bias develop during the design phase; consequently, selection bias must be addressed during the design phase of the study.

Information Bias

A valid study requires similar collections of information from cases, controls, and exposed/unexposed groups. Information bias may occur in several situations including: 1) misclassification of exposure or disease, 2) inaccurate recall, 3) misinterpretation of assessment data, 4) inability to access important unpublished data from regulatory, chemical, and pharmaceutical organizations, or 5) inconsistent data obtained at different time periods. Information bias involves intra-interviewer/inter-interviewer bias, recall bias, questionnaire bias, and diagnostic or exposure suspicion bias.[110] The potential for recall bias is greatest when substantial concern about the potential adverse effects of an exposure exists, particularly as a result of media coverage, litigation, trade union negotiations, or passionate group discussions. *A priori* knowledge of subject classification may affect the intensity of the search for exposure or disease. These actions produce exposure suspicion bias. Most sources of information bias overestimate the relationship between exposure and disease.

In case-control studies, information bias results from the differential collection of exposure data from cases and controls. Observation bias most seriously affects case-control studies that often rely on information from questionnaires rather than direct measurements. Information bias also may occur in cohort studies when exposure status influences the collection of information on disease status. Retrospective cohort studies may also suffer from observation bias as a result of the tendency to more closely examine exposed populations. Prospective cohort studies can avoid observation bias by blinding the investigators.

TABLE 49.17. Direction of selection and information bias in epidemiological studies. (Adapted from Choi and Noseworthy).[110]

Type	Cross-Sectional	Case-Control	Retrospective Cohort	Prospective Cohort
		Selection Bias		
Berkson's	↑↓	↑↓	–	–
Prevalence, incidence	↑↓	↑↓	U	U
Detection	U	↑↓	↑↓	↑↓
Membership	↑↓	↑↓	↑↓	↑↓
Health worker effect	↓	↓	↓	↓
Volunteer	↑↓	↑↓	↑↓	↑↓
Lost to follow-up	–	–	↑↓	↑↓
		Information Bias		
Interviewer	↑↓	↑↓	↑↓	↑↓

Reporting and Publication Bias

The systematic error of reporting bias occurs when researchers base their decision to publish certain results on the magnitude, direction, and/or statistical significance of their results, whereas publication bias refers to the systematic failure to publish certain types of studies. Additionally, authors or study sponsors may selectively report specific analyses or results (selective outcome reporting bias).[111] Publication is often less likely for negative than positive studies;[112,113] publication bias occurs when the direction and magnitude of the studies are more important determining factors for publication than quality, relevance, and/or study design.[114] Although asymmetry in funnel plots suggests the presence of publication bias, detecting publication bias is difficult in systematic reviews. The presence of bias reduces confidence in the estimates. Consequently, success in obtaining results of unpublished studies reduces the chance of publication bias and increases confidence in the estimates.

Potential Confounding Variables

Determination of causation requires an understanding of the role of confounding in observational study results. The presence of confounding distorts the results of these studies; the changes induced by confounding may weaken, strengthen, or reverse the true effect of an exposure, with the overall effect depending on the number and degree of confounders. Confounding variables (e.g., smoking) are outside factors that influence the assessment of the outcome under study, resulting in different risk factors for the outcome in exposed and unexposed groups. These causal risk factors are determinants of the disease associated with the exposure group and affect the development of the disease. A confounder meets the following criteria: 1) an independent risk factor for the outcome (causal or surrogate), 2) associated with the exposure, and 3) unaffected by the exposure.[115] A confounder is not usually an intermediate step in the causal pathway between the exposure and the disease (e.g., cancer).

Confounding results from a lack of comparability between exposed/unexposed groups, and the presence of confounding biases the estimation of the effect of exposure on the disease (e.g., cancer). In a cohort study, a confounding variable is a risk factor for the disease that is distributed asymmetrically between the exposed and unexposed groups. Conversely, in a case-control study, the confounding factor correlates with disease occurrence and is a determinant of exposure. Thus, the issue of confounding involves the comparability of the exposed and unexposed members of the underlying study population (exposed and unexposed subjects in the control group). Fundamental problems with case-control studies include estimates of exposure only for cases and a sample of noncases (controls). Selection bias also complicates the interpretation of case-control studies because of changes in residences or jobs. Confounding is usually a less serious problem in occupational studies compared with selection bias; however, lifestyle risk factors and prior or concomitant occupational exposures remain potential confounders, depending on the net effect of all factors, including confounding.[92]

Without limited opportunity to randomize exposure, confounding frequently occurs in observational studies; consequently, inaccurate estimates of the relationship between exposure and outcome may result from failure to adjust for confounding. Internal comparisons between groups classified by cumulative exposure may develop confounding issues due to time-related factors. Such confounding results from: 1) differences in cumulative exposure groups between generations, 2) differential health status at entry into the cohort, and 3) groups classified by cumulative exposure may become noncomparable with time due to the healthy worker survivor effect. These confounders attenuate the true dose-response relationship between cumulative exposure and disease.

Methods to control confounding during the design and data analysis phases include study design (matching on baseline characteristics, restriction, randomization when available, stratification of subjects, standardization of exposure categories, worst-case assumptions) and statistical procedures (linear or logistical regression modeling, stratified analyses, propensity scoring).[116] Study design alone is unlikely to fully resolve issues of confounding in nonrandomized studies. The propensity score ranging from 0–1 improves the estimate of a relationship between a nonrandomized factor (e.g., chemical exposure) and the outcome of interest (e.g., cancer) using multivariable statistical methods (e.g., logistic regression) based on available measured subject characteristics and the surrounding environment.[117] The probability is used to adjust for differences in the study populations (e.g., propensity score matching, stratification based on the propensity score, covariate adjustment of confounders using the propensity score), where a score of ≤ 0.1 is considered a negligible difference between groups. Statistical methods require the recognition and measurement of confounding variables; unmeasured confounders and inadequate quality or data size reduce the likelihood of effectively adjusting for confounding. Control of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the confounding variables may be difficult when the confounding variable is large compared with the relative risk being studied.[118] Residual confounding may occur in observational studies when statistical analyses do not adequately adjust for confounding including the following: 1) unmeasured confounding, 2) overly broad categories for confounders, and 3) inaccurate or misclassified measures of confounder characteristics. The uniform distribution of confounding factors between the two study groups modifies, but does not confound, the incidence of the disease. Randomized controlled trials use randomization processes to limit all forms of confounding; therefore, this type of study does not use statistical methods to adjust for confounding.

Lifestyle Overview

Variation in cancer rates exists worldwide, with the highest overall age-standardized rates (i.e., ~300 cases/10,000 person-years) occurring in North America, Europe, New Zealand, and Australia.[119] Migrants from less-industrialized countries adopting Western lifestyles and diets develop cancer incidences similar to those of native members of developed countries.[120,121] The population attributable fraction (PAF) reflects the portion of cancers that would not occur with absent exposure to the causal factor under study. Lifestyle factors represent a large portion of avoidable cancers, including tobacco and alcohol use, solar ultraviolet radiation, body fatness, insufficient physical activity, and dietary factors (salt, inadequate fiber content, red and processed meat, insufficient fruit and/or vegetables) with the strength of the association with the latter three factors relatively small and subject to design issues. Typically, the relatively risks in positive studies evaluating diet, body fatness, and physical activity are below the commonly accepted level of >2 (particularly <1.5), leading to questions regarding the causality of the associations detected in observational studies. In the 1990s, evaluations of most case-control studies suggested vegetables and fruits provided some protection against certain cancers, leading to recommendations for ≥5 portions (i.e., >400 g) of fruits and vegetables daily;[122] however, evidence for an inverse relationship between total fruits and vegetable intake and overall cancer rates in subsequent cohort studies was less robust.[123] The relatively low relative risks reflect the wide variation in the prevalence and strength of modifiable factors (excluding tobacco and alcohol use) between countries, selected populations, cancer subtypes, sexes, and specific lifestyle factors. In a review of modifiable PAFs based primarily on case-control studies, tobacco smoking (larynx, lungs), excessive weight (gallbladder), and insufficient fruit intake (oral cavity/pharynx) account for the most avoidable cancers in women, whereas tobacco smoking accounts for a majority of avoidable tumors (lungs, larynx, esophagus, oral cavity/pharynx) in men.[124] Although some studies associate dietary vegetables and fruit, antioxidant vitamins, carotenoids, isothiocyanates, and physical exercise with reducing cancer risks, the overall protective effect of diet and exercise accounts for a small fraction of the total attributable risk associated with tobacco smoking. Thus, smoking cessation remains the most important intervention to reduce the high incidence of cancer among smokers.[125] Table 49.18 lists the factors associated with lifestyle that may confound cancer studies.

TABLE 49.18. Potential lifestyle factors associated with an increased risk of cancer based on sufficient epidemiological data. (Adapted from Pitot).[57]

Factor	Associated Tumor
Alcoholic beverages	Esophagus, larynx, liver, oropharynx
Aflatoxins	Liver
Betel chewing	Mouth
Diet[a] (fat, protein, calories, smoked/pickled foods)	Breast, colon, endometrium, gallbladder, gastric
Late age at first pregnancy	Breast
Nulliparous	Ovarian
Sexual promiscuity (human papillomavirus, HPV)	Cervix, vagina, vulva, penis, anus, oropharynx
Tobacco smoking	Bladder, esophagus, kidney (renal cell), larynx, lung, mouth, pancreas, pharynx
Smokeless tobacco	Larynx, mouth, pharynx

[a] The strength of the associations is relatively small, with potential methodological issues obscuring the true values.

Physical Activity

Energy consumption during an activity depends on the product of duration and intensity; the latter is measured by metabolic equivalents (METs) relative to the basal metabolic rate. Typically, descriptions of activity levels are light (≤3 METs), moderate (3–5.9 METs), and vigorous (≥6 METs). Alternatively, percentage of maximum aerobic capacity (i.e., the beginning of anaerobic metabolism) is a measure of activity levels defined by vigorous (≥80% maximum) and moderate (60–75% maximum); light physical activity involves minor changes in heart and respiratory rates with sedentary lifestyle involving no change in cardiorespiratory parameters. METs are usually converted to MET-hours/day or week to sum up daily or weekly physical activity, respectively.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Physical activity (i.e., any movement using skeletal muscles) may modify some of the risk factors for colon, endometrial, and female breast cancer incidence and mortality by altering insulin-mediated pathways, energy balance, and/or circulating estrogen concentrations, particularly in postmenopausal, obese women.[126,127] A meta-analysis comparing high versus low physical activity in 33 studies involving 19,558 cases of endometrial cancer detected a statistically significant inverse relationship with endometrial cancer for postmenopausal women (RR = 0.81, 95% CI: 0.67–0.97) but not for premenopausal women (RR = 0.74, 95% CI: 0.49–1.1, $P_{\text{difference}} = -0.78$).[128] The inverse relationship with physical activity as statistically significant for overweight or obese women (RR = 0.69, 95% CI: 0.52–0.91), whereas the inverse relationship was not statistically significant for normal-weight women (RR = 0.97, 95% CI: 0.84–1.13). The World Cancer Research Fund/American Institute for Cancer Research (WCRF) concluded that the scientific evidence convincingly supported a lower colorectal cancer risk with higher overall physical activity levels and probably provides some protection for postmenopausal breast and endometrial cancers.[123] Reporting bias from self-reporting questionnaires, heterogeneity in study design, misclassification from measurement errors, and confounding of obesity with diabetes and cardiovascular diseases complicate firm conclusion regarding the quantitative effect of physical activity on cancer incidence and mortality.

Body Fat and Obesity

Excessive body fat is difficult to measure accurately and varies across different populations. Underwater weighing, computerized tomography, magnetic resonance imaging, and dual-energy X-ray absorptiometry are precise measures of body fat; however, these techniques are impractical in epidemiology studies because of cost and technical complexity. The BMI is a common measure of weight adjusted for height; however, very muscular and lean persons (e.g., athletes, manual laborers) have relatively high BMI with low fat stores; Asians typically have higher body fat stores at an equivalent BMI than European Caucasians.[129] The pattern of fat stores varies with gender, age, and genetic factors. The size of abdominal fat stores correlates to the risk of chronic diseases (e.g., cardiovascular diseases, diabetes) with the waist circumference (body roundness index) and the waist/hip ratio potentiality being better measures of metabolically active intra-abdominal fat stores and subcutaneous fat than BMI, but they lack strong validation.[130] The ideal body weight (BMI = 18.5–24.9) usually correlates to adult body fat of 15–20% in men and 25–30% in women.[131] The approximate equivalence of a BMI of 25 (upper ideal weight limit) and 30 (lower limit of obesity) is 37 in. (94 cm) and 40.2 in. (102 cm), respectively, in men and 31.5 in. (80 cm) and 34.6 in. (88 cm), respectively, in women. Adult weight gain typically involves the accumulation of fat rather than lean tissues.

In addition to BMI as an imprecise measure of obesity in population studies (e.g., BMI versus visual fat area reflected by waist circumference), methodological issues complicate interpretation of results on obesity and the risk of developing cancer, including obesity-associated detection bias, collider bias (i.e., unmeasured confounding induced by selection bias), reporting bias from use of self-reporting questionnaires, confounding, reverse causality, weight change over course of study, and the complexity of the relationship between obesity and associated comorbidities (diabetes, cardiovascular diseases);[132] some studies associate overweight and early obese states with improved cancer survival.[133] In 2002, the IARC determined the evidence was sufficient to conclude avoidance of weight gain reduced the risk of esophageal adenocarcinoma, colon cancer, renal-cell carcinoma, postmenopausal breast cancer, and cancer of the corpus uteri.[134] The IARC reassessed the preventive effects of weight control on cancer risks based on BMI; the review involved primarily observational studies because of the sparse number of studies on cancer risks following weight loss or weight-control interventions.[135] The IARC working group confirmed the original IARC findings, concluding the association between BMI and cancer risk was strong and dose-related for esophageal adenocarcinoma, colorectal cancer, and cancers of the gastric cardia, pancreas, liver, gallbladder, and kidney. These results were consistent across geographical regions and among sexes. The World Cancer Research Fund/American Institute for Cancer Research (WCRF) supported the IARC findings affirming convincing evidence for a dose-response relationship between body fatness as measured by the BMI and esophageal adenocarcinoma, colorectal cancer, postmenopausal breast cancer, and cancers of the endometrium, kidney, and pancreas.[123] The epidemiological evidence for an association between body fatness as measured by the BMI and gallbladder was probable, whereas the association between abdominal fatness using waist circumference, waist/hip ratio, and weight gain patterns was convincing for colorectal cancer and probable for pancreatic and postmenopausal breast cancers.

The strength of the association and dose-response between body fat and cancer remains variable and

[a] IARC evaluation of observational epidemiological studies; [b] International Agency for Research on Cancer relative risk with confidence interval of highest body-mass index (BMI) versus normal BMI (18.4–24.9); [c] WCRF/AICR = World Cancer Research Fund/American Institute for Cancer Research as measured by BMI; [d] Body fatness probably protects against premenopausal breast cancer.

relatively small compared with smoking and alcohol, depending on sex and cancer type. In random effects meta-analyses and meta-regressions of study-specific incremental estimates of cancer risk, the association between postmenopausal breast cancer and BMI was weakly positive with an increased relative risk of ~1.1/5 BMI units above normal weight (BMI = 18.5–24.9), whereas the risk of premenopausal breast cancer was inversely related to BMI.[136] Suspected mechanisms for this association included alteration of sex hormone metabolism and chronic inflammation disrupting the balance between cell proliferation and apoptosis.[137] In this study, the association between a 5-kg/m^2 increase in BMI for women was stronger for endometrial (RR = 1.59, $P < 0.0001$), gallbladder (RR = 1.59, $P = 0.04$), esophageal adenocarcinoma (RR = 1.51, $P < 0.0001$), and renal (RR = 1.34, $P < 0.0001$) cancers. Table 49.19 lists the cancer sites sufficiently associated with obesity and their estimated relative risks based on the IARC and WCRF reviews. The IARC considered the evidence limited for elevated body fatness-related increased risks for male breast cancer, fatal prostate cancer, and diffuse large B cell lymphoma, whereas the evidence was inadequate for squamous cell carcinoma of the esophagus, cutaneous melanoma, brain or spinal cord glioma, and cancers of the gastric noncardia, extrahepatic biliary tract, lung, testis, and urinary bladder.

Diet

Diet influences many types of cancer, depending on the cancer type and age at exposure;[138] however, the exact dietary components and the degree of influence remain unclear due to multiple methodological issues, including the complexity of chemical compounds in foods, difficulty classifying unique food groups, the absence of biomarkers to confirm exposure, reporting bias (self-reported questionnaires), collinearity of dietary and behavioral factors, confounding (e.g., smoking, fiber intake, body fatness) from nonrandom study designs, lack of uniformity in diets over time, and limited data on the influence of exposure timing on cancer incidence and mortality.[139] Consequently, nutritional studies are subject to cumulative biases, selective reporting, and extensive residual confounding, particularly following the use of big data to reach statistical significance at relatively modest absolute risk levels.[140] Separating the influence of a single dietary component on health outcomes is difficult when using limited self-reported nutrition data containing few questions to cover the exceedingly complex interactions of dietary items and multiple ingested chemicals.

Potential genotoxic carcinogens introduced during the consumption of processed food include polycyclic aromatic hydrocarbons (PAHs) from the effect of intense heat on fat extruded from meats or fish, heterocyclic amines from cooking meat or fish, nitrosamines

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from cured meat or fish products, and acrylamide from heat-induced reactions between carbonyl sugar groups (e.g., glucose) and free amino acid asparagine, including bread, potato chips, French fries, and baked goods. Additionally, diet and lifestyle may enhance epigenetic effects that promote tumor development by reducing the presence of anti-inflammatories, antioxidants, and endocrine disrupters.[141] Several studies in highly developed countries, including migrants immigrating to these countries,[142,143] suggest the consumption of promoting agents and dietary carcinogens along with poor dietary practices (e.g., inadequate nutrients, antioxidants, or fiber, excessive fat, or caloric intake) may increase the incidence of certain cancer types (e.g., breast, colon, endometrium, prostate);[144,145] however, analytical epidemiological studies indicate the association between diet and human cancer is relatively weak compared with other lifestyle factors (e.g., tobacco, alcohol) and biological agents (bacteria, viruses, parasites, aflatoxins), excluding obesity.[146]

A well-balanced diet remains the optimal approach to ensuring adequate intake of essential micronutrients for maintenance of overall health, including cancer prevention unless a person has vitamin or mineral deficiencies; typically, the absorption of micronutrients into the body is better through foods than supplements.[147] Most randomized clinical trials of vitamin and mineral supplements have not demonstrated definite benefits for cancer prevention in cancers unrelated to nutritional deficiencies.[148] Several clinical trials suggest supplementation of micronutrients in doses exceeding the recommended dietary allowance may increase cancer mortality, including β-carotene in smokers (i.e., ~18%),[149] folic acid, and vitamin E.[150]

Fat

In comparison with vegetables and fruits, fats are high energy-dense foods (i.e., >225–275 kcal/100 g). Meat, milk, and dairy products are significant sources of fat in high-income countries, with fat content being higher in most domestically bred than wild animals depending on animal type, rearing, processing, and preparation. Fatty acid classifications include saturated (solid at room temperature, typically of animal origin), unsaturated (liquid at room temperature, typically of plant or marine origin), and semisynthetic, partially hydrogenated *trans*-fatty acids (harder at lower temperatures than unsaturated fats). Complete hydrogenation of the latter converts the compound to saturated fatty acid, improving shelf life and increasing energy density and saturated fat consumption. Monounsaturated fatty acids have only one double bond, whereas polyunsaturated fatty acids have multiple double bonds. An "*n*" denotes the first double bond along the carbon chain of a polyunsaturated fatty acid (e.g., $n = 3$ for α-linolenic acid, omega 3′ fatty acid). Cattle and sheep contain more saturated fatty acids than poultry or pork. Dietary fat is necessary to absorb fat-soluble vitamins (A, D, E, K). The average Western diet contains 30–40% total fat, depending on the consumption of meat and dairy products. The average fat consumption in the United States is 36–38% of total caloric intake, whereas the National Cancer Institute (NCI) recommends an upper limit of 30% of total dietary calories.

Evidence suggesting diets high in fats and oils independently increase cancer incidence (e.g., colorectal, lung, postmenopausal breast cancers) is limited. Some epidemiology and animal studies suggest an association between increased dietary fat consumption and the incidence and mortality of some cancers (e.g., breast, colon, endometrium, prostate), primarily as a promoting rather than initiating agent. This association is strongest for breast cancer; however, the results are inconsistent, particularly with different estrogen-receptors and menopausal status.[151,152] Although some animal, ecological, and case-control studies suggest high total dietary fat content modestly increases breast cancer risks,[153] prospective cohort studies are inconsistent with positive results primarily in postmenopausal women.[154,155] Although most case-control studies support a modest association, less consistent cohort studies suggest the possibility of differences in the amount of fat consumption between international studies (i.e., as low as 15% fat in diet) and national studies (i.e., 34–44%).[156] An 8-year follow-up cohort study of 1,439 incident breast cancer cases (~54% postmenopausal) in the US Nurses' Health Study did not detect a positive association between total fat consumption and breast cancer comparing the highest and lowest quintiles.[157] Similarly, a prospective cohort study of 49,261 women aged 30–49 years at enrollment yielded 974 breast cancer cases with no association between total fat, monounsaturated fat, polyunsaturated fat, or saturated fat and breast cancer risks.[158] However, subgroup analysis suggested a reduced breast cancer risk after the age of 50 years, comparing the highest quintile of monounsaturated fat (HR = 0.45, 95% CI: 0.25–0.99) and polyunsaturated fat (HR = 0.54, 95% CI: 0.35–0.85) with the lowest quintile. Estrogen or progesterone status did not affect the hazard ratios.

Fiber

Fibers in the diet are complex carbohydrates typically classified as soluble and insoluble. Soluble fibers occur in fruits, vegetables, and particularly legumes (pulses) and certain minimally processed grains (e.g., oats), whereas

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

insoluble fibers typically exist in bran cereals (e.g., rice, wheat).[159] The outer grain parts (bran, aleurone layer) contain nonstarch polysaccharides typical of carbohydrates that characterize dietary fiber. Soluble fibers undergo intestinal metabolism by bacterial enzymes to produce metabolites that moderately increase stool size; insoluble fibers substantially increase stool size and water content. Consequently, fiber dilutes fecal contents (e.g., short-chain fatty acids produced during gut fermentation), increases stool weight, and decreases intestinal transit time. Plant cells are the main dietary source of fiber; whole fruits and vegetables contain variable amounts of fiber; however, the fiber content of juices made from these foods is low. The daily fiber intake varies from 7–25 g with a typical intake of 10–13 g in Japan and the United Kingdom to ≥15–20 g in Africa and India.[160] The mean fiber intake of adult Americans is ~11 g/day, below the NCI recommended consumption of 20–30 g/day.

Studies of Western countries with high-fat, low-fiber diets demonstrate an increased colon cancer incidence compared with Asian countries (e.g., Japan) with low-fat, high-fiber diets.[161] Wheat bran is the most consistent product that reduces colon cancer incidence in experimental animals.[162] Although the findings could not exclude confounding, the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) meta-analysis of 10 cohort studies on the influence of fiber on colorectal cancer concluded dietary fiber probably protected against colorectal cancer based on a consistent dose-response relationship and plausible mechanisms.[123] The summary effect estimate was 0.90 (95% CI: 0.84–0.99)/10 g daily increments with moderate heterogeneity. The funnel plot indicated that the relative risks in only one cohort study were statistically significant. The evidence for an inverse association between dietary fiber and esophageal cancer was considered limited and inconsistent. The Harvard pooled analysis of 13 prospective cohort studies with 725,628 participants and 8,081 colorectal cancer cases during 6–20 years of follow-up demonstrated a significant inverse association in the age-adjusted model (RR = 0.84, 95% CI: 0.77–0.92), but not after the inclusion of all risk factors (RR = 0.94, 95% CI: 0.86–1.03).[163] Fiber intake from cereals, fruits, and vegetables was not associated with colorectal cancer risk. In the European Prospective Investigation into Cancer and Nutrition (EPIC) study of >500,000 Western Europeans, the inverse association for cancer types comparing the highest and lowest quintiles of dietary fiber intake was statistically significant for colorectal (RR = 0.82, 95% CI: 0.72–0.96; n = 4,517; P_{trend} = 0.013)[164] and liver (RR = 0.51, 95% CI: 0.31–0.83; n = 191; P_{trend} = 0.013) cancer,[165] whereas the results for breast cancer were borderline (RR = 0.95, 95% CI: 0.89–0.101; n = 11,576; P_{trend} = 0.03).[166]

Fruits and Vegetables

Fruits and nonstarchy vegetables are usually low-energy-dense foods that contain fiber and a variety of bioactive compounds (e.g., minerals, vitamins, phytochemicals). The latter accounts for up to 100,000 different compounds categorized as glucosinolates, lectins, monoterpenes, phytoestrogens, phytosterols, polyphenols, protease inhibitors, sulfides, and terpenes.[123] Although some phytochemicals are antioxidants, these compounds are not essential dietary constituents. The specific composition of fruits and vegetables depends on species, strain, farming practices, environmental conditions, production processes, storage conditions, and cooking methods. Cooking usually reduces the total nutrient content of vegetables; however, cooking increases the bioavailability of some nutrients (e.g., lycopene in tomatoes).[167]

Vegetables are edible plant parts (bulbs, flowers, leaves, roots) classified as allium vegetables (e.g., garlic, leeks, onions), cruciferous vegetables (e.g., pok choy, broccoli, cabbage, watercress), and leafy vegetables (e.g., lettuce, spinach). Fruits are the seed-containing plant parts used for foods (e.g., apples, apricots, bananas, berries, citrus, figs, grapes including raisins, mangoes, melons). Some botanical fruits are usually included as vegetables when typically used in cooking as vegetables (cucumbers, peppers, squash, tomatoes). Legumes (pulses) are dried edible seeds from plants that produce pods as their fruits (e.g., beans, lentils, peanuts, peas), whereas nuts are edible seeds circumscribed by a dry, durable shell (e.g., almonds, chestnuts, hazelnuts, walnuts). Brazil nuts, cashews, and macadamia nuts botanically are seeds rather than nuts. Cereals (grains) are the seeds of cultivated grasses including barley, corn or maize, millet, wheat, oats, sorghum, rice, and rye. The food groups contain a variety of bioactive compounds, including carotenoids (α- and β-carotene, lycopene), water-soluble vitamins (folate, vitamin C), and fat-soluble vitamins (D, E).

Although the enhancement of total fruits and vegetables in the diet is a plausible means to reduce cancer rates because these foods are good sources of anti-proliferatives and antioxidants (i.e., fiber, vitamins, phytochemicals), cohort studies have not established a convincing causal association between fruit and vegetable consumption and overall cancer incidence. A review of case-control and cohort studies detected limited evidence for a cancer-preventive effect of fruit and vegetable consumption for cancers of the mouth

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and pharynx, larynx, esophagus, stomach, colorectum, lung, bladder (fruit only), kidney, and ovary (vegetables only).[168] The estimated population-preventable fraction for low fruit and vegetable intake was 5–12%. The World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) Report concluded that total fruit and vegetable consumption was not convincingly associated with reduced cancer risks in any tissues; however, decreased risks of cancer at some sites were probable or limited, as displayed in Table 49.20.

In a prospective cohort study of 49,261 Swedish women (2,347 cases of invasive cancer), the median daily intake of fruits and vegetables was 204 g with a 90th CI of 37–564 g.[170] The association between overall cancer incidence and total fruit and vegetable intake was not statistically significant. Comparing the highest and lowest quintiles, the incident rate ratio was 1.0 (95% CI: 0.88–1.16). A Japanese study of 191,519 participants (17,681 overall cancers) did not detect an association stratified for smoking and alcohol drinking between fruit or vegetable consumption and overall cancer rates.[171] The hazard ratios comparing the highest versus lowest quartiles of fruit intake for men were 1.03 (95% CI: 0.97–1.10; P_{trend} = 1.00) and 1.03 (95% CI: 0.95–1.11; P_{trend} = 0.97) for women. For vegetables, the hazard ratios were 1.07 (95% CI: 1.01–1.14; P_{trend} = 0.18) for men and 0.98 (95% CI: 0.91–1.06; P_{trend} = 0.99) for women. The European Prospective Investigation into Cancer and Nutrition (EPIC) study is a prospective cohort study involving 23 study centers in 10 Western European countries with >500,000 participants and substantial variation in diets.[172] The study compared incident cancer trends for quintiles of daily intake of total fruit (range, <89 g to ≥356 g), vegetable (range, ≤99 to ≥305 g), and fiber (range, ≤16.4 to ≥28.5 g) daily intake. The evidence for an inverse relationship between upper aerodigestive tract (mouth, pharynx, larynx, and esophagus) was weakly positive for total fruit intake and negative for total vegetable intake. Similarly, the data for combined fruit/vegetable intake and colorectal cancer were weakly positive, whereas the data for lung cancer were positive only for smokers. Overall, there was little evidence for an association between quintiles of vegetable intake and various cancer sites and small inverse associations between some cancer sites and fruit consumption. The study investigated total fruit and vegetable consumption; however, the study did not exclude an inverse association between cancer subtypes (e.g., estrogen receptor-negative breast cancer)[173] or fruit and vegetable subgroups (e.g., blueberries, nectarines, citrus).[174,175]

Evidence for an inverse association between breast cancer risk and total fruit and vegetable intake is inconclusive. Generally, reviews of case-control studies are positive, whereas cohort studies usually demonstrate a weakly positive or statistically insignificant association. In a systematic review and meta-analysis of 15 prospective studies comparing the highest and lowest intakes, the summary relative risk was weakly positive (RR = 0.89, 95% CI: 0.80–0.99, I^2 = 20%) for total fruits and vegetables, whereas the RR did not reach statistical significance for total fruits or total vegetables individually.[176] A review of 7,377 cases of invasive breast cancer did not detect statistically significant associations between consumption of total fruits (pooled multivariate RR = 0.93, 95% CI: 0.86–1.00) or total vegetables (pooled multivariate RR = 0.96, 95% CI: 0.89–1.04) and breast cancer.[177]

Meat

The carcinogenic effect of red and processed meats is difficult to separate from other dietary and lifestyle factors, considering the relatively weak observed effects and wide variation between studies. Epidemiological evidence for an association between overall red and processed (i.e., salted, cured, smoked) meat consumption and increased overall cancer rates is suggestive with the strongest evidence for colon cancer, whereas evidence for fish, eggs, and poultry is very limited.[133] Processed meats with preservatives (nitrites) typically include bacon, bratwurst, frankfurters, ham, pastrami, salami, and sausage; however, meats preserved only by refrigeration are usually not classified as processed meat, even if cooked. Plants naturally contain some nitrates with vegetables accounting for 70–97% of dietary nitrate consumption; the body converts ~5–20% of the absorbed nitrates to nitrites.[123] The curing process or *in vivo* metabolism can convert nitrates and intestinal degradation products of amino acids into *N*-nitroso compounds (e.g., nitrosamines). Heterocyclic amines and polycyclic aromatic hydrocarbons form in temperature-dependent processes during the cooking process (e.g., grilling, broiling, frying, barbecuing) because of the reaction of amino acids and creatine or the heat-induced degradation of fat, respectively.

Potential genotoxic mechanisms for developing gastrointestinal cancers from meats include: 1) mutagenic effect of heterocyclic amines contained in well-cooked meat processed at temperatures of >180°C for extended time periods and 2) endogenous formation of *N*-nitroso compounds in the gastrointestinal tract. Cured meats account for most of the dietary exposure to *N*-nitrosamine compounds, whereas fish and cheese contribute smaller nitrosamine exposures.[178]

TABLE 49.20. Strength of evidence for *decreased* cancer risk at various sites for total vegetable and total fruit intake based on data from the World Cancer Research Fund/American Institute for Cancer Research (WCRF/AICR) and the European Prospective Investigation into Cancer and Nutrition (EPIC) study on dietary fruits, vegetables, and fiber. The EPIC study compared significant trends across quintiles of fruit, vegetable, and fiber intake, whereas the WCRF/AICR used meta-analysis techniques to develop categories reflecting the strength of the evidence of an inverse association or insufficient data.

Cancer Site	Total Non-starchy Vegetables		Total Fruits		Total Fiber	
	WCRF/AICR	EPIC	WCRF/AICR	EPIC	WCRF/AICR	EPIC
Mouth	Probable[a]	None[a]	Probable[a]	Significant[a]		Insufficient
Nasopharynx	Limited	–	Limited	–		–
Pharynx	Probable[a]	None[a]	Probable[a]	Significant[a]		Insufficient

Abbreviations: Insufficient = inadequate data to calculate relative risks and confidence intervals; – = not reported in study.
[a] Combined cancer sites; [b] Combined total fruit and vegetable intake; [c] Subsequent analysis suggests an 11% reduction in esophageal adenocarcinoma per 100 g of vegetables/day in 3 studies and 16% reduction in esophageal squamous cell carcinoma per 100 g of fruit/day in 3 studies.[169]

N-nitrosation reactions between secondary or tertiary amines and nitrites (or other nitrosating agents) in cured meat cause the formation of *N*-nitrosamines (*N*-nitrosodimethylamine, *N*-nitrosopyrrolidine, *N*-nitrosoproline); these chemicals are recognized animal and probable human carcinogens. Nitrites, aldehydes, and quinones enhance nitrosation, whereas ascorbic acid, vitamin E, and polyphenols (found in vegetables and fruit) inhibit this process.[10]

Benzo(a)pyrenes and heterocyclic amines (MeIQ, IQ, Glu-P-1) occur in broiled or smoked meats; 2-amino-1-methyl-6-phenylimidao[4,5-*b*]-pyridine (PhIP) is an aryl amine formed in meat during cooking, particularly at high temperatures. The confounding factors in the evaluation of meat diets complicating the interpretation of studies associating PhIP with colon cancer include the presence of polyaromatic hydrocarbons, fat intake, and iron. PhIP and related heterocyclic amines (e.g., 2-amino-3,4-dimethylimidazo[4,5-*f*]quinolone, MeIQ; 2-amino-3,8-dimethylimidazo[4,5-*f*]quinolone, MeIQx) are mutagenic animal carcinogens that produce small and large intestine lymphomas and prostate tumors in experimental studies.

Trace amounts of animal carcinogens appear in food because of food processing; however, conclusions regarding positive epidemiology studies supporting a firm causal connection between well-done meats and cancer (e.g., breast, colon, stomach) remain controversial.[179] Some epidemiological evidence suggests that *N*-nitroso compounds contribute to the development of human cancers (e.g., esophageal cancer in high-risk Chinese areas, colorectal cancer in developed countries). These compounds are potential explanations for higher colon cancer incidences in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. studies of diet in developed countries (North America, Western Europe, Japan, Australia, New Zealand); however, interpretation of studies involving cancer and diet requires complex evaluations of numerous methodological issues, including measuring dietary patterns in different populations, standardizing food intake, defining food categories, determining proper outcomes, controlling bias, adjusting for confounding, predicting the effect of multicollinearity, determining genetic susceptibilities, developing statistical models, and evaluating differences in analytical metrics. Additionally, the typically weak magnitude of the observed effect between specific portions of the diet and cancer (i.e., relative risk 0.8–1.25) potentially allows confounding, exposure misclassification, and biases (information, selection, publication) to obscure the true effect.

In a meta-analysis of 21 studies comparing the highest versus lowest intake of red and processed meat with the risk of colorectal cancer, the summary relative risk (SRR) for colorectal cancer was 1.22 (95% CI: 1.11–1.34), whereas the SRR for red meat alone was 1.10 (95% CI: 1.00–1.21, statistically nonsignificant).[180] The mean for the highest category of red mean intake ranged from 26–197 g/day. The standardized measure for red meat in the meta-analysis was 50 g and 120 g for red/processed meat. Nonlinear dose-response analyses demonstrated increasing colorectal cancer risk up to ~140 g of red and processed meat/day, then the curve plateaued. The authors attributed substantial heterogeneity in the studies mostly to intake unit conversion in the meta-regression analysis. A subsequent meta-analysis of 27 independent prospective cohort studies using random effects models to examine red meat (beef, pork, lamb) and colorectal cancer risks demonstrated a summary relative risk of 1.11 (95% CI: 1.03–1.19).[181] There was substantial heterogeneity ($P = 0.014$, $I^2 = 33.60$) with no clear dose-response relationship. Nine studies reporting median red meat intake of <40 g/day have summary relative risk for colorectal cancer of 1.02 (95% CI: 0.98–1.07) without significant heterogeneity ($P = 0.014$, $I^2 = 0.0$). The authors noted that the association weakened over time.

Dysplastic changes in colorectal epithelium probably represent a stepwise progression from an adenoma to a malignant carcinoma, with the risk of an adenoma becoming malignant depending on the size, type, and number of adenomas.[182] Studies on the association between red meat and colorectal adenomas are limited. In a meta-analysis of 19 case-control studies and 7 prospective cohort studies of red or processed meat consumption and colorectal adenoma risk, the overall summary relative risk/daily consumption of 100 g red meat and colorectal adenomas was 1.27 (95% CI: 1.16–1.49, $I^2 = 5\%$, $n = 16$) and 1.29 (95% CI: 1.10–1.53, $I^2 = 27\%$, $n = 10$) per daily consumption of 50 g processed meat.[183] The results for red meat appeared stronger for case-control than cohort studies, whereas the opposite was true for the results involving processed meats. Linear dose-response analysis per 100 g red meat daily indicated a plateauing of the response near a relative risk of 1.5, with the greatest effect at the lower portion of the dose-response curve; most of these studies did not demonstrate a statistically significant difference between colorectal adenoma when comparing high and low red meat consumption. A meta-analysis of 19 studies of meat subtypes (5 beef, 5 pork, 2 lamb, 1 veal, 19 poultry) and colorectal cancers suggested different risks for various meat subtypes as well as variation between countries.[184] The colon cancer summary of relative risks was elevated comparing the highest and lowest intake categories for beef (RR = 1.24, 95% CI: 1.07–1.44); however, the Asian studies on beef demonstrated no statistically significant association between beef consumption and colon cancer risk. The studies on pork and poultry consumption did not demonstrate a statistically significant increase in the overall relative risk of colon cancer.

Pickled Vegetables

Investigations in areas with high esophageal and stomach cancer rates have not identified a specific dietary cause to account for these relatively high rates.[185] In a population-based case-control study of 250 lower esophageal cancer cases in 5 Chinese areas with high esophageal cancer rates using personal food interviews, multivariate logistic analysis identified multiple potential risk factors including not taking regular meals, overnight vegetable intake, GERD, hot food, passive smoking, pickled food, alcohol drinking, seldom eating breakfast, and false dining posture.[186] The odds ratio for pickled food was 2.273 (95% CI: 1.350–3.828) with a value less than several other identified factors (e.g., not taking regular meals, overnight vegetable intake, GERD, hot food). Statistical analyses for the multiple comparisons were not reported. A meta-analysis of 34 almost exclusively case-control studies on Asian pickled vegetable consumption and esophageal squamous cell carcinoma risks reported an overall random effects odds ratio of 2.08 (95% CI: 1.66–2.60, $P = <0.001$) and high heterogeneity (Q-statistic = 282.18, $I^2 = 88\%$).[187] A matched case-control study of 185 esophageal cancer cases from Yanting, Sichuan Province, reported a statistically nonsignificant odds ratio for frequent pickled vegetable intake of 2.12 (1.00–4.49) using conditional logistic regression.[188] Other identified risk factors with higher odds ratios included eating food rapidly

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(OR = 5.84, 95% CI: 2.05–16.7) and drinking shallow groundwater (OR = 4.18, 95% CI: 1.30–13.4). In contrast to most other countries in the world, the pickling processes in Japan and China use natural fermentation with an increased risk of fungal contamination.

Vitamins and Chemoprevention

Although some observational studies on diets high in fruits, vegetables, and antioxidants suggest these foods and nutrients may prevent cancer,[189] most randomized trials of the association between antioxidants and cancer incidence do not support the use of vitamin or mineral supplementation in primary cancer prevention in healthy adults. Several meta-analyses did not demonstrate a significant reduction in cancer rates with antioxidant vitamins, β-carotene, or mineral supplementation over 4–6 years, with the possible exception of a selenium-associated reduction in mortality.[190,191] Antioxidant supplementation did not significantly reduce total cancer incidence (RR = 0.99, 95% CI: 0.94–1.04) or mortality (RR = 1.03, 95% CI: 0.92–1.15), whereas β-carotene supplementation was associated with an increase in lung cancer incidence in current smokers (RR = 1.10, 95% CI: 1.03–1.10).[190] Selenium supplementation was associated with reduced cancer incidence in men (RR = 0.77, 95% CI: 0.64–0.92) but not in women (RR = 1.00, 95% CI: 0.89–1.13). The randomized, double-blind, placebo-controlled Women's Antioxidant Cardiovascular Study using 500 mg vitamin C qd, 600 IU vitamin E qd, and 50 mg β-carotene qod over a mean of 9.4 years detected no statistically significant effects of any antioxidant or any combination on total cancer incidence.[192] Most women were obese (mean BMI = ~30) and postmenopausal (77%) with only 27% reporting multivitamin use at baseline. A meta-analysis by the United States Preventive Services Task Force (USPSTF) did not find substantial evidence supporting the use of vitamin and mineral supplements to prevent cancer in healthy adults, although two trials demonstrated a small, borderline significant benefit from multivitamin supplements on cancer in men only.[147] Neither β-carotene nor vitamin E prevent cancer, whereas several studies suggest β-carotene supplementation increases lung cancer risk in smokers. The USPSTF concluded the evidence was insufficient to assess the balance between risk and benefit for single or multiple nutritional supplements in healthy adults with well-balanced diets, except possibly increased risks with β-carotene and vitamin E.[193] Consequently, they recommended against the use of vitamin E or β-carotene to prevent cancer.

Vitamin A

Vitamin A (retinol) is a generic term for retinoids (retinal, retinol, retinoic acid) derived from plant provitamin A carotenoids (e.g., β-carotene). A review of retrospective, mostly case-control epidemiology studies on the association between reduced vitamin A (retinol) intake and the overall cancer incidence suggested an ~2-fold increase in patients with low vitamin A consumption.[162] Recall bias and lack of control over other dietary and lifestyle factors (e.g., smoking) influencing cancer incidence limit interpretation of the validity of this study; subsequent observational studies do not support a consistent relationship between increased total cancer incidence and reduced vitamin A or β-carotene intake. Randomized clinical trials indicate β-carotene supplementation increases lung cancer risks in heavy current smokers with genetic susceptibilities (glutathione-*S*-transferase μ_1 variant, *GSTM1*; Arg/Arg genotype) based on subgroup analysis of a nested, case-control study of 29,133 white male Finnish smokers followed for 5–8 years.[194]

Vitamin D

Observational studies on the effect of vitamin D on cancer risk are limited and inconsistent, primarily focusing on colorectal and prostate cancer.[195] Limited data from several randomized clinical trials suggest high-dose vitamin D supplementation (i.e., 1,000 IU/day) reduces total cancer risk; however, observational studies suggest higher (25-[OH]D) concentrations are associated with an increased cancer risk. Mixed-effects dose-response meta-analysis data from 9 nested case-control studies of fair quality indicated a 10-nmol/L increase in prediagnosis blood 25-hydroxyvitamin D concentration and was associated with reduction in colorectal cancer risk of 6% (95% CI: 3–9%).[196] The results for a dose-response relationship between vitamin D and prostate or breast cancer risks were not statistically significant. Methodological issues limit conclusions, particularly potential residual confounding and the difficulty in determining true vitamin D status, including the contribution of endogenous vitamin D synthesis from sunlight; consequently, the US Preventive Services Task Force concluded that evidence is insufficient to determine the benefits or harms of vitamin D supplementation for cancer prevention. The Cohort Consortium Vitamin D Pooling Project of Rarer Cancers involving 10 international cohorts did not detect evidence of a protective association between higher concentrations of blood 25-hydroxyvitamin D (>75 nmol/L) and 7 cancer outcomes (endometrial, esophageal, gastric, kidney, non-Hodgkin lymphoma, ovarian, pancreatic).[197]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Vitamin E

Evidence from observational studies on the role of vitamin E supplementation in reducing colorectal adenoma or cancer risks is equivocal. Most colorectal cancers arise from premalignant colorectal adenomas. In the randomized trial of Selenium and Vitamin E Cancer Prevention Trial (SELECT) enrolling 35,533 men over the age of 50–55 years, subgroup analysis identified 2,286 men with colorectal adenomas.[198] Vitamin E supplementation (400 IU α-tocopherol daily) did not affect the occurrence of colorectal adenomas compared with placebo (RR = 1.03, 95% CI: 0.96–1.10; $P = 0.38$). The lack of efficacy for reducing prostate cancer risk ended the trial early after 5.5 years, with overall follow-up ranging from 7–12 years after enrollment. Analysis of the data indicated a statistically significant increase in prostate cancer among healthy men on dietary supplementation with vitamin E compared with placebo (HR = 1.17, 99% CI: 1.004–1.36; $P = 0.008$).[199] The increased risk of prostate cancer first appeared 3 years after the trial began, with the hazard ratio increasing by 1.12–1.17 over the next 3 years. In the randomized, double-blind, placebo-controlled Women's Antioxidant Cardiovascular Study using 600 IU vitamin E qd for a mean of 9.4 years, vitamin E supplementation did not reduce the overall cancer incidence compared with placebo (RR = 0.93, 95% CI: 0.79–1.09).[192] Vitamin E (α-tocopherol) supplementation in the study on genetic susceptibilities in current smokers did not reduce lung cancer risks.[194]

Folic Acid

Folates are water-soluble B vitamins present in green, leafy vegetables, and cereals that provide 1-carbon units for cellular metabolism and are important coenzymes in genetic (e.g., nucleotide synthesis) and epigenetic (e.g., DNA methylation) pathways that prevent genomic instability and global DNA hypomethylation, respectively. The effects of folate deficiency on DNA methylation are highly complex and gene-/site-specific, depending on cell type, target organs, cancer stage, gene polymorphisms, and lifestyle factors.[200] Epidemiology studies suggest adequate folate consumption may slightly reduce colorectal cancer risk; however, confounding factors complicate the interpretation of these studies. A meta-analysis of 7 cohort and 9 case-control studies demonstrated a small reduction in the risk of colon cancer when comparing high and low intakes of dietary folate (RR = 0.75, 95% CI: 0.64–0.89), whereas the RR for colorectal cancer in groups with high and low intakes of *total* folate from food/supplements was not significantly reduced (RR = 0.95, 95% CI: 0.81–1.11).[201] Some studies suggest that high-dose folate supplements may increase the growth of precancerous lesions. In a nested, case-control study of Chinese men, plasma folate concentration was positively associated with colorectal cancer risk among men potentially with preneoplastic lesions based on the highest tertile of folate concentrations for men with late-stage colorectal cancer (OR = 2.66, 95% CI = 1.03–6.86).[202]

Coffee, Teas, and Caffeine

Coffee is a complex mixture of caffeine, acids (aliphatic, chlorogenic, citric, quinine), polysaccharides, proteins, lipids, and caramelized products, as well as endogenous (polycyclic aromatic hydrocarbons, heterocyclic amines, nitrosamines) and potentially exogenous contaminates (pesticides, mycotoxins, alkanes).[203] Although coffee contains hundreds of chemicals, the constituents in this beverage are not unique to coffee as a food product.[204] Some of these chemicals are possible carcinogens (caffeic acid, catechol, naphthalene), human carcinogens [benzo(*a*)pyrene], or mutagens (chlorogenic acid, naphthylglyoxal, caffeic acid),[205,206] whereas other constituents possess anticarcinogenic properties, including diterpenes (cafestol, kahweol), polyphenols (flavonoids, lignan phytoestrogens), and antioxidants (chlorogenic acid).[207,208] Most chronic animal studies on coffee did not detect carcinogenic effects.[209,210,211] The effect of coffee as a promoter is highly variable, with some studies demonstrating promoting effects and other studies demonstrating tumor-inhibiting effects.[203] Evidence indicating coffee consumption causes human cancer is weak.[212,213] An evaluation by an IARC Working Group found limited evidence for a weak correlation between coffee consumption and development of bladder cancer; however, the possibility of bias or confounding could not be excluded.[214] The evidence for an association with pancreatic and other cancers was inadequate. Consequently, the IARC lists coffee as unclassifiable (Group 3), with evidence suggesting lack of carcinogenicity in humans drinking coffee for cancers of the urinary bladder, female breast, pancreas, and prostate along with an inverse association with cancers of the liver and uterine endometrium.[214,215] Inadequate control for potential confounding, measurement error, selection bias, and/or recall bias, insufficient power, and inconsistent findings limited conclusions regarding brain, colorectal, esophageal, oral cavity, ovarian, oral cavity, and other cancers.

Although there is a correlation between national coffee consumption and US mortality rates for pancreatic cancer, evidence of a strong, dose-response relationship between coffee consumption and the occurrence of pancreatic cancer is weak.[216] Some ecological[217]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and retrospective case-control studies[218] suggest an association with pancreatic cancer; however, most prospective studies demonstrate no association between coffee consumption and pancreatic cancer rates.[204,219] A meta-analysis of 40 prospective cohort studies relatively equally divided between the United States, Europe, and Asia using random effects meta-analyses and meta-regressions of study-specific incremental cancer estimates demonstrated a pooled relative risk of 0.82 (95% CI: 0.74–0.89) comparing high and non/lowest coffee drinker groups.[220] There was significant heterogeneity between studies (Q-statistic = 114.71, $P < 0.001$, $I^2 = 67.7\%$) reflecting international differences in coffee types, brewing methods, and serving sizes. An increase of 1 cup of coffee/day was associated with an overall 3% reduction (95% CI: 2–4% reduction) in cancer risk. Subgroup analyses demonstrated inverse associations with leukemia and breast, buccal/pharyngeal, colorectal, endometrial, esophageal, hepatocellular, pancreatic, and prostate cancers with no association for kidney, lung, and stomach cancers.

Teas are classified as black teas produced by an enzymatic oxidation process involving fermentation, whereas green tea is produced without fermentation. The latter is the most common tea accounting for ~80% of the world production.[214] Green tea contains polyphenols (catechins) including flavonols, flavandiols, flavonoids, and phenolic acids; catechins account for ~30% of the dry weight of these teas.[221] During the fermentation process for black tea, bisflavanols, theaflavins, and thearubigins form from the oxidative polymerization of monomeric flavan-3-ols. Caffeine accounts for ~3–4% of the dry weight (i.e., ~30–50 mg/cup).[214] Herbal teas contain various known and unknown components; their composition differs substantially from that of tea brewed from *Camellia sinensis*. Studies correlating cancer of the breast, intestine, larynx, lung, and colon with tea consumption are inconsistent; consequently, there is no clear association between tea and cancer development.[221] A Japanese study found an inverse association (HR = 0.43, 95% CI: 0.22–0.84) between the daily consumption of three cups of green tea and the risk of Stage I breast cancer recurrence.[222] The IARC classifies tea in Group 3 based on inadequate evidence of cancer in experimental animals and humans.[214]

Maté is an aqueous infusion of the herb *Ilex paraguayensis* prepared in a gourd, drunk hot (63–69°C) with a metal straw, and consumed primarily in South America; during the traditional drying process with burning organic material, polycyclic aromatic hydrocarbons enter the infusion in substantial concentrations.[223] Urinary concentrations of polycyclic aromatic hydrocarbon metabolites correlate with self-reported amounts of recent maté consumption.[224] Pooled results from two South American case-control studies demonstrate an odds ratio (OR) for esophageal squamous cell cancer comparing ever with never maté use of 1.60 (95% CI: 1.2–2.2); the OR increased linearly with cumulative maté consumption; however, the trend was statistically significant only for maté consumed hot or very hot.[225] The lack of studies demonstrating the carcinogenicity of cold maté and experimental animal studies demonstrating the tumor promoter properties of hot water at >65°C resulted in an IARC classification of Group 3 (unclassifiable) for not very hot maté and probable carcinogen (Group 2A) for drinking very hot beverages at >65°C.[215]

Tobacco

The IARC classifies tobacco smoke, environmental tobacco smoke, and smokeless tobacco as carcinogenic to humans (Group 1).[125] Tobacco smoke is a strong promoting agent (e.g., inflammation, oxidative damage) and complete carcinogen containing a complex mixture of procarcinogens, carcinogens, tumor promoters, and cocarcinogens; however, nicotine is not classified as a carcinogen.[226] Smokeless tobacco contains fewer identified carcinogens than cigarette smoke. Most carcinogens in tobacco smoke require metabolic activation, resulting in individual variation in susceptibility due to differences in metabolic activation and detoxification pathways. These genetic polymorphisms include *NAT2* slow acetylator genotype in bladder and breast cancer and *GSTM1* null genotype in combination with CYP1A1 polymorphism in lung cancer.

Genotoxic carcinogens react with nucleophilic sites in DNA to form covalent binding products (i.e., adducts). Tobacco smoking is associated with genotoxic effects in at least eight tissues (bladder/ureter, cervix, esophagus, myeloid organs, lung, oral/nasal, pancreas, pharynx/larynx).[227] Failure of DNA repair mechanisms to eliminate these adducts during DNA replication produces miscoding, and the insertion of wrong bases into the DNA strand causes permanent mutations. Dysregulation of cell cycle control occurs when these mutations appear in critical areas regulating cell growth (e.g., oncogenes, tumor suppressor genes). The specific gene mutations responsible for the development of tobacco-related cancer remain poorly defined; however, a meta-analysis of human epidemiology data demonstrated interindividual and histological differences in lung cancer mutations.[228] The odds of presenting with epidermal growth factor receptor (EGFR, a receptor tyrosine kinase) and the anaplastic lymphoma receptor tyrosine kinase-echinoderm microtubule-associated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

protein-like 4 (ALK-EML4) mutations were increased in: 1) never-smokers compared with ever-smokers and 2) patients with adenocarcinomas compared with nonsmall cell lung cancers, particularly adenocarcinomas.[229] These findings suggest key driver mutations in lung cancer patients may differ when developing in smokers from tobacco smoke or in never-smokers developing lung cancer after exposure to chromium, asbestosis, radon, or other nonsmoking-related lung carcinogens.

Composition

The physiochemical composition of the cigarette smoke depends on the origin and processing of the tobacco leaves, the porosity and treatment of the cigarette paper, the humidity, the age of the smoke as rapid coagulation of particles occurs, and the filter tip. The composition of cigarettes and cigarette smoke gradually changed over the last hundred years, resulting in particularly high tar concentrations prior to the introduction of "low-tar" cigarettes composed of filters with and without perforations, highly porous cigarette paper, and altered tobacco blends in the 1950s.[230,231] The latter resulted from changes in selection of tobacco types and varieties, incorporation of reconstituted tobacco into blends, opened and cut ribs, and "expanded tobacco" (i.e., tobacco with reduced weight and tar/cigarette resulting from cellular expansion and freeze drying). Variation in tobacco composition occurs between different countries. Figure 49.4 displays the modern commercial cigarette. Cigarette packages contain cigarette tar yields and nicotine concentrations in mainstream smoke as measured by smoking machines under highly standardized conditions using constituents identified by Dietrich Hoffmann and colleagues (Hoffmann analytes).[232]

The US sales-weighted average "tar" yields declined from 38 mg in 1954 to 12 mg in 1992 because of the changes listed above; during the same period, average nicotine yields declined from 2.7 to 0.95 mg.[233] In the United States, an increase in nitrate concentrations and enhancement of tobacco combustion accompanied these changes (i.e., 0.3–0.5 to 0.6–1.35%). More complete combustion decreases the carcinogenic polycyclic aromatic hydrocarbons (PAHs), whereas increased generation of nitrogen oxides produces higher concentrations of carcinogenic *N*-nitrosamines in cigarette smoke, particularly tobacco-specific *N*-nitrosamines.[234] Higher yields of the latter in mainstream smoke occur when smokers adjust to the lower nicotine yields by increasing smoking intensity (i.e., puff volume and frequency).

Tobacco smoke is a complex aerosol composed of a particulate phase (minute solid/liquid droplets) plus a vapor phase containing a mixture of gases (e.g., CO, CO_2, NO_x) and semivolatile compounds; tar refers to the particulate matter represented by the particulate phase minus nicotine and water.[235] During the burning of tobacco leaves, a variety of pyrolysis and reaction products form. Tobacco smoke contains over 5,000 chemical compounds, including over 80 carcinogens comprised of many genotoxic compounds (polycyclic aromatic hydrocarbons, heterocyclic amines, nitrosamines) and strong promoting agents in the acidic fraction.[236] The constituents of processed tobacco remain fairly constant over a variety of growing locations; however, the proportion of individual chemicals in tobacco including carcinogens depends on growing conditions and processing methods.[237] The lungs retain ~50–90% of the inhaled particulate matter in smoke, with most of the vapor phase constituents and gases reaching the alveoli.[238] The concomitant increase in tobacco-specific nitrosamines associated with increased use of blended tobaccos and the compensatory adjustment of smokers to lower nicotine intake complicate the analysis of the impact of reduced "tar" and filter-tipped cigarettes introduced in the 1950s. However, these changes in cigarette composition probably reduced lung cancer risks.[230] Regardless of tar content, the lung cancer risk is far greater in current smokers than in former or never-smokers.[239] Compared with nonmentholated

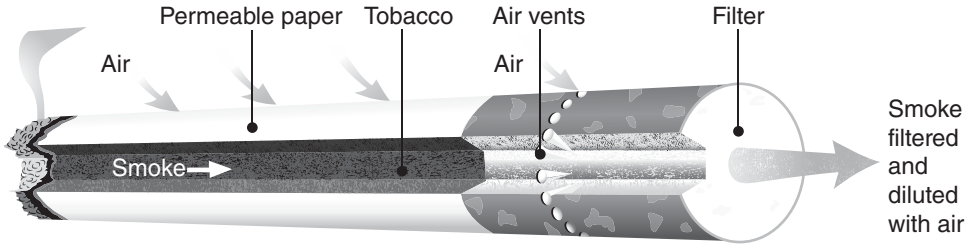

FIGURE 49.4. The modern cigarette contains a tobacco blend, paper, and usually a filter. The most common tobacco types worldwide are Burley, Oriental, and Virginia/Bright. Combustion occurs during a puff when the air drawn into the cigarette during inhalation forms mainstream smoke; combustion continues between puffs when the smoldering cigarette releases sidestream smoke into the environment from the lit cigarette end. After aging and dilution, the mixture of sidestream and exhaled mainstream smoke becomes environmental tobacco smoke (ETS). (Adapted from Thielen).[230]

cigarettes, smoking mentholated cigarettes does not increase lung cancer risk above the rate for nonmentholated cigarettes after adjustment for total cigarette consumption (i.e., pack–years). In a case-control study of 693 lung cancer cases and 4,110 controls, the lung cancer risk for long-term smokers of menthol and nonmenthol cigarettes (≥20 years) was similar (odds ratio = 0.97, 95% CI: 0.70–1.34).[240]

Mainstream Smoke The chemicals in tobacco smoke either pass through the mouth-end cigarette condensing a short distance behind the burning cone (mainstream smoke), or exit the burning end into ambient air (sidestream smoke). Mainstream smoke becomes progressively stronger as the cigarette shortens from the addition of previously condensed material. The particulate phase accounts for 4.5–8% of mainstream smoke on a w/w basis, including nicotine, nitrosamines, metals (arsenic, beryllium, cadmium, nickel, zinc, ^{210}Po), polycyclic aromatic hydrocarbons (PAHs), and carcinogenic amines; the vapor phase accounts for ~5% on a w/w basis including ammonia, benzene, carbon dioxide, carbon monoxide, formaldehyde, hydrogen cyanide, *N*-nitrosodimethylamine, and *N*-nitrosodiethylamine.[241,242] Table 49.21 lists the main IARC Group 1 and 2A carcinogens in unburned tobacco and mainstream cigarette smoke.

Typically, stronger carcinogens (e.g., aromatic amines, metals, nitrosamines, PAHs) occur in relatively smaller amounts (0.001–0.2 μg/cigarette) than weaker IARC Group 2B carcinogens (~1,000 μg/cigarette).[179] The most prevalent carcinogens in unburned tobacco are nitrosamines (e.g., *N*′-nitrosonornicotine, NNN; 4-(*N*-Nitrosomethylamino)-1-(3-pyridyl)-1-butanone, NNK).[243] Table 49.22 lists some reported ranges of selected human carcinogens released into mainstream smoke during cigarette smoking.

Sidestream Smoke Sidestream smoke differs from mainstream and environmental tobacco smoke in acute toxicity, chemical concentrations, and genotoxicity.[244] The generation of sidestream smoke occurs at lower burning temperature than mainstream smoke (i.e., 500–600°C vs. 850–950°C, respectively) in a reducing atmosphere. Sidestream smoke is slightly alkaline, whereas mainstream smoke from most common cigarettes is slightly acidic. Qualitatively, the composition is similar for sidestream and mainstream smoke; however, the yield/cigarette and the ratio of sidestream/mainstream concentrations of individual substances vary depending on specific physiochemical properties and cigarette construction. Sidestream smoke contains higher concentrations of some carcinogens than mainstream smoke (e.g., *N*-nitrosodimethylamine, *N*-nitrosodiethylamine, cadmium, nickel).[235] Table 49.23 displays estimated sidestream/mainstream cigarette smoke ratios of selected chemicals.

TABLE 49.21. Human (IARC Group 1) and probable human carcinogens (IARC Group 2A) reported in cigarette smoke and/or unburned tobacco. Cigarette smoke contains more carcinogens than unburned tobacco (i.e., cigarette tobacco and smokeless tobacco products including chewing tobacco and oral snuff) because of the formation of carcinogens during combustion. (Adapted from Borgerding and Klus).[241]

IARC Group 1 (Human Carcinogen)	IARC Group 2A (Probable Human Carcinogen)
4-Aminobiphenyl	2-Amino-3-methylimidazo (4,5-*f*)quinoline (IQ)
Arsenic	Acrylamide
Benzene	Dibenz[*a,h*]anthracene
Benzo[*a*]pyrene	Glycidol
Beryllium	Nitrogen mustard
1,3-Butadiene	*N*-Nitrosodiethylamine (DEN)
Cadmium	*N*-Nitrosodimethylamine (DMN)
Chromium (hexavalent)	Tetrachloroethylene
Ethylene oxide	
Formaldehyde	
N-Nitrosonornicotine (NNN)	
2-Naphthylamine	
Nickel	
o-Toluidine (2-methylaniline)	
^{222}Radon and decay (^{210}Po) products	
Trichloroethylene	
Vinyl chloride	

Environmental Tobacco Smoke Also known as second-hand, involuntary, or passive smoke, environmental tobacco smoke (ETS) is the aged, diluted mixture of exhaled mainstream and sidestream smoke released from the burning cigarette tip. ETS undergoes various physical and chemical changes during rapid diffusion and dispersion into the atmosphere, including reactions with chemicals in the atmosphere that are absent in tobacco smoke. Consequently, chemical concentrations in ETS vary with environmental conditions and time.[245] Although environmental tobacco smoke contains the same chemical compounds as mainstream and sidestream smoke, the concentrations, phase distributions, and component particle sizes of environmental tobacco smoke differ from mainstream and sidestream smoke.[246] Environmental tobacco smoke contains ~$^3/_4$ of the particulate matter in mainstream smoke along with very little formaldehyde; the latter reacts almost instantaneously with ammonia in the atmosphere to form hexamethylenetetramine.[241] Nicotine

TABLE 49.22. Yield of several human carcinogens (IARC Group 1) reportedly released into mainstream cigarette smoke during smoking, expressed as μg/cigarette. (Adapted from Smith et al.).[242]

Substance	IARC Cancer Group	Reported Range (μg/Cigarette)
4-Aminobiphenyl	1	0.00019–0.005
Arsenic	1	0–1.4
Benzene	1	0.05–104
Beryllium	1	0–0.0005
Cadmium	1	0–6.67
Chromium	1	0.0002–0.5
2-Naphthylamine	1	0.0002–0.022
Nickel	1	0–0.51
Vinyl chloride	1	0.0013–0.0158

in ETS exists almost exclusively (i.e., ~95%) in the gaseous phase. Table 49.24 lists typical concentrations of selected constituents of ETS demonstrating the substantial quantitative differences in these constituents between ETS and other types of cigarette smoke. As the atmosphere dilutes sidestream smoke and ETS ages, nicotine evaporates from sidestream smoke.[247]

Smokeless Tobacco Smokeless tobacco refers to unburned tobacco that is applied to the gums or buccal mucosa, chewed (e.g., betel quid, areca nut, slaked lime, zarda), sucked (gutka, mawa, moist snuff, khaini, shammah, safa, snus, toombak), or insufflated as a fine powder (dry or liquid snuff). Most uses of smokeless tobacco involve placement of the material adjacent to the lips or between the gums and cheek rather than sniffing. The specific constituents of smokeless tobacco vary substantially by geographical region, with the largest medical literature on American and Swedish smokeless tobacco products; although the chemical concentrations within both individual contemporary products are relatively uniform, tobacco-specific nitrosamine concentrations are traditionally lower in moist Swedish snus than American snuff.[248,249] The American product contains lightly chopped, baked, or fire-cured tobacco leaves compared with finely chopped Swedish snus that contains moist, sun-cured, or air-fired tobacco leaves mixed with salts, humidifying agents, and substantially higher nicotine concentrations.[250]

The chemical composition of these tobacco products depends on the specific tobacco species/strain, growing conditions, processing/curing, and aging used to determine the pH and nicotine bioavailability.

TABLE 49.23. Estimated sidestream/mainstream ratios for the yield of some components of cigarette smoke. The actual yields depend on the physiochemical properties of the specific chemical and the cigarette construction (e.g., filter, paper, tobacco blend). (Adapted from Borgerding and Klus).[241]

Substance	Sidestream/ Mainstream Ratio
3-Methylvaleric acid	0.8–1.5
4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanone (NNK)	1–4
4-(*N*-Nitrosomethylamino) 1-(3-pydridyl)-1-butanone (NNK)	0.40
Acetaldehyde	1.4
Acetic acid	1.9–3.9
Acetonitrile	3–5
Acrolein	8–18
Ammonia	40–450
Aniline	30
Anthracene	30
Benzene	5–10
Benzo[*a*]pyrene	2–20
Cadmium	4–7
Carbon dioxide	8–11
Carbon monoxide	2.5–4.7
Catechol	0.6–0.9
Formaldehyde	36
Hydrogen cyanide	0.06–0.5
Isoprene	13–19
Methylamine	4.2–6.4
Naphthalene	17
Nicotine	2.6–7
N-Nitrosoanatabine	0.3–1
N-Nitrosodimethylamine	10–50
N-Nitrosonornicotine (NNN)	0.4–3
N-Nitrosopyrrolidine	6–30
Phenanthrene	2–30
Phenol	1.6–3.0
Pyridine	6.5–20
Quinoline	8–11
Toluene	6–8
Water	24–30

The pH influences nicotine absorption, whereas the nitrate/nitrite content affect nicotine-derived tobacco-specific *N*-nitrosamine concentrations.[251] These tobacco products contain at least 30 carcinogens, including tobacco-specific *N*-nitrosamines (e.g., *N*′-nitrosonornicotine, 4-(methylnitrosamino)-1-(3-pyridyl)-1-butanone), *N*-nitrosamine acids (e.g., *N*-nitrososarcosine, *N*-nitrosoazetidine-4-carboxylic acid, 3-(methylnitrosamino)propionic acid, 4-(methylnitrosamino) butyric acid), volatile *N*-nitrosamines (*N*-nitrosodimethylamine, *N*-nitrosopyrrolidine, *N*-nitrosopiperidine), polycyclic aromatic hydrocarbons (benzo[*a*]pyrene, benz[*a*]anthracene, chrysene, benzo[*b*]fluoranthene, dibenz[*a*,*h*]-

TABLE 49.24. Typical concentrations of some constituents of environmental tobacco smoke. (Adapted from IARC).[245]

Substance	Concentration ($\mu g/m^3$)
1,3-Butadiene	20–40
4-(*N*-Nitrosomethylamino) 1-(3-pydridyl)-1-butanone (NNK)	0.0007–0.023
Acetaldehyde	200–300
Benzene	15–30
Benzo[*a*]pyrene	0.00037–0.0017
Carbon monoxide	6,250–25,000
Formaldehyde	100–140
Nicotine	10–100
N-Nitrosonornicotine (NNN)	0.0002–0.0293

anthracene), and volatile aldehydes (acetaldehyde, formaldehyde).

Lung Cancer

Lung cancer is the leading cause of cancer-related deaths in men and women, with lung cancer mortality increasing in women from the 1930s until 2003; lung cancer mortality in men began decreasing in the 1980s.[252,253] The lung cancer incidence in women exceeded breast cancer for the first time in 1987. Approximately twice as many women as men with the same smoking history develop lung cancer; potential genetic susceptibilities in women include increased CYP1A1 expression and PAH metabolism, decreased glutathione S-transferase M1 and enhanced formation of reactive oxygen species, increased mutations of the tumor suppressor gene *P53*, and decreased activation of gastrin-releasing peptide receptor.[254] Occupational exposure to chemical carcinogens causes a relative small portion of lung cancers in men compared with tobacco smoking;[255,256] an acknowledged history of current or prior smoking occurs in ~85–90% of US lung cancer cases, primarily involving cigarette smoke.[257]

Smoking duration is the strongest determinant of lung cancer incidence; the risk is dependent, to a lesser extent, on intensity (i.e., daily cigarette consumption), based on studies using self-administered questionnaires.[258] Using questionnaire-based assessments of absolute, age-adjusted excess rates of lung cancer among smoking British physicians and multistage modeling, the hypothetical dose-response curve for absolute excess lung cancer rate fits a linear relationship to the fourth power of smoking duration and the second power (square) of smoking intensity.[259] For lung cancer and cigarette smoking, the lung cancer risk is monotonically related to cumulative smoking (pack-years). In contrast to low linear energy transfer radiation (e.g., fractionated X-ray exposure), modeling of excess odds ratios for total exposure based on pack-years suggests greater risk for a cumulative exposure delivered at a lower intensity (i.e., <20 cigarettes/day) for a longer duration than an equivalent cumulative exposure delivered at a higher intensity and shorter duration.[260] This difference may reflect different mechanisms involved with X-ray and cigarette smoke exposures. Using data from 15 case-control studies of cigarette smoking and lung cancer in the SYNERGY study, a flexible excess odds ratio model that was linear in cumulative exposure and nonlinear in exposure intensity also detected reduced effects of cumulative cigarette smoking on the higher portion of the dose-response curve (i.e., >20–30 cigarettes/day).[261] Studies using serum or urine cotinine concentrations to assess smoking intensity did not demonstrate a similar plateau on the upper portion of the dose-response curve. In a prospective study of 1,741 Norwegian volunteers with lung cancer and 1,741 matched controls (serum cotinine ≤5 ng/mL), the odds ratio of lung cancer increased linearly up to the highest exposure level (serum cotinine level of >378 ng/mL; OR = 55.1, 95% CI: 35.7–85.0).[262] These findings suggest altered smoking techniques (e.g., reduced inhalation/cigarette) and/or exposure misclassification may account for the differences in the models. Serum cotinine concentrations are measures of recent (i.e., few days) exposure, and pack-years of cigarette smoking have a limited sensitivity at lower smoking intensities.

Histology Lung cancer consists of four major histological subtypes: squamous cell carcinoma, adenocarcinoma, large cell carcinomas (primarily undifferentiated tumors), and small cell carcinomas. The first three tumor types are frequently classified together as non-small cell carcinomas. Most squamous cell and small cell carcinomas arise from the epithelial cells of the centrally located large- and medium-sized bronchi. In contrast, most adenocarcinomas arise from the epithelial cells in the peripherally located bronchioles and alveoli. Although cigarette smoking increases the risk of all histological types of lung cancer, the association is weaker between smoking and adenocarcinoma (i.e., relative risk, ~2–5) than squamous or small cell lung carcinomas. Histological patterns of smoking-related lung cancer in men and women have changed since the 1950s because of the increased incidence of adenocarcinoma compared with squamous cell carcinoma. A histological study of bronchogenic cancer in 1950 demonstrated that squamous cell carcinoma was ~17 times more common than adenocarcinoma.[263] A more recent study indicated the squamous cell carcinoma/adenocarcinoma ratio in male smokers decreased to 2.4:1 in 1970 and 1.4:1 by

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

1986.[264] The ratio of women smokers decreased from 3.4:1 in 1950 to 0.57:1 by 1986. Adenocarcinoma is now the most common lung cancer type in the United States. Part of the increased prominence of adenocarcinoma may reflect the reduction in the risk of squamous cell carcinoma associated with changes in smoking habits (i.e., the lifelong use of filter cigarettes) and cigarette construction, particularly in women.[265] In a case-control study of 2,292 lung cancer patients, the odds ratio for squamous cell carcinoma in male lifelong filter and nonfilter cigarette smokers was not statistically different (OR = 0.8, 95% CI: 0.5–1.2); however, the odds ratio for squamous cell carcinoma in female lifelong filter cigarette smokers was significantly reduced (OR = 0.4, 95% CI: 0.2–0.8) compared with female lifelong nonfilter cigarette smokers. There was no reduction in the risk of adenocarcinoma for male and female lifelong filter cigarette smokers in comparison to the risks for nonfilter cigarette smokers.[266]

TABLE 49.25. Dose-response data on risk ratios for lung cancer and smoking. (Adapted from Damber and Larsson).[267]

Study	Study Type	Cigarettes/ Day	Risk Ratio
Doll and Peto[277]	Cohort	1–14	7.8
		15–24	12.7
		≥25	25.1
Hammond[275]	Cohort	1–9	4.6
		10–19	8.6
		20–39	14.7
		≥40	18.8
Cederlof et al.[276]	Cohort	1–7	2.3
		8–15	8.8
		≥16	13.9
Damber and Larsson[267]	Case-control	1–7	2.3
		8–15	7.3
		≥16	10.2

Mainstream Cigarette Smoke Tobacco smoking accounts for the vast majority of lung cancer mortality in the world.[255,267] In US birth cohorts over the last 75 years, lung cancer incidence and mortality primarily reflect patterns of active cigarette smoking.[268] The percentage of lung cancers associated with adenocarcinoma has increased dramatically since the 1980s, despite substantial reductions in the amount of tar and nicotine in cigarette smoke, partially reflecting the enhancement of nitrogen oxides and volatile tobacco-specific *N*-nitrosamines in cigarette smoke.[269] Factors contributing to lung cancer risks include coexposure to other potential carcinogens (e.g., arsenic, asbestos, cadmium, environmental tobacco smoke, PAHs, radon, vinyl chloride), diet, genetic susceptibility, hormonal influences/estrogen receptors in women with nonsmall cell lung cancer,[270,271] and chronic inflammation (e.g., HPV infections),[272] particularly in women without a smoking history.[254,257]

The risk of developing cancer from smoking is a dose-related phenomenon. Individuals smoking >40 cigarettes/day are high-risk candidates for lung cancer, whereas the increased risk in a person smoking <4 cigarettes/day is difficult to quantify. In a case–control study of 194 cases of lung cancer, the odds ratio (OR) for developing lung cancer in patients with a >40 pack-years history was 16.19 (95% CI: 5.1–51.33) compared with 8.33 (95% CI: 2.77–25.05) for smoking histories of >20–40 pack-years.[273] Cigar smoking is also causally associated with lung cancer; however, the risk of developing lung cancer is substantially lower for cigar smokers than for cigarette smokers.[235] Women appear more susceptible to the carcinogenic effects of cigarette smoke; the adjusted odds ratios for the major lung cancer subtypes at all smoking levels are consistently higher for women than men, particularly adenocarcinoma.[274] Table 49.25 enumerates the risk ratios between smokers and nonsmokers based on the number of cigarettes smoked per day in several studies.[275,276]

The risk of acquiring lung cancer from smoking declines beginning ~5 years after cessation of cigarette smoking, initially from elimination of the promoting effects of cigarette smoke.[278] Thereafter, the risk declines exponentially until mortality ratios of former smokers and nonsmokers are similar ~15–20 years after cessation of cigarette smoking.[277,279] The reduction in the elevated risk of lung cancer is partly dependent on the duration and intensity of previous smoking.

Mainstream Cigar/Pipe Smoking Although cigar, pipe, and cigarette smoke contain similar carcinogens, cigar and pipe tobacco consumption has increased while cigarette tobacco consumption has decreased. From 2000–2015, US cigarette tobacco consumption decreased by ~39% compared with increased large cigar (~180%) and pipe (~550%) tobacco consumption.[280] Most epidemiology studies indicate cigar and pipe smoking produce smaller, albeit significant lung cancer risk compared with cigarette smoking; potential factors contributing to the relatively lower risk associated with cigar/pipe smoking include less overall daily carcinogen exposure (e.g., inhalation depth, cigar size, smoking frequency, nicotine delivery).[281] Using Cox regression and random effects models in a meta-analysis of five prospective cohort studies from the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

United States, Netherlands, and Australia, the adjusted hazard ratio for lung cancer in exclusive cigar and/or pipe smokers was 2.04 (95% CI: 1.68–2.47) when compared with never-smokers of any tobacco product.[282] The risk of developing a smoking-related cancer in ever-smokers of cigars and/or pipes was also increased (overall HR = 1.07, 95% CI: 1.03–1.12). The US Cancer Prevention Study II recorded 23,589 deaths during an 18-year follow-up; Cox proportional hazard models demonstrated increased lung cancer mortality in current pipe smokers (adjusted HR = 5.00, 95% CI: 4.16–6.10) compared with never-smokers.[283] The increase in the relative risk was dose-dependent, characterized by a statistically significant increase with duration (smoking years) and intensity (pipefuls/day). The relative risk of lung cancer in exclusive pipe smokers was similar to or greater than that in cigar smokers.

Environmental Tobacco Smoke (ETS) In 1982, the IARC classified ETS as carcinogenic to humans (Group 1), with a causal association with lung cancer in adults. Estimates of the equivalency of ETS and mainstream cigarette smoking based on plasma cotinine suggest daily ETS exposure of a nonsmoking spouse to ETS from a smoking spouse ranges in a dose-dependent relationship from 0.1–1 cigarette, depending on the amount of the spouse's smoking.[284] In a population survey of English adults, the cotinine concentrations of nonsmoking spouses averaged ~0.6–0.7% of the smoking spouse.[285] The distribution of cotinine values in nonsmokers was positively skewed, with the geometric mean ranging from 0.31 ng/mL in nonsmoking households to 1.99 ng/mL when the other spouse reportedly smoked ≥30 cigarettes daily. Physical differences (e.g., age, cytotoxicity, particle size and deposition, inhalation pattern, clearance mechanism, pH, enzyme induction) between mainstream and ETS smoke and questions regarding the exposure necessary for ETS to induce and/or promote the carcinogenic effects observed in epidemiological studies complicate the extrapolation of ETS risks based on mainstream smoking data.[286,287]

Several analyses of epidemiology studies of nonsmoking spouses living with cigarette smokers indicate ETS smoke increases lung cancer risk in the nonsmoking spouse when compared with spouses living with nonsmokers.[288] These studies indicate the association between a lifelong nonsmoker living with a smoking spouse and lung cancer is relatively small (i.e., RR = ~1.1–1.3) compared with mainstream smoke and consistent with some evidence suggesting the lung cancer risk decreases significantly when the first exposure occurs after the third decade of life.[289] In a meta-analysis of 33 case-control and 4 cohort studies of lifelong nonsmokers living with smoking spouses, the estimated pooled relative risk for lung cancer in nonsmoking spouses was 1.24 (95% CI: 1.13–1.36).[290] Although most case-control and cohort studies adjusted for confounding variables did not reach statistical significance, the authors believed strongly that heterogeneity, misclassification bias, and/or confounding did not account for the elevated pooled relative lung cancer risk. Other authors disagreed with the conclusions regarding the importance of bias and confounding factors.[291,292] In a meta-analysis of 7 cohort, 25 population-based case-control, and 23 hospital-based case-control studies, the pooled relative risk for lung cancer in never-smoking spouses of tobacco smokers was 1.27 (95% CI: 1.17–1.37).[293] A meta-analysis of 22 studies of workplace environmental tobacco smoke exposure from multiple locations worldwide and lung cancer risk demonstrated similar relative risks. This study by Stayer and Bena et al. published in 2007 reported a 24% increase in lung cancer risk among workers exposed to environmental tobacco smoke (RR = 1.24, 95% CI: 1.18–1.29) with a 2-fold increased risk for workers classified as highly exposed to ETS (RR = 2.01, 95% CI: 1.33–2.60).

Smokeless Tobacco The association between lung cancer and smokeless tobacco products is relatively weaker compared with tobacco smoking.[294] In the prospective US Cancer Prevention cohort study of exclusive snuff and chewing tobacco users followed from 1982–2000 (CPS-II), the multivariate-adjusted hazard ratio for lung cancer mortality in current chew/snuff users was statistically significant (HR = 2.00, 95% CI: 1.23–3.24; n = 18) compared with nontobacco users based on questionnaires.[295] The first Cancer Prevention Study (CPS-I 1959–1972) did not detect a similar elevated risk of lung cancer mortality in current chew/snuff users (HR = 1.08, 95% CI: 0.64–1.83; n = 18). The Mumbai cohort study of 33,682 exclusive smokeless tobacco male users followed for an average of 5.5 years did not demonstrate an elevated risk of developing bronchial or lung cancer when compared with nontobacco users (adjusted HR = 1.59, 95% CI: 0.87–2.90; n = 34).[296] Similarly, the Swedish cohort study of 279,897 male construction workers followed from 1969–1992 did not find an elevated rate of lung cancer in current exclusive snuff (snus) users compared with never-tobacco users (RR = 0.8, 95% CI: 0.4–1.3; n = 15).[297]

Nonpulmonary Cancers

Mainstream Cigarette Smoke Nonpulmonary sites causally associated with cigarette smoking include the mouth, larynx, nasal cavity (squamous cell carcinoma), nasopharynx, esophagus, stomach (adenocarcinoma), pancreas, kidney, and urinary bladder.[235] Mouth, larynx, and esophagus (squamous cell and adenocarcinoma) cancers are strongly correlated to tobacco consumption; studies of mouth, pharyngeal, and laryngeal cancers indicate cessation of smoking reduces cancer risks to near unity after ≥10 years compared with nonsmokers. In a Brazilian case-control study of 784 cases of mouth, pharynx, and larynx cancers and 1,578 noncancer controls, the relative risk of all upper aerodigestive tract cancers for ex-smokers was 1.98 (95% CI = 1.0–3.8) compared with never-smokers.[298] After quitting commercial cigarettes for >10 years, the relative risk was nonsignificant (RR = 1.45, 95% CI: 0.7–3.0) when compared with never-smokers. The relative risk of current smokers was ~6. In comparison with pharyngeal and laryngeal cancers, the relative risks for esophageal cancer based on smoking duration and intensity are somewhat lower.

Tobacco smoking is a significant contributory cause of pancreatic, bladder, and renal cell cancers.[299] In a meta-analysis of 82 published studies (1950–2007) containing epidemiological information about smoking and pancreatic cancer, the overall pancreatic cancer risk for current smokers was 1.74 (95% CI: 1.61–1.87) and 1.2 (95% CI: 1.11–1.29) for former smokers, with substantial heterogeneity between studies.[300] The results of studies on smoking and renal-cell cancer are somewhat inconsistent. In a meta-analysis of 19 case-control and 5 cohort studies, the relative risk for smoking men was 1.54 (95% CI: 1.42–1.68) and 1.22 (95% CI: 1.09–1.36) for smoking women, with a dose-response relationship between cumulative smoking history and the risk of renal-cell cancer. In an update of a prospective cohort study of 17,363 London-based male government employees (age 40–69 years) followed for 38 years, the hazard ratio for 68 deaths from kidney cancer was 0.64 (95% CI: 0.32–1.26) for former smokers and 1.29 (95% CI: 0.69–2.41) for current smokers.[301] Smoking increases the risk of transitional cell and squamous cell carcinomas of the bladder, ureter, and renal pelvis in men and women; the relationship is dose-dependent. In the 50-year follow-up of British physicians, the mortality rates/100,000/year for bladder cancer were 13.7 in never-smokers, 37.7 in smokers of 1–14 cigarettes/day, 31.8 in smokers of 15–24 cigarettes/day, and 51.4 in smokers of ≥25 cigarettes/day based on 220 bladder cancer-related deaths.[302] The mortality rate for bladder cancer in lifelong nonsmokers was 13.7.

Weaker, but significant, associations also occur between tobacco smoking and myeloid leukemia, stomach cancer, and liver cancer.[303] The risk of myeloid leukemia increases with the amount of tobacco smoked in studies with adequate design. A cohort study of 330,000 Swedish construction workers included 372 incident cases of acute and chronic myeloid leukemias.[304] The association between acute myeloid leukemia and smoking intensity was statistically significant in current smokers (RR = 1.5, 95% CI: 1.06–2.11), whereas there was no statistically significant association between smoking and chronic myeloid leukemia. When compared with never-smokers, current smokers have ~50% increased risk of developing stomach cancer. In a meta-analysis of high-quality gastric cancer studies (1997–2006), the odds ratios of current and ever-smokers developing gastric cancer were 1.57 (95% CI: 1.24–2.01) and 1.48 (95% CI: 1.28–1.71), respectively, compared with never-smokers.[305] After quitting for 5–15 years, the difference in gastric cancer incidence between never-smokers and ex-smokers becomes statistically non-significant.[306] In a meta-analysis of 38 cohort and 58 case-control studies, almost exclusively from Asia, the adjusted summary relative risk of liver cancer for current smokers was 1.51 (95% CI: 1.37–1.67) and 1.12 (0.78–1.60) for former smokers compared with never-smokers.

The risk of developing colorectal cancer from cigarette smoking is relatively small. A meta-analysis of 36 cohort studies demonstrated a 15% increase in colorectal cancer incidence and a 27% increase in colorectal cancer mortality, with the association stronger for rectal than colon cancer. Data suggest the association between colorectal cancer and smoking may primarily result from a subtype of colorectal cancer developing during hyperplastic polyp progression.[125] The association between breast cancer and tobacco smoking is weaker and less consistent than that between most other smoking-related cancers, with relative risks ranging from 1.2–1.3. Tobacco smoking does not significantly affect the cancer incidence of the postmenopausal uterus, prostate, or thyroid.[125] Confounding factors associated with cigarette smokers when compared with nonsmokers in epidemiology studies include higher alcohol consumption, physical inactivity, lower fruit/vegetable consumption, higher fat/meat consumption, and less screening for colorectal cancer.

Mainstream Cigar/Pipe Smoke The risk of developing nonpulmonary cancers is substantially lower in cigar/pipe smokers than in cigarette smokers.[280] Although the risk of lung cancer is considerably lower for cigar smokers than for cigarette smokers, cigar smoking is causally

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

associated with cancer of the oral cavity, pharynx, pancreas, and urinary bladder.[307] In an analysis of pooled data from the International Head and Neck Cancer Epidemiology (INHANCE) Consortium comprising 13,935 cases and 18,691 controls in 19 studies from 1981–2007, the risk of developing head and neck cancer in exclusive cigar smokers was 3.49 (95% CI: 2.58–4.73; n = 110 cases) and 3.71 (95% CI: 2.59–5.33; n = 77 cases) in exclusive pipe smokers.[308] The study excluded esophageal, nasopharyngeal, and salivary gland cancers. A meta-analysis of five cohort studies indicated exclusive cigar and/or pipe smoking is associated with a statistically significant increase in the risk for head and neck cancers (HR = 1.51, 95% CI: 1.22–1.87) and liver cancers (HR = 1.56, 95% CI: 1.08–2.26) when compared with never-smokers based on questionnaire data.[282] The hazard ratios for pancreatic cancer (HR = 1.19, 95% CI: 0.91–1.57; n = 128 cases) and bladder cancer (HR = 1.16, 95% CI: 0.98–1.37; n = 242 cases) were not statistically different than never-smoker rates. The US Cancer Prevention Study II detected statistically significant increases in multivariable-adjusted hazard ratios in current exclusive pipe smokers for death from oropharyngeal cancer (HR = 3.90, 95% CI: 2.15–7.08; n = 15 cases), laryngeal cancer (HR = 13.1, 95% CI: 5.2–33.1; n = 10), and pancreatic cancer (HR = 1.61, 95% CI: 1.24–2.09; n = 64) compared with never-smokers.[283] The hazard ratio for bladder cancer was not statistically different from never-smokers (HR = 1.50, 95% CI: 0.94–2.39; n = 20 cases).

Environmental Tobacco Smoke The associations between environmental tobacco smoke and risk of nonpulmonary cancers are relatively weak and inconsistent, including cancers of the nasopharynx, brain and central nervous system, stomach, colon, rectum, pancreas, liver (hepatocellular carcinoma), kidney (renal cell carcinoma), urinary bladder, cervix, ovary, and testes.[309] Although large cohort studies in Europe and North America do not support an association between ETS and breast cancer,[310,311] subgroup analysis of some case-control studies suggests an increased breast cancer risk in premenopausal women exposed to ETS;[312] however, weaker association of cohort studies and lack of a plausible explanation why the effect on lung cancer risk would be much greater for ETS than mainstream smoking limit conclusions regarding causation.

Major childhood cancer sites are extremely heterogeneous, and subtypes are difficult to study because of the lack of adequate sample sizes and exposure assessments. Although these studies suggest the possibility of an association between preconception paternal and/or maternal smoking and several childhood cancers (e.g., hepatoblastoma, RR ≅ 2.0–5.5;[313] leukemia, RR ≅ 1.5–4),[314] conclusions regarding causality are limited by small sample sizes, adequate adjustment of cofounders (e.g., socioeconomic status, race, parental age, sex, birth weight, gestational age, age at exposure), and potential recall bias. Maternal tobacco smoking during pregnancy generally demonstrated inconsistent results, including modest increases in risk, null results, and inverse relationships. Most evidence associating other childhood cancers is inconsistent or null, including brain cancer, Ewing's sarcoma, germ cell tumors, neuroblastoma, rhabdomyosarcomas, reticuloendothelial sarcomas, soft tissue sarcomas, and Wilms' tumor.[125]

Smokeless Tobacco Several factors complicate the determination of the magnitude and significance of the cancer risk following the use of smokeless tobacco products including small case numbers and inconsistent results, recall bias from the use of questionnaires, potential misclassification of cancer coding and smoking status, inconsistent definitions of exposure, and wide variation in the carcinogenic potency of smokeless tobacco products. Analysis of 53 oral tobacco products from 5 World Health Organization regions detected an ~500-fold variation in unionized nicotine content (0.2–99.1%) and extremely large variations in tobacco-specific *N*-nitrosamines with 4-(N-Nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK) ranging from 0.0045–516 μg/g product.[315] The latter carcinogen exists in some products (e.g., khaini, toombak, zarda) in particularly high concentrations. Consequently, the results of studies differ between countries.

The association between smokeless tobacco use and cancer is strongest for oropharyngeal cancer in the United States, whereas the association is weaker for the use of Scandinavian snuff.[294] In a US population-based case-control study of 1,046 cases and 1,239 frequency-matched controls, the association between ever-smokeless tobacco use and squamous cell carcinoma of the head and neck was not statistically significant (OR = 1.20, 95% CI: 0.67–2.16).[316] The association was statistically significant comparing lifetime smokeless tobacco users with ≥10 years of use and never-users (OR = 4.43, 95% CI: 1.47–13.36; n = 16 cases); however, the wide confidence intervals suggest design issues (recall bias, confounding). Although a meta-analysis of US and Asian epidemiological data found an increased risk of oral cancer (overall RR = 2.6, 95% CI: 1.3–5.2), northern European studies did not confirm the increased risk (RR = 1.0, 95% CI: 0.7–1.3).[317] Analysis of pooled data from 11 US

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

case-control studies from 1981–2006 in the International Head and Neck Cancer Epidemiology (INHANCE) Consortium demonstrated a statistically significant difference in the risk of head and neck cancer between never-cigarette smoking snuff users and nontobacco users (OR = 1.71, 95% CI: 1.08–2.70; $n = 44$ cases), but not among never-cigarette smoking, chewing tobacco users (OR = 1.20, 95% CI: 0.81–1.77; $n = 61$ cases).[318] The study did not detect a dose-response relationship between the intensity of snuff use or tobacco chewing and the development of head and neck cancer. The association was strongest for oral cancers in ever snuff users (OR = 3.01, 95% CI: 1.63–5.55; $n = 20$ cases) and ever chewing tobacco users (OR = 1.81, 95% CI: 1.04–3.17; $n = 23$ cases); however, the dose-response relationship was not statistically significant. Mortality from oropharyngeal cancers was not increased in exclusive US snuff and chewing tobacco users in the Cancer Prevention Studies when compared with never-tobacco users based on questionnaire responses.[295] Oral cancer was not associated with Scandinavian moist snuff (snus) when comparing current male construction workers using snus with never-users of any tobacco products (RR = 0.9, 95% CI: 0.4–1.8; $n = 9$ cases).[297] Similarly, in a prospective study of 10,136 Norwegian men enrolled since 1966, the incidence of oropharyngeal cancer was not increased in current snus users compared with never-tobacco users (RR = 1.13, 95% CI: 0.45–2.83; $n = 6$).[319] The relative risk of pancreatic cancer was borderline significant in current snus users (RR = 1.60, 95% CI: 1.00–2.55; $n = 27$ cases).

Alcohol

Exposure

Most alcoholic beverages contain primarily ethanol and water along with volatile and nonvolatile flavoring compounds and contaminants. Although the exact constituents of many alcoholic beverages are trade secrets, potential carcinogens include acetaldehyde (a metabolite that disrupts DNA repair, methylation, and synthesis.), aflatoxins, arsenic, asbestos, nitrosamines, and ethyl carbamate (urethane); the latter is an IARC Group 2A carcinogen present in alcoholic beverages (whisky, wine) and fermented food products (e.g., bread, cheese, soy sauce).[320] These alcohol contaminants are usually present in relatively low concentrations, particularly in more current times.[321] Typically, the ethanol source in alcoholic drinks is biological rather than synthetic because of the potential presence of impurities in ethanol produced from ethylene. In the general population, individual-level alcohol consumption data are preferred to sales data as an exposure measure; the former allows comparison of drinking patterns between population subgroups and evaluation of medical consequences after adjustment for confounders and individual characteristics. However, self-reported alcohol consumption accounts for only 40–60% of total alcohol sales, particularly among heavy drinkers.[322,323] In addition to recall bias, general population surveys usually canvas private households rather than populations without permanent locations (e.g., homeless, institutionalized residents, prisoners, students, military personnel); these groups are often associated with heavy drinking patterns.[324] Factors important in the evaluation of alcohol consumption include average volume, alcohol consumption status, frequency, and occurrence/volume of binge drinking. The alcohol content in standard measures for most alcoholic drinks (e.g., wine, beer, spirits) ranges from 10–14 g; however, these measures vary between countries. The US Department of Agriculture food consumption tables list the following ethanol content for standard alcoholic drinks: wine, 11.3 g; regular beer, 12.8 g; light beer, 11.3; and hard liquor, 14.0 g.[325] The Dietary Guidelines for Americans define 14 g of ethanol as a standard drink, equivalent to approximately 12oz of beer, 5 oz of wine, and 1.5 oz of distilled spirits. In Canada, the standard drink typically contains 13.6 g compared with 8 g in the UK and 10 g in Australia and New Zealand; however, several studies indicate actual serving sizes of drinks vary substantially from the "standard drink."[326] Assuming a standard drink contains 14 g of ethanol, the corresponding volumes are typically 330 mL of beer, 150 mL of wine, and 36 mL of hard liquor. The definition of heavy drinking varies between institutions and regions, with heavy drinking variously defined as ≥5 drinks or >50–60 g of alcohol.[327,328] Drinking in moderation typically is a daily drinking pattern not exceeding two drinks in men and one drink in women. Evidence is insufficient to support an association between daily alcohol consumption in men drinking ≤2 standard drinks or women drinking ≤1 standard drink and cancers of the esophagus, larynx, oral cavity, or pharynx.

Cancer Sites

The US National Toxicology Program (USNTP) lists alcohol beverage consumption as a known carcinogen based on sufficient evidence of carcinogenicity from human studies. IARC classifies alcoholic beverages as human carcinogens (Group 1) based on sufficient evidence in humans and experimental animals, including sufficient evidence of carcinogenicity in experimental animals for the carcinogenicity of the ethanol metabolite, acetaldehyde. The biological basis underlying the association between alcohol consumption and cancer is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

not well defined; potential mechanisms include reactive metabolites, acetaldehyde-induced cell proliferation from disruption of DNA synthesis, methylation, and repair, oxidative stress with lipid peroxidation, reduced retinoic acid concentrations, alteration of hormone levels/estrogen receptors, and epigenetic influences (e.g., decreased methylation). Both organizations categorize oral cavity, pharynx, larynx, and esophagus as sites of alcohol-related cancers. Genetic epidemiological studies suggest alcohol dehydrogenase 1B variant (*ADH1B*1/*1*) polymorphism and the heterozygous aldehyde dehydrogenase 2 (*ALDH2*) genotype increase interindividual susceptibility to esophageal cancer and cancers of the upper aerodigestive tract combined, particularly the hypopharynx in Japanese studies with a high prevalence of *ALDH2* genotype.[329] These studies indicate the importance of the variant allele and elevated acetaldehyde concentrations in the development of head and neck cancers. East Asians and Caucasians with the *ADH1B*1/*1* genotype have an elevated risk of excessive alcohol consumption because of less active alcohol dehydrogenase.[330]

The IARC also associates alcohol beverages with cancer in the colorectum, liver, and female breast, whereas the NTP considers the evidence supporting cancer in the latter two sites weaker than the above four cancer types and possibly causal. Studies associating other cancer sites are inconsistent and/or limited in determining a causal relationship including bladder, brain, cervix, endometrium, Hodgkin disease, leukemia, lung, melanoma, multiple myeloma, ovary, pancreas, prostate, stomach, testis, thyroid, vagina, and vulva.[321] The risks of developing alcohol-related cancers do not typically vary significantly by beverage type or sex.

Many studies evaluate current drinking patterns (e.g., alcohol use at the beginning of a cohort or prior to diagnosis in case-control studies); however, lifetime alcohol consumption is also associated with elevated risks of cancer at multiple sites. A meta-analysis of long-term alcohol consumption and cancer comparing the highest and lowest intake categories demonstrated elevated adjusted, pooled relative risks for oral cavity and pharynx (RR = 4.84, 95% CI: 2.51–9.32), larynx (RR = 2.25, 95% CI: 1.49–3.42), esophagus (RR = 6.71, 95% CI: 4.21–10.70), and colorectal (RR = 1.45, 95% CI: 1.22–1.71) cancers.[331] The association between breast cancer and cumulative alcohol consumption was weak and nonlinear, whereas the dose-response relationship for colorectal cancer was modest and linear. In the National Institutes of Health-AARP Diet and Health Study of ~500,000 persons, the hazard ratio comparing light (0.5–>1 drink/day) and nonalcohol drinkers was 0.89 (95% CI: 0.82–0.96), whereas the hazard ratio for heavy alcohol drinkers (>7 drinks/day) was not statistically significant at 1.11 (95% CI: 1.00–1.24).[332] The authors noted a modest increase in adenocarcinoma among heavier drinkers and a nonlinear reduction in squamous cell carcinoma that attenuated with increasing alcohol consumption.

Oral Cavity/Pharynx Cancers of the mouth and pharynx are consistently and strongly associated with alcohol consumption and tobacco smoking in a dose-related relationship across various regions and populations after adjustment for confounding (e.g., smoking), particularly among heavy drinkers. Compared with nondrinkers, the risk for these cancers in heavy drinkers (i.e., regular consumption of ~50 g ethanol daily) is ~3-fold with a range of ~4–8.[321] Risks of developing these cancers is small and difficult to detect in light alcohol drinkers (<1–2 drinks daily).[333,334] Elevated risks of mouth and pharyngeal cancers occur in nonsmoking and smoking drinkers of alcoholic beverages; the risk of these cancers with smoking and drinking alcoholic beverages is multiplicative, characterized by higher risks than nondrinking smokers or nonsmoking drinkers. Most studies demonstrate synergistic effects of cigarette smoking and alcohol consumption, primarily as a multiplicative interaction.[335] Heterogeneity among studies, small number of cases in nondrinking, nonsmoking individuals, and difficulty identifying the amount of each type of drink consumed complicate the determination of risks associated with each type of alcoholic beverage. In US studies, beer consumption has the highest risk of developing oral cavity/pharyngeal cancers,[336] whereas wine and hard liquor have the highest risks in Italy[337] and Latin America,[335] respectively. The risk of these cancers is lower in former than current alcoholic beverage drinkers, with risks returning to levels associated with nondrinkers after 10–20 years.[338]

Larynx Multiple studies across various populations throughout the world associate laryngeal cancer with alcohol consumption and tobacco smoking; this relationship is dose-dependent with an ~2-fold increased risk when comparing heavy drinkers (>50 g alcohol daily) with nondrinkers and light drinkers.[321] In a meta-analysis of 38 case-control, 2 cohort studies, the relative risk of developing laryngeal cancer was 1.90 (95% CI: 1.59–2.28) for alcohol drinkers compared with nondrinkers.[339] The risk of light alcohol drinking (≤1 drink/day) was not statistically significant (RR = 0.88, 95% CI: 0.71–1.08), whereas elevated relative risks were detected in moderate drinkers (>1–<4 drinks/day; RR = 1.47, 95% CI: 1.25–1.72) and heavy drinkers (≥4 drinks/day; RR = 2.62, 95% CI:

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

2.13–3.23). Tobacco smoking is a strong risk factor for developing laryngeal cancer with the interaction of tobacco smoking and heavy alcohol drinking being multiplicative.[340] Increased risk of laryngeal cancer occurs in alcohol drinkers and abstainers. In a pooled analysis of never-tobacco users, the odds ratio for laryngeal cancer in heavy drinking (≥5 drinks/day) never-tobacco users was 2.81 (95% CI: 1.49–5.27; $n = 65$).[341] Based on limited information, data suggest the most frequently consumed beverage in each population is usually associated with the highest risk of developing laryngeal cancer.[342]

Esophageal The risk of developing esophageal squamous cell carcinoma is consistently elevated in most studies worldwide, with an overall ~2-fold increase in heavy alcohol drinkers (>50 g alcohol/day) compared with nondrinkers after controlling for tobacco smoking. The specific risk varies with study type, outcome measures, drinking intensity, population characteristics, and histological type. Most studies demonstrate a dose-response relationship between alcohol consumption and the risk of esophageal squamous cell cancer. In a prospective cohort study on *mortality* from esophageal cancer in the American Cancer Society Cancer Prevention Study I, the adjusted relative risk for 6 drinks daily was 5.79 (95% CI: 3.44–9.74, $n = 22$) compared with 1.61 (95% CI: 0.94–2.77, $n = 18$) for 2 drinks daily.[332] Elevated risks of esophageal squamous cell cancer are not consistently related to beverage type.[343]

Studies of the interaction of tobacco smoking and alcohol consumption indicate the relationship is usually multiplicative, with a few studies suggesting a relationship between additive and multiplicative. Compared with never-users, the adjusted risk of esophageal squamous cell carcinoma is significantly elevated in heavy Swedish users of tobacco and alcohol (OR = 23.1, 95% CI: 9.6–56.0).[343] The presence of the heterozygous aldehyde dehydrogenase two genotype increases acetaldehyde concentrations in blood and saliva; this polymorphism increases the susceptibility of these individuals to the development of esophageal squamous cell carcinoma, particularly in Asian studies where this polymorphism and cigarette smoking are relatively high.[344,345] The association between alcohol and esophageal squamous cell carcinoma is relatively weak in the absence of tobacco use. European case-control studies of former drinkers indicate that the risk of squamous cell carcinoma decreases after 10 years of abstinence.[346] Compared with nonsmoking, current drinkers, the risk of esophageal cancer decreased significantly after 10 years of abstinence (OR = 0.37, 95% CI: 0.14–0.99).[347]

Adenocarcinoma accounts for ~5% of esophageal cancers; in comparison to esophageal squamous cell carcinoma, the association between alcohol consumption and esophageal adenocarcinoma is weak and inconsistent.[321] Most case-control studies of esophageal cancer do not demonstrate a statistically significant increased risk of esophageal adenocarcinoma, even with high alcoholic beverage consumption levels. In a Swedish population-based, case-control study, the multivariately adjusted risk of developing esophageal adenocarcinoma in heavy drinkers (>70 g alcohol/day) was not significantly elevated compared with never-alcohol users (RR = 0.6, 95% CI: 0.3–1.1).[343]

Colorectum Cohort studies and meta-analyses suggest a modestly increased colorectal cancer risk with the consumption of alcoholic beverages, primarily with moderately heavy alcohol consumption (e.g., >30 g alcohol/day).[348] In a meta-analysis of eight European and North American prospective cohort studies, increased colorectal cancer risk was limited to persons consuming ~≥2 drinks daily.[349] Compared with nondrinkers, the adjusted, pooled multivariate relative colorectal cancer risk for consumers of 2–3 drinks daily was 1.16 (95% CI: 0.99–1.36) and 1.41 (95% CI: 1.16–1.72) for persons consuming ≥4 drinks daily. Adjustment for the multivariate analysis included age, family history of colorectal cancer, height, education, physical activity, tobacco smoking, body mass index, use of nonsteroidal anti-inflammatory drugs/multivitamins, and energy intake/intake. In a meta-analysis of 27 cohort and 34 case-control studies using the random effects model and nondrinkers or occasional alcohol drinkers as referents, the estimated summary relative risk for moderate drinkers (2–3 drinks/day) was 1.21 (95% CI: 1.13–1.28) and 1.52 (95% CI: 1.27–1.81) for heavy drinkers (≥4 drinks/day).[350] The RR for light drinkers (≤1 drink/day) was 1.00 (95% CI: 0.95–1.05). For heavy drinkers, the association between colorectal cancer and alcohol consumption was stronger in Asian compared with Western populations (RR = 1.81, 95% CI: 1.33–2.46). A majority of prospective cohort studies of alcohol consumption and colorectal cancer did not detect statistically significant associations, while most positive cohort studies evaluated Japanese men or men of Japanese descent.[321]

Studies on the dose-response relationship between colorectal cancer and alcohol consumption are inconsistent; tobacco smoking does not appear to affect the relationship between colorectal cancer and alcohol use. Some studies suggest the possibility of a J-shaped dose-response curve for moderate alcohol consumption (≤3 drinks/day). In a Greek case-control study of 250

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

consecutive patients initially diagnosed with colorectal cancer and matched community controls, the odds ratio for moderate alcohol intake in men (12–35 g alcohol/day) was 0.35 (95% CI: 0.16–0.74) compared with controls (<12 g/day); the odds ratio for moderate intake in women was 0.40 (95% CI: 0.18–0.91).[351] The odds ratio for heavy drinkers (>48 g/day) was statistically significant only in men (OR = 3.45, 95% CI: 1.35–8.83).

Liver Heavy, but conceivably not light, consumption of alcoholic beverages is an independent risk factor for the development of primary liver cancer (hepatocellular carcinoma, HCC) based on worldwide cohort and case-control studies. Potential recall bias and altered ethanol intake from alcohol-related illness (e.g., cirrhosis) prior to the development of liver cancer complicate the interpretation of the precise risks associated with alcohol intake and liver cancer;[352] however, the risk from alcohol consumption is more moderate for liver cancer than upper aerodigestive tract cancers.[353] In a meta-analysis of six primarily nested case-control studies, the pooled relative risk (RR) for HCC in heavy drinkers (≥6 drinks/day, >75 g ethanol/day) compared with nondrinkers was 1.22 (95% CI: 1.10–1.35) with no significant heterogeneity ($I^2 = 0\%$, $P = 0.786$).[354] The pooled RR for moderate drinkers (<3 drinks/day) and HCC was not statistically significant (RR = 0.91, 95% CI: 0.81–1.02), based on 16 studies with significant heterogeneity ($I^2 = 65.6\%$, $P < 0.001$). In a meta-analysis of 2,294 cases from 17 case-control and 3 cohort studies, the pooled RR for liver cancer in heavy drinkers (≥~7 drinks/day) was 1.86 (95% CI: 1.53–2.27) compared with a RR of 1.17 (95% CI: 1.11–1.23) for light drinkers (<2 drinks/day).[352] A meta-analysis of light drinkers in 7 cohort and 13 case-control studies did not detect a statistically significant risk of liver cancer (RR = 1.03, 95% CI: 0.90–1.17).[355]

Confounders for HCC include tobacco smoking, aflatoxin-contaminated food, nonalcoholic fatty liver disease, and hereditary hemochromatosis. Most, but not all, cases of HCC involve cirrhotic livers with the cirrhosis being part of the pathogenic process of liver carcinogenesis. Chronic infections by hepatitis B and C viruses (HBV, HCV) are major confounders in studies of liver cancer, with an estimated 20-fold increase in HCC risks.[356] In a meta-analysis of 32 case-control studies, the odds ratio (OR) for HBsAg positivity and anti-HCV/HCV RNA negativity was 22.5 (95% CI: 19.5–26.0), whereas the OR for anti-HCV/HCV RNA positivity and HBsAg negativity was 17.3 (95% CI: 13.9–21.6). The increased risk of primary liver cancer occurs in HBV/HCV infected and uninfected individuals.

Female Breast Most recent case-control and cohort studies on the association between breast cancer and ethanol suggest moderate and heavy alcohol consumption (i.e., >1–2 drinks/day) increases the relative risk of breast cancer ~50–100%.[157,357] A pooled analysis of 6 cohort studies revealed a multivariate-adjusted relative risk of 1.41 (95% CI: 1.18–1.69) for 2–5 drinks/day compared with nondrinkers as measured by dietary questionnaire.[358] The risk was not linear as the risk of breast cancer was not significantly increased in women consuming >5 drinks/day; however, in a pooled analysis of 58,515 women with breast cancer (Collaborative Group on Hormonal Factors on Breast Cancer), the risk of breast cancer increased linearly with increasing alcohol consumption.[359] Compared with abstainers, the pooled RR was 1.32 (95% CI: 1.19–1.45, $P < 0.00001$) for women consuming 3–4 drinks daily, whereas the risk of breast cancer in women drinking >4 drinks (median = 58 g ethanol) daily was 1.46 (95% CI: 1.33–1.61, $P < 0.00001$). The relative risk of breast cancer for women consuming 1½ drinks/day was slight (RR = 1.13, 95% CI: 1.07–1.20). Smoking status (i.e., ever-smokers vs. never-smokers) did not affect breast cancer rates in alcohol consumers.

Most case-control studies have not demonstrated a dose-response relationship between female breast cancer and cumulative alcohol consumption,[360,361,362] with the exception of the Longnecker et al. study of non-Hispanic white and Hispanic women in the Cancer Surveillance Program of Los Angeles County.[363] The latter study demonstrated a linear dose-response relationship between alcohol consumption and breast cancer risks, with the exception of women consuming ≥46 g of alcohol daily for a lifetime (OR = 0.94, 95% CI: 0.46–1.93; $n = 16$ cases).

In the European Prospective Investigation into Cancer and Nutrition (EPIC) study, the incidence rate ratio per 10 g of alcohol/day increasing recent alcohol intake for 4,285 cases of invasive breast cancer followed for an average of 6.4 years was 1.03 (95% CI: 1.01–1.05).[364] When adjusted for confounding, the risk of breast cancer did not correlate to lifetime alcohol intake. The risk of breast cancer in women using alcoholic beverages does not vary with age at diagnosis, beverage type, oral contraceptive use or hormone replacement, family history of breast cancer, tobacco smoking, menopausal status, or child-bearing patterns.[321]

Pharmaceutical Preparations

The successful treatment of cancer patients and some nonmalignant conditions revealed that certain chemo-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

therapeutic agents produce hematopoietic and lymphatic cancers.

Table 49.26 lists the therapeutic agents associated with recognized or suspected human cancers. Radiation and chemotherapeutic drugs are frequent adjunctive agents.[365] Breast, thyroid, and bone marrow are the most susceptible organs to radiation carcinogenesis, whereas bone marrow is frequently susceptible to adverse effects from chemotherapy with the combination of intensive radiotherapy and chemotherapy, particularly leukemogenic.[366] Coal tar is a complex mixture of polycyclic aromatic hydrocarbons (PAHs) and tumor initiators used for >100 years in various vehicles for the treatment of psoriasis; potent corticosteroids have replaced pharmaceutical coal-tar preparations because of their far superior efficacy and limited safety data on the latter.[367] Some,[368] but not all,[369,370] studies of the application of coal tar prior to UV radiation treatment of psoriasis (Goeckerman therapy) associate the treatment with an increased risk of skin cancer. Therapeutic drugs associated with cancer in experimental animals but with inadequate human epidemiological evidence (IARC Group 2B, possible carcinogen) include dantron, digoxin, hydrochlorothiazide, methylthiouracil, metronidazole, mitoxantrone, niridazole, panfuran S, pentosan polysulfate sodium, phenazopyridine, phenoxybenzamine, phenobarbital, phenolphthalein, phenytoin, primidone, propylthiouracil, sulfasalazine, triamterene, zalcitabine, and zidovudine (AZT).[371] Some of these agents are suspected tumor promoters (e.g., digoxin with its structural homology to steroid hormones and association with breast cancer). Tumors associated with hormone therapy typically occur in organs responsive to hormonal stimulation. Diethylstilbestrol (DES) acts transplacentally on the vagina and cervix of female offspring; DES may also affect the testicle of male offspring of mothers exposed *in utero* to DES. Epidemiology studies suggest estrogen replacement therapy and sequential oral contraceptives increase the incidence of endometrial cancer, whereas anabolic steroids probably increase the incidence of liver cancer (IARC Group 2A).[372] The IARC classifies phenobarbital as a possible carcinogen (Group 2B) based on inadequate evidence in humans and sufficient evidence in rodents. In mice, phenobarbital consistently produces hepatocellular adenomas and carcinomas, whereas rats less consistently develop hepatocellular adenomas. The sequential administration of phenobarbital and carcinogens enhances the incidence of hepatocellular preneoplastic foci, adenomas, and carcinomas, consistent with epigenetic effects. *In vitro* and *in vivo* studies of phenobarbital demonstrate proinflammatory effects on hepatic mesenchyme and mesenchymal-epithelial interactions along with the release of tumor necrosis factor alpha from mesenchymal cells and inhibition of apoptosis in hepatocytes.[373]

Natural Carcinogens

Potential environmental carcinogens include naturally occurring, semisynthetic, and synthetic chemicals, radiation (fallout, solar, radon), and some biological agents (viruses, bacteria, fungi, parasites).[374] Although the environment contains many substances that increase cancer incidence in laboratory animals following exposure to high carcinogen doses, only a few of these animal carcinogens (e.g., tobacco, asbestos, aflatoxin-contaminated food) contribute significantly to human cancers based on our present knowledge. The risk of human cancer from these agents at doses typically encountered in the environment is not well defined, except for biological agents, tobacco use, and heavy contamination with aflatoxins, particularly with hepatitis B virus (HBV) coinfection.

Biological Agents

Epidemiological studies associate certain retroviruses with several hematological malignancies, including human T-lymphocyte viruses and T cell malignancies,[375] human immunodeficiency viruses and AIDS-associated lymphomas,[376] hepatitis B/hepatitis C, viruses, and liver cancer,[377] and Epstein–Barr virus with nasopharyngeal cancer.[378] Hepatitis D is not considered a carcinogen (IARC Group 3). Table 49.27 lists some biological agents associated with human cancers by the International Agency for Research on Cancer (IARC).

Epstein–Barr virus (EBV) was the first oncogenic virus discovered when Epstein et al. demonstrated EBV particles in cultured lymphoblasts from Burkitt's lymphoma.[379] Other cancers associated with EBV include Hodgkin lymphoma, immunodeficiency-related non-Hodgkin lymphoma, nasopharyngeal carcinoma, and nasal-type extranodal natural killer (NK)/T cell lymphoma. Human immunodeficiency virus type 1 (HIV-1) is associated with increases in the risks of Hodgkin lymphoma, genital cancers including invasive anal, vaginal, vulvar, and penile cancers, conjunctival eye cancer, nonmelanoma skin cancer, non-Hodgkin lymphoma, Kaposi sarcoma, and cervical cancer.[380] The latter three are AIDS defining cancers used to diagnose acquired immunodeficiency syndrome (AIDS). Most of the cancers associated with HIV-1 occur after coinfection with another cancer-causing virus. Human T cell lymphotropic virus type 1 (HTLV-1) causes adult T cell leukemia/lymphoma, with a high percentage of patients demonstrating high anti-HTLV-1 antibodies

TABLE 49.26. Therapeutic agents associated with (Group 1, carcinogenic) or suspected of (Group 2A, probable) causing an increased risk of human cancer in specific tissues based on epidemiological studies, animal data, and specific IARC criteria for each classification and group (https://monographs.iarc.fr/agents-classified-by-the-iarc/). (Adapted from Agents Classified by the IARC Monographs, WHO).

Agent	Associated or Suspected Neoplasm	IARC Classification of Epidemiological Evidence[a]	IARC Group[a]
Alkylating agents (busulfan, cyclophosphamide, melphalan, methyl-CCNU[b])	Acute myeloid leukemia, bladder	Sufficient	1
Inorganic arsenicals	Skin, liver	Sufficient	
Azathioprine	Non-Hodgkin's lymphoma, squamous cell skin carcinoma	Sufficient	1
Chlornaphazine	Bladder	Sufficient	1
Chlorambucil	Acute myeloid leukemia	Sufficient	1
Coal tar	Nonmelanoma skin cancer	Sufficient	1
Cyclosporin	Non-Hodgkin's lymphoma, squamous cell skin carcinoma, enhanced risk at multiple sites	Sufficient	1
Diethylstilbestrol (nonsteroidal estrogen)	Vaginal/cervix (clear cell adenocarcinoma) cervix/testis (squamous cell carcinoma) from *in utero* exposure; female breast cancer from exposure during pregnancy; endometrium	Sufficient	1
Estrogen – menopausal			
Estrogen-only	Endometrium, ovary, female breast	Sufficient	1
Estrogen and progesterone	Endometrium, female breast	Sufficient	1
Estrogen and progesterone – premenopausal contraceptives	Female breast, cervix, liver	Sufficient	1
5-Methoxypsoralen with UV light	Squamous cell skin carcinoma	Sufficient	1
MOPP chemotherapy (combined mechlorethamine, vincristine, procarbazine, prednisone)	Acute myeloid leukemia, lung	Sufficient	1
Phenacetin-containing analgesic mixtures	Renal pelvis, ureter	Sufficient	1
Tamoxifen	Endometrium	Sufficient	1
Thiotepa	Leukemia	Sufficient	1
Thorotrast	Hepatic angiosarcoma	Sufficient	1
Treosulfan	Acute myeloid leukemia	Sufficient	1
Androgenic (anabolic) steroids, oxymetholone	Liver	Limited	2A
Chloramphenicol	Aplastic anemia, leukemia	Limited	2A
Etoposide[c]	Acute myeloid leukemia	Limited	2A
Nitrogen mustard	Squamous cell skin cancer, possibly leukemia	Limited	2A
Pioglitazone	Bladder	Limited	2A
Teniposide (semisynthetic podophyllotoxin derivative)	Acute myeloid leukemia	Limited	2A

[a] International Agency for Research on Cancer classification; [b] Methyl-CCNU = 1-(2-chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea; [c] Etoposide with cisplatin and bleomycin is classified as a Group 1 (human) carcinogen increasing the risk of acute myeloid leukemia.

and host cells (CD4 T cells) producing oncogenic viral proteins; this retrovirus infection precedes diagnosis of adult T cell leukemia/lymphoma based on examination of monoclonal insertion sites in tumors.[381] The association between human papilloma virus and cervical cancer is strongly based on epidemiological studies and mechanistic data. HPV 16 and 18 are also associated with cancers of the vulva, vagina, penis, anus, and oral cavity.[382] Infection with Kaposi sarcoma-associated herpesvirus causes Kaposi sarcoma, a plasmablastic variant of multicentric Castleman disease, and primary effusion lymphoma primarily in immunosuppressed patients.

TABLE 49.27. Some biological agents associated with human cancers using criteria established by the International Agency for Research on Cancer (IARC) and the US National Toxicology Program (USNTP). (Adapted from Lagiou et al.).[146]

Cancer Site	Biological Agent
Anal cancer	Human papilloma viruses (HPV 16, 18, 33), human immunodeficiency virus 1
Bladder, urinary	*Schistosoma hematobium*
Cervical cancer	Human immunodeficiency virus type 1, human papilloma viruses 16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, but not types 6 or 11[a]
Cholangiocarcinoma	*Clonorchis sinensis*, *Opisthorchis viverrini*
Leukemia, adult T cell	Human T cell lymphotropic virus type 1
Liver	*Aspergillus flavus*/*parasiticus* (Aflatoxins B1, B2, G1, G2), Hepatitis B/C viruses
Lymphoma, non-Hodgkin's	Human Epstein–Barr virus (immunosuppression-related), human immunodeficiency virus type 1, but not type 2
Lymphoma, Burkitt's, extranodal NK/T cell, and Hodgkin	Human Epstein–Barr virus (human herpesvirus 4)
Lymphoproliferative diseases	Human Epstein–Barr virus (human herpesvirus 4)
Nasopharyngeal cancer	Human Epstein–Barr virus (human herpesvirus 4)
Sarcoma, Kaposi	*Herpes simplex* virus 8 (HHV-8), human immunodeficiency virus 1,
Skin cancer, Merkel cell carcinoma	Merkel cell polyomavirus[b]
Stomach	*Helicobacter pylori*

[a] Human papillomavirus types 26, 30, 34, 53, 66, 67, 69, 70, 73, 82, 85, 97 are classified as possibly carcinogenic (IARC Group 2B);
[b] Merkel-cell virus is common, whereas skin cancer is much less common; hence, other risk factors are necessary to cause cancer.

These viruses produce RNA and protein products that transform host cells and promote the survival and growth of transformed cells.[383]

Mycotoxins

Aflatoxins are the most important natural carcinogens in food; these hepatocellular carcinogens are highly substituted coumarin metabolites of *Aspergillus flavus* (B1, B2) and the closely related species *Aspergillus parasiticus* (B1, B2, G1, G2), classified by their blue fluorescence (B1, B2) and green-yellow fluorescence (G1, G2) under ultraviolet light.[380] These four aflatoxins are listed by the IARC as human (Group 1) carcinogens. Aflatoxin B1 is the most potent hepatocellular carcinogen in animal studies and the most common aflatoxin contaminant of human foods, whereas aflatoxin M1 (a metabolite of B1) is listed as a possible carcinogen (IARC Group 2B). The highest contamination of food sources with aflatoxins occurs in maize, beans, grains, and groundnuts stored in hot, humid conditions common in subsistence farming communities in tropical and subtropical areas in Eastern Asia, sub-Saharan Africa, and parts of South America. Milk consumption from cows fed aflatoxin B1-contaminated feed is an additional source of aflatoxin exposure.

Normal cooking processes do not destroy aflatoxins. Implementation of food monitoring and rapid use of optimal drying and storage facilities (i.e., <10% moisture) substantially reduced harmful aflatoxin exposure in developed countries. Cytochrome P450 enzymes (i.e., 3A4, 1A2, 3A5, 3A7) metabolize aflatoxins to highly reactive exo-epoxides that ultimately form adducts and DNA mutations including alteration of the p53 tumor suppressor gene.[384,385] The multiplicative interaction between aflatoxin B1 and HBV contributes significantly to the high incidence of hepatocellular carcinomas in Africa and East Asia.[386]

Other natural substances are animal carcinogens including fumonisins, ochratoxin A, and sterigmatocystin; however, human data are limited with insufficient data to conclude these substances contribute to human cancers (IARC Group 2B, possible carcinogens). Fumonisins are mycotoxins produced by some strains of *Fusarium* (e.g., *Fusarium moniliforme*) that occur primarily in corn (maize) and corn products; fumonisin B1/B2 and fusarin C are classified as possible carcinogens (IARC Group 2B) based on inadequate human studies and sufficient evidence in experimental animals. *Fusarium graminearum*, *Fusarium culmorum*, and *Fusarium crookwellense* strains producing deoxynivalenol, fusarenon X, nivalenol, or zearalenone are considered noncarcinogenic. *Penicillium verrucosum*, *Aspergillus ochraceus*, and rare *Aspergillus* species (*Aspergillus alliaceus*, *Aspergillus melleus*, *Aspergillus sclerotiorum*, *Aspergillus sulphureus*) produce ochratoxin A; many commodities contain this mycotoxin including pork, grains, cereals, peas, coffee beans, corn, and flour, particularly wheat and barley from northern temperate zones.[387] The IARC considers ochratoxin A possibly carcinogenic (Group 2B) based on inadequate human studies (i.e., ecological studies associating urothelial urinary tract tumors and high ochratoxin A in patients with Balkan endemic nephropathy) and sufficient evidence in experimental animals (hepatocellular tumors in mice, renal cell adenomas, and carcinomas in rats and mice). Sterigmatocystin is a metabolite of *Aspergillus versicolor* that is structurally similar to aflatoxins; hosts for this mycotoxin include salami,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

ham, grains, corn, bread, cheese, spices, soybeans, pistachio nuts, animal feed and silage, green coffee beans, and wheat.[388] The IARC classifies sterigmatocystin as a possible carcinogen (Group 2B) based on suggestive experimental animal data and no evidence of carcinogenicity in humans.

Plants and Medicinal Herbs

Foods Based on animal studies, a genotoxic cycasin metabolite glycoside (methylazoxymethanol) and a nor-sesquiterpene glucoside (ptaquiloside) derived from the bracken fern, *Pteridium aquilinum* are potent plant carcinogens.[389] Foods derived from seeds, roots, or leaves of cycad plants (Cycadaceae family) found in tropical and semitropical regions contain methylazoxymethanol along with starch depending on preparation processes; hepatocellular carcinoma developed in 2 of 9 monkeys receiving oral cycasin or methylazoxymethanol acetate doses over a mean of 57 months (range, 2–133 months) sufficient to cause hepatitis and cirrhosis.[390] There were no controls. Ptaquiloside forms an unstable dienone that develops covalent DNA adducts, with guanine and adenine causing subsequent breaks in DNA strands and apoptosis in cell cultures; very limited studies suggest ptaquiloside exposure causes mammary, intestinal, and urinary bladder cancer in several animal species,[391] and esophageal cancer in humans.[392] A Japanese case-control study of 98 cases of esophageal cancer and 476 controls reported a relative risk of 2.7 for the daily consumption of bracken fern; however, limited data on confidence intervals, potential information/selection bias, and a lack of adjustment for confounders complicate the determination of the results validity.[393] The IARC classifies cycasin and bracken fern consumption as possible carcinogens (Group 2B) based on animal data and insufficient (weak) human data.

Safrole (shikimol) is a component of certain essential oils (star anise, camphor, sassafras, cinnamon leaf) and spices (mace, ginger, cinnamon, nutmeg, black pepper, California bay laurel). The highest safrole concentration occurs in sassafras root. Relatively high amounts of safrole produce liver tumors in rats; subsequently, safrole was removed as a flavoring agent from the Generally Recognized As Safe (GRAS) list by the US Food and Drug Administration (FDA). The IARC classifies safrole, cycasin, and ptaquiloside in Group 2B as possible human carcinogens. Betel quid with or without tobacco in nonsmokers is a human carcinogen (oral/pharyngeal cancers, oral potentially malignant disorders, nitrosation to stomach carcinogens)[394] that contains high concentrations of safrole and potentially safrole-DNA adducts;[395] however, the contribution of safrole to the betel quid carcinogenicity remains unclear.

Herbs and Dietary Supplements Several species in the *Aristolochia*, *Asarum*, and *Thottea* genera from the *Aristolochiaceae* family contain aristolochic acid I and the de-methoxylated metabolite (aristolochic acid II); for a wide variety of illnesses, traditional Chinese medicine uses these ingredients in many herbal medicines, including Guang Fang Ji (*Aristolochia fangchi*), particularly in Taiwan.[396] In the 1990s, over 100 cases of interstitial renal fibrosis frequently progressing rapidly to kidney failure and urothelial carcinomas (i.e., ~40%) appeared in Belgian women using slimming agents containing Guang Fang Ji.[397,398] Subsequent studies in Taiwanese herbalists using aristolochic acid-containing herbs confirmed the increased risk of renal failure and upper tract urothelial carcinomas following exposure to these herbs. The IARC upgraded aristolochic acid to a Group 1 carcinogen based on strong mechanistic evidence (e.g., aristolactam-DNA adducts, TP53 suppressor gene mutations, apoptosis, and interstitial cell proliferation), sufficient evidence in experimental animals, and consistent data (e.g., DNA adducts, A to T mutations) in patients with urothelial (renal pelvis, ureter) cancers and either Balkan endemic or aristolochic acid nephropathy in areas where aristolochic acid-containing plants contaminate wheat fields.[399,400]

Animal studies suggest the possibility of carcinogenicity (i.e., IARC Group 2B) from exposure to several herbs, including *Aloe vera* whole leaf extract, coltsfoot (*Tussilago farfara*), comfrey (*Symphytum officinale*), *Ginkgo biloba*, goldenseal (*Hydrastis canadensis*), gordolobo yerba, (*Senecio vulgaris*, *Senecio riddellii*), groundsel (*Senecio flaccidus*), and kava extract (*Macropiper methysticum*); however, epidemiology data are insufficient to link these herbs to human carcinogenicity. In rodent studies, *A. vera* whole-leaf extract is an intestinal irritant producing goblet cell hyperplasia of the large intestine during a 13-week study involving oral doses of 1, 2, and 3%.[401] Subsequent studies of $B6C3F_1$ mice and F344/N rats gavaged with daily doses of 0.5, 1, and 1.5% *A. vera* whole-leaf extract demonstrated no large intestine neoplasms in controls, mice, or the 0.5%-dose group of rats; however, a dose-related increased incidence of large intestinal tumors developed in male and female rats fed 1 and 1.5% *A. vera* whole-leaf extract. Compared with controls, survival decreased in the 1.5% dose group of female rats, and intestinal hyperplasia occurred in all groups receiving 1 and 1.5% *A. vera* whole-leaf extract. Epidemiological studies of *G. biloba* are limited and inconsistent with substantial methodological flaws (e.g., low participation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

rates, low statistical power, relatively weak hazard ratios with wide confidence intervals including 1, potential exposure misclassification) to establish this herb as a human carcinogen. Rodent studies suggest the possibility of liver cancer based on the increased incidence of hepatoblastomas and hepatocellular carcinomas; however, the findings are not consistent between species and sexes.[402]

Coltsfoot, comfrey, gordolobo yerba, and groundsel contain pyrrolizidine alkaloids associated with liver inflammation and hepatocellular carcinomas in rodents. Inadequate data are available to evaluate the human carcinogenic risk from this widespread group of plants containing a pair of linked pyrrole rings (pyrrolizidine alkaloids). Riddelliine (IARC Group 2B) is a genotoxic pyrrolizidine alkaloid present in many western US plants that is mutagenic in rat liver cells.[403,404] Goldenseal roots contain isoquinoline alkaloids (e.g., berberine, canadine, hydrastine). In a 2-year study of $B6C3F_1$ mice and F344/N rats fed *ad libitum* diets containing 0 (control), 3,000, 9,000, or 25,000 ppm goldenseal root powder, the incidence of hepatoblastoma and hepatocellular adenoma increased in male but not female mice.[405] In male and female rats, the incidence of hepatocellular adenoma increased, and one case of hepatocellular carcinoma occurred (a rare tumor in F344/N rats). Human data on the carcinogenicity of goldenseal root powder is unavailable.

Kavalactones (e.g., α-pyrones, kavapyrones) are the active ingredients in kava rhizomes widely cultivated in Oceania for use as ritual beverages to promote a sense of well-being and relaxation. Epidemiological data on kava consumption and cancer are primarily ecological with significant methodological flaws (crude exposure and outcome measures, inadequate adjustment for confounding). In rats and mice administered Kava Kava (27% kavalactones) up to 1 g/kg body weight for 2 years, examination of male mice demonstrated a significant dose-related increase in the incidence of hepatoblastomas, whereas female mice demonstrated a significant increase in the combined incidence of hepatocellular adenoma and carcinoma in the low- and mid-dose but not the high-dose groups.[406] Treatment-related increases in carcinogenic activity were not observed in male or female rat livers. In these chronic studies, dose-related increases in the incidences of hepatocellular hypertrophy and centrilobular fatty change developed.

The madder root (*Rubia tinctoria*) contains red coloring material used as a dye; the extract contains several hydroxyanthraquinones (e.g., purpurin, rubiadin). Inadequate animal and human data are available to classify this herb as a carcinogen (IARC Group 3).[407]

Methoxsalen (8-methoxypsoralen) with ultraviolet A radiation is a recognized human carcinogen (IARC Group 1) and 5-methoxypsoralen is a probable carcinogen, whereas other psoralens (3-carbethoxypsoralen, 7-methylpyrido [3,4-*c*] psoralen, pyrido [3,4-*c*] psoralen, 4,5′,8-trimethylpsoralen) are not classifiable by their carcinogenicity (IARC Group 3).

STATISTICS

Statistical Significance and *P* Value

The *P* value is a measure of the chance variation of the results; therefore, this statistical measure does not quantify the actual risk of developing the disease and does not convey information regarding the strength of the respective association. However, a causal association is unlikely if the *P* value in non-significant. When the sample size is large, small and clinically non-significant differences may yield statistically significant differences. *P*-values are numerical fractions of 1 with a value of 0.05 indicating a 5% or less chance the association would occur when there was no true association. Traditionally, most medical research accepts a *P*-value of ≤0.05 as evidence the observed association did not arise from chance; however, small *P*-values (i.e., <0.05) do not guarantee an association is genuine or causal. Highly unlikely events associated with extremely small *P*-values can occur by chance, particularly when the study examines multiple comparisons. The respective *P*-values lose their collective interpretability in the presence of multiple tests and/or comparisons.[146] The odds ratio is a more informative measure of the strength of the association between the disease and an exposure compared with the *P*-value. No test of statistical significance separates unidentified bias or residual confounding from true effect in observational epidemiology studies. In contrast to more homogeneous experimental studies, normal (Gaussian) distribution is less applicable to epidemiology studies that include subjects with substantial genetic variability and highly variable exposure scenarios. Consequently, statistical significance may overstate the real significance of the results of observational epidemiology studies.[408]

When study results indicate a true difference exists between two populations under study, the next question is whether the difference is clinically significant and what degree of overlap occurs between the two groups. Statistical significance is not equivalent to clinical significance.[409] The *P*-value is a measure of the probability that a test outcome results from chance rather than an indication of a strong association or an important clinical difference. A weak, inconsequential association may

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

be highly statistically significant in a large study, whereas a strong association may be statistically nonsignificant in a small, underpowered study. The confidence interval and *P*-value are intimately linked. The 95% confidence interval of a statistically significant association ($P < 0.05$) does not include the null value (i.e., 1 for relative risk) 95% of the time; however, normal (Gaussian) distribution is less applicable to heterogeneous human populations than inbred experimental animals. Thus, the use of normal distributions may overstate statistical significance unless higher standard errors than the usual ±1.96 standard errors are used to generate genuine 95% confidence intervals.[408] Confidence intervals (CI) provide all the information a *P*-value does. Additionally, the CI provides information about precision of the observed estimate (e.g., the inclusion of 1 indicates the results are statistically nonsignificant) with the range determining if clinically significant values are compatible with the results.[410] The complete overlap of confidence intervals indicates little difference between the two groups or subgroups. Effect sizes (e.g., odds ratios) also help determine the clinical importance of study results as measures of the amount and utility of the difference between two groups. The upper bound of the CI indicates if the data are compatible with clinically significant effect, particularly when the CI is precise (i.e., narrow).

Logistic Regression and ROC Curve

Logistic regression is a common statistical method that quantifies the relationship between individual characteristics and the outcome of interest. This method demonstrates which factors (independent variables) have the strongest association with an outcome of interest (dependent variables), while providing a measure of the magnitude of the factors effect on the outcome. The ability to adjust for confounding factors that are associated with both independent and dependent variables provides a mechanism to limit the influence of confounders. The validity of a logistic regression model depends on the following: 1) the number and suitability of the measured independent variable, 2) the variables remain constant across the range of values for the variable, and 3) the absence of an interaction between independent variables.[411] A receiver operating characteristic (ROC) curve can assess the ability of a logistic regression model to predict outcomes. The ROC curve is a plot of sensitivity of the model on the vertical axis and 1 minus the specificity on the horizontal axis for all possible cutoffs used to separate patients. The area under the ROC curve (C statistic, concordance) reflects the difference between the model estimates of risk and the observed risk with a range of 0–1. One indicates the model has perfect sensitivity and specificity, whereas 0.5 implies the model produces results no better than chance. Typically, a C statistic below 0.7 indicates the model is not clinically useful, a higher than 0.7 implies fair predictive value, and a 0.9 indicates a well-calibrated model.[412]

Population Attributable Fraction

The population attributable fraction helps policymakers understand the effects of public health interventions and policies on exposed populations. The population attributable fraction is the amount of a specific disease burden that could be eliminated by the eradication of certain causal factors (i.e., exposures) from the population. This value reflects the estimated population attributable risk fraction rather than the etiological fraction,[413] which cannot be estimated in an individual without robust biological assumptions.[414] Consequently, the population attributable fraction is the proportional reduction in the average disease risk over a specified time interval resulting from the elimination of the specified causal exposure(s), while the other disease risk factors in the population remain unaffected.[415] Population attributable risk proportion implies the subjects in the numerator are part of the population in the denominator, whereas the excess fraction may not include the subjects in nominator in the denominator (i.e., whole population). Statistical methods can adjust for confounding when estimating attributable risk from retrospective data; however, some attributable fraction formulas require the absence of confounding in the exposure-disease association.[416]

The population attributable fraction may be divided into exposure-category-specific attributable fractions that sum to the population attributable fraction.[415] For a specific disease with multiple causal factors, the sum of each single attributable fraction may exceed 1; hence, the use of broad factors (e.g., unknown causes) to sum to 1 is inappropriate. Furthermore, the population attributable fraction does not determine the probability that a specific case was or was not caused by the exposure; similarly, estimation of the attributable fraction does not identify which cases were or were not caused by the exposure. The attributable fraction is most useful for strong causal relationships that are amenable to interventions (e.g., smoking and lung cancer). In these situations, the risk factor should be immediately modifiable and the unexposed setpoint should be established at a realistically attainable exposure value for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the exposed population. The use of broad exposure definitions also reduces the precision and increases the standard error of the attributable fraction, particularly when the proportion of exposed cases and controls exceeds 50%.[417]

Systematic Reviews and Meta-analyses

Determination of the true effect of chemical exposure on cancer risks depends on the totality of evidence rather than on an individual study because single studies may be misleading and unrepresentative of the totality of the evidence.[418] Systematic reviews are research summaries focusing on a clinical question by a structured, reproducible approach; often, a statistical pooling of results from various studies (i.e., meta-analysis) accompanies the review.[419] The latter provides a single estimate of effect. The role of meta-analyses remains controversial because no statistical summarization can account for problems caused by unidentified bias, residual confounding, or selective presentation of data.[420] These techniques address the issue of chance; however, meta-analyses do not guarantee the absence of bias, unrecognized confounding, or selective reporting. To reduce error and subjectivity, systematic reviews usually include two or more reviewers along with a measure of agreement on study selection and quality appraisal (e.g., κ statistic). Several guidelines are available for evaluation of the quality of evidence, including those from Oxford Centre for Evidence-Based Medicine, the American Heart Association,[421] and the Grading of Recommendations Assessment, Development, and Evaluation (GRADE). The latter categorizes confidence in very low, low, moderate, and high categories.[422] Increasing confidence ratings is unusual, primarily involving observational studies with large effect sizes. Table 49.28 lists important questions to evaluate the credibility and validity of systematic reviews and meta-analyses.

TABLE 49.28. Questions for the evaluation of results from a systematic review and meta-analysis. (Adapted from Murad et al.).[419]

Judgment	Questions
Credibility of methods	1. Was the review evaluating a sensible question?
	2. Did the search include a representative or complete sample of available eligible studies?[a]
	3. Were study selections and assessments reproducible?
	4. Are results applicable to the environmental or occupational question?
	5. How confident were the authors in their estimates of effect?
Confidence in effect estimates	1. How serious was the risk of bias?
	2. How consistent are the results across studies?
	3. How precise are the estimates?
	4. How serious are reporting and publication biases?
	5. Should the confidence rating be changed?
	6. Do the results answer the question in a quantitatively important way?

[a] Typically, the minimum requirements for most questions include Medline, Embase, and the Cochrane database.

Effect Size

Systematic reviews and meta-analyses provide a synthesis of available evidence to help understand the relationship between chemical exposure and cancer, as well as other focused clinical questions. The credibility of the review process depends on appropriate eligibility criteria, exhaustive literature search, and optimum summarization of the results, whereas the quality of evidence depends on the exclusion of biased studies, consistent results (i.e., homogeneity), and adequate sample size to produce precise estimates of effect size. The latter is a statistical measure for the magnitude of the difference between two outcomes adjusted for an estimate of variability; effect size measures dichotomous (binary) and continuous data. The latter includes the difference between the mean values and standardized difference between mean values, whereas the former includes relative risk, odds ratio, and absolute risk difference. In contrast to the absolute risk difference, the relative risk and odds ratio rely less on the underlying risk. For rare events, the odds ratio and relative risk are similar; however, the odds ratio is significantly greater than the relative risk for more frequent events (i.e., >20%), resulting in overestimation of risk (e.g., the number of patients with a disease/total number of patients); additionally, the odds ratio displays a greater risk compared with the relative risk when the effect size is <2.[423] Effect sizes of large trials in the same direction and within 30% of the pooled values in meta-analyses are usually considered concordant.[424,425]

Meta-analysis results are usually displayed as forest plots with the confidence interval as a horizontal line, the point estimate as a square with the size proportional to the weight of the study, and the pooled estimate as a diamond. Large differences in point estimates and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 49.5. Forest plot. The effect size in this forest plot is the absolute risk difference between two different interventions. Failure of the confidence interval to cross zero on the *y*-axis indicates a statistically significant outcome. (Adapted from Leucht et al.).[423]

confidence intervals that do not overlap on the forest plot reduce confidence in the pooled estimates by suggesting random error is unlikely (i.e., low *P* value).[419] Figure 49.5 is a forest plot summarizing the effect size (pooled absolute risk difference) for a meta-analysis of 11 studies on 2 types of intervention. The size of the square reflects effect size, whereas the horizontal line through the square represents the 95% confidence interval. Failure of the 95% confidence interval to intersect zero on the *y*-axis indicates a statistically significant outcome. Small and/or imprecise studies typically have large confidence intervals, whereas large studies usually have smaller confidence intervals.

Publication Bias

Assessing the risk of bias is problematic with no single correct method; the review/meta-analysis should include an overall assessment of bias with a corresponding alteration of the confidence in estimates as needed. The results of the systematic review and meta-analysis are only as reliable as the quality of the studies summarized. Publication bias represents a serious concern for evidence-based medicine because of the tendency to publish positive rather than negative studies, particularly if a study reports a selected subset of significant predictors. This tendency creates a systematic bias against the null hypothesis raising the potential for false positive studies and limiting the validity of the meta-analyses that do not require comprehensive reporting, including preregistered hypotheses and disclosure of the number of tests conducted. Several factors contribute to publishing false positive findings including: 1) small sample size, 2) increased pursuit of novelty, 3) various forms of multiple testing and researcher flexibility, and 4) incorrect *P*-values from lack of independent data points (clustered data).[426] HARKing[427] is the use of Hypothesizing After the Results are Known and hindsight bias (knew-it-all-along)[428] contributes to the publication of false positive studies; the latter overestimates the plausibility of the "*post hoc* hypotheses" derived from data rather than the testing. Although data exploration is not fundamentally inappropriate, these analyses may cause an array of relationships and interpretations that are difficult to objectively correct for multiple testing.[429] Such exploratory work should be published in the Results section rather than the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. FIGURE 49.6. Hypothetical funnel plots graph study size n (*y*-axis) and effect size (*x*-axis). Graph (a) is a symmetric plot demonstrating an inverted funnel characteristic of a meta-analysis with publication bias unlikely, whereas graph (b) is asymmetric in the region of smaller studies on the lower right of the graph. The absence of published studies in this region indicates the presence of publication bias. (Adapted from Leucht et al.).[423]

TABLE 49.29. Sources of funnel plot asymmetry. Bias indicates the presence of systematic, non-random errors. (Adapted from Egger et al.).[424]

Source	Explanations
Selection bias	Publication bias, location bias (English language, multiple publications, citation)
True heterogeneity	Effect size varies by study size (intensity of intervention, underlying risk differences)
Data issues	Methodological problems with small studies, inadequate analysis, misrepresentation
Artifactual Chance	Inappropriate choice of outcome measure

Introductory section to prevent misinterpreting the hypothesis as *a priori* rather than *post hoc*.

The funnel plot graphically represents effect sizes of individual studies against precision or the number of participants; larger studies with higher precision appear at the top of the graph. The basis for interpreting funnel plots is the assumption that small negative studies are less likely to be published, resulting in an asymmetric plot, as displayed in Figure 49.6. Table 49.29 lists potential sources of asymmetry in funnel plots.

Heterogeneity

Heterogeneity in a meta-analysis partially determines the validity of study conclusions. Certain statistical evaluations help determine the degree of heterogeneity (e.g., Cochran Q test); however, this test does not easily detect true heterogeneity, particularly when the meta-analysis includes small studies with low power.[430] The I^2 statistic is a calculated measure of heterogeneity that reflects the magnitude of the variability in studies included in a meta-analysis, with less dependence on power and statistical significance than the Cochran Q test.[431,432] The value of I^2 statistic ranges from 0–100%, with 0% indicating no heterogeneity and chance explaining variability in the point estimates. As the I^2 increases progressively, heterogeneity and concern about variability increase. The confidence interval includes the range where the value of the true effect plausibly lies; consequently, the confidence interval reflects the precision of the estimate (i.e., how closely individual estimates are to each other). The weight of an individual study depends on its precision.

Subanalyses

Systematic reviewers may use subgroup analyses to identify groups of subjects responding differently to an exposure or treatment than the whole group; however, compelling subgroup effects are often spurious. Criteria for assessing the validity of subgroup analyses include: 1) identification of the hypothesis as an effect *before* the study began, 2) the possibility of chance explaining the effect, 3) consistency of the effect across studies, 4) strong preexisting biological support for the effect, and 5) evidence supporting the effect based on within- or between-study comparisons (systematic reviews only).[433] The credibility of apparent subgroup differences arising *post hoc* rather than *a priori* is suspect.

TABLE 49.30. Calculation of test characteristics.

Test Outcome	Value	Disease (Carcinogen) Present	Disease (Carcinogen) Absent
Test positive		A (true positive)	B (false negative)
Test negative		C (false positive)	D (true negative)
Sensitivity	A/(A + C)		
Specificity	D/(B + D)		
Total positive tests	A + B		
Total negative tests	C + D		
Total tests	A + B + C + D		
Positive predictive value	A/(A + B)		
Negative predictive value	D/(C + D)		
Accuracy (concordance)	(A + D)/A + B + C + D		

Abbreviations: A = true positive; B = false negative; C = false positive; D = true negative.

Negative Studies and Predictive Values

Sensitivity measures the *proportion* rather than the *absolute* number of subjects with the condition detected by the test, whereas specificity is the proportion of subjects without the condition that have a negative test. The actual number of individuals with the condition missed by the test is highly dependent on the prevalence of the condition in the studied population. The predictive value measures the actual number of subjects missed by the test. *Positive predictive value* describes the probability that a positive test result will be a true positive, whereas *negative predictive value* describes the probability that a negative test result will be a true negative. If the sensitivity and specificity are constant, the positive predictive value increases as the prevalence of the condition increases. The negative predictive value decreases as the prevalence increases. Table 49.30 outlines the calculation of these test characteristics. Accuracy (i.e., total true tests/total tests) measures how often the tests are correct (i.e., true values) in contrast to precision that measures how closely values are to each other.

A true negative study requires the following: 1) a large sample size with sufficient follow-up and disease prevalence in a cohort study or adequate case size and common exposure in a case-referent study, 2) a sensitive measure of outcome (e.g., disease in a cohort study or exposure in a case-referent study, and 3) accurate exposure data.[434] The statistical power of a study is the chance of detecting a specific outcome when the outcome truly occurred in the population given a specified level of significance (usually, $\alpha = 0.05$) and a probability of failing to detect the true difference (usually, $\beta = 0.2$). Hence, a negative study with good statistical power indicates the lack of a correlation in the test population between the study variable and the outcome. Nomograms are available to aid in the calculation of the power of a study.[435] Given the conditions of exposure and the biases in a study, the results can exclude a rate ratio above the upper confidence limit. Difference in the dose frequently explains the apparent conflict between "positive" and "null" studies using the same chemical. This difference in dose often outweighs other sources of variability.[436]

EXTRAPOLATION

Extrapolation of test results from an observational study population to another population requires an analysis of potential errors including: 1) extrapolation of results to a population with a different prevalence of disease or exposure, 2) failure to account for confounding factors in the general population affecting the outcome, 3) using population data to reach conclusions about individuals, and 4) extrapolation beyond or below the exposure range.[437] Causation in cancer studies is typically multifactorial, with no single factor both necessary and sufficient for cancer occurrence; furthermore, no single factor is usually sufficient (albeit not necessary) to cause cancer in a particular individual. Despite the presence of strong carcinogens or susceptibility factors (e.g., long-term, heavy smoking, dominant breast cancer genes) in individuals, not all individuals will develop cancer. Although observational epidemiological studies suggest a causal relationship between chemical exposure and an increased cancer risk in a selected population, attributing causality to an association between cancer and a chemical exposure in an individual within the population is complicated, depending on the individual cumulative dose and latency.[438] Criteria for determination of causation in an individual following a chemical exposure include: 1)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the chemical is an established carcinogen with strong epidemiological evidence, an appropriate, reproducible animal model, and some insight into the underlying carcinogenic process; 2) the individual exposure is comparable (e.g., latency, duration, intensity); 3) the cancer type is etiologically linked to the exposure; 4) the individual was not exposed to another established or likely cause of the specific cancer type; and 5) the fully adjusted relative risk of the individual's cancer type following similar exposure is >2.[146] A relative risk of >2 suggests the excess risk due to the exposure (i.e., >1) is larger than the background risk of 1 and the individual is more likely than not to develop cancer from the exposure rather than the background causes of the cancer type. This magnitude of relative risk suggests the results are quantitatively rather than statistically significant, allowing for the possibility of unidentified bias and residual confounding.[439]

Chapter 50

CARCINOGEN CLASSIFICATIONS

Several public health organizations (e.g., World Health Organization's International Agency for Research on Cancer, IARC; the United States National Toxicology Program, NTP), and governmental agencies (e.g., the United States Environmental Protection Agency, USEPA) review the available evidence on carcinogenicity and then categorize chemicals based on the evaluation of the probability the chemical causes human cancer. The US National Institute for Occupational Safety and Health (NIOSH) classifies occupational carcinogens by evaluating existing cancer hazard assessments from NTP, USEPA, and IARC.[1] This determination depends on one of the following methods: 1) evaluation of chemical carcinogen hazard assessments by the US Department of Health and Human Services' National Toxicology Program (NTP), the Integrated Risk Information System (IRIS) from the USEPA, or the IARC; 2) nomination by NIOSH for classification by NTP; or 3) classification by NIOSH. When developing a new chemical carcinogen classification, NIOSH uses the United Nations' Globally Harmonized System for Classification and Labelling of Chemicals (GHS) as interpreted by the US Occupational Safety and Health Administration (OSHA). NIOSH designates a substance an occupational carcinogen if the evidence meets GHS classes 1A, 1B, or 2.

Although all these agencies rely on a qualitative evaluation of the *weight* and *strength* of the evidence on potential carcinogenicity hazards, each of these organizations emphasizes different aspects of the carcinogen evaluation process. These classification systems typically do not consider potency as a criteria for determining carcinogenicity;[2] however, some governmental agencies have developed databases integrating data on carcinogenic risks (e.g., NTP Carcinogenic Potency Database, CPDB, https://healthdata.gov/dataset/Carcinogenic-Potency-Database-CPDB-/sqjy-rr5s/about_data; USEPA Integrated Risk Information System, IRIS, https://www.epa.gov/iris) to help set exposure standards for chemical carcinogens. The CPDB provides current historical information involving the interpretation/experimental details of bioassays, TD_{50s}, and calculation of carcinogenic potency. Besides potency, the relationship between cancer risk and exposure to a carcinogen in an individual depends on several other factors specific to the individual, including internal dose and susceptibility.

NATIONAL TOXICOLOGY PROGRAM

The NTP classifies carcinogens based on internally derived experimental data, published scientific studies, and reviews by nongovernmental expert panels. Five categories (i.e., clear, some, equivocal, no, inadequate) of evidence summarize the carcinogenic activity demonstrated in each study. Positive (clear, some) results indicate a potential cancer hazard from exposure to the chemical based on animal studies, whereas negative (no) studies indicate the lack of an increased tumor incidence under the experimental conditions.

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Hence, negative studies do not necessarily eliminate the potential for a chemical to cause cancer. The difference between clear and some evidence of carcinogenicity reflects a dose-related increase in tumor incidences in the former and only a chemically related increase in tumor incidences in the latter. Equivocal studies demonstrate a marginal increase in tumor incidences in contrast to inadequate studies that contain major design flaws preventing proper interpretation of the data.

Based on the weight of the evidence from these studies, chemicals are classified into two categories: 1) substances known to be human carcinogens, and 2) substances reasonably anticipated to be human carcinogens, as displayed in Table 50.1. Evidence supporting inclusion in these categories includes traditional cancer epidemiology studies, clinical studies, and/or *in vivo* studies clarifying the chemical-induced carcinogenic mode of action (i.e., the sequence of events from chemical absorption to ultimate effect). The former category implies the existence of sufficient evidence of carcinogenicity in epidemiology studies that indicate a causal relationship between human cancer and exposure to the agent, substance, or mixture. The latter includes several types of evidence including: 1) limited evidence of carcinogenicity from human studies that indicates a credible causal interpretation; however, alternative explanations (e.g., bias, chance, confounding) could not be excluded; 2) evidence in human or laboratory animal studies is less than sufficient; however, the agent, mixture, or substance belongs to a well-defined, structurally related substance listed as a potential carcinogen in previous reports or the existence of convincing mode of action data indicates the substance is a likely human carcinogen; or 3) sufficient evidence of carcinogenicity from experimental animal studies indicates an increased incidence of malignant and/or a combination of malignant/benign tumors in: a) multiple species or multiple tissue sites; b) multiple exposure routes; or c) an unusual degree of tumor incidence, site, type, or age at onset.[3] Table 50.2 lists the chemicals assigned by the NTP to these two categories. The NTP publishes the results of their reviews in the congressionally mandated Report on Carcinogens involving 243 substances by 2014, and updated in 2021, as displayed in Table 50.2.[3]

TABLE 50.1. National Toxicology Program (NTP) carcinogen classifications with criteria.

Classification	Criteria
Known to be a human carcinogen	Sufficient evidence of human carcinogenicity in epidemiology studies demonstrates a causal relationship
Reasonably anticipated to be a human carcinogen	1) Limited human evidence indicating a credible causal relationship, but an alternate explanation (bias, chance, or confounding factors) cannot be excluded or 2) Sufficient animal evidence of carcinogenicity indicating increased malignant and/or malignant plus benign tumors in: a) multiple species or multiple tissues; b) multiple exposure routes; or c) unusual incidence, onset, site, or tumor type or 3) Convincing mechanistic data on carcinogenicity likely to cause human cancer or less than sufficient animal or human data for a chemical with a well-defined, structural relationship to a previously recognized human carcinogen

INTERNATIONAL AGENCY FOR RESEARCH ON CANCER

Rather than relying only on internal data, the International Agency for Research on Cancer (IARC) produces comprehensive evaluation of ~1,000 chemicals based on reviews of all published experimental and epidemiological data (https://monographs.iarc.fr/agents-classified-by-the-iarc/). Selection of chemicals for review depends on the results of questionnaires sent to governments involved in the organization. The IARC does not produce experimental data; therefore, IARC publications rely on expert analysis and interpretation of available data rather than new experimental data.[4] The overall IARC evaluation involves human, animal, and mechanistic data, with strong mechanistic data providing evidence for raising or lowering the category, as displayed in Table 50.3.

Many human carcinogens produce various biological changes in the multi-stage process of carcinogenesis; these changes involve modification of cell signaling and gene expression that govern the creation and maintenance of cell identity (i.e., epigenetic mechanisms) as well as the previous emphasis on altered morphology and genotoxicity (alteration of DNA sequences).[5] The role of epigenetic changes in classifying carcinogens in previous monographs has been modest.[6] To identify and organize the plethora of mechanistic data including

TABLE 50.2. US National Toxicology Program Summary of 243 known and suspected human carcinogens as listed in the 15th Report on Carcinogens. (https://ntp.niehs.nih.gov/ntp/roc/content/listed_substances_508.pdf, NTP).[3]

Known to Be Carcinogenic	Reasonably Anticipated to Be Carcinogenic
Aflatoxins	Acetaldehyde
Alcoholic beverage consumption	2-Acetylaminofluorene
4-Aminobiphenyl (4-aminodiphenyl)	Acrylamide
Analgesic mixtures containing phenacetin	Acrylonitrile
Aristolochic acids	Adriamycin® (doxorubicin hydrochloride)
Arsenic compounds, inorganic	2-Aminoanthraquinone
Asbestos	*o*-Aminoazotoluene
Azathioprine	1-Amino-2,4-dibromoanthraquinone
Benzene	1-Amino-2,4-methylanthraquinone
Benzidine	2-Amino-3,4-dimethylimidazo(4,5-f)quinoline
Beryllium and beryllium compounds	2-Amino-3,8-dimethylimidazo(4,5-*f*)quinoxaline
bis(Chloromethyl) ether and technical-grade chloromethyl methyl ether	1-Amino-2-methylanthraquinone
1,3-Butadiene	2-Amino-3-methylimidazo(4,5-*f*)quinoline
1,4-Butanediol dimethylsulfonate	2-Amino-1-methyl-6-phenylimidazo (4,5-*b*)pyridine
Busulfan (Myleran®)	Amitrole
Cadmium and cadmium compounds	*o*-Anisidine and its hydrochloride
Chlorambucil	Antimony trioxide
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea	Azacitidine (5-azacytidine®,5-AzaC)
Chromium hexavalent compounds	Basic Red 9 monohydrochloride
Coal tars and coal-tar pitches	Benz[*a*]anthracene[b]
Coke oven emissions	Benzo[*b*]fluoranthene[b]
Cyclophosphamide	Benzo[*j*]fluoranthene[b]
Cyclosporin A	Benzo[*k*]fluoranthene[b]
Diethylstilbestrol	Benzo[*a*]pyrene[b]
Dyes metabolized to benzidine (Benzidine Class Dyes, Direct Black 38/Blue 6)	Benzotrichloride
Epstein–Barr virus	2,2-Bis(bromomethyl)-1,3-propanediol (technical grade)
Erionite	Bis(chloroethyl) nitrosourea
Estrogens, steroidal	Bromochloroacetic acid
Ethylene oxide	Bromodichloroacetic acid
Formaldehyde	Bromodichloromethane
Helicobacter pylori (Chronic infection)	1-Bromopropane
Hepatitis B virus (HBV)	Butylated hydroxyanisole (BHA)
Hepatitis C virus (HCV)	Captafol
Human immunodeficiency virus Type 1 (HIV_1)	Carbon tetrachloride
Human papilloma virus (HPV)	Ceramic fibers (respirable size)
Human T-cell lymphotrophic virus Type 1	Chloramphenicol
Kaposi Sarcoma-associated Herpes virus	Chlorendic acid
Melphalan	Chlorinated paraffins (C12, 60% Chlorine)
Merkel cell polyoma virus	Chlorodibromoacetic acid
Methoxsalen with ultraviolet A therapy (PUVA)	1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea
Mineral oils, untreated/mildly treated	Chloroform
Mustard gas	3-Chloro-2-methylpropene
2-Naphthylamine	4-Chloro-*o*-phenylenediamine
Neutrons	Chloroprene
Nickel compounds	*p*-Chloro-*o*-toluidine and its hydrochloride
Radon	Chlorozotocin
Silica, crystalline (respirable size)	Cisplatin
Solar radiation including broad-spectrum ultraviolet radiation and exposure to sunlamps or sunbeds	Cobalt and cobalt compounds releasing cobalt ions *in vivo*
Soots	Cobalt–tungsten carbide powder/hard metals
Strong inorganic acid mists containing sulfuric acid	*p*-Cresidine

	Urethane
	Vinyl bromide
	4-Vinyl-1-cyclohexene diepoxide
	Vinyl fluoride

[a] Including dyes metabolized to 3,3′-dimethoxybenzidine. [b] Polycyclic aromatic hydrocarbons.

epigenetic alterations (i.e., inherited, stable changes in gene expression and chromatin organization independent of DNA sequences), the IARC convened two workshops in 2012 that identified 10 key mechanistic characteristics of established human carcinogens, as displayed in Table 50.4.[7] Consideration of these characteristics facilitates the evaluation of experimental data by upgrading or downgrading the animal data according to the strength of the mechanistic data. Evaluating the mechanistic information involves: 1) identifying relevant information through comprehensive searches of the medical literature for end points associated with key characteristics following exposure to the agent and metabolites; 2) screening and organizing the results by population (animal, human) end points related to key characteristics and toxicokinetics; and 3) synthesis of mechanistic information and development of adverse outcome networks using key characteristics to evaluate evidence for mechanistic events as a function of relevant features (dose, temporal relationship, species).[8]

Morphological evidence for human carcinogenicity is stronger if based on cohort studies than case-referent studies and only suggestive if based on case series, ecological, or mortality studies. Sufficient data in animal studies requires positive results in ≥2 studies or species, whereas positive results in one study or species provide limited data. Table 50.5 outlines the criteria for epidemiological evidence, and Table 50.6 summarizes the assessment of animal data.

TABLE 50.3. International Agency for Research on Cancer (IARC) classifications and criteria.

Category	Classification	Criteria
Group 1	Carcinogenic to humans	Sufficient causal evidence in humans or Sufficient animal evidence and strong mechanistic evidence through a carcinogenic mode of action relevant to exposed humans
Group 2A	Probably carcinogenic to humans	Limited human evidence and sufficient experimental animal evidence or Inadequate human evidence and sufficient experimental animal evidence along with strong mechanistic evidence in exposed humans
Group 2B	Possibly carcinogenic to humans	Limited human evidence and less-than-sufficient animal evidence or Insufficient human evidence and sufficient animal evidence or Limited animal evidence and other supporting data.
Group 3	Not classifiable as to carcinogenicity to humans	Inadequate human evidence and inadequate or limited animal evidence or Sufficient animal evidence and strong mechanistic evidence the chemical does not act on humans
Group 4	Probably not carcinogenic to humans	Strong and consistent evidence of lack of carcinogenicity in humans and animals (rare)

TABLE 50.4. Summary of key mechanistic characteristics associated with human carcinogens. The presence of multiple characteristics (e.g., genomic instability, oxidative stress, chronic inflammation) rather than single processes (e.g., oxidative stress) provides stronger evidence of a carcinogenic process. (Adapted from Smith et al.).[7]

Characteristic	Relevant Examples
Electrophilic structure	Parent compound or metabolite possesses electrophilic properties, forming DNA or protein adducts (e.g., epoxide, quinone)
Genotoxicity	Causes DNA damage (DNA-protein crosslinks, strand breaks, unscheduled DNA synthesis), cytogenetic changes (chromosome aberrations, micronuclei), gene mutations
Genomic instability, altered DNA repair processes	Abnormal DNA replication/repair (double-stranded breaks or base-excision repair, topoisomerase II)
Epigenetic alterations	DNA methylation, histone modification, miRNA expression
Oxidative stress	Macromolecular oxidative damage (DNA, lipids), oxygen free radical formation
Chronic inflammation	Altered cytokine and/or chemokine production, leukocytosis, increased myeloperoxidase activity
Immunosuppression	Immune dysfunction, ↓immunosurveillance
Altered receptor function	Modulation of endogenous ligands (e.g., hormones), ↓↑ receptor activation (e.g., estrogen, peroxisome proliferation/activation, aryl hydrocarbons)
Immortality	Cell transformation, ↓ senescence
Modulation of nutrient supply, cell proliferation, cell death	↑ Angiogenesis, alteration of cell replication and cell cycle control pathways, ↑ cell proliferation, ↓ apoptosis

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 50.5. International Agency for Research on Cancer (IARC) assessment of human evidence of carcinogenicity in case-control and cohort studies. (Adapted from Richter and Goldsmith).[4]

Strong Association	Negative Association
No positive bias	No negative bias
No positive confounding	No negative confounding
Chance unlikely	Misclassification of exposure or outcome
Dose-response relationship	Type B error minimized
Many positive studies	Many negative studies
Latency period consistent	Latency not considered

TABLE 50.6. International Agency for Research on Cancer (IARC) assessment of animal studies for carcinogenicity. (Adapted from Richter and Goldsmith).[4]

Category	Definition	Criteria
Sufficient	Causal relationship between agent and human cancer	Positive results from two or more studies or species
Limited	Causal relationship credible, but chance, bias, confounders may explain relationship	Positive result from one study or species
Inadequate	Data insufficient or studies negative	

All agents classified as human carcinogens also produced positive results in at least one animal experiment based on 2006 criteria. The IARC does not include short-term (*in vitro*) testing in the classification scheme, but positive results in such studies may result in a higher classification. The IARC categorizes ~1,000 agents divided into 122 Group 1 (human) carcinogens (Table 50.7), 93 Group 2A (probable human) carcinogens, 319 Group 2B (possible human) carcinogens, 501 Group 3 (not classifiable), and 1 Group 4 (probably not a carcinogen).[9] In contrast to the USEPA, the IARC does not include chemicals with limited evidence in animals and limited evidence in humans as probable human carcinogens (IARC Group 2A).

Tables 50.8 and 50.9 list IARC Group 1 carcinogens for chemical mixtures and specific exposures (industrial processes and byproducts). Epidemiological studies of foundry workers consistently demonstrate a relative risk of lung cancer of 1.5–2.5 compared with the general population.[10] Chromium and nickel fumes are additional lung carcinogens in steel foundries. Most of the epidemiological studies have not measured the relationship between exposure to these suspected carcinogens and excess mortality from lung cancer. In a meta-analysis of 27 studies (cohorts, record linkage, case-control) of lung cancer among painters, the summary relative risk of lung cancer in painters was 1.35 (95% CI: 1.21–1.51) after controlling for smoking.[11] Exposure-response analyses suggested that the increased duration of employment as a painter increased the lung cancer risk.

Table 50.10 lists Group 2A (probable human carcinogens) for chemicals, mixtures, and specific exposures. Although these classification schemes now include mechanism of action data in the carcinogen classification, these databases do **not** typically include biological data (e.g., route of exposure, pharmacokinetics, mechanism of tumor induction, cell proliferation) that allow an estimation of the potential cancer risk in an individual.[2]

UNITED STATES ENVIRONMENTAL PROTECTION AGENCY

Table 50.11 outlines the 1986 alphanumeric cancer classification of the US Environmental Protection Agency (USEPA). The USEPA revised those guidelines in 2005; however, the USEPA did not reclassify all chemicals previously classified under the 1986 guidelines. Information used to categorize chemicals into the 1986 classification scheme includes human data, animal data, and supporting data using a weight-of-evidence approach. First, a chemical is assigned a category based on an evaluation of human and animal data on the specific chemical. The following terms describe the weight-of-evidence for the chemical: sufficient, limited, inadequate, no data, and no evidence of carcinogenicity. The preliminary classification is revised based on an evaluation of the supporting data (e.g., genotoxicity, toxicokinetics, and mechanistic data).[13] The USEPA cancer classifications of over 540 potential carcinogens have evolved from the alphanumeric categories listed in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 50.7. International Agency for Research on Cancer (IARC) list of Group 1 human carcinogens based on IARC volumes 1–125, including biological organisms, chemicals/mixtures, dusts/fibers, metals, personal habits, pharmaceuticals, and radiation. Other categories include occupations and occupational processes. The IARC frequently updates the classification of carcinogens through the publication of new volumes with a complete list of all chemicals in Groups 1–4 available on their website. (https://monographs.iarc.who.int/agents-classified-by-the-iarc/). (Adapted from Cogliano et al.).[10]

Substance [CAS Number]	Main Tissue Tumor Types
Acetaldehyde in alcoholic beverages	Esophagus, upper aerodigestive tract
Acid mists, strong inorganic	Larynx
Aflatoxins	Liver, hepatocellular carcinoma
4-Aminobiphenyl [92-67-1]	Bladder
Aristolochic acid [313-67-7][a]	Renal pelvis[b], ureter[b]
Aristolochic acid, plants containing	Renal pelvis, ureter
Arsenic [7440-38-2] and arsenic compounds[c]	Lung, skin, bladder
Asbestos [1332-21-4]	Lung, pleural/peritoneal mesothelioma, ovary
Azathioprine [446-86-6]	Non-Hodgkin lymphoma, squamous cell carcinoma, skin
Benzene [71-43-2]	Leukemia
Benzidine [92-87-5]	Bladder
Benzo[*a*]pyrene [50-32-8][a]	—
Beryllium [7440-41-7] and beryllium compounds[a, c]	Lung
N,*N*-Bis(2-chloroethyl)-2-naphthylamine (chlornaphazine) [494-03-1]	Bladder
Bis(chloromethyl)ether [542-88-1] and chloromethyl methyl ether [107-30-2] (technical-grade)	Lung
Busulfan (Myleran®)	Acute myeloid leukemia
1,3-Butadine [106-99-0]	Hemolymphatic system
1,4-Butanediol dimethanesulfonate (Busulphan; Myleran) [55-98-1]	Hematopoietic system
Cadmium [7440-43-9] and cadmium compounds[c]	Lung
Chlorambucil [305-03-3]	Acute myeloid leukemia
Chlornaphazine [494-03-1]	Bladder
1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea (methyl-CCNU; semustine) [13909-09-6]	Hematopoietic system
Chromium[VI] compounds[c]	Lung
Clonorchis sinensis, chronic infection	Cholangiocarcinoma
Coal, indoor emissions from combustion	Lung
Coal tar pitch	Skin, lung
Cyclosporin [79217-60-0]	Non-Hodgkin lymphoma, non-melanotic skin
Cyclophosphamide [50-18-0]/[6055-19-2]	Acute myeloid leukemia, bladder
Diethylstilbestrol [56-53-1], during pregnancy	Breast
Diethylstilbestrol [56-53-1], *in utero*	Cervical clear cell adenocarcinoma, vaginal clear cell adenocarcinoma

TABLE 50.7. (Continued)

Substance [CAS Number]	Main Tissue Tumor Types
Epstein–Barr virus	Burkitt lymphoma, extranodal NK/T-cell lymphoma, Hodgkin and non-Hodgkin (immune suppression related) lymphoma, nasopharynx
Erionite [66733-21-9]	Pleural/peritoneal mesothelioma
Estrogen menopausal therapy	Endometrium ovary
Estrogen-progestogen contraceptives	Breast, cervix, hepatocellular liver carcinoma
Ethylene oxide [75-21-8]	Hematopoietic system[b]
Etoposide [33419-42-0] in combination with cisplatin and bleomycin	Acute myeloid leukemia
Fission products including ^{90}strontium	Leukemia, solid cancers
Formaldehyde [50-00-0]	Nasopharynx, leukemia
Helicobacter pylori chronic infection	Stomach
Hepatitis B virus (chronic infection)	Liver-hepatocellular carcinoma
Hepatitis C virus (chronic infection)	Liver-hepatocellular carcinoma, non-Hodgkin lymphoma
Herpesvirus, Kaposi sarcoma	Kaposi sarcoma, primary effusion lymphoma
Human immunodeficiency virus type 1 (infection)	Anus, cervix, eye-conjunctiva, Hodgkin and non-Hodgkin lymphoma, Kaposi sarcoma
Human papillomavirus type 16	Anus, cervix, oral cavity, oropharynx, penis, tonsil, vagina, vulva
Human papillomavirus type 18, 31, 33, 35, 45, 51, 52, 56, 58, 59	Cervix
Human T cell lymphotropic virus type 1	Leukemia, T-cell lymphoma-adult
Kaposi sarcoma herpes virus	Kaposi sarcoma, primary effusion lymphoma
Melphalan [148-82-3]	Acute myeloid leukemia, lung
8-Methoxypsoralen (methoxsalen) [298-81-7] plus ultraviolet A radiation	Skin squamous cell carcinoma
4,4′-Methylenebis(2-chloroaniline) (MOCA) [101-14-4][a]	—
Mineral oils, untreated/mildly treated	Skin
MOPP and other combined chemotherapy including alkylating agents	Acute myeloid leukemia
Mustard gas (sulfur mustard) [505-60-2]	Pharynx, larynx, lung
2-Naphthylamine [91-59-8]	Bladder
Nickel compounds[c]	Lung, nasal cavity, paranasal sinuses
N′-Nitrosonornicotine (NNN) [16543-55-8][a]	—
4-(N-Nitrosomethylamino)-1-(3-pyridyl)-1-butanone (NNK) [64091-91-4][d a]	—
Opisthorchis viverrini, chronic infection	Liver-cholangiocarcinoma
3,4,5,3′,4′-Pentachlorobiphenyl (PCB-126) [57465—28-8][a]	—
2,3,4,7,8-Pentachlorodibenzofuran [57117-31-4][a]	—
Pentachlorophenol [87-86-5]	—
Phenacetin [62-44-2]	Renal pelvis, ureter

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 50.7. (Continued)

Substance [CAS Number]	Main Tissue Tumor Types
Polychlorinated biphenyls (PCBs 77, 81, 105, 114, 118, 123, 126 156, 157, 167, 169, 189)[a]	Melanoma
^{32}Phosphorus	Acute leukemia
Plutonium	Bone, liver, lung
Radioiodines including ^{131}Iodine	Thyroid
^{222}Radon [10043-92-2] and its decay products	Lung
^{224}Radium and decay products	Bone
^{226}Radium and ^{228}Radium plus decay products	Bone, mastoid process, paranasal sinus
^{232}Thorium and decay products	Bile duct, gall bladder, leukemia except chronic lymphocytic leukemia, liver hemangiosarcoma
Schistosoma haematobium, chronic infection	Bladder
Semustine (methyl-CCNU)	Acute myeloid leukemia
Silica dust, crystalline [14808-60-7] (occupational exposure to inhaled quartz/cristobalite)	Lung
Solar radiation	Skin
Soot	Skin
Sulfur mustard	Lung
Talc containing asbestiform fibers	Lung
Tamoxifen [10540-29-1] [d]	Endometrium
2,3,7,8-Tetrachlorodibenzo-*p*-dioxin [1746-01-6]	Overall cancer rate
o-Toluidine [95-53-4]	Bladder
Thiotepa [52-24-4]	Leukemia
Treosulfan [299-75-2]	Acute myeloid leukemia
Trichloroethylene [79-01-6]	Kidney
Vinyl chloride [75-01-4]	Liver, angiosarcoma, hepatocellular
Gamma (γ)-, X-ray radiation	Bladder, bone, brain and central nervous system, breast-female, colon, esophagus, kidney, leukemia except chronic lymphocytic leukemia, lung, salivary gland, skin-basal cell carcinoma, stomach, thyroid
Ultraviolet radiation (UVA, UVB, UVC), tanning devices	Skin-basal cell carcinoma, melanoma (eye), squamous

[a] Upgraded to Group 1 based on mechanistic and/or other relevant data rather than sufficient human data alone. [b] Limited evidence only. [c] Evaluation applies to the group of compounds as a whole and not necessarily to all individual compounds within the group. Metallic nickel and nickel alloys are classified as Group 2B. [d] There is also conclusive evidence that this agent (tamoxifen) reduces the risk of contralateral breast cancer.

Table 50.11 to a narrative paragraph with standardized descriptions based on guidelines published in 1996, 1999, and 2005. These guidelines permit consideration of the relevance of bioassays to human exposures, including analysis of the mode of action and similarity of the routes of exposure, with preference given to peer-reviewed scientific journals.

The USEPA scheme is more rigorous than the IARC classification because the probable human carcinogen and the noncarcinogenic categories require human data; however, the USEPA tends to classify animal carcinogens into higher cancer categories in the absence of human data consistent with their primary goal of protecting human health as described

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 50.8. International Agency for Research on Cancer (IARC) Group 1 human carcinogens associated with specific exposures (industrial processes, by-products, environmental carcinogens) with suspected carcinogens. Other chemicals may contribute to the carcinogenic process (e.g., chromium/nickel fumes contribute to lung cancer in steel foundries).[12] IARC frequently updates the classification of carcinogens through the publication of new volumes. For the most current list of Group 1 carcinogens, refer to the IARC website at https://monographs.iarc.who.int/wp-content/uploads/2019/12/OrganSitePoster.PlusHandbooks.pdf. (Adapted from IARC).[9]

Specific Exposure	Main Tumor Tissue Types
Acheson process, occupational exposure	Lung
Aluminum production (PAH, tar volatiles)	Lung, bladder
Auramine manufacturing (auramine, aromatic amines)	Bladder
Coal gasification	Ling
Coal-tar pitches [65996-93-2]	Skin, lung
Coal tar [8007-45-2] distillation	Skin
Coke production	Lung
Diesel engine exhaust	Lung
Fluoro-edenite fibrous amphibole	Mesothelioma
Furniture and cabinet making (wood dust)	Nasal cavity
Hematite underground mining (radon exposure)	Lung
Iron and steel founding	Lung
Isopropanol manufacture (strong-acid process)	Nasal cavity and paranasal sinuses
Leather dust	Nasal cavity and paranasal sinuses, nasopharynx
Magenta, manufacture of	Bladder
Mineral oils, untreated and mildly treated	Skin
Painter, occupational	Bladder, lung, mesothelioma
Rubber industry (benzene, aromatic amines)	Bladder, leukemia, lymphoma, lung, stomach
Shale oils [68308-34-9]	Skin
Strong inorganic acid mists containing sulfuric acid (occupational exposure)	Larynx
Welding	Eye-melanoma

Abbreviation: PAH = polycyclic aromatic hydrocarbons.

TABLE 50.9. IARC Group 1 human carcinogens associated with mixtures of chemicals. IARC frequently updates the classification of carcinogens with the publication of new volumes. For the most current list of Group 1 carcinogens, refer to the IARC website https://monographs.iarc.who.int/agents-classified-by-the-iarc/. (Adapted from IARC).[9]

Mixtures	Main Tumor Tissue Type
Air pollution/particulate matter, outdoors	Lung
Alcoholic beverages	Female breast, colorectum, esophagus, larynx, hepatocellular liver, oral cavity, pharynx
Betel quid without tobacco	Esophagus oral cavity
Betel quid with tobacco	Esophagus, oral cavity, pharynx
Salted fish (Chinese-style)	Nasopharynx
Solar radiation	Skin
Soots associated with chimney sweeps	Skin, lung
Tobacco, environmental	Lung
Tobacco smoking	Oral cavity, pharynx, esophagus
Tobacco smoke	Bladder, cervix, colorectum, esophagus (adenocarcinoma, squamous cell carcinoma, kidney, myeloid leukemia, larynx, liver, lung, nasal cavity/paranasal sinus, ovary, pancreas, pharynx, stomach, ureter pharynx, larynx, esophagus, pancreas, kidney)
Tobacco, smokeless	Esophagus, oral cavity, pancreas

in Table 50.12.[14] The weight-of-evidence does not correspond to a specific quantitative probability of chemical carcinogenicity as a result of the difficulty in assigning a probably from supportive data. However, the USEPA database provides quantitative estimates of carcinogenic risk for oral and pulmonary routes of exposure as well as reference concentrations and doses that estimate the daily oral or continuous inhalation exposure that is unlikely to produce an appreciable risk of deleterious effects during a lifetime for the human population including sensitive subgroups.[15]

TABLE 50.10. IARC list of Group 2A carcinogens (probable human carcinogens). A complete listing of chemical substances and mixtures is available on the IARC website (https://monographs.iarc.who.int/agents-classified-by-the-iarc/).

Substance	CAS No.
Chemicals	
Acrylamide	79-06-1
Adriamycin	
Androgenic (anabolic) steroids	23214-92-8
Azacitidine	320-67-2
Bischloroethyl nitrosourea (BCNU)	154-93-8
Captafol	2425-06-1
Chloral	75-87-6
Chloral hydrate	302-17-0
Chloramphenicol	56-75-7
α-Chlorinated toluenes combined exposure ((benzal chloride [98-87-3], benzotrichloride [98-07-7], benzyl chloride [100-44-7]), and benzoyl chloride [98-88-4])	
1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea (CCNU)	13010-47-4
p-Chloro-*o*-toluidine and its strong acid salts[a]	95-69-2
Chlorozotocin	54749-90-5
Cisplatin	15663-27-1
Cobalt metal (7740-18-4) with tungsten carbide	12070-12-1
Cyclopenta[*c*,*d*]pyrene[b]	27208-37-3
Diazinon	333-41-5
Dibenz[*a*,*j*]acridine	224-42-0
Dibenz[*a*,*h*]anthracene	53-70-3
Dibenzo[*a*,*l*]pyrene	191-30-0
4,4′-dichlorodiphenyltrichloroethane (DDT)	50-29-3
Dichloromethane (methyl chloride)	75-09-2
Dieldrin (60-57-1) and aldrin (309-00-2) metabolized to dieldrin	
Diethyl sulfate	64-67-5
Dimethylcarbamoyl chloride	79-44-7
Dimethylformamide	68-12-2
1,2-Dimethylhydrazine	540-73-8
Dimethyl sulfate	77-78-1
Epichlorohydrin	106-89-8
Ethyl carbamate (urethane)	51-79-6
Ethylene dibromide	106-93-4
N-Ethyl-*N*-nitrosourea	759-73-9
Glycidol	556-52-5
Glyphosate	1071-83-6
Human papillomavirus type 68	
Hydrazine	302-01-2
Indium phosphide	22398-80-7
IQ (2-Amino-3-methylimidazo[4,5-*f*]quinoline)	76180-96-6
Lead compounds, inorganic	
Malaria, infection by *Plasmodium falciparum* in holoendemic area	
Malathion	121-75-5
2-Mercaptobenzothiazole	149-30-4
Merkel cell polyomavirus (MCV)	
5-Methoxypsoralen	484-20-8
Methyl methanesulfonate	66-27-3
N-Methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG)	70-25-7
N-Methyl-*N*-nitrosourea	684-93-5
Nitrite/nitrate from endogenous nitrosation	
6-Nitrochrysene	7496-02-8

EUROPEAN GLOBALLY HARMONIZED SYSTEM

As a method to standardize the carcinogenic hazards of chemicals, the United Nations Conference on Environment and Development (UNCED) developed the Globally Harmonized System (GHS) to classify chemical carcinogenicity; this system uses two categories of known or presumed human carcinogens (Categories 1A, 1B) and suspected human carcinogens (Category 2), as displayed in Table 50.13.[16] Allocation of substances to these categories depends on an evaluation of the inherent properties of the chemical or mixture, including the strength of human/animal evidence and a weight-of-evidence approach to additional information relevant to the potential of these substances to produce cancer. Although determination of the category may be specific to the route of exposure, these categories do not necessarily provide information about potency, risk, or exposures relevant to humans.[17] The GHS considers a chemical demonstrating evidence of carcinogenicity in a well-designed experimental study as a presumed or

TABLE 50.11. 1986 United States Environmental Protection Agency (USEPA) classification of carcinogenicity and cancer types associated with human and probable human carcinogens based on epidemiological evidence. The cancer type associated with a specific chemical depends on the route of exposure (see IRIS database for specific details on individual chemicals). The latest USEPA guidelines allow multiple descriptors for individual chemicals or mixtures (e.g., hexavalent chromium). From USEPA Integrated Risk Information System (IRIS) Database (https://cfpub.epa.gov/ncea/iris/search/index.cfm). (Adapted from IRIS Advanced Search, USEPA).

Carcinogen Group	Description of Evidence	Chemical (Cancer Type – Human or Animal)
A (Human)	Sufficient human	Arsenic, inorganic (skin, lung); asbestos (lung, mesothelioma); benzene (leukemia); benzidine (bladder); bis(chloromethyl)ether (respiratory tract); chromium VI (lung); coke oven emissions (respiratory); nickel subsulfide or refinery dust (lung); vinyl chloride (liver angiosarcoma, hepatocellular carcinoma)
B1 (Probable Human)	Limited human	Acrylonitrile (brain or spinal cord astrocytomas, Zymbal's gland carcinoma, stomach papillomas, and carcinomas/respiratory); beryllium and compounds (lung); cadmium (lung, trachea, bronchus); formaldehyde (squamous cell carcinoma)
B2 (Probable Human)	No or inadequate human data and sufficient animal	Acetaldehyde, aldrin, aniline, aramite, azobenzene, benzotrichloride, benzyl chloride, bis(chloroethyl)ether, bromate, bromodichloromethane, bromoform, chlordane, chloroform, di(2-ethylhexyl)phthalate (DEHP), 3,3′-dichlorobenzidine, *p*,*p*′-dichlorodiphenyldichloroethane (DDD), dichlorodiphenyldichloroethylene (DDE), dichlorodiphenyltrichloroethane (DDT), 1,2-dichloroethane, 1,3-dichloropropene, dichlorvos, dieldrin, 2,4/2,6-dinitrotoluene mixture, 1,2-diphenylhydrazine, epichlorohydrin, furmecyclox, heptachlor, hexachlorobenzene, hexachlorocyclohexane, hexachlorodibenzo-*p*-dioxin mixture, hydrazine/hydrazine sulfate, 4,4′-methylene bis(*N*,*N*′-dimethyl)aniline, *N*-nitroso-*N*-methylethylamine, *N*-nitroso-di-*n*-butylamine, *N*-nitrosodi-*N*-propylamine, *N*-nitrosodiethanolamine, *N*-nitrosodiethylamine, *N*-nitrosodimethylamine, *N*-nitrosodiphenylamine, *N*-nitrosopyrrolidine, polychlorinated biphenyls (PCBs), propylene oxide, quinoline, toxaphene, 2,4,6-trichorophenol
C (Possible human)	No human and limited animal	Di(2-ethylhexyl)adipate, dibromochloromethane, hexachlorobutadiene, β-hexachlorocyclohexane, hexahydro-1,3,5-trinitro-1,3,5-triazine, isophorone, prochloraz, 1,1,1,2-tetrachloroethane, 1,1,2-trichloroethane, trifluralin, 2,4,6-trinitrotoluene (TNT)
D (Not classifiable)	No or inadequate human and animal	Chromium VI inhalation
E (Noncarcinogenic)	At least two negative animal studies or negative human and animal studies	None

suspected human carcinogen unless the mechanism of tumor formation is not relevant to humans.

Additional information via a weight-of-evidence evaluation may increase or decrease the likelihood that the substance is a human carcinogen and elevate the suspected carcinogen to Category 1. Typically, the requirement for changing a category is more stringent for decreasing than increasing the level of concern. The weight-of-evidence evaluation involves multiple factors including tumor type, number, background incidence, latency, progression, routes of exposure, structural similarity to known carcinogens, relevance of toxicokinetics of test animals to humans, carcinogenic responses of multiple species and sexes, dose-response, and relevance of mode of action to humans.

AMERICAN CONFERENCE OF GOVERNMENTAL AND INDUSTRIAL HYGIENISTS

The American Conference of Governmental and Industrial Hygienists (ACGIH, https://www.acgih.org/) is a private US organization that classifies potential carcinogens into five categories, as displayed in Table 50.14, based on their evaluation of evidence. In evaluating occupational carcinogens, ACGIH places

TABLE 50.12. 2005 US Environmental Agency (USEPA) criteria for classification of carcinogenicity. More than one descriptor can apply to a chemical exposure when the carcinogenic effect differs by internal dose (e.g., poor absorption) or route of exposure. (Data adapted from Environmental Protection Agency).[15]

Descriptor	Weight-of-Evidence	Description of Evidence
Carcinogenic to humans	Strong evidence in humans	Convincing epidemiological evidence of causal association or Lesser epidemiological evidence with strong association, extensive animal evidence, identified mode of action, **AND** consistent biological mechanisms in animals and humans
Likely to be carcinogenic to humans	Adequate carcinogenic potential with likely rather than strong evidence in humans[a]	Broad spectrum including plausible, but not causal association in epidemiology studies with supporting biological or experimental evidence, strongly positive animal evidence (<1 study type) with/without human evidence, strongly positive tumor study with highly malignant, early tumor onset, or relevant rare response, The A positive tumor study with a supportive mechanistic or epidemiological data
Suggestive evidence of carcinogenic potential	Suggestive without sufficient evidence for stronger association	Varying concerns for carcinogenicity including small increased tumor incidence in single animal or human study less than likely category, small increased tumor rate with high background rate with inability to exclude alternative to chemical carcinogenicity, or Evidence of positive study with design flaws or no dose-response
Inadequate information to assess carcinogenic potential	Inadequate information to assess carcinogenic potential	Little or no information, conflicting evidence, or negative study without sufficient evidence to raise descriptor to suggestive level
Not likely to be carcinogenic to humans	Robust data indicating no human carcinogenic hazard	Extensive, convincing evidence that a chemical is not carcinogenic by exposure route, above threshold, or Strong evidence of lack of animal carcinogenicity with no human data suggesting carcinogenic effect

[a] The term does not imply a quantifiable probability.

TABLE 50.13. Carcinogenic categories of the UN Globally Harmonized System of Classification and Labelling of Chemicals. Sufficient evidence indicates a causal association between the substance and cancer development, whereas limited evidence implies a positive association between the exposure and the substance that is not definitely causal. (Adapted from United Nations).[16]

Category	Classification	Criteria
1A	Known human carcinogen	Based primarily on epidemiology data demonstrating a causal relationship between exposure and tumor formation.
1B	Presumed human carcinogen	Based primarily on sufficient evidence from animal studies. Depending on a weight-of-evidence evaluation of additional information, a substance may be elevated to a higher category with limited evidence of carcinogenicity in humans and experimental animals.
2	Suspected human carcinogen	Limited evidence in human and/or animal studies with insufficient evidence to place substances in category 1.

TABLE 50.14. American Conference of Governmental and Industrial Hygienists (ACGIH) classification of carcinogens.

Category	Classification	Criteria
A1	Confirmed human carcinogen	Carcinogenic to humans based on weight-of-evidence from epidemiological studies.
A2	Suspected human carcinogen	Human data is adequate but conflicting (insufficient) to elevated to A1 or An experimental animal carcinogen (sufficient) at relevant occupational exposures.
A3	Confirmed animal carcinogen with unknown relevance to humans	Animal carcinogens at doses, routes or Mechanisms not relevant to occupational exposures and unlikely to cause human cancers.
A4	Not classifiable as a human carcinogen	Agents of concern without adequate data including lack of animal data.
A5	Not suspected as a human carcinogen	Existing studies of sufficient quality demonstrate no significant cancer risk or lack of experimental animal data supported by mechanistic data. This category also contains substances with no reported human or experimental animal carcinogenicity.

greater emphasis on human evidence in order of preference beginning with cohort studies and then case-control studies, case reports, and descriptive studies. The criteria for interpreting these epidemiology studies include strength of statistical association, dose-response relationships, temporal relationship between exposure and disease, consistency with previously reported epidemiological studies, coherence with known biological mechanisms, specificity of risk in high-exposure workplaces, and statistical significance. The ACGIH considers experimental animal data preferring long-term bioassays in two mammalian species at doses and routes relevant to workplace exposures.

Chapter 51

RISK ASSESSMENT

BACKGROUND

Risk assessment provides a conceptual framework for the structured review of chemical toxicity and adverse health effects that could potentially result from chemical exposure by evaluating the hazard (toxicity) and exposure to the chemical, compound, or mixture.[1] Toxicity is an inherent property of all chemicals; consequently, all chemicals are hazardous depending on the dose necessary to develop adverse effects. A hazard connotes the *potential* to produce an adverse effect. The Environmental Protection Agency and the International Agency for Research on Cancer identify cancer hazards by classifying the potential of a chemical to cause cancer based on animal, human, and computational data. Risk is the *probability* that an adverse effect (e.g., cancer) will occur. This probability depends on the dose delivered to the critical target organ and the carcinogenic potency;[2] hence, the presence of an environmental carcinogen does not necessarily imply cancer will develop. Risk assessment determines the likelihood of an adverse effect (e.g., cancer) given the uncertainties involved in the analysis.

Risk assessment possesses no units of measure. Numerical risk values range from zero (i.e., no chance of occurrence) to one (i.e., absolute certainty). Chemical use produces risks of adverse health effects including cancer; however, the reduction of the risk to zero is not possible because many carcinogens occur naturally. Consequently, the presence of these chemicals cannot be completely eliminated without unacceptable social and economic costs.[3] The concept of acceptable risk recognizes the impracticality of eliminating all cancer risks as an alternative to the concept of zero risk.

The US regulatory agencies (Food and Drug Administration, FDA; Environmental Protection Agency, USEPA) establish carcinogen exposure concentrations in food, consumer products, water, and the environment based on the Acceptable Risk Concept.[4] Therefore, governmental agencies balance relatively small cancer risks with public interests by establishing exposure concentrations that produce negligible or *de minimus* risk.[5] Typically, these agencies set the acceptable level at 1 excess cancer death/1,000,000 lifetime exposures. An acceptably low risk (i.e., 1×10^{-6}) rather than an absolute absence of risk (i.e., 0) defines a safe risk.

EPA and Quantitative Risk Assessment

Risk assessment quantifies the probability that an adverse effect will occur by using mathematical models to extrapolate high-dose animal exposures to the low-dose exposures present in the human environment. Consequently, qualitative risk assessment depends on the validity of the mathematical assumptions used in the modeling process rather than on epidemiological data.[6] The critical data points define the slope of the dose-response curve rather than the NOAEL; the latter approximates the threshold for adverse health effects. Although the appropriate methodology and modeling for the estimation of these critical data points are somewhat controversial, the linear, no-threshold model that extrapolates relevant animal exposure data to humans

remains the default method for evaluating carcinogenic risk given the concern for safety and existing uncertainty.[1] Health protective risk assessment procedures, as described in the USEPA cancer guidelines, mean cancer estimates contain some uncertainty; however, these estimates are more likely to overstate than understate hazard and/or risk.[7]

Most US government agencies use this methodology to estimate the risk of exposure to suspected carcinogens. This process depends on the potency of the chemical and the amount of absorbed dose and uses four steps: 1) hazard identification – what is the identity and circumstances of the suspected human carcinogen based on existing scientific evidence? 2) exposure assessment – what are the conditions (amount, frequency, duration) of human exposure? 3) dose-response assessment – what effects occur at the estimated exposure level based on human, extrapolated animal, *in vitro*, and mechanistic data? and 4) risk characterization – what is the summarized character of the risk and validity of supporting data (extent, nature) for the estimated risk to the suspected carcinogen including the uncertainty? Risk assessments are conducted without consideration of the consequences of regulatory action; however, risk management combines risk assessment with the directives of legislation to determine the necessity to control specific chemical exposures. Other factors involved with the determination of final policies regarding chemical exposure include socioeconomic values, cost, technical feasibility, duration and magnitude of risk, and the population at risk as well as political and trade considerations.

The USEPA Integrated Risk Information System (IRIS) assessment program evaluates the quantitative and qualitative risk information on >540 potential environmental contaminants for hazard identification and dose-response evaluation.[8] These hazard assessments provide quantitative data for noncarcinogens (oral/inhalational reference doses) and carcinogens (oral slope factors, inhalation unit risks). For the latter, the USEPA uses a weight-of-evidence approach based on animal, human, pharmacokinetic, and mechanistic (mode-of-action) data, including analysis of study design (e.g., appropriate statistical analysis), as outlined in Figure 51.1. The use of mode-of-action in the potential carcinogen assessment is a primary focus of USEPA

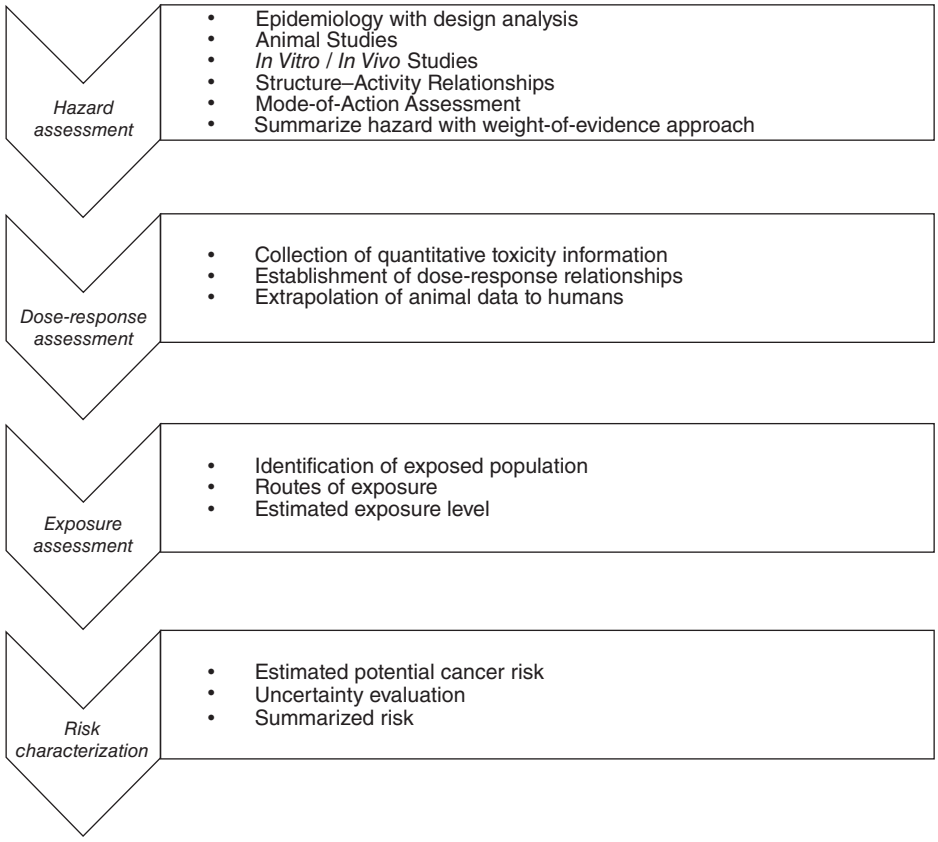

FIGURE 51.1. Four main elements of risk assessment with descriptors. (Adapted from Derelanko).[10]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cancer guidelines to integrate recent significant scientific advances involving the causation of cancer into the risk assessment process. The mode-of-action represents the sequence of key events and processes (e.g., mutagenicity, mitogenesis, cytotoxicity with subsequent cell proliferation, inhibition of cell death, immune suppression) that proceeds from the initial cell–agent interaction through anatomical and operational alterations to malignant tumor formation. Understanding these processes helps identify susceptible populations and life stages. The weight-of-evidence approach summarizes the results of hazard assessment by providing conclusions regarding the likelihood of human carcinogenic effects and the conditions necessary for cancer formation, including an analysis of the data (i.e., strengths, limitations, significant issues). The standard hazard descriptors with the older alphanumeric group classification include: 1) carcinogenic to humans – Group A, 2) likely to be carcinogenic to humans – Group B, 3) suggestive evidence of carcinogenic potential – Group C, 4) inadequate information to assess carcinogenic potential – Group D, and 5) not likely to be carcinogenic to humans – Group E.[7,9]

Most risk assessments of low-dose exposure to chemical carcinogens accept conservative assumptions designed to overestimate the true risk in order to provide an extra margin of safety.[11] These conservative assumptions include the following: 1) the risk to humans is similar to the risk of the most sensitive animal species, 2) benign tumors are included in the assessment, unless there is scientific evidence to the contrary, 3) there is no threshold dose, 4) cross-species scaling factors (e.g., $(\text{body weight})^{3/4}$) are appropriate, and 5) mathematical models accurately predict the dose-response curve at levels of exposure below the lowest experimental dose. Hence, chemical exposure at concentrations near regulatory levels does not necessarily imply cancer will develop.

The accuracy of risk assessment depends on the adequacy of the data, the appropriateness of the extrapolation from experimental data to actual situations, and the extent of our understanding of the biological mechanisms and modes of action that relate exposure to cancer outcomes. Two priorities of the EPA are the development of more accurate models (e.g., biologically based dose-response models) and a better estimation of the amount of chemical exposure in the environment.

Safety Factor Analysis

The safety factor technique for food additives, drinking water, and air is an alternative to quantitative risk assessment as a method to establish safe chemical concentrations without properties of germ cell mutagens or genotoxic carcinogens; this method uses a variety of indices to determine safety including acceptable daily intake (ADI), reference dose, tolerable daily intake, potency index, minimal risk level, and hazard index. This semiquantitative approach for noncarcinogens assumes the presence of a threshold level (i.e., the no observable adverse effect level, NOAEL) determined by animal testing below which adverse health effects do not occur. The NOAEL is an experimentally derived value with biological variability rather than an absolute value; consequently, the chemical concentration defining the NOAEL depends on the sample size of the study. Furthermore, the estimated NOAEL for a rare toxicological event in the study population usually lacks precision. The major limitation of safety indices is the lack of information on the likelihood of adverse effects following exposure to concentrations exceeding the index value for carcinogens and noncarcinogens.[12]

A safety or uncertainty factor provides a protective margin to account for extrapolation from animal models to humans while protecting susceptible segments of the population.[13] Hence, wide safety margins for the protection of public health should not be confused with the establishment of causation when exposures exceed the regulatory limits.[14] Equation 51.1 describes the relationship between the safety factor and the acceptable level as defined by the Food and Agriculture Organization of the United Nations (FAO) and the World Health Organization (WHO).

$$\text{Acceptable daily intake (ADI)} = \frac{\text{NOAEL (animal data)}}{\text{Safety factor}} \qquad \text{(Equation 51.1)}$$

The uncertainty factor is usually 10-fold, with the size of this factor depending on an evaluation of chronic bioassay data, chemical properties, and interspecies variability. The USFDA adds an additional 10-fold factor when only subchronic studies are available to establish the NOAEL. The addition of a 10-fold factor for individual human variability means that an acceptable margin of safety is 100. Table 51.1 lists factors that increase or decrease the safety factor. Both the US EPA and the FAO/WHO initially used the ADI-derived method to establish safe concentrations of chemicals for adverse effects **other than** carcinogens and mutagens. The acceptable daily intake (ADI) is an estimate (i.e., within an order of magnitude) of the daily uptake in a human population, including sensitive people, that would not result in an appreciable risk of deleterious effects over a lifetime exposure.[15] The USEPA redefines the ADI as the reference dose (RfD) and the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 51.1. Factors modifying the value of the safety factor.

Factor	Increase	Decrease
Mechanism of action	Unknown	Known
Evidence of threshold effect	Absent	Present
Human evidence	Limited	Substantial
Human exposure	Continuous	Intermittent
Human elimination	Slow with accumulation	Rapid
Most sensitive species	Man	Animal
Test species	Not most sensitive	Most sensitive
Induction of adverse effects	Several species	One species
In vitro tests	Genotoxic	Nongenotoxic
Majority of tumors	Malignant with rapid metastasis	Benign
Tumor sites	Multiple	Single
Tumor development	Both sexes	One sex
Tumor type	Rare	Common

safety factor as the uncertainty factor. Although the safety factor process assumes a threshold exists below which exposure to the chemical produces no adverse effect, chemical exposures to concentrations near the RfD (i.e., ADI) level do not necessarily cause adverse effects because of the addition of the safety factor. Figure 51.2 displays the dose-response curve from a typical (noncarcinogenic) toxicology study.

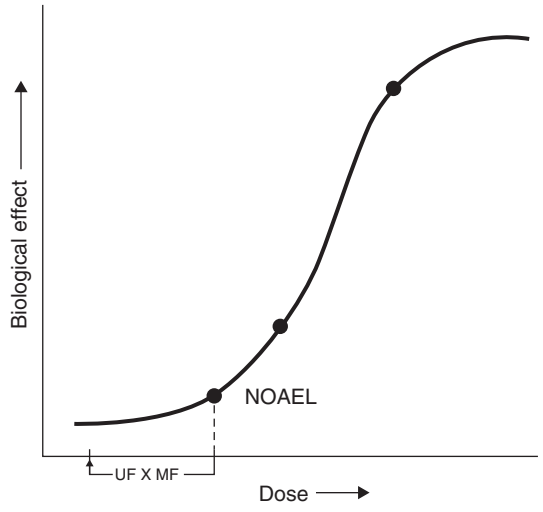

FIGURE 51.2. Schematic representation of noncarcinogenic dose-response curve displaying the relationship between the RfD (reference dose) or RfC (reference concentration) and the No Observable Adverse Effect Level (NOAEL) usually derived from animal data. The RfD and RfC assume a threshold value and include a safety factor derived from the product of an uncertainty factor (UF) and modifying factor (MF) that may deviate from the NOAEL by several orders of magnitude, depending on the quality of the data and modifying factors listed in Table 51.1. (Adapted from Derelanko).[10]

Risk Management

Risk management is a political process that integrates social, economic, and technical considerations with the scientific estimation of health risk to reach a decision on the extent to which chemical exposure is controlled. This decision-making process evaluates alternative regulatory actions and selects the appropriate response based on socioeconomic and political considerations. Defining strategies to control chemical exposures involves a value judgment regarding the acceptability of risk. Traditionally, the acceptable risk for a carcinogen is 1×10^{-6} or one excess cancer death per 1 million lifetime exposures.

Risk Communication

Risk is an inescapable part of life; risks are considered acceptable when the benefits outweigh the risk. However, the risk of exposure to a chemical often is not shared proportionally with the benefits associated with the chemical. Furthermore, involuntary exposure issues are compounded by the inability to decide the extent of exposure; this situation results in highly emotional debates when strongly held perceptions are not consistent with scientific reality. In such settings, the communication of factual information should be done by comparison of relative risks of similar situations. Acceptance of risk depends on factors (e.g., severity of outcome, perceived probability of occurrence, peer pressure, ability to control exposure, suffering associated with outcome, visibility of alternate source to blame, perceived benefit, and degree of uncertainty.[16]

The acceptance of risk for an undesirable outcome from a chemical exposure or an activity is specific to the individual (e.g., smoking, riding a motorcycle). When the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

individual does not accept the risk and the undesirable outcome occurs, the situation may provoke emotional distress and rage in the individual. This situation should be considered when communicating the risks of an outcome to an audience. Table 51.2 presents comments on the important factors that affect risk communication.

HAZARD IDENTIFICATION

Hazard identification is a *qualitative* risk assessment process that first determines which chemicals are present in the environment and then evaluates the potential of the chemicals to produce cancer or another adverse effect, including the circumstances necessary to express that potential risk.[9] The hazard identification process answers the following two questions: 1) does the chemical cause cancer or another health hazard? and 2) when does the identified hazard appear? A weight-of-evidence approach assesses the available data, including the quality and results of animal and epidemiological studies, *in vitro*/*in vivo* data, structure–activity relationships, and modes of action.[1] The ability of a chemical to cause cancer depends on its ability to reach the appropriate site in a biologically active form. Part of the hazard identification process includes an analysis of the physiochemical, metabolic, and pharmacokinetic properties as well as the routes and patterns of exposure to determine the extent a chemical presents an environmental carcinogenic hazard. The result of the hazard identification process is a scientific judgment on the potential of a chemical to cause human cancer or another adverse event.

Physiochemical Properties

Although this section intuitively seems to be part of exposure assessment, both the toxic potential and the physicochemical properties are considered together because both factors help determine the potential for a health hazard.[17] Figure 51.3 demonstrates the passage of chemicals through the environment. The physicochemical properties of a chemical determine the fate of a chemical in the environment by altering its migration, accumulation, and degradation in various media; however, direct measurements of the fate of a particular chemical in a specific medium are the most accurate estimation of the presence of the chemical in a similar environment. The Hazardous Substances Data Bank (HSDB) and the USEPA Environmental Fate Database have been combined with the National Library of Medicine's PubChem. The new PubChem database (https://pubchem.ncbi.nlm.nih.gov/) contains specific information on the fate of many chemicals.

Water Solubility

Highly water-soluble chemicals tend to remain dissolved in water rather than in soil and sediment. This type of chemical does not typically accumulate in aquatic organisms, with volatilization into the air being relatively less common depending on their vapor pressure. Highly water-soluble compounds usually biodegrade more readily than chemicals with less water solubility. Many environmental contaminants (e.g., dioxin, DDT, polychlorinated biphenyls) are chemicals with low water solubility; these chemicals are relatively more resistant to degradation in soil and water.

Vapor Pressure

Equilibrium vapor pressure (i.e., the solubility of a chemical in the air) is an important determinant of the transport of the chemical to the air; this physical property is a function of the inherent properties of the chemical and temperature. The volatility of a chemical in water varies with the vapor pressure and water solubility. Even though low water solubility and low vapor pressures discourage volatilization from water, some environmental contaminants (e.g., DDT) volatilize from concentrated areas because of the low concentrations in the environment. Chemicals with vapor pressures of $<10^{-6}$ exist mostly in particulate matter rather than air.[19]

Dissociation Constant

The dissociation constant (pK_a) is the pH at which 50% of the chemical exists in the ionized form; this value measures the extent to which the chemical breaks into charged forms. The ionic charge of a chemical affects its binding to soil and sediment. Most soils are negatively charged and bind chemicals with positive charges more effectively. Chemicals (e.g., paraquat, diquat) that form cations at existing soil pH generally adsorb strongly to soil materials (e.g., clay). The dissociation constant also affects the ability of the chemical to penetrate biological membranes because only the nonionized form can penetrate lipid membranes.

Log Octanol/Water Partition Coefficient

This physical property (K_{ow}) is the ratio of the chemical concentration in octanol divided by the concentration of the chemical in water at equilibrium. Chemicals with high K_{ow} display hydrophobic properties, tend to partition away from water, and distribute into aquatic organisms. For nonionized chemicals, this ratio correlates well with bioconcentrations in aquatic organisms and adsorption to soil or sediment;[20] however, the K_{ow} explains only part of the bioconcentration of chemicals

TABLE 51.2. Observations on risk and risk communication. (Adapted from Cox and Strickland).[16]

Issue	Observation
Risk	1. Life involves risk.
	2. Societies require risk to grow and prosper.
	3. Beneficial actions require some risk.
	4. All societies require change, and change involves risk.
	5. Proving the absence of risk is very difficult, even though such risks are inconsequential, whereas proving the presence of risk is much easier.
	6. Although the risk of harm in our society is lower, the acceptance of risk is also lower.
Emotion	1. Risk intensifies one of the strongest human emotions, fear.
	2. Uncertainty strengthens emotions related to risk.
	3. Risk implies uncertainty, which is uncomfortable for most people.
	4. Lack of scientific understanding reduces the willingness to accept risk, assuming that benefits and risk remain constant.
	5. Risk should be analyzed in the whole context of all alternatives to actions and inactions.
Individuals	1. Freedom of an individual directly relates to the responsibility accepted for individual actions.
	2. The ability to manage risk requires experience with uncertainty and responsibility for the consequences of risk.
	3. Individuals accept greater risk when comfortable rather than when struggling for survival.
	4. Individuals will accept risks considered unacceptable by society when they believe in substantial personal benefit.
Society	1. Society determines reasonable risk based on benefits to many and risks to individuals.
	2. Societal benefits do not justify excessive individual risks without individual benefits.
	3. Society values indicate that involuntary risk should be compensated by society or involved entities.
	4. Older individuals usually accept less risk than younger individuals, and as the population ages society's acceptance of risk probably will decrease.
	5. As the industrial base of society decreases, the acceptance of risk also decreases.
Perception	1. Public perception requires evaluation and appropriate actions, even though the perceptions are not scientifically based.
	2. Most individuals consider risk undesirable.
	3. Problems require both technical and political solutions.
	4. Achieving technical solutions during a political crisis is difficult. Political action responds to crises, whereas technical solutions require a dispassionate logic that is usually not present during a political crisis.
Communication	1. Communicating a positive concept (e.g., degree of safety) is easier than a negative concept (e.g., risk).
	2. Numerical calculations should not be used to communicate risk because of the focus on large numbers rather than small risks.
	3. The risk communicator must be a knowledgeable, skilled communicator.
	4. The media tends to focus on controversial issues rather than a dispassionate analysis of the scientific issues of risk. Good risk communication creates little reaction.
	5. The media reports what is wrong rather than what is right.
	6. Activists create stories that emphasize risk rather than safety, but the media generally does not report stories that emphasize industrial safety.
	7. Issues are much easier to resolve before extensive media coverage crystalizes public opinions.

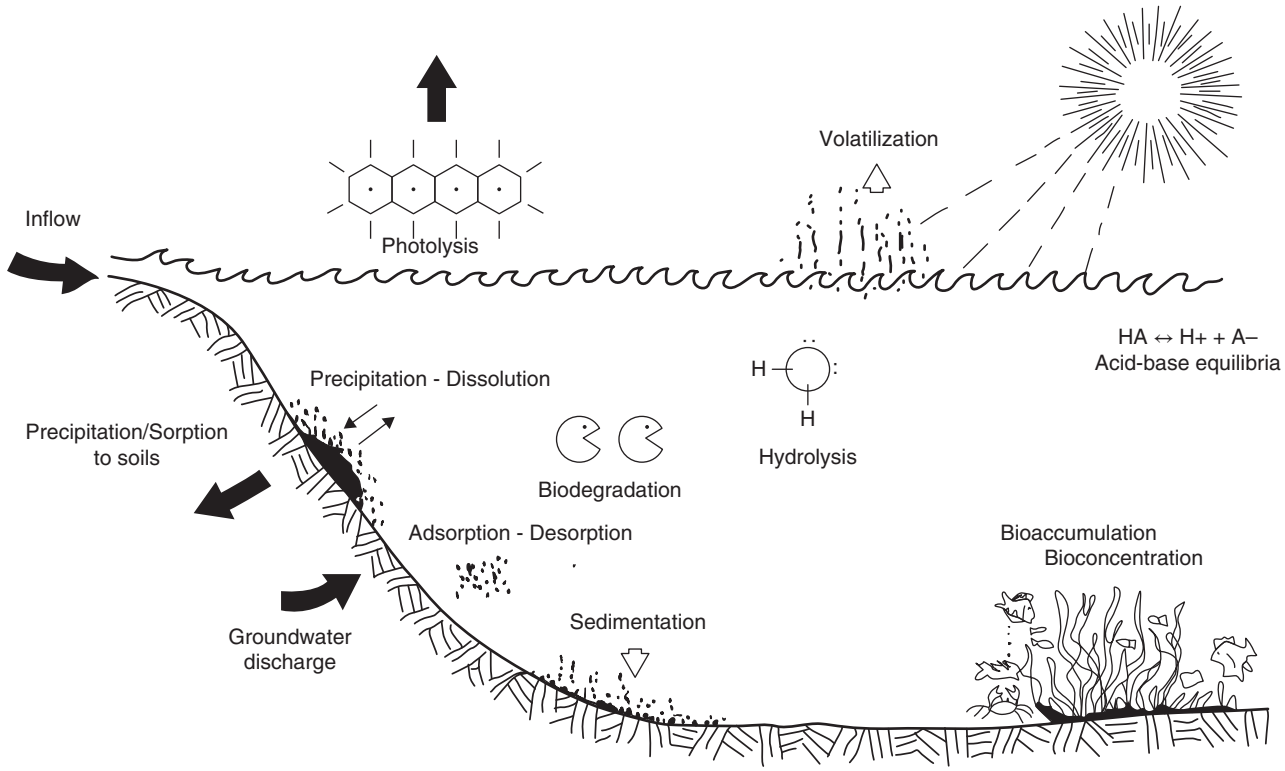

FIGURE 51.3. Schematic representation of the environmental fate of chemical carcinogens. (Adapted from Paustenbach).[18]

in the environment. Other factors contributing to bioconcentration and biomagnification (i.e., the transfer of the chemical up the food chain) include the type of food chain, metabolism, bioavailability, and persistence of the chemical in the environment.[18] The K_{ow} does not accurately predict the adsorption or bioaccumulation of metallic organic complexes, ionic compounds, or inorganic chemicals.

Henry's Law Constant

Henry's law constant is the air/water partition coefficient at equilibrium; this constant expresses the rate of evaporation of a chemical from water. Chemicals with a Henry's Law constant below the constant for water (i.e., 10^{-7} atm-m^3/mol) tend to concentrate in water, whereas chemicals with Henry's Law constants above 10^{-3} atm-m^3/mol volatilize rapidly. Other factors in the environment affecting the volatilization of chemicals include water depth, flow rate, sediment and organic material content, turbulence, adsorbents, emulsions, and electrolytes. A slow river model is available to estimate the volatilization of chemicals that requires only the Henry's Law constant and the molecular weight of the chemical;[21] however, this model overestimates the volatilization from ponds, lakes, and deep rivers.

Ultraviolet–Visible Absorption Spectrum

The ultraviolet–visible absorption spectrum (UV–Vis) is a measure of the ability of a chemical to absorb radiation in this wavelength region (200–750 nm). Chemicals that cannot absorb sunlight cannot undergo direct photodegradation. Indirect photodegradation forms reactive intermediates (e.g., hydroxyl radicals) and is the main process of degradation in the atmosphere. Biodegradation results from the metabolic activity of microorganisms (e.g., fungi, bacteria). This process is the main metabolic pathway in soil because ultraviolet light does not penetrate below the top centimeter of the surface. Chemical hydrolysis is an important degradation process in aqueous environments; this process is independent of the presence of sunlight, microorganisms, or oxygen.

Data Validation

Toxicological data vary in quality, resulting in the need for criteria on objective and standardized methods to evaluate data quality, especially when deciding which data to include in systematic reviews, meta-analyses, public databases (e.g., Chemical Effects in Biological Systems, CEBS, https://cebs.niehs.nih.gov/cebs/),

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and globally harmonized system (GHS) classifications. Although major chemical assessments are still driven primarily by traditional data, collaboration between organizations involved in risk assessment (e.g., Next Generation of Risk Assessment, NexGen, https://cfpub.epa.gov/ncea/risk/recordisplay.cfm?deid=286690) is improving approaches to risk assessment, including adverse outcome networks (AON) and pathways (AOP) that better define modes of action and causal relationships.[22]

Quality criteria systems exist to help evaluate individual sites and the appropriateness of including these studies in the overall body of evidence, as listed in Table 51.3. These systems share common areas to consider while assessing study quality including adequate details on study conditions, design, and protocols; selection/randomization of study groups; validity and reliability of outcome assessment methods; approach to avoid selective reporting; and evaluation of potential confounders and/or bias.[23] The latter implies potential systematic or directional error rather than imprecision of test results from statistical fluctuations produced by design flaws (e.g., inadequate exposure control, small study numbers). Assessing study quality is not equivalent to evaluating the risk of bias in the study; this risk reflects the internal validity of the study as a result of study design that introduces a systematic error affecting the value of outcome measures.

The Navigation Guide is a systematic review process to synthesize scientific evidence from human and nonhuman research to reach overall conclusions regarding strength of evidence in the hazard identification part of risk assessment. This process involves: 1) specifying the study question, 2) selecting the evidence, and 3) rating the quality and strength of the evidence.[35] Figure 51.4 demonstrates the integration of the risk of bias assessment with determination of the quality and strength of evidence to reach conclusions regarding hazard identification.

Observational Studies

Transparency and harmonization in publications and data exchanges between collaborators require the inclusion of information useful to determine the reliability of study data. Important components of information about observational epidemiological investigations include: 1) subject characteristics (age, sex, race/ethnicity, medical history, disease description) and procedures applied to subjects (observational place/time), 2) study design

TABLE 51.3. Study quality criteria systems. Lynch et al. provide an overview of guidance systems for the evaluation of the quality of human studies, including over 40 specific areas involved in the evaluation. Answers to questions regarding these areas involved reporting requirement, scoring for category based on the extent issues were addressed (e.g., definitely low, probably low, probably high, definitely high risk of bias), or fulfillment of yes/no criteria. (Adapted from Lynch et al.).[23]

Study Quality Criteria System	Publication Year	Applicable Studies
Integrated Risk Information System (IRIS) Risk of Bias (RoB) evaluation	2013–2014	Human, animal, systematic reviews
National Toxicology Programs (NTP) Office of Health Assessment and Translation (OHAT) approach[24]	2013, 2015	Human, animal, systematic reviews
Navigation Guide[25]	2013–2014	Human, animal, systematic reviews
Strengthening the Reporting of Observational Studies in Epidemiology (STROBE) system[26]	2007	Human

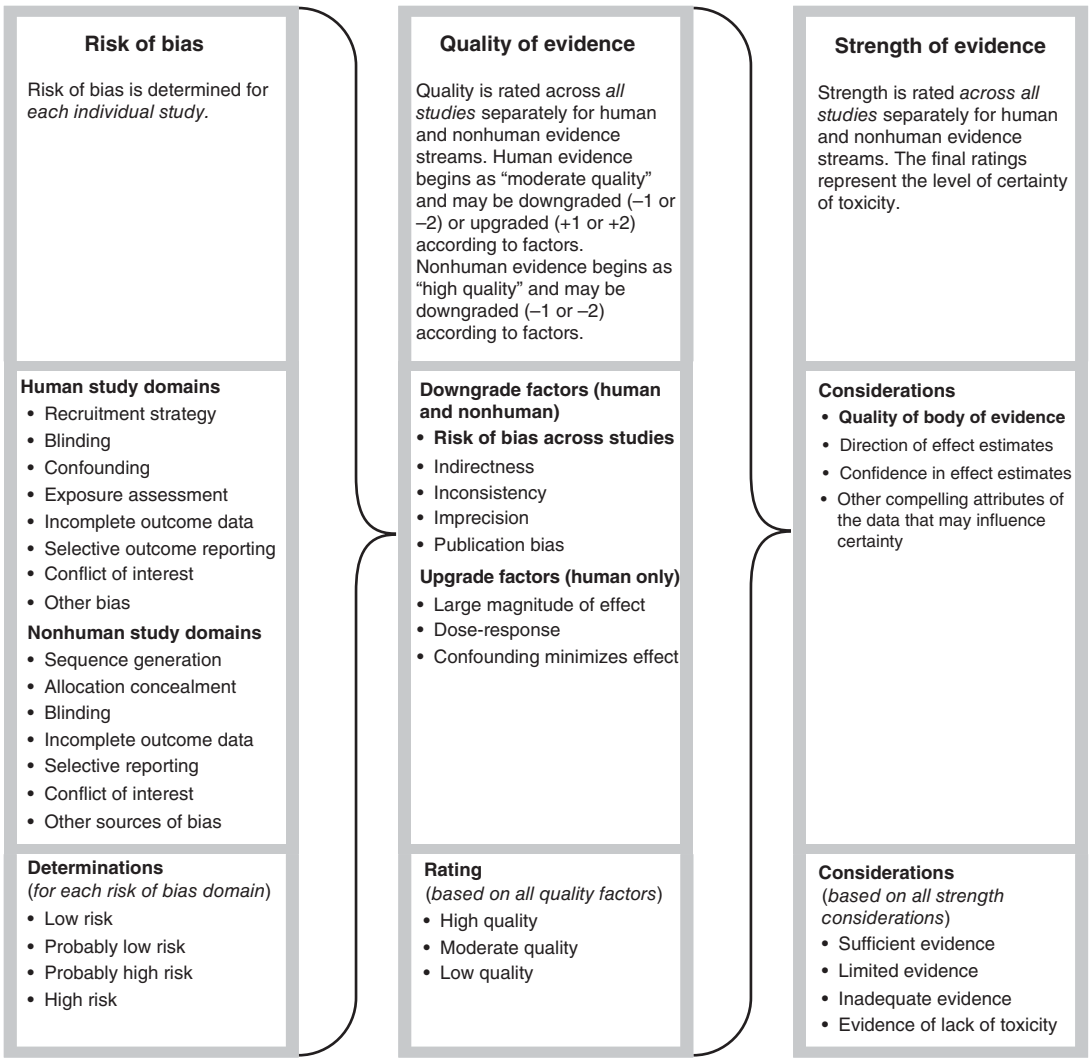

FIGURE 51.4. Navigation Guide systematic review process overview outlining evaluation of risk of bias, quality of evidence, and strength of evidence during the hazard identification part of risk assessment. (Adapted from Lam et al.).[35]

and implementation (classification, timeline, organization), 3) biomaterials collected and preserved with description of methods, and 4) assays performed and results obtained (method, unit of measure, values).[36] The exact checklist depends on the study design and subject characteristics; no single criterion determines the overall adequacy of a study.

The primary objective of a quality evaluation is the determination of the internal validity of the study as demonstrated by the lack of ambiguity about the study results achieved by controlling all potential influences other than the intended outcome. For observational epidemiological studies, this objective involves the careful identification and selection of study population, investigating and adequately controlling confounding factors, and avoiding selective reporting.

Well-documented analytical (cohort, case-control) epidemiological studies provide more relevant data for the hazard identification process than ecological epidemiological studies or animal data. Reasons for preferring epidemiological data include the inclusion of heterogeneous human populations, the avoidance of extrapolation from animal to human species, and the inclusion of concomitant risk factors (e.g., smoking, diet). Case-control and cohort studies are more reliable studies for hazard identification because they allow better control of confounding factors than other observational studies. Analytical studies with precise exposure estimates and specific biomarkers have greater weight than less well-designed studies. Case reports or case series describe a particular effect (e.g., cancer cluster) in a group of patients as observed by one or

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

several health professionals. Usually, these case reports are highly selective and anecdotal. The lack of statistical stability limits the usefulness of this type of data for incorporation into hazard identification. These descriptive studies generate hypotheses about exposure factors; however, subsequent analytical designs are necessary to determine causality. The presence of dose-response effects is particularly helpful for hazard identification. If well-designed epidemiological studies with good exposure data demonstrate no effects at a specific level of exposure, then the overall weight-of-evidence indicates the agent is potentially carcinogenic in humans, including the correlation of upper estimates of the potential human risk with estimates from animal data.

Bias

Integrating the use of systematic reviews into risk assessment helps modernize evidence-based decision-making and strengthen the process of developing safe chemical limits. The National Academy of Science recommends risk of bias assessment (i.e., credibility of the relationship between exposure and outcome) to verify the internal validity of studies used to formulate hazard identification and dose-response assessment for the development of oral and inhalational reference doses.[37] The assessment of risk of bias involves the use of a formal process to critically appraise the study quality and potential of the study design to compromise the credibility of the relationship between exposure and outcome (i.e., the presence of systematic error that causes deviation from the true effect). Several agencies have developed tools for risk of bias analysis on environmental health hazard assessments, including the Grading of Recommendations Assessment, Development, and Evaluation (GRADE) Working Group, the Navigation Guide, the National Toxicology Program Office of Health Assessment and Translation (OHAT, https://www.niehs.nih.gov/research/atniehs/labs/iha/ohat/index.cfm#:~:text=The%20Health%20Assessment%20and%20Translation,health%20research%20and%20regulatory%20agencies) and Office of the Report on Carcinogens, and the Integrated Risk Information System (IRIS) of the US Environmental Protection Agency.[38] The OHAT is a risk of bias rating tool for six types of bias (selection, confounding, performance, attrition/exclusion, detection, selective reporting) in human and animal studies;[39] this tool consists of 11 questions (domains) designed to detect different types of bias and determine the suitability of the study for inclusion in the risk assessment process, as displayed in Table 51.4. Each question is rated on a 4-point scale (definitely low, −; probably low, −/NR; probably high or not reported, +; definitely high, ++) with higher methodological quality producing lower scores.

The core questions are unique to the systematic review; consequently, the investigator adapts the questions to the specific research hypothesis.

Animal/In Vitro Data

Animal data are important for hazard identification because of the lack of adequate epidemiological data for many chemicals. Assays in genetically engineered rodents (e.g., transgenic, knock-out strains) provide insight into the chemical and gene interactions involved in carcinogenesis.[40] Current standardized rodent carcinogenicity studies require at least 50 animals/sex/dose group in each of the 3 treatment groups and a concurrent control group followed long-term (18–24 months) for neoplasms. Although toxicological results from animal studies anticipate effects in humans, both negative and positive results are difficult to interpret when the animal studies are inadequately designed. The high dose in long-term studies typically should detect treatment-related carcinogenic effects without compromising the outcome of the study through excessive toxicity or inducing inappropriate toxicokinetics; the two or more lower doses help define the shape of the dose-response curve. Considerations for the relevance of an animal study to human exposure include the size of groups, statistical analysis, reliability of end-points, physicochemical properties of substances, adequate or excessive doses, relevance of route of exposure, intensity of exposure compared with humans, and consistency of applied dose. The doses should be chosen to produce a graded response including the expected NOAEL. Whenever species-specific pharmacokinetics vary, the animal species with pharmacokinetics most similar to humans should be selected.

In 1997, Klimisch et al. published a system for categorizing the reliability of animal and *in vitro* studies into four classifications based on: 1) reliability (inherent quality of the study to provide clarity and plausibility to the study results), 2) relevance (suitability of the results to hazard identification or risk characterization), and 3) adequacy (usefulness of data for hazard or risk assessment with greater weight for more reliable and relevant data).[29] Table 51.5 describes the definition of the four categories of reliability defined by Klimisch et al.

Data from reliability categories 1 or 2 are sufficient as stand-alone information on the specified outcome, whereas category 3 data serve only as additional data in weight-of-evidence evaluations. A reliability assessment tool (Toxicological data Reliability assessment Tool, ToxRTool) is available to improve the reliability

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 51.4. Eleven questions (domains) of the National Toxicology Program Office of Health Assessment and Translation (OHAT). (Adapted from Office of Health Assessment and Translation).[39]

Question Number	Description	Subdomain	Bias Type
1	Was administered dose or exposure level adequately randomized?		Selection
2	Was allocation to study groups adequately concealed?		Selection
3	Did selection of study participants result in appropriate comparison groups?		Selection
4	Did the study design or analysis account for important confounding and modifying variables?		Confounding
5	Were experimental conditions identical across study groups?		Performance
6	Were the research personnel and human subjects blinded to the study group during the study?		Performance
7	Were outcome data complete without attrition or exclusion from analysis?		Attrition or Exclusion
8	Can we be confident in the exposure characterization?		Detection
9	Can we be confident in the outcome assessment?		Detection
10	Were all measured outcomes reported?		Selective reporting
11	Were there no other potential threats to internal validity (e.g., statistical methods were appropriate and researchers adhered to the study protocol)?		Other
11a		Were statistical methods appropriate?	Other
11b		Did researchers adhere to the study protocol?	Other
11c		Did the study design or analysis account for important confounding and modifying variables (including unintended co-exposures) in experimental studies?	Other

TABLE 51.5. Reliability categories defined by Klimisch et al. (Adapted from Klimisch et al.).[29]

Number	Descriptor	Definition
1	Reliable without restrictions	Implemented with generally valid and/or internationally/nationally accepted testing guidelines according to good laboratory practice or closely related/comparable guidelines.
2	Reliable with restrictions	Implemented with test parameters not totally complying with specific testing guidelines (e.g., good laboratory practice), but sufficient to accept as a well-documented, scientifically acceptable testing guideline.
3	Unreliable	Literature/reports indicate interferences between measuring system and test substance; organisms/test systems used are not relevant to exposure and/or implemented with a method inadequate to evaluate outcome measure based on expert judgment.
4	Unassignable	Study or medical literature contains insufficient experimental details or data to evaluate outcome measures.

assessment of toxicological data (https://joint-research-centre.ec.europa.eu/scientific-tools-and-databases/toxrtool-toxicological-data-reliability-assessment-tool_en).[32]

Toxicogenomics

Toxicogenomics refers to the global analysis of toxin-induced modifications of biomolecules (genome, transcriptome, metabolome, proteome) involved in pathways causing toxicity; this approach helps improve the risk assessment process by increasing knowledge on low-dose responses, exposure assessment, dose-response modeling, intra/interspecies extrapolation, and genetic variability.[41] High-throughput and high-content assays along with robotic implementation generate data at unprecedented speeds along with advances in molecular, computational, and systems biology. Consequently, the amount of existing toxicological and toxicogenomic data has increased exponentially in the last several decades, particularly since the completion of the Human Genome Project.

Transcriptomic studies differ substantially from whole-animal toxicity studies evaluated by criteria systems (e.g., ToxRTool) in Table 51.3. Specialized assessment tools (e.g., Systematic Omics Analysis Review tool, SOAR, https://journals.plos.org/plosone/article/file?id=10.1371/journal.pone.0110379&type=printable) are available to assess the quality of transcriptomic studies using established community standards (e.g., Minimum Information About a Microarray Experiment standard, MIAME).[42] The SOAR tool focuses on data analysis and study design of transcriptomics RNA microarray studies.[43]

Systematic Reviews

A MeaSurement Tool to Assess systematic Reviews (AMSTAR, https://amstar.ca/Amstar_Checklist.php) was published in 2007 as a practical and critical appraisal method for evaluation of the rapid assessment of the quality of systematic reviews involving randomized, controlled studies;[44] however, a substantial number of published systematic reviews include nonrandomized studies, particularly studies involving environmental exposures. These studies require different risk of bias assessments because nonrandomized studies potentially contain a range of biases that are much less prominent in randomized studies. Additionally, observational studies often contain very large populations that generate precise estimates of effects that may be inaccurate because of residual biases, resulting in meta-estimates weighted toward the observational study estimates. Consequently, AMSTAR was revised (AMSTAR 2, Figure 51.5) to include 16 questions relevant to randomized and nonrandomized study evaluations.[45]

Although all questions are important steps to conducting a systematic review and meta-analysis, seven domains are critical to the validity of the conclusions, as listed in Table 51.6.

Rather than creating an overall score, the authors of AMSTAR 2 recommend using the following scale: 1) high – no or 1 noncritical weakness, 2) moderate – more than 1 noncritical weakness, 3) low – 1 critical flaw with or without noncritical weaknesses, and 4) critically low – more than 1 critical flaw with or without noncritical weaknesses, as outlined in Table 51.7. The presence of several noncritical weaknesses may reduce confidence in the review, resulting in a reduction in the rating. The AMSTAR 2 broadly assesses study quality, including flaws introduced through poor conduct of the review. In contrast to the more general approach of AMSTAR 2, the Risk Of Bias In Systematic (ROBIS) review focuses specifically on the risk of bias introduced by conducting reviews of nonrandomized intervention studies.[34] Interpretation of the outcome of the review involves judgment on low, moderate, serious, critical, or inadequate information on risks of bias based on seven domains; these domains include bias from confounding, selection of study participants, classification of interventions, deviations from intended interventions, missing data, outcome measurements, and selective reporting.

Alternative methods to systematic review tools include scoping reviews that rapidly map available evidence on a particular topic or research area to identify data gaps, key concepts, and sources of evidence.[46] The depth of coverage of available literature depends on the purpose of the review. Purposes of scoping reviews include summarizing and disseminating research discoveries, examining the range, extent, and type of research activity, identifying research needs, and determining the value of a full systematic review.[47] The latter focuses on well-defined questions using appropriate, predetermined study designs, whereas scoping reviews use different study designs as needed to cover broader topics. Systematic reviews also answer questions based on a relatively narrow range of quality studies, while scoping reviews focus less on specific questions or study quality; however, study details should be sufficient to allow replication of the scoping review by other researchers. The methodological framework of a scoping review includes the following: 1) identifying the research question, 2) determining relevant studies, 3) selecting appropriate studies for research question, 4) charging the data, and 5) collating, summarizing, and reporting the results.[47]

AMSTAR 2

1. Did the research questions and inclusion criteria for the review include the components of PICO?

For Yes:
- ☐ Population
- ☐ Intervention
- ☐ Comparator group
- ☐ Outcome

Optional (recommended)
- ☐ Timeframe for follow-up

☐ Yes
☐ No

2. Did the report of the review contain an explicit statement that the review methods were established prior to the conduct of the review and did the report justify any significant deviations from the protocol?

For Partial Yes:
The authors state that they had a written protocol or guide that included ALL the following:
- ☐ review question(s)
- ☐ a search strategy
- ☐ inclusion/exclusion criteria
- ☐ a risk of bias assessment

For Yes:
As for partial yes, plus the protocol should be registered and should also have specified:
- ☐ a meta-analysis/synthesis plan, if appropriate, *and*
- ☐ a plan for investigating causes of heterogeneity
- ☐ justification for any deviations from the protocol

☐ Yes
☐ Partial Yes
☐ No

3. Did the review authors explain their selection of the study designs for inclusion in the review?

For Yes, the review should satisfy ONE of the following:
- ☐ *Explanation for* including only RCTs
- ☐ OR *Explanation for* including only NRSI
- ☐ OR *Explanation for* including both RCTs and NRSI

☐ Yes
☐ No

4. Did the review authors use a comprehensive literature search strategy?

For Partial Yes (all the following):
- ☐ searched at least 2 databases (relevant to research question)
- ☐ provided key word and/or search strategy
- ☐ justified publication restrictions (eg, language)

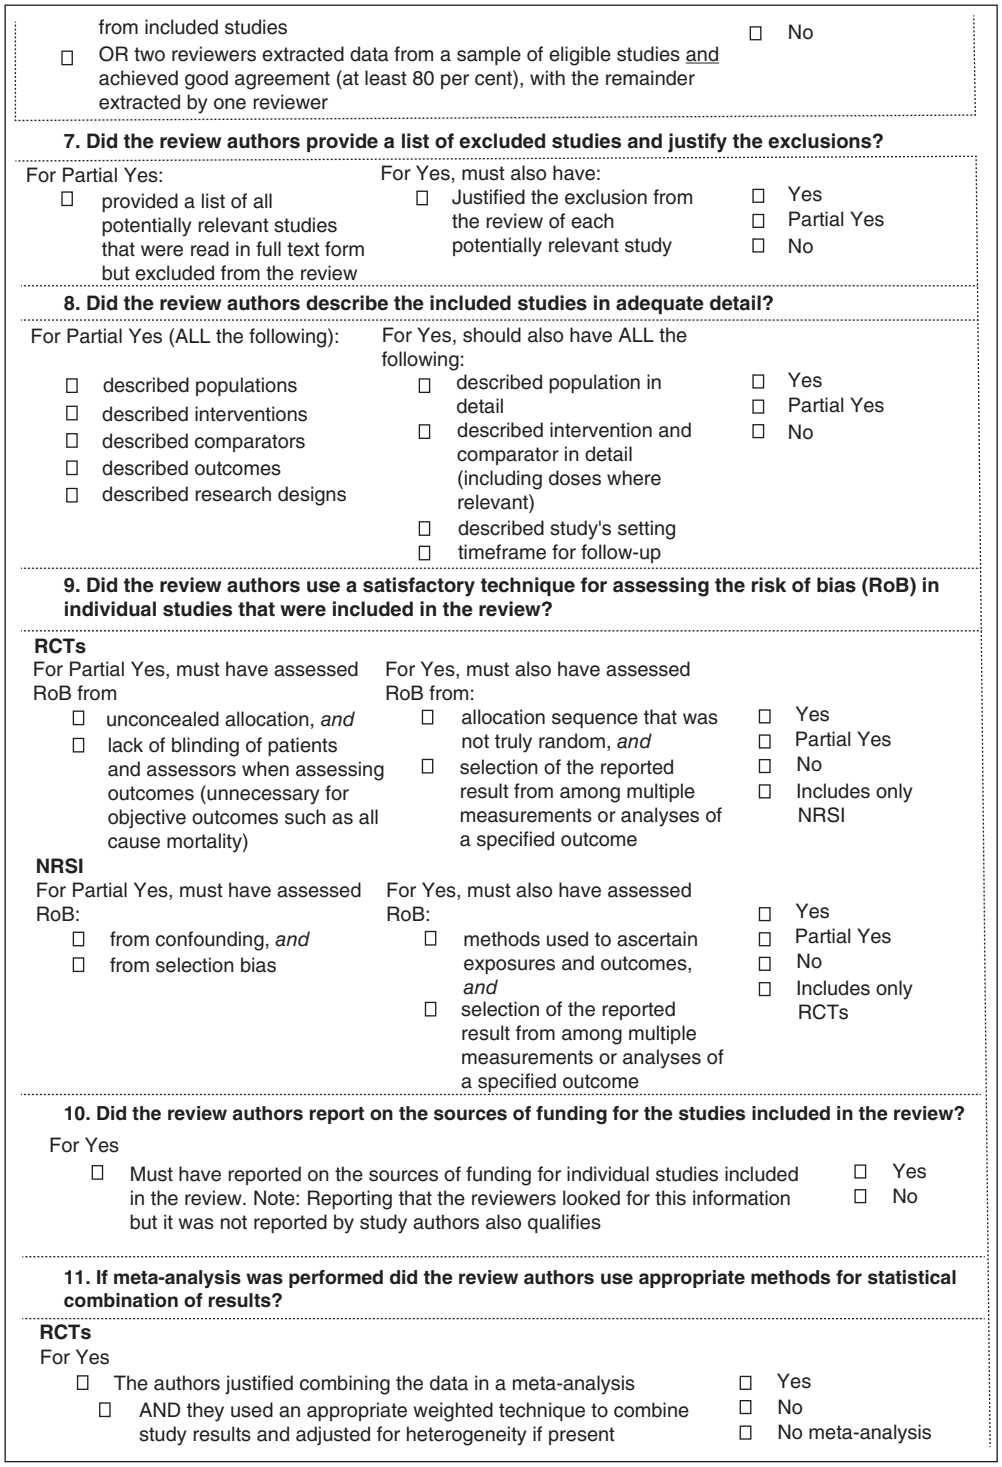
For Yes, should also have (all the following):
- ☐ searched the reference lists/bibliographies of included studies
- ☐ searched trial/study registries
- ☐ included/consulted content experts in the field
- ☐ where relevant, searched for grey literature
- ☐ conducted search within 24 months of completion of the review

☐ Yes
☐ Partial Yes
☐ No

5. Did the review authors perform study selection in duplicate?

For Yes, either ONE of the following:
- ☐ at least two reviewers independently agreed on selection of eligible studies and achieved consensus on which studies to include
- ☐ OR two reviewers selected a sample of eligible studies and achieved good agreement (at least 80 per cent), with the remainder selected by one reviewer

☐ Yes
☐ No



6. Did the review authors perform data extraction in duplicate?

For Yes, either ONE of the following:
- ☐ at least two reviewers achieved consensus on which data to extract

☐ Yes

FIGURE 51.5. For evaluation purposes, items 2, 4, 7, 9, 11, 13, and 15 are considered critical domains (denoted by asterisks), whereas items 1, 3, 5, 6, 8, 10, 12, 14, and 16 are noncritical domains. This appraisal tool for randomized and nonrandomized studies is not designed to generate an overall numerical score.
Abbreviation: PICO = Population, Intervention, Comparator, and Outcome framework.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from included studies
- ☐ OR two reviewers extracted data from a sample of eligible studies and achieved good agreement (at least 80 per cent), with the remainder extracted by one reviewer

☐ No

7. Did the review authors provide a list of excluded studies and justify the exclusions?

For Partial Yes:
- ☐ provided a list of all potentially relevant studies that were read in full text form but excluded from the review

For Yes, must also have:
- ☐ Justified the exclusion from the review of each potentially relevant study

☐ Yes
☐ Partial Yes
☐ No

8. Did the review authors describe the included studies in adequate detail?

For Partial Yes (ALL the following):
- ☐ described populations
- ☐ described interventions
- ☐ described comparators
- ☐ described outcomes
- ☐ described research designs

For Yes, should also have ALL the following:
- ☐ described population in detail
- ☐ described intervention and comparator in detail (including doses where relevant)
- ☐ described study's setting
- ☐ timeframe for follow-up

☐ Yes
☐ Partial Yes
☐ No

9. Did the review authors use a satisfactory technique for assessing the risk of bias (RoB) in individual studies that were included in the review?

RCTs

For Partial Yes, must have assessed RoB from
- ☐ unconcealed allocation, *and*
- ☐ lack of blinding of patients and assessors when assessing outcomes (unnecessary for objective outcomes such as all cause mortality)

For Yes, must also have assessed RoB from:
- ☐ allocation sequence that was not truly random, *and*
- ☐ selection of the reported result from among multiple measurements or analyses of a specified outcome

☐ Yes
☐ Partial Yes
☐ No
☐ Includes only NRSI

NRSI

For Partial Yes, must have assessed RoB:
- ☐ from confounding, *and*
- ☐ from selection bias

For Yes, must also have assessed RoB:
- ☐ methods used to ascertain exposures and outcomes, *and*
- ☐ selection of the reported result from among multiple measurements or analyses of a specified outcome

☐ Yes
☐ Partial Yes
☐ No
☐ Includes only RCTs

10. Did the review authors report on the sources of funding for the studies included in the review?

For Yes
- ☐ Must have reported on the sources of funding for individual studies included in the review. Note: Reporting that the reviewers looked for this information but it was not reported by study authors also qualifies

☐ Yes
☐ No

11. If meta-analysis was performed did the review authors use appropriate methods for statistical combination of results?

RCTs

For Yes
- ☐ The authors justified combining the data in a meta-analysis
  - ☐ AND they used an appropriate weighted technique to combine study results and adjusted for heterogeneity if present

☐ Yes
☐ No
☐ No meta-analysis

FIGURE 51.5. (*Continued*)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

☐ AND investigated the causes of any heterogeneity	conducted
For NRSI For Yes: ☐ The authors justified combining the data in a meta-analysis ☐ AND they used an appropriate weighted technique to combine study results, adjusting for heterogeneity if present ☐ AND they statistically combined effect estimates from NRSI that were adjusted for confounding, rather than combining raw data, or justified combining raw data when adjusted effect estimates were not available ☐ AND they reported separate summary estimates for RCTs and NRSI separately when both were included in the review	☐ Yes ☐ No ☐ No meta-analysis conducted
12. If meta-analysis was performed, did the review authors assess the potential impact of RoB in individual studies on the results of the meta-analysis or other evidence synthesis?	
For Yes: ☐ included only low risk of bias RCTs ☐ OR, if the pooled estimate was based on RCTs and/or NRSI at variable RoB, the authors performed analyses to investigate possible impact of RoB on summary estimates of effect	☐ Yes ☐ No ☐ No meta-analysis conducted
13. Did the review authors account for RoB in individual studies when interpreting/discussing the results of the review?	
For Yes: ☐ included only low risk of bias RCTs ☐ OR, if RCTs with moderate or high RoB, or NRSI were included the review provided a discussion of the likely impact of RoB on the results	☐ Yes ☐ No
14. Did the review authors provide a satisfactory explanation for, and discussion of, any heterogeneity observed in the results of the review?	
For Yes: ☐ There was no significant heterogeneity in the results ☐ OR if heterogeneity was present the authors performed an investigation of sources of any heterogeneity in the results and discussed the impact of this on the results of the review	☐ Yes ☐ No
15. If they performed quantitative synthesis did the review authors carry out an adequate investigation of publication bias (small study bias) and discuss its likely impact on the results of the review?	
For Yes: ☐ performed graphical or statistical tests for publication bias and discussed the likelihood and magnitude of impact of publication bias	☐ Yes ☐ No ☐ No meta-analysis conducted
16. Did the review authors report any potential sources of conflict of interest, including any funding they received for conducting the review?	
For Yes: ☐ The authors reported no competing interests OR ☐ The authors described their funding sources and how they managed potential conflicts of interest	☐ Yes ☐ No

FIGURE 51.5. (*Continued*)

Carcinogenic Potential

Previously, the USEPA used a weight-of-evidence approach to characterize the extent and strength of the evidence for chemical carcinogenesis, as described under the section on Qualitative Classification Schemes of Cancer.[9] This scheme is a continuum of the carcinogenic potential of a chemical based on scientific judgment, and classification ranges from definite (Group A) to no evidence (Group E). The weight-of-evidence approach depended primarily on long-term animal data at or near the maximum tolerated dose to evaluate the potential of a chemical to cause cancer. This process did not assess the potency of the chemical to induce tumors, even though the actual risk of cancer depends

TABLE 51.6. Seven critical domains in an AMSTAR 2 evaluation. The prominence of risk of bias reflects the potential impact of nonrandomized studies in systematic reviews. (Adapted from Shea et al.).[45]

Question	Description
2	Protocol registered before commencement of review
4	Adequacy of literature search
7	Justification for excluding individual studies
9	Risk of bias in studies included in review
11	Appropriateness of meta-analytical methods
13	Consideration of risk of bias during interpretation of review results
15	Assessment of the presence and impact of publication bias

TABLE 51.7. Overall rating and outcome of systematic reviews involving randomized and nonrandomized healthcare intervention studies using AMSTAR2 questions. The purpose of the evaluation is to recognize high-quality systematic reviews; however, the overall evaluation does not generate an overall score to compare individual studies within a specific category. Table 51.6 identifies the seven critical domains. (Adapted from Shea et al.).[45]

Category	Overall Number of Weaknesses	Descriptor
High	≤1 noncritical with no critical flaws	Accurate/comprehensive summary of studies that addresses outcome of interest
Moderate	>1 noncritical with no critical flaws	May provide an accurate summary of available studies in the review
Low	1 critical with/without noncritical flaws	Critical flaw may not provide an accurate and comprehensive summary of studies on outcome of interest
Critically low	>1 critical with/without noncritical flaws	Does not provide an accurate/comprehensive summary of study results

on absorbed dose and potency. The potency of individual carcinogens varies substantially, as indicated by four orders of magnitude variation in the USEPA potency estimates for IARC Group 1 (human carcinogens).[48] Other factors relevant to the weight-of-evidence approach include the results of short-term test (e.g., point mutations, DNA damage/repair), the presence of toxic effects that enhance carcinogenesis (e.g., immunosuppression, endocrine abnormalities), mode-of-action, and the appearance of structure–activity relationships to known carcinogens. Key questions regarding hypothesized mode-of-action involve the strength of supportive animal evidence, its relevance to humans, and susceptible populations or life stages. Currently, the USEPA uses a weight-of-evidence narrative describing conclusions regarding weight-of-evidence of carcinogenic potential and a summary of the data forming the basis for the conclusions.[7] This brief summary with the hazard characterization (e.g., carcinogenic to humans – not likely to be carcinogenic to humans) replaces the alphanumeric classification system of Groups A–E used in the 1986 USEPA cancer guidelines.

Chemical carcinogens display a wide spectrum of activity ranging from direct DNA damage (genotoxic mechanisms) to epigenetic mechanisms (e.g., recurrent cytotoxicity and cell proliferation). Many recognized carcinogens act through genotoxic mechanisms; these carcinogens do not depend on the development of tissue toxicity at the maximum tolerated dose.[49] Animal data suggest the existence of at least eight pathophysiological classes of animal carcinogens including: 1) cytotoxic kidney, 2) cytotoxic bladder, 3) cytotoxic liver, 4) mitogenic liver, 5) peroxisome proliferating/mitogenic liver, 6) solid state, 7) promoters, and 8) genotoxic.[50] Not all of these mechanisms produce the same cancer risks in humans; kidney tumors in male rats do not accurately predict human carcinogenicity because of the unique accumulation of an $\alpha_{2\mu}$-globulin–metabolite complexes in the rat kidney that causes proximal tubule damage.[51] Evidence on mode(s)-of-action preceding tumor development (e.g., mutagenesis, receptor activation, alteration of signaling pathways, increased cell proliferation, apoptosis) could potentially help determine the likelihood of a cancer hazard and the dose-response relationship below the range of observable tumor

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. response. Key questions involve the potential of the chemical or the activated metabolite to produce mutations by interacting directly with DNA (genotoxic) or causing mutations in gene expression via epigenetic processes. The significance of different mechanisms of carcinogenesis (e.g., genotoxic vs. epigenetic) to risk assessment is the possible existence of a threshold and the necessity of using several models to describe the true risk of developing cancer. Experience at the National Toxicology Program (NTP) suggests DNA-reactive substances that produce gene mutations causing tumors are often unique, in certain anatomical sites, whereas tumors at other sites may develop from both mutagenic and/or epigenetic influences.[52]

DOSE-RESPONSE ASSESSMENT

The second step of risk assessment for carcinogens is the estimation of the relationship between a particular exposure level of interest and the subsequent potential human risk based on the mode(s)-of-action for each tumor type and the strength of human and experimental data. Mathematical modeling helps incorporate a wide range of experimental data into the dose-response assessment; the dose-response assessment usually involves agents considered carcinogenic to humans or likely to be carcinogenic to humans.[7] The dose-response assessment involves the following two steps: 1) the derivation of a point of departure (POD) from the observed range of human and experimental data, and 2) the extrapolation of the relationship to levels below the POD as necessary. The POD is the starting point for subsequent extrapolations and analyses that calculate a slope factor for linear extrapolation commonly used in cancer risk assessment and a reference dose or concentration used for nonneoplastic risk assessment. The use of the POD below all observed data points introduces model inaccuracy and parameter uncertainty (i.e., lack of knowledge about the values of a model's parameters) along with issues related to human variability that increase with the distance between the lowest observed data points and the POD.

The POD is an estimated dose near the lower end of the observed range without significant extrapolation to lower doses as expressed in human-equivalents.[7] Exposure refers to the amount of substance in contact with the outer boundary of the organism, whereas dose is the amount of substance available to interact with metabolic processes or biologically significant receptors after crossing the outer boundary of an organism. The dose may be applied (available for absorption), absorbed (amount crossing a specific area of the organism), internal (general term used without respect to specific absorption barriers or exchange boundaries), and delivered (amount available for interaction with specific cell or organ). Without evidence to the contrary, the recommended long-term measure of exposure to a carcinogen is the cumulative dose received over a lifetime expressed as average daily exposure prorated over a lifetime with an assumption that a high dose of a carcinogen received over a short time is equivalent to a corresponding low dose spread over a lifetime.[7] Variable lifetime exposures to carcinogens are summed to express the cumulative exposure as an average daily exposure.

Data from epidemiological studies with sufficient quality are preferred to extrapolation of animal data using toxicokinetic information for cross-species dose scaling or appropriate default values. When using tumor data from long-term cancer bioassays with ~50 animals, empirical modeling usually supports extrapolating increased tumor incidences to 1–10%, whereas large epidemiological studies support increased tumor incidences below 1%.[7] The default procedure is the standard USEPA model unless sufficient quantitative and mode-of-action data are available to develop a biologically based model. The POD for extrapolating to an environmental exposure of interest outside the range of observed data is usually the lower 95% confidence limit on the lowest dose level supported by mathematical or biological models of the data. When a chemical produces multiple tumor types, the dose-response assessment analyzes all tumor types, followed by the synthesis of strength of mode-of-action evidence, characterization of individual tumor risk estimates, and evaluation of the relevance of each tumor type to all human populations including susceptible ones. A NOAEL is not usually used for assessing the carcinogenic potential when one or more empirical models fit the data unless the data support a nonlinear mode-of-action.

The ultimate purpose of the dose-response assessment is to determine a safe dose that does not produce a significant increase in the risk of human cancer. The distinction between dose-response relationships between genotoxic carcinogens and other types of toxic reactions is based on the premise that genotoxic events (e.g., *in vitro* activation, covalent binding) are linear over many orders of magnitude. This assumption implies the lack of a threshold; however, this assumption remains unproven experimentally. Consequently, such estimates require extrapolation outside the range of the experimental data (i.e., from high-dose animal experiments to low-dose levels present in the environment). Such an extrapolation involves biological and statistical uncertainties. Because the incidence of tumors is so small at these low doses, testing would require

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. prohibitively large numbers of animals; therefore, mathematical models must be used to estimate the risk of cancer.

Thresholds

Regulatory agencies generally adhere to the policy that carcinogens do not display a threshold effect; these agencies use linear models to describe the risk of a chemical causing cancer. Based on computer models, these agencies extrapolate data from human studies (e.g., BEIR VII) or rodent experiments using maximum tolerated doses for their lifetime (2 years) to the relatively low chemical doses absorbed by humans from the environment. This extrapolation frequently spans four to five orders of magnitude; differences exist between the nonlinear slopes seen in animal studies and the relatively linear dose-response curves seen in epidemiological studies of humans exposed to carcinogens.

A major concern in risk assessment is an accurate description of the dose-response curve at low doses. A low-dose linear model assumes no threshold exists and small increases in dose at a low exposure concentration cause a proportionate increase in the risk of developing tumors, whereas a nonlinear model exhibits a threshold effect so that a small increase in dose at low exposure levels does **not** increase the incidence of tumors. The linear approach is preferred in the absence of sufficient information regarding modes-of-action or mode-of-action evidence indicates the dose-response curve at low doses is or probably is linear.[7] The choice of a linear model when the carcinogen demonstrates a true threshold effect would result in an overestimation of the true risk of inducing a tumor, whereas the choice of a nonlinear model when there is no threshold would underestimate the true risk at low doses. Unfortunately, standard experimental designs currently do not differentiate between promoters (epigenetic carcinogens) that exhibit nonlinear dose-response curves and initiators (genotoxic carcinogens) that demonstrate a linear dose-response curve.[53]

The principal argument favoring the lack of a threshold is the description of cancer as a disease that begins with the heritable alteration of a single cell by the interaction of a chemical carcinogen with DNA or other intracellular molecules. The dose-response curve for radiation-induced cancer does not display a threshold effect. Evidence supporting the existence of a threshold includes the following: 1) some chemical carcinogens (e.g., promoters) require tissue damage before cancer appears, 2) integrity of the immune system affects the formation of tumors, 3) reduction of the latent period with decreasing dose may extend the latent period beyond the life of the animal, 4) alteration in the homeostasis of the animal modulates the response to the carcinogen, and 5) interference with a specific stage of the multistage process of cancer may limit the emergence of a tumor.[54] Low-dose threshold would most likely occur when the carcinogen has no endogenous counterpart.[55]

Thresholds detected in human or animal studies occur at lower levels following exposure to genotoxic than epigenetic carcinogens, probably because of pharmacological and toxicological effects. The classic S-shaped dose-response curve with a high threshold describes the carcinogenic effects of epigenetic carcinogens.[56] A no-effect level does occur in rodent assays (i.e., the application of a suspected promoter after administration of a genotoxic carcinogen) following administration of promoting agents (e.g., saccharin,[57] phenobarbital, butylated hydroxytoluene);[58] consequently, thresholds of dose or exposure duration may exist for certain carcinogens that do not produce irreversible disease below the threshold.[59]

In 2006, the National Academies Biological Effects of Ionizing Radiation (BEIR) VII Committee concluded the available scientific evidence was consistent with a linear dose-response relationship between ionizing radiation and the development of human cancers.[60] These conclusions were based primarily on mechanistic and animal studies combined with epidemiological data from ionizing radiation exposures mostly above 100 mGy. The report acknowledged the difficulty of conducting very large epidemiological studies to detect very small cancer risks associated with ionizing radiation exposures of <100 mGy. In 2018, the National Council on Radiation Protection (NCRP) published a critical review of 29 high-quality epidemiological studies on leukemia and total solid cancers in populations exposed to low-dose LET ionizing radiation reported in the medical literature from 1999–2017.[61] The interdisciplinary committee considered support for the linear-nonthreshold model strong in five studies (Life Span Study,[62] pooled childhood thyroid cancer,[63] tuberculosis fluoroscopic examinations and breast cancer, INWORKS, occupational solid cancers[64]), moderate in six studies, weak-to-moderate in nine studies, and no support in five studies (Mayak and Techa River, Hanford ^{131}I fallout, Kerala, India high background radiation, Canadian worker study, US nuclear weapons test participants). Three studies were inconclusive. The committee concluded that recent epidemiological studies support the continued use of the linear-nonthreshold model for radiation protection. A US National Cancer Institute international committee

conducted a systematic review of recent epidemiological studies to assess the magnitude and direction of potential biases in recent studies of excess cancer risks from low-dose (<100 mGy) ionizing radiation, particularly in sensitive populations (e.g., childhood leukemia and thyroid cancer, breast cancer).[65] The 26 eligible studies included 8 environmental, 4 medical, and 14 occupational exposures published from 2006–2017 involving 91,000 solid cancers and 13,000 leukemias with mean doses ranging from 0.1–82 mGy. Most studies reported positive dose-response relationships for solid cancer and/or leukemia risks.[66] For childhood exposures, the metaERR$_{100\,mGy}$ for leukemia was 2.84 (95% CI: 0.37–5.32). For adult exposures, metaERR$_{100\,mGy}$ for leukemia was 0.16 (95% CI: 0.07–0.25) and 0.29 (95% CI: 0.011–0.047) for solid cancers. A systematic assessment for biases (selection bias, confounding, misclassification of outcome) suggested a few positive studies were biased away from the null. The authors concluded that the magnitude of the cancer risks from low-dose LET radiation was compatible with the 95% confidence limits of solid cancers and leukemia risks extrapolated from atomic bomb survivors.

Nonneoplastic Effects

For nonneoplastic, toxic effects, the experimentally derived, no observable adverse effect level (NOAEL) is divided by an uncertainty factor to provide a margin of safety for exposures at concentrations present in the environment. Increasingly, models are being used to estimate a "benchmark dose" as a substitute for the NOAEL based on an estimate (i.e., lower confidence limit) of a particular incidence level (e.g., 5%) associated with a critical effect;[1] this benchmark dose usually exists in or near the observed experimental dose range. Prior to the 1990s, the USEPA determined reference doses (RfD), reference concentrations (RfC), and cancer slope factors from NOAELs or the lowest-observed-adverse-effect levels (LOAEL) with enhanced safety factors in the absence of NOAELs. Together with other scientific information, the USEPA uses these data for setting public health standards regarding chemical exposures. Several limitations of the NOAEL approach involve the inability to account for variability in the dose-response (e.g., estimate, slope), the use of a single dose dependent on study design, and the absence of a NOAEL other than using an uncertainty factor. In the later 1990s, the USEPA developed the benchmark dose (BMD) method to replace NOAELs; this method is more independent of study design.[67] The BMD uses mathematical modeling of dose-response data to select a BMD associated with a predetermined benchmark response (e.g., 1–10% increased incidence of a pathological lesion).

Animal studies usually involve chemical exposures at doses near toxic concentrations, whereas human exposures typically occur at chemical concentrations near values of 1/100–1/1,000th of the NOAEL as determined in rodent bioassays. In contrast to the estimation of the NOAEL as an approximation of the threshold, the critical data point for the dose-response of carcinogens is the slope of the dose-response curve. Because of the uncertainty in low-dose risk extrapolation, there is increasing reliance on specification of the margin between potency in the experimental range and estimation of exposure.[68]

Substantial variation exists between humans and experimental animals in how they interact with exposure to a toxicant. Toxicokinetics represents what the body does to the toxic agent (i.e., the fate of the toxicant in the body), whereas toxicodynamics involves what the toxic agent does to the body (i.e., injury, adaptation, repair).[69] Examples of toxicokinetic processes include absorption, distribution, elimination, and biotransformation of the toxicant. Toxicodynamics involves the effect of the toxic agent on multiple biological processes, including interference with metabolic systems, formation of reactive oxygen species and DNA adducts, and alteration of signal transduction and apoptosis. Toxicokinetic effects depend on the external and internal dose (i.e., absorption from the exposure site, distribution, elimination), whereas toxicodynamic effects depend primarily on toxicant concentration in the target organ and receptor site sensitivity. Factors that affect interspecies and intraspecies variability in toxicokinetics include differences in physiological function (e.g., blood flow, filtration rate, gastric pH) of various organs, anatomy, and metabolic kinetics. Common areas of variability between species include liver enzymes, detoxification processes, gastrointestinal tract enzymes, and hormone levels. Physiological and anatomical differences also account for some of the variability in toxicodynamics. The extrapolation of animal data outside the range of observation requires the acceptance of unverifiable assumptions about the mathematical character of the dose-response curve near the zero-dose concentration. An additional uncertainty factor is the interspecies extrapolation from rodent data to humans that involves dose scaling of body weight and total body surface area along with species differences in metabolism and oncogene suppression/enhancement.[70] Unfortunately, there is no consistently reliable scaling factor. Determinants other than body weight (metabolic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

rate, species lifetime) may more accurately extrapolate chemical doses across species weight.[71] Modifying factors for adverse health effects at a given dose include sex, age, and lifestyle.

Various national and international agencies have developed comparable schemes for determining the exposure level that causes minimal or no risk of producing nonneoplastic effects in the general population. These schemes include minimal risk levels (US ATSDR), reference dose/concentrations (US Environmental Protection Agency), Tolerable/Acceptable Daily Intakes (IPCS), and tolerable daily intakes/concentrations (Health Canada). These schemes use the NOAEL of the benchmark data as an estimate of the highest dose that does not produce a statistically significant increase in the incidence of physiological or pathologically significant effects when compared with unexposed control groups. The NOAEL is an estimate of an observed value; this value may overestimate or underestimate the true biological threshold. The NOAEL does not account for the steepness of the dose-response level. Dividing the NOAEL by an uncertainty factor that accounts for variabilities and uncertainties produces a tolerable daily intake (ADI). This uncertainty factor accounts for uncertainties in interspecies (default factor 10) and intraspecies (default factor 10) variations. Additional factors that may modulate the uncertainty factor include the adequacy of the database, the severity of the effect, extrapolation from a LOAEL to a NOAEL, and the use of subchronic exposure data rather than chronic exposure data.

Neoplastic Effects

Traditionally, extrapolation of the dose-response of genotoxic neoplastic effects from high-dose experimental animal studies to the low-dose range involves the use of linearized mathematical models (e.g., linearized Armitage–Doll multistage model). The validity of linear models is difficult to prove or disprove experimentally, even when using bioassays with extremely large numbers of animals.[72] Although some authors criticize linear models as being too conservative,[73] the precision of the risk estimates is probably low.[1] Measures of dose-response other than linear models include estimation of carcinogenic potency in the experimental range, division of the carcinogenic effect level by a margin of protection, and calculation of margins of exposure based on T25 (daily dose in mg/kg body weight obtained by linear extrapolation) or BMDL10 (a mathematically derived value calculated from lower 5% confidence bound on a dose resulting in a 10% increase in experimentally derived tumor incidence above background).[74]

Tumor Incidence Models

The USEPA modeling process assumes a measure of dose (equivalent dose, ED) exists for which the tumor-onset rate in animals and humans is equivalent. To relate the dose of a carcinogen in animals and humans, the following two classes of models are necessary: 1) species extrapolation and 2) tumor incidence.[75] The former relates the administered dose in animal studies or the exposure level in humans to an equivalent dose; the model corrects for differences in production of the active carcinogenic agent across species. The latter class of models correlates the equivalent chemical dose to the probability of developing cancer. Several types of tumor incidence models establish the equivalent dose-response (i.e., tumor incidence) curve by formulating different mathematical functions that fit experimental animal data. The two major categories of these mathematical models are mechanistic and tolerance distribution models.

These models predict the safe equivalent dose defined as the dose predicted by the tumor incidence model that results in a negligible increase in the tumor incidence compared with the spontaneous tumor rate in animals. The equivalent dose in animals and humans is considered safe in both. The safe equivalent dose is then converted to safe concentrations for human exposure by extrapolation with models similar to species extrapolation models used to convert the administered dose in animal studies to an equivalent dose (ED) in humans. Table 51.8 outlines the steps in the modeling process that determine a safe exposure level.

TABLE 51.8. Method for determination of a safe exposure level. (Adapted from Portier et al.).[75]

Consider Mechanism of Toxicity
Estimate equivalent dose (ED)
Determine appropriate tumor incidence model
Estimate relationship between administered dose and equivalent dose in animal model
Express administered dose in carcinogenicity experiment as units of equivalent dose
Estimate parameters of tumor incidence model as function of equivalent dose
Determine safe equivalent dose level
Estimate relationship between equivalent dose and human exposure
Express human safe equivalent dose in units of exposure/dose

Mechanistic Models

Mechanistic models include one-hit, multi-hit, multistage, and linearized multistage models. These mechanistic models depend on the assumption that tumors originate from a single, damaged cell; however, these models use divergent equations to describe the tumor incidence curve. Although these models predict substantially different risks as the dose approaches zero, they usually fit the observed data well.[76] A major issue regarding the accurate estimation of the true risk of developing cancer is the shape of this curve in the low-dose region, because a low-dose linear model predicts a much smaller safe dose compared with a low-dose nonlinear model as demonstrated in Figure 51.6.

The use of a nonlinear model when the true tumor incidence curve is linear would underestimate the true risk to the human population, whereas the use of a linear model when the real low-dose curve is nonlinear would overestimate the true risk. The former situation would increase the cancer risk in the exposed population; the latter situation could result in the exclusion of a useful chemical from the marketplace. The USEPA prefers a low-dose linear model when data are limited, unless this type of model conflicts with known data.[9]

Many regulatory agencies including the USEPA use a modification of the multistage model called the linearized multistage model. The multistage model assumes that the induction of cancer results from a number of random molecular events that occur in linear relation to the carcinogen dose.[77] To account for biological variability in animal studies, the linearized multistage model uses the 95% **upper** (but not the lower) confidence limit of tumor incidence; thus, this model produces conservative, upper bound estimates rather than point estimates.[13] The net effect of the linearized multistage model assumptions is the resemblance of the one-hit model at low-dose and linearity at doses near zero. This model produces a large, but indeterminate, overestimate of the actual risk of human cancer with the virtually safe dose (VSD) being dependent primarily on the chemical dose used in the study rather than actual experimental results.[78]

Tolerance Distribution Models

This class of models includes log-probit (probit), logit, Weibull, and γ-multi-hit. These models assume that human cancer develops when chemical exposure exceeds a critical level. The range of threshold values for an individual within a population includes zero; different model types in this class of models use divergent mathematical functions to describe the probability distributions of individual tolerance to the development of cancer within a population. The tolerance distribution models produce similar shapes within the range of experimental data, but they differ substantially in the low-dose range.[13] Table 51.9 describes the comparative range of potential risks predicted by various models.

The time-to-tumor model is another class of model that includes the log-normal distribution, Weibull distribution, Armitage–Doll, and Hartley–Sielken models. These models attempt to characterize the cancer process by mathematically describing the relationship between dose and tumor latency. Therefore, these models require a large set of biological data that frequently are incomplete.

Biologically Based Models

The statistical "curve-fitting" models described above do not consider biological changes (e.g., pharmaco-

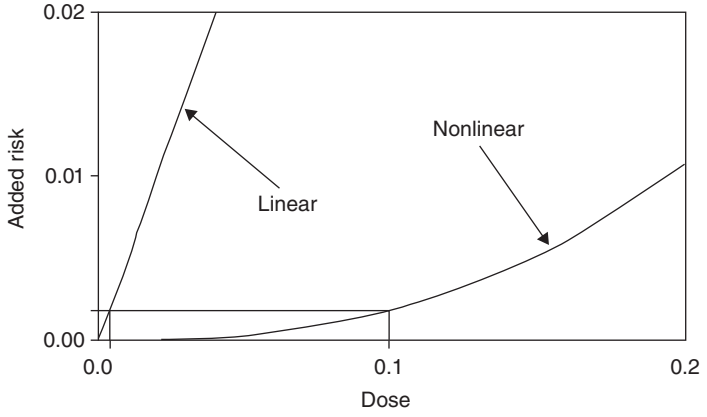

FIGURE 51.6. Linear and nonlinear dose-response curves in the low-dose range. (Adapted from Portier et al.).[75]

TABLE 51.9. Relative differences in relative risk estimates between various models compared with actual risks. (Adapted from Johannsen).[13]

Model	Model Classification	Comparative Risk Estimate
Linearized Multistage	M	High
One-Hit	M	High
Linear	L	High
Multistage	M	High
Weibull	TD	Medium
Multi-hit	M	Medium
Logit	TD	Low
Probit	TD	Low

Abbreviations: L = Linear; M = Mechanistic; TD = Tolerance Distribution.

kinetics, metabolism, and mechanism); these factors may modify the tumor incidence predicted by these empirical models in the low-dose range. The Moolgavkar–Venzon–Knudson (M–V–K) model[79] attempts to incorporate biological data on cell proliferation and transformation into a 2-stage (mutation) stochastic carcinogenesis model. The first stage produces an intermediate cell type that alters growth characteristics, whereas the second mutational event produces malignant transformation.[80] The cancer incidence is related to the birth, death, mitotic, and transition rates of normal, initiated, and transformed cells.

The cancer incidence rate varies with a power of age for epithelial cancers.[81] The biologically based dose-response models provide the best method of estimating the relationship between **delivered** dose and health effects.[82] Although multistage mechanistic models (e.g., Armitage–Doll) partially account for age variation in cancer incidence for adult epithelial cancers, the model uses unrealistically large numbers of stages (e.g., 5–7) to fit cancer data (e.g., colorectum).[83] In contrast to mechanistic models, the M–V–K model allows consideration of the effects of cocarcinogens, promoters, and initiators,[84] resulting in better statistical fits for biological models than mechanistic models, particularly for processes involving genomic instability.[85] Various revisions of the existing biological model were developed to describe the dose-response curve for specific types of cancer. Moolgavkar and Leubeck developed a 3-mutation model to fit colorectal incidence data with plausible mutation rates without accounting for genomic instability,[86] whereas Little fit solid tumor and leukemia mortality rates in Japanese atomic bomb survivors[87] and lung cancer mortality in Colorado Plateau uranium miners[88] with a 2- or 3-mutation M–V–K model assuming genomic destabilization. In the latter model, the fit was superior for the 3-mutation model to the 2-mutation model.

Pharmacokinetic Models

Pharmacokinetic models describe the compartmental disposition of a chemical and metabolite in the body over time by **mathematical** analysis of the processes of absorption, distribution, metabolism, and excretion. The advantage of this model type is the calculation of an internal dose present at the target site rather than an administered dose or an ambient air concentration. This nonlinear exponential model correlates tissue concentration and time profile of the active carcinogen with the administered dose of the parent chemical.

Pharmacokinetic models improve extrapolation across different exposure routes and among various animal species by calculating the difference between the administered dose in animals and the equivalent dose (ED) in humans.[89] Such models help evaluate the impact of the pharmacokinetic process (e.g., metabolic saturation) across different species that may produce nonlinear risk estimates at the low-dose range; however, this model lacks the ability to account for intraspecies differences in pharmacokinetic parameters, with subsequent limitations on the extrapolation of dose-related tumor incidence to humans.

Physiologically based pharmacokinetic models differ from pharmacokinetic models because the former models depend on actual **physiological** measurement of pharmacokinetic data in test species rather than mathematical calculations. The actual measurement of the physiological deposition of the chemical and the use of mass balance equations allow more accurate extrapolation from high dose to low dose within the same species. The physiologically based pharmacokinetic models provide the best method for converting the **applied** dose into the **delivered** dose at the target organ.[82] Potentially, these biologically based *deposition* models can simulate the behavior of the chemical in different biological systems. Additionally, these models account for such differences as saturation (zero order) and Michaelis–Menten kinetics, nonlinear tissue binding, enzyme induction and inhibition, hepatobiliary circulation, receptor affinity, and unequal diffusion across cell membranes.[90] This model also

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

allows cross-species extrapolation by adjusting the appropriate constants permitting modeling of other routes of administration by adding the appropriate equations. Substantial differences in calculated risk may result from the use of this model compared with the risk estimated from linearized multistage model (LMS). For a lifetime exposure to 1 μg dichloromethane/m^3 air, the estimated risk of cancer was two orders of magnitude lower for the PBPK model compared with the LMS model.[91]

Potency Estimation and the Experimental Range

Under the Canadian Environmental Protection Act, the measure of dose-response for genotoxic carcinogens is the tumorigenic dose or concentration$_{05}$ (TD5).[92] This dose is associated with a 5% increase in the tumor incidence in experimental or epidemiological studies. The exposure/potency index (EPI) is the estimated daily human intake divided by the TD5. An EPI of 10^{-6} represents a 1-million-fold difference between human exposure and the lower end of the dose-response curve (i.e., TD5). The choice of the model is not critical because of the use of data within the experimental range.

In contrast to Canada and Europe, the USEPA uses the linear model as the default model when the mode-of-action is not established, or the dose-response curve has a linear component below the POD. Evidence of nonlinearity is necessary to use an estimation of a margin of exposure (EPI). The dose-response curve is usually nonlinear in the high-dose range. The slope of the dose-response curve is the slope factor; this value is an upper-bound estimate of risk/dose increment used to estimate risk probabilities for different exposure levels. The slope factor is equal to 0.01/LEDxx (lower bound xx of the central estimate) when LEDxx is used as the POD and xx typically ranging from 1–10% increased tumor incidence.

Calculated slope factors may overestimate the true slope factor when using the largest of several slope factors, the default linear extrapolation model extends over several orders of magnitude, or the slope factor is based on highly susceptible animal strains. Underestimation of the slope factor may occur when the study design did not include exposure during a susceptible life stage, the study population does not reflect the general population (e.g., healthy workers), the existence of random exposure misclassification/measurement error, or the slope factor is derived from a subset of several tumor types.

The USEPA defines potency (q_1) as the quantitative expression of increased tumorigenic response per unit dose rate at very low dose levels (i.e., levels well below experimental data). For regulatory purposes, the lifetime increased cancer probability following exposure to a carcinogen at a lifetime, time-weighted average dose rate (D) is approximately equal to the product of $q_1 \times D$.

EXPOSURE ASSESSMENT

The objective of this process is a qualitative and quantitative determination of the amount of a chemical in contact with the body over a specified period of time by assessment of magnitude, frequency, exposure duration, and internal dose. Factors in this evaluation include important sources, pathways, and routes (air, soil, food, and water), intensity, frequency, and duration of contact, potential dose, and rate of uptake.[1,93] This analysis also includes separate analyses of susceptible subgroups within the population of interest (e.g., life stages, pregnant women, genetic susceptibility). Figure 51.7 displays how the terms of exposure and dose relate to chemical transport through the body after contact with the chemical in the environment. Exposure assessment typically involves four major steps: 1) elucidating the assessment questions, 2) defining the conceptual and mathematical models, 3) evaluating and collecting available data, and 4) exposure characterization.[7] Carcinogen risk assessment models usually assume the risk is proportional to the lifetime cumulative exposure expressed as a lifetime average daily dose; however, short-term, less-than-lifetime exposure estimates may be more appropriate when the data fits nonlinear dose-response curve.[9]

Childhood and adult exposures differ substantially, including age-specific exposure pathways (e.g., transplacental exposures *in utero*, breast milk consumption, enhanced hand-to-mouth exposures from crawling).[94] Additionally, relatively increased childhood exposures may result from their higher respiratory rates, large food and water intakes, and high surface area to body weight ratios compared with adults. The metabolic pathways of children are age-dependent, particularly *in utero* and the first months of life when their organs are very immature.[95] Age-specific developmental stages result in periods of susceptibility defined by critical windows of exposure, critical windows of development, and windows of vulnerability. The long lifespan of children allows more time to develop chronic diseases initiated by early environmental exposures.

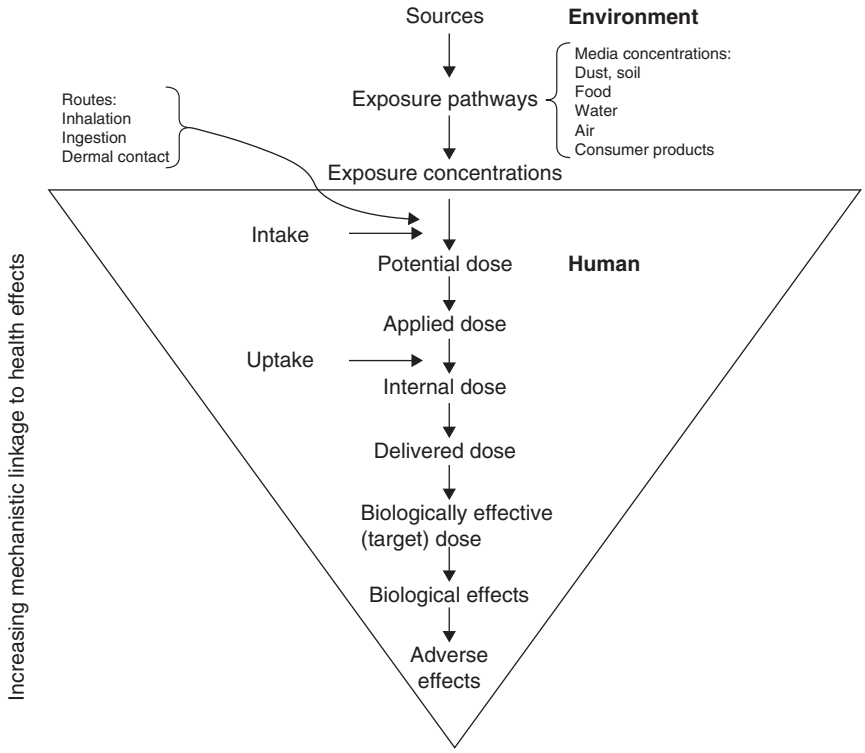

FIGURE 51.7. Paradigm of chemical transport from the environment through the body. (Adapted from IPCS).[1]

Exposure

Exposure is the amount of a chemical in contact with the outer surface of the organism.[96] Although there is some ambiguity about the location of this contact, USEPA guidelines define contact as the visible exterior (i.e., outer boundary) of the person rather than the exchange boundaries where absorption occurs.[97] The outer boundary of the person is the skin, mouth, and nostrils. The *dose* is the amount of the chemical that crosses the outer boundary of the organism after contact. A complete exposure assessment will provide information on the duration, intensity, frequency, exposure routes, and characteristics (such as size, sex, number, health status [e.g., obesity, chronic diseases], lifestyle [e.g., physical activities, personal habits], local environment, hobbies, para-occupational exposure) of the populations exposed to the chemical. Additional factors include work practices (e.g., control measures, handling procedures, personal protection, pattern and amount of chemical use, potential for misuse or accidental exposure), and physiochemical properties.

Dose

Potential dose is the amount of chemical present at the site of contact (skin, mouth, nares), whereas the *applied dose* is the amount of chemical present at the site of absorption (skin, lung, gastrointestinal tract). The applied dose frequently is difficult to measure because the site is usually inside the body; therefore, the potential dose (i.e., amount of chemical ingested, inhaled, or applied to the skin) is the surrogate measure for the applied dose. The applied dose is usually smaller than the potential dose, depending on the chemical characteristics and bioavailability. These parameters vary between different routes of exposure (e.g., anaerobic conditions in the colon may alter chemical bioavailability prior to absorption).

The *internal dose* is the amount of the applied dose that crosses the site of absorption and subsequently is available to interact with the receptors in the body. Once absorbed, the chemical undergoes metabolic transformation followed by transport throughout the body. The amount delivered to a specific site of interest

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(e.g., tissue, organ, fluid) is the *delivered dose*; this value is substantially smaller than the internal dose. The *biologically effective dose* is the amount of the chemical reaching the site (e.g., cell, membrane) where adverse effects occur. The biologically effective dose is often smaller than the delivered dose, depending on the ability of the chemical to diffuse across membranes to the site of interaction.

Exposure Estimates

Estimation of the total daily intake (i.e., μg/kg body weight) of a substance is critical to assessing the true magnitude of the cancer risk following contact with a particular substance. The major routes of chemical exposure for humans include ingestion of dust/soil or contaminated food and water; inhalation of dust, vapors, or aerosols; and the direct dermal absorption of liquids or contaminated solids. Computer programs (e.g., USEPA Risk Assistant) are available to conduct site-specific risk assessments for environmental chemicals. These programs prompt the user to identify the chemicals of concern, automatically list exposure pathways, and set default assumptions for exposure parameters that are modified as needed. The distribution of contaminants in soil, air, water, and food usually follows a log-normal rather than a normal distribution, as displayed in Figure 51.8; hence, statistical analysis of these distributions requires geometric means and geometric standard deviations. Table 51.10 lists the factors to consider when estimating the exposure (potential dose) of a chemical.

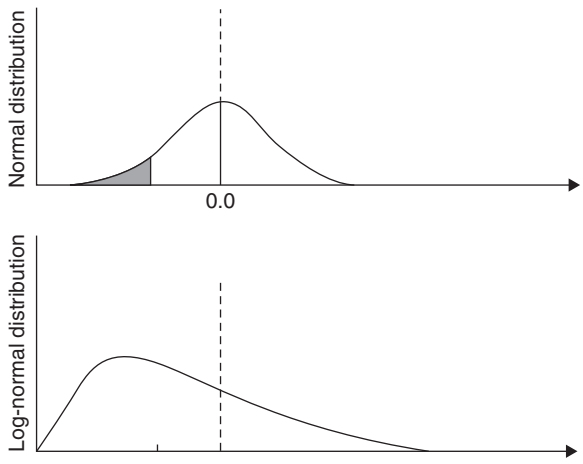

FIGURE 51.8. Schematic representation of normal and log-normal distributions. Log-normal distributions contain only positive numbers, whereas normal distributions may contain negative numbers. Additional, the mean of a log-normal distribution is always higher than the symmetrical normal distribution. (Adapted from Paustenbach).[18]

TABLE 51.10. Factors used to estimate uptake of a contaminant. (Adapted from Paustenbach).[18]

Route	Factor
Lungs	Ambient concentration, particle size distribution, concentration in dust, respiratory rate, duration of exposure.
Skin	Concentration in soil/dust, deposition rate on skin (direct and soil/dust), area of exposed skin, duration of exposure.
Gastrointestinal tract	Daily amount of contaminated source, concentration of contaminated source.

Evaluation of the potential dose usually involves: 1) measurement of the chemical at the point of contact with the outer boundary of the body over a period of time (point-of-contact or personal measurement); or 2) separate measurement of environmental concentrations of the chemical and the time of contact (scenario evaluation).[1] The data should be evaluated for quality and reflect the risks in the population of interest, including adjustment for susceptible, age/sex-related, and highly exposed subgroups. The potential dose also can be estimated from an analysis of internal indicators (biomarkers, body burden, biological fluids) after exposure (reconstruction). Point-of-contact exposure measurements provide the most accurate value for the potential dose because this value reflects a direct measurement of the chemical concentration at the interface of the person and the environment over a period of time. Instruments for these measures include radiation dosimeters, carbon monoxide monitors, and absorbent pumps for hydrocarbons; however, these devices are not source-specific, and some assumptions are necessary to extrapolate these short-term measurements to lifetime exposures. Scenario evaluation involves estimation of the concentration at the point-of-contact by modeling or indirect measurements of the environmental chemical rather than at the point-of-contact. When monitoring data are inadequate, environmental fate models are used to estimate chemical concentrations. These models involve a wide range of complex analyses of spatial dimensions and temporal changes; these fate models include transport models, dispersions models, equilibrium models, and simple dilutions models. The reliability of these estimates depends on the validity and uncertainty of the underlying assumptions, reliability of

the model under similar conditions, and quality of the input data. Confidence in the validity of the exposure estimates increases with more knowledge about these parameters. Reconstruction is the third option for estimating the potential dose using biomarkers of internal dose. The use of biomarkers requires a thorough understanding of the relationship between the internal and potential doses along with the exclusion of interfering reactions from the metabolism of unrelated chemicals. Optimization of sampling conditions (e.g., timing of the sample) is necessary to correlate exposure with the biomarker. Unfortunately, these conditions exist for relatively few chemicals.

If the chemical contaminant is a vapor, the most direct estimation of the concentration is an actual measurement, particularly in the occupational setting where more data are available than in environmental locations. The suitability of estimating exposure data for a specific population depends on how closely the data represent actual concentrations, time periods, and processes of the selected worker groups. The most common measure of exposure is cumulative exposure (average intensity multiplied by time); however, these measurements do not incorporate intermittent peak exposures that may alter the response to a given exposure.[98] In the absence of direct measurements, computer models can estimate the ambient concentration of a contaminant from volatilization of the chemical from water or soil to the air. The amount of contaminant absorbed from nonvolatile chemicals depends on the inhalation of respiratory particles (i.e., aerodynamic diameter <20 μm) that contain the chemical. Published data provides the total amount of particulates in air at a particular location. Once the amount of a chemical in a volume of air is determined, the systemic uptake can be estimated from assumptions about the pulmonary bioavailability of the chemical and the respiratory rate, as demonstrated in Table 51.11.

Assessment of chemical exposure in consumer products involves the combination of contact parameters and estimates of chemical concentrations. Data important for the development of realistic exposure assessments for consumer products are listed in Table 51.12. A variety of information sources are available to assess common exposure scenarios for consumer products.[99]

Table 51.13 lists average values recommended by the USEPA for parameters used in the risk assessment of exposures to contaminants in the air, soil, and water. The daily sum of maximum dermal, pulmonary, and oral doses represents an average daily exposure prorated over a lifetime to approximate the cumulative carcinogen dose. For risk assessment, the USEPA assumes from a risk assessment perspective that a high dose of

TABLE 51.13. USEPA Recommended human parameters for risk assessment. (Adapted from USEPA).[101]

Parameter	Value
Body Weight (kg)	
2–5 years	13.2
6 years	20.8
Adult	70
Lifespan (years)	75
Exposed Skin Surface (m^2)	
Adult	0.20
Worst case	0.53
Swimming or bathing	1.94 (♂), 1.69 (♀)
Respiratory Volume (m^3/day)	
8-hour work shift	10
Average adult	20
Worst case	30
Drinking Water (L/day)	
Adult (average)	1.4
Adult (worst case)	2.0
Infant (≤10 kg)	1.0
Showering (minutes [gallons used])	
Median	7 (56)
90th percentile	12 (96)
Average Food Consumption (Worst Case)	
Adult total (g/day)	2000
Beef (g/day)	100
Dairy (g/day)	400
Fruit (g/day)	140
Vegetable (g/day)	200
Sport fish (g/day)	30 (140)
Soil Ingestion (≤7 years)	
Average (g/day)	0.2
90th percentile (g/day)	0.8

a carcinogen over a short period of time is equivalent to a low dose over a correspondingly longer period of time.[9] Worst-case scenarios involving maximally exposed individuals (i.e., 95th–99th percentile exposure) to all contaminated media are useful as screening tools to dismiss insignificant hazards; however, this type of estimation does not accurately estimate real risks. A more practical approach is the use of a single 95th percentile exposure (i.e., food source, residence, **or** childhood ingestion) as a measure of the maximally exposed individuals in the population.[100]

Dose Estimation

Most risk assessments use the potential internal dose for estimation of dose-response relationships because of the lack of adequate toxicokinetic data to estimate the delivered or biologically effective dose. The internal dose depends on the chemical concentration in a particular medium and chemical characteristics. These doses are usually measured as dose rates (i.e., amount of dose/unit time). These intake rates represent units of mass/time (e.g., mg/day); they usually vary over a period of time. Hence, many risk assessments use average intake (potential dose) rates or average uptake (internal dose) rates.

The intake of chemicals in vapors is usually insignificant from dermal exposures compared with inhalation. The dermal intake of chemicals from soil depends on the physicochemical properties of the contaminant and the soil, in addition to factors listed in Table 51.10. Typically, dermal exposures in the occupational setting involve the hands and forearms (i.e., ~2000 cm^2). Oral bioavailability of chemical contaminants also varies widely, depending on the same factors listed above. The bioavailability of chemicals in liquids is usually much higher for oral than dermal absorption.

Estimation of the daily or lifetime intake of chemicals is a complex process because this analysis requires consideration of multiple factors. These factors include bioaccumulation, dermal uptake, degradation, environmental migration through soil and air, deposition of particulates and dust, and ingestion of contaminated foods (e.g., plants, milk). Pharmacokinetics and consumption patterns over a lifetime frequently vary.[18] For cancer, lifetime probabilities usually describe the biological response. In these cases, the dose is described as a lifetime average daily dose, even though the exposure does not occur over the entire lifetime.[1] In some experimental animals administered high-dose potent carcinogens rather than doses commonly present in the environment, single-dose exposures to carcinogens can produce an increased tumor incidence.[102,103]

Oncogene proteins appear in the extracellular environment; therefore, immunoprecipitation techniques can detect these proteins in biological fluids. The challenge of developing reliable markers of oncogene activation remains; however, the identification of such markers provides valuable insights into the cause of occupational cancer and the true cancer risk in an individual worker. The efficacy of biological monitoring (sister chromatid exchange, oncoproteins, miRNA, DNA methylation, signaling pathway inhibition, tumor suppressor gene products) of workers exposed to

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. carcinogens depends on a better understanding of confounding variables, prognostic value, and the outcome of early screening and treatment.[104,105,106]

Variation, Uncertainty, and Exposure Characterization

Variation in exposure estimates results from variability in the exposure of individuals within the population and uncertainty about the correct value for a specific exposure measure. Most risk assessments evaluate exposure variability and, less often, the uncertainty involved with these estimates. Characterization of the variability and uncertainty of the internal dose is more difficult because of more limited data. Depending on the complexity of the risk assessment, evaluation of the uncertainty in exposure risk assessments may involve only the qualitative discussion of the reasons for the selection of specific data or scenarios. Quantitative assessment of uncertainty includes: 1) scenario uncertainty – missing or limited information needed to define exposure, 2) parameter uncertainty – inadequate data on some parameters, and 3) model uncertainty – gaps in the scientific theory required to mathematically predict certain events.[1] Historically, many risk assessments used worst-case scenarios rather than realistic estimations of variability and uncertainty of the risk calculations. In these situations, the use of highly exposed individuals and upper confidence bounds on physical data implies that the risk estimates do not exceed the upper bound during exposure to highly exposed individuals. The true risks are probably much lower for individuals with exposures near the group mean.

RISK CHARACTERIZATION

Risk characterization is a summary review of the major scientific evidence and reasoning of a risk assessment that quantifies the likelihood of the development of adverse effects including cancer in a population exposed to certain chemicals.[107] This final step in the risk assessment process summarizes the preceding three steps by presenting the following: 1) a numerical risk estimate and 2) a discussion of validity and significance of the risk estimate. The risk characterization process estimates the risks associated with a range of exposures to help risk managers decide on appropriate regulatory, economic, and technological options. Risk assessment is only one part of the decision-making process for these options. Other considerations include political implications, trade impact, cost, socioeconomic values, feasibility, duration and magnitude of the risk estimate, populations at risk, and risk comparisons.[1] Risk estimates are expressions of uncertainty; these estimates change as knowledge regarding risks improves. Estimates of carcinogenic risk involve risk by analogy to animal data.[108] This process requires the comparison of carcinogenic potency in animals and humans along with extrapolation of high-dose animal data to low-dose human exposures. In relation to dose-response and exposure assessments, the major assumptions, uncertainties, scientific judgments, and relevant biological information should be analyzed to evaluate the risk estimates in relation to the actual risks in the environment.[109] Estimation of these risks improves the decision-making process regarding the hazards by understanding the cause and magnitude of the risks. Table 51.14 lists the important areas to evaluate during the risk characterization process.

Individual and Population Risks

With linear extrapolations associated with cancer risks, risk below the POD is typically approximated by multiplying the slope factor by an exposure estimate (i.e., Risk = Slope Factor × Exposure). The risk characterization should include expected or central estimates of risk, upper and lower bounds (e.g., confidence limits) based on the point of departure (POD) along with

TABLE 51.14. Areas pertinent to the evaluation of a risk assessment. (Adapted from International Programme on Chemical Safety, IPCS).[1]

Pertinent Areas to Evaluate
1. Conclusions and confidence in the existence and magnitude of risk
2. Identification of specific exposure in general population causing risk and evaluation of true exposure (body burden)
3. Presence of sensitive subgroups and evidence for true increased risk in these populations
4. Range of uncertainty and magnitude of risk near likely exposure levels
5. Likelihood of zero risk
6. Presence or absence of adequate information for regulatory decisions
7. Presence and importance of data gaps
8. Source and precision of key parameters that drive risk analysis
9. Results of peer review, if any
10. Presence of relevant ongoing research
11. Importance and validity of studies excluded from analysis

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. characterization of uncertainty of the risk. For exposure levels above the POD, a point in the curve of the dose-response model provides the value rather than a calculated estimate. With nonlinear extrapolations, the risk assessment approach depends on the chosen procedure. When the nonlinear dose-response curve is available, the risk is a function of the expected exposure and the value at the appropriate point on the curve. Calculation of a reference dose (RfD) or reference concentration (RfC) allows the expression of a hazard quotient (HQ) defined as HQ = exposure estimate/(RfD or RfC).

Regulatory agencies traditionally accept assumptions that are least likely to underestimate the actual risk to human populations; therefore, the risk estimates are usually conservative as a means to protect vulnerable subpopulations.[110] The USEPA uses an upper bound (95%) confidence limit around the best estimate of risk rather than the maximum likelihood or central tendency (e.g., mean). The USEPA then applies this upper bound risk estimate to the maximum exposed individual (i.e., 24 hour/day over 70 years of maximum exposure, 2 L of water/day, 20 m^3 inhaled air/day, 100 mg ingested soil/day, 100% bioavailability). In the absence of contrary data, the USEPA also uses conservative quantitative assumptions for all dose-response assessments. These assumptions include: 1) surface area as a scaling factor for extrapolation from animals to humans, 2) low-dose linear models without thresholds, 3) the combination of malignant and benign tumors in the calculation of tumor incidence, and 4) positive results from the most sensitive species or strain.

Individual risk is the probability that a specific person or subgroup of a population will develop adverse health effects from exposure to a chemical over an established period. Individual risk requires the presence of carcinogenic (i.e., stochastic) effects or noncarcinogenic (nonstochastic) effects at concentrations above threshold values. Individual risks vary within a population. Identification of individuals with high risk depends on the degree of susceptibility, the exposure level relative to the population average, and the probability of developing an adverse health effect at a given exposure level. Factors predisposing individuals within a population to an increased risk of adverse health effects include preexisting diseases, lifestyle (tobacco, alcohol consumption), nutritional deficiencies, developmental processes, and prior or concurrent chemical exposure.[1]

Determining individual risks from these models requires careful analysis of the assumptions used to develop the models. Quantitative risk assessment evaluates the risks in a theoretical population; consequently, these risk estimates should not be applied directly to an individual.[111] The risk assessment process provides a good scale to compare the upper bound risk of different chemicals or mixture of chemicals with various exposures in a population; however, these risk estimates do not have precisely defined endpoints.[112] The true risk of an **individual** exposed to a chemical would not be higher than the estimated risk; the true risk probably would be much lower (and, if fact, may be zero). The true risk depends on the actual individual exposure, the susceptibility of the host to cancer, and the validity of

TABLE 51.15. Comparison of the annual risk of death from common actions and exposures in the United States during the 1980s. (Adapted from Wilson and Crouch).[108]

Action	Annual Risk ($\times 10^{-6}$)	Uncertainty
Cigarette smoking (1 ppd)	3,600	3
All cancer	2,800	10%
Mountaineer	600	50%
Motor vehicle accident	240	10%
Police, killed in line of duty	220	10%
Home accident	110	5%
Frequent flying professor	50	50%
Sea-level background radiation	20	3
4 Tablespoons peanut butter/day	8	3
Electrocution	5.3	5%

Abbreviation: ppd. = pack per day.

the assumptions that extrapolate risk from animal data to the specific exposure level in humans. Major factors influencing the validity of the assumptions involved in risk assessment include: 1) variation in the environment, population, and exposure level, 2) multiple exposures, 3) species differences, 4) absorbed dose, 5) dose calculations based on body weight vs. surface area, 6) use of statistical rather than biological significance, 7) wide confidence intervals, 8) uncertainty factors, and 9) extrapolation from high-to low-dose.[10]

Risk Comparisons

Risk implies uncertainty, whereas understanding the meaning of a risk requires knowledge of the concept of probability that compares calculated and background risks. There is no consensus about the appropriate background risks to compare the output of risk assessment, particularly involuntary assumed risks. Many people do not perceive various risks as simply a matter of probability, particularly when comparing choices in personal lifestyle (smoking, motorcycle riding) with risks from unintentional chemical exposures.[113] Different people perceive risk differently depending on the seriousness of the effect, the theoretical benefit of the risk, the likelihood of the adverse effect, the individual at risk, their familiarity with the adverse effect, and how the hazard affects them personally.[114] For comparison, Table 51.15 lists the annual risk of death from common actions or exposures along with estimates of uncertainty based on data from the 1980s.

Chapter 52

CANCER SURVEILLANCE

Most human cancers occur in epithelial tissue (carcinomas) from the interaction of a variety of host factors (genetic susceptibility, health, lifestyle) and the external environment.[1] Although mortality from cardiovascular diseases, infectious diseases, and many cancer types (e.g., hematopoietic) has steadily declined over the last 50 years, many advanced epithelial (carcinomas) and mesenchymal (sarcomas) tumors remain mostly incurable.[2] Consequently, monitoring individuals at risk (e.g., carcinogen-exposed workers, susceptible patients) is important to identifying early biological changes, when medical therapy has the best chance of reducing morbidity and mortality during the preclinical stage of cancer. The chapter on Qualitative Carcinogen Categories lists human carcinogens and recognized target organs based on information in public databases (IARC, USNTP, USEPA, GHS). These databases provide a plethora of information on proteins involved in signal transduction pathways that enable movement of external signals from cell surface rectors to enhancer-promoter regions along the chromosomes. These growth factors regulate gene expression required for cell growth, differentiation, and death (apoptosis), with crosstalk among the pathways exponentially increasing the complexity of the molecular and biochemical changes associated with cancer. Alterations of these pathways occur during the multiple stages of cancer, including the development of the increasing resistance of late-stage cancer cells to chemotherapeutic and radiation treatments as a result of genomic instability causing new pathways of epithelial-to-mesenchymal cell transitions. These free-floating, amoeba-like mesenchymal cells develop resistance to the hypoxic tumor microenvironment surrounding neoplasms and targeted chemotherapeutic drugs allowing proliferation and metastasis to noncancerous tissues (brain, liver, lungs).

MEDICAL SCREENING

Medical screening involves the application of population-wide tests to identify *asymptomatic*, at-risk persons (e.g., age, sex, family history) requiring further testing or preventive action to improve their outcome compared with no interventions.[3] Criteria for cancer screening include: 1) an important medical condition, 2) availability of effective treatment, 3) access for diagnosis and treatment of the cancer, 4) latent period between screening and cancer treatment sufficient for an improved outcome compared with treatment at clinical presentation documented by large, randomized clinical trials, 5) availability of a sensitive, specific test acceptable to the population tested, 6) adequate knowledge of cancer progression and presentation, 7) a well-defined policy for treatment options, 8) benefit of the screening program should outweigh harm from the screening, and 9) the cost–benefit compares favorably with other medical expenditures.[4] Despite the dramatic increase in knowledge regarding genetic and epigenetic molecular pathways through whole-genome, high-input screening of over 200 human genes (e.g., *TP*53 tumor suppressor genes, *KRAS* oncogenes) involved as drivers of carcinogenesis, most population-based screening techniques for early cancer detection remain investigational.[2] Using next-generation sequencing-by-synthesis technologies to examine tissues from 24 pancreatic

tumors, Jones et al. identified 63 genetic alterations (primarily point mutations) in 12 cellular signaling pathways and processes.[5]

The common, effective cancer screening techniques include fecal occult blood testing and flexible sigmoidoscopy for colorectal cancer at ≥50 years of age,[6] Papanicolaou (PAP) test for cervical cancer in women of >21 years of age and HPV DNA test at >30 years of age, mammography for breast cancer in women at >45 years of age, human chorionic gonadotropin (HCG) for gestational trophoblastic disease in pregnant women, and low-dose computed tomography for lung cancer in high-risk persons (age 55–74 years in good health with ≥30 pack-year history).[7] Table 52.1 lists the 2020 United States Preventive Services Task Force (USPSTF) recommendations for cancer screening.

Common cancer screening tests without unequivocal validation in large clinical trials include α-fetoprotein (AFP) for hepatocellular cancer in high-risk persons, prostate-specific antigen (PSA) for prostate cancer in men aged ≥50 years, homovanillic and vanillylmandelic acid for newborn neuroblastoma, and cancer antigen 125 (CA-125) with ultrasound for ovarian cancer.

Limitations for the development of early screening tests involve low prevalence of specific cancer types in asymptomatic persons along with poor sensitivity and specificity. The receiver operating characteristic (ROC) curve is a measure of the ability of the dichotomous biomarker to accurately classify tumor and nontumor tissue. The ROC curve plots the sensitivity versus 1 minus the specificity of biomarker while varying the threshold to designate the biomarkers as positive. The area under the curve (AUC) of an ROC curve determines the accuracy of classifying tumor and nontumor tissues, with 1 being a perfect marker and 0.5 being an uninformative biomarker. Realistically accurate biomarkers have values of 0.80–0.90, with 0.70 being a fairly accurate biomarker.

Preemployment Physical Exam

Currently, validated, sensitive, and specific techniques to identify which workers will develop cancer following exposure to carcinogens are unavailable. Preemployment physical examinations can detect certain risk factors (smoking, family history, nutrition status, preexisting disease) depending on the cancer type associated with the associated industrial process. Counseling workers with known risk factors may help mitigate their exposure to carcinogens by encouraging them to use appropriate personal protective equipment, observe standard work site techniques, and modify their lifestyles. Individual susceptibility may result from variations in metabolism (cytochrome P-450, aryl hydrocarbon hydroxylase, debrisoquine hydroxylase, *N*-acetylation)[8,9] or the presence of certain diseases (e.g., xeroderma pigmentosum with UV-induced skin cancer). Preexisting conditions (e.g., nutritional deficiencies) may render DNA more susceptible to point mutations or translocations associated with cancer initiation. More data are necessary to accurately identify the genetic and/or epigenetic processes that enhance susceptibility to cancer.

Screening Examinations

Agencies listing known carcinogens include: the European IARC, the European Globally Harmonized System of Classification and Labelling of Chemicals (GHS), the US National Toxicology Program (US Department of Health and Human Services), the US Environmental Protection Agency (USEPA), and the American Conference of Governmental and Industrial Hygienists (independent, non-governmental body). Exposure to known carcinogens should be minimized with exposure never exceeding regulatory standards or recommended threshold limit values (e.g., TLV); however, exposure to concentrations above these standards does **not** imply that cancer will necessarily result because of the safety factors built into these standards.[10]

Older screening tests for lung cancer (sputum cytology, chest X-ray) and bladder cancer (urine cytology, urinalysis for red blood cells) are not valid biomarkers for early cancer detection. The formulation of a specific program for employees depends on the potency (known vs. suspected) of the carcinogen, the extent of exposure, and the documented efficacy of the outcome of screening. Numerous genetic and epigenetic markers are being tested based on data from molecular and biochemical studies on carcinogenesis.

BIOMARKERS

Analysis of chemical concentrations in air determines the **potential** amount (i.e., applied dose) of a carcinogen available for uptake into the body. Therefore, chemical concentrations in ambient air are an indirect measure of carcinogen uptake into the blood (i.e., internal dose) or the amount (i.e., biologically effective dose) of the carcinogen present at the site of action in the cell nucleus or cytoplasm.[11] The amount of carcinogen transferred from the external environment to nuclear DNA depends on the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 52.1. United States Preventive Services Task Force (USPSTF) 2020 recommendations for cancer screening. (Based on Smith et al.).[7] These recommendations are updated as new evidence becomes available.

Cancer	Description	Grade
Bladder	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for bladder cancer in asymptomatic adults.	I
BRCA risk assessment and genetic counseling/testing	The USPSTF recommends that primary care clinicians assess women with a personal or family history of breast, ovarian, tubal, or peritoneal cancer or who have an ancestry associated with breast cancer susceptibility 1 and 2 (BRCA1/2) gene mutations with an appropriate brief familial risk assessment tool. Women with a positive result on the risk assessment tool should receive genetic counseling and, if indicated after counseling, genetic testing.	B
Breast	The USPSTF recommends screening mammography for women, with or without clinical breast examination, every 1–2 years for women aged 40 years and older.	B
Cervical	The USPSTF recommends screening for cervical cancer every 3 years with cervical cytology alone in women aged 21–29 years. For women aged 30–65 years, the USPSTF recommends screening every 3 years with cervical cytology alone, every 5 years with high-risk human papillomavirus (hrHPV) testing alone, or every 5 years with hrHPV testing in combination with cytology (cotesting).	A
Colorectal	The USPSTF recommends screening all adults for colorectal cancer starting at age 50 and continuing until age 75. The USPSTF also recommends screening for adults 40 to 49 years. For adults aged 76 to 85, the USPSTF recommends selective screening for colorectal cancer based on patient's prior screening history, overall health, and preferences.	A B C
Lung	The USPSTF recommends annual screening for lung cancer with low-dose computed tomography in adults aged 50–80 years who have a 20-pack-year smoking history and currently smoke or have quit within the past 15 years. Screening should be discontinued once a person has not smoked for 15 years, develops a health problem that substantially limits life expectancy, or the has ability or willingness to have curative lung surgery.	B
Oral (asymptomatic adults)	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of screening for oral cancer in asymptomatic adults.	I
Ovarian (asymptomatic adults)	The USPSTF recommends against screening for ovarian cancer in asymptomatic women who are not known to have a high-risk hereditary cancer syndrome.	D
Pancreatic (adults)	The USPSTF recommends against screening for pancreatic cancer in asymptomatic adults.	D
Prostate (55–69 years)	For men aged 55–69 years, the decision to undergo periodic prostate-specific antigen (PSA)–based screening for prostate cancer should be an individual one based on a discussion of the potential benefits and harms. Over the age of 70, prostate cancer screening is not recommended (category D).	C
Skin cancer (asymptomatic adolescents and adults)	The USPSTF concludes that the current evidence is insufficient to assess the balance of benefits and harms of visual skin examination by a clinician to screen for skin cancer in adults.	I
Behavioral counseling	The USPSTF recommends counseling young adults, adolescents, children, and parents of young children about minimizing exposure to ultraviolet (UV) radiation for persons aged 6 months to 24 years with fair skin types to reduce their risk of skin cancer.	B

Abbreviations: A = recommends the service with high certainty that the net benefit is substantial; B = recommends the service with high certainty that the net benefit is moderate or there is moderate certainty that the net benefit is moderate to substantial; C = recommends selectively offering or providing this service to individual patients based on professional judgment and patient preferences. There is at least moderate certainty that the net benefit is small; D = recommends against the service. There is moderate or high certainty that the service has no net benefit or that the harms outweigh the benefits; I = the current evidence is insufficient to assess the balance of benefits and harms of the service. Evidence is lacking, of poor quality, or conflicting, and the balance of benefits and harms cannot be determined.

physiochemical properties (e.g., volatility, solubility) of the chemical, toxicokinetic characteristics (absorption, metabolism), and the route of exposure as well as individual susceptibility. Potential tumor-associated markers include: proteins (metabolites, cell surface receptors (e.g., receptor-tyrosine kinases),[12] serum proteins/enzymes, oncoproteins, carcinoembryonic proteins); circulating cell-free DNA including methylated DNA markers, histone modification patterns, microRNAs, and other RNA subtypes; and circulating tumor cells encoded by promoter/suppressor genes.[13] Of these tumor-associated biomarkers, DNA methylation has significant advantages (e.g., restriction to limited genome locations, amplification at relatively low costs, stability).[14] Advantages of cancer-associated biomarkers include relatively easy access (e.g., urine, blood), automated, high-throughput, relatively inexpensive assays, and quantitative data with objective endpoints; however, there is a lack of sensitive assays with high specificity for early malignancy in asymptomatic persons in populations with a low prevalence of cancer. The Early Detection Research Network (EDRN, https://edrn.nci.nih.gov/) is a research consortium established in 1999 by the US National Cancer Institute with the mission of translating promising cancer biomarkers to clinics for use in assisting with medical decisions.[15]

Table 52.2 outlines the role of biomarkers in the multistage process of carcinogenesis that results in difficulty separating external exposure, internal dose, and the biologically effective dose.[16] Emerging technologies include genomics (copy number, heritable variation, somatic mutations); epigenomics; proteomics (protein measurement); transcriptomics (mRNA and microRNA expression); and metabolomics (small metabolite concentrations).[17] However, effects of exposure to chemical carcinogens are not simply additive because of nonlinear relationships in signaling pathways between genotype and phenotype along with the biological complexity of nonlinear interactions at a molecular level between multiple genes, environmental risk factors, and epigenetic changes.

The National Research Council Committee on Biological Markers divided biomarkers into measures of **exposure**, **effect**, or **susceptibility**;[18] however, a biomarker does not always measure a single carcinogenic exposure or effect because of the complexity of signaling pathways and the cross-talk between them during the multistate process of cancer.[19] Figure 52.1 illustrates an overview of biomarker types and the interactions of various biomarkers during carcinogenesis. Biomarkers of exposure measure a chemical, metabolite, or product of the interaction of the chemical with a target molecule in the exposed individual, whereas a biomarker of effect measures a biochemical, behavioral, physiological, or other alteration in the person associated with a suspected or established disease process. Biomarkers of susceptibility assess the acquired or inherent ability of a person to respond to a specific chemical exposure. Typically, these biomarkers focus on the early stages of the exposure-response process (internal dose, biological effective dose, early biological effects), when an intervention is most likely to be successful.[20] Internal dose is the amount of chemical and metabolite found in the person, whereas biologically effective dose represents the integration of external exposure, toxicokinetics, and chemical interaction with the target site (e.g., DNA, essential enzyme). The early biological effect correlates to a specific health effect (e.g., lymphocyte chromosomal aberrations) caused by the exposure.

Many biomarkers are not unique to malignant neoplasms. Lipid peroxidation continuously produces substantial amounts (e.g., 5,400 adducts/cell) of DNA modification in healthy persons.[21] Consequently, the presence of carcinogen-DNA adducts is a necessary but not sufficient condition for the initiation of chemical carcinogenesis because tumors do not always develop in tissues that contain these adducts. Chemical carcinogenesis develops along a

TABLE 52.2. Biomarkers and their relation to the stages of carcinogenesis.

Biomarker	Site	Carcinogenic Equivalent
Susceptibility	Preexposure metabolism or DNA repair capacity	Enhancement of the progression of cancer stages
Exposure	Toxin–body interface	External dose of pro-carcinogen or direct carcinogen
Internal dose	Body fluids (blood, urine) or exhaled air	Ultimate carcinogen
Biologically effective dose	Sub-cellular level	Initiate cell
Early biological effect	Sub-clinical tumor	Pre-neoplastic lesion
Clinical disease	Altered structure or function	Malignant tumor

continuum from environmental contamination to clinically apparent disease, as reflected in Figure 52.1; the classification of a biomarker depends on events in this sequence that approximate the biomarker. The goal of biomarker development focuses on a molecular biology approach (epigenomic, genomic, transcriptomic, proteomic, metabolomic) that detects cancer during the preclinical phase, when treatment is most effective. With the exception of some measures of internal dose and cytogenic techniques,[1] the principle limitation to biomarker effectiveness among the plethora of potential biomarkers currently is the lack of adequate validation through molecular cancer epidemiological studies with sufficient power, especially given the diversity of individual lifestyle, environment, and occupation.[22] Other potential limitations of epidemiological biomarker studies include small sample sizes, selection bias, information bias (measurement error), false positives from multiple comparisons when using genome-wide scans, and confounding.[23,24] The latter bias complicates the interpretation of these studies because biomarkers are measures of exposure and outcome. Effective biomarkers of genetically susceptible populations should demonstrate the lowest risk for nonsusceptible, nonexposed groups and the highest risk for susceptible, exposed groups. Although there are a variety of biomarkers for exposure, response, and susceptibility, distinguishing adaptive and reversible responses from irreversible pathological changes is difficult.

Exposure

Biomarkers of exposure indicate the presence or the likelihood of previous exposure to a chemical or to alterations (e.g., DNA adducts, oncogene protein products, chromosomal aberrations) of the target organs from the chemical; potential biomarkers include measurements of external exposure, internal dose, biologically effective dose (e.g., level of DNA damage), and markers of harm. The latter three biomarkers quantify exposure at the cellular level, allowing characterization of exposures in low-risk populations. Biomarkers of gross chromosomal mutations from the formation of DNA adducts include chromosome breaks, gaps, and translocations; however, no single biomarker is sufficiently validated to determine the cancer risk in all individuals exposed to a chemical carcinogen.[25] Occupation is often a proxy for exposure to specific chemical carcinogens.[26] Assessment of exposure includes historical data (questionnaires, interviews), personal monitoring,

and measurements of the carcinogen in the ambient environment. The latter is complicated by the changing distribution of chemicals in samples over time. Other biomarkers of exposure include biologically active substances absorbed from the environment (e.g., blood and urinary cotinine for quantitating cigarette smoke exposure). Tobacco-specific nitrosamines (e.g., 4-[methylnitrosamino]-1-[3-pyridyl]-1-butanone, NNK) and polycyclic aromatic hydrocarbons (e.g., benzo[*a*] pyrene) are recognized human carcinogens present in cigarette smoke. 4-(Methylnitrosamino)-1-(3-pyridyl)-1-butanol (NNAL) and the glucuronidated conjugates are metabolic biomarkers of NNK exposure, whereas urinary concentrations of 1-hydroxypyrene and tetraol, *r*-1,*t*-2,3,*c*-4-tetrahydroxy-1,2,3,4-tetrahydrophenanthrene (PheT) are biomarkers of exposure to polycyclic aromatic hydrocarbon.[27] These urinary metabolites are biomarkers of internal dose.[28] Current data on the influence of genetic variation in PAH metabolism on urinary metabolite biomarkers are variable and inconclusive.[29]

Internal Dose

The internal dose represents the amount of carcinogen absorbed into the body as measured in body fluids (blood, urine, exhaled air, breast milk, adipose tissue, nails, hair). Consequently, the internal dose is a more accurate determination of the actual amount of the chemical transferred from the external environment to sites of action compared with measurements of concentrations in ambient air. However, these body fluids are usually not the target organs. Hence, measures of internal dose do not directly reflect the molecular interaction between the chemical and the macromolecules of the cell that initiate or promote carcinogenesis. Unless bioaccumulation occurs, measures of internal dose represent recent exposure only. Glutathione detoxifies reactive chemicals following exposure, and measurement of specific metabolites (e.g., mercapturic acids) is a good biomarker of internal dose;[11] however, such testing requires knowledge of the kinetics of individual carcinogens and sophisticated analytical techniques.

Biologically Effective Dose

Biomarkers of the biologically effective dose measure the interaction of a chemical with cellular macromolecules in the target organ or a surrogate (e.g., blood, urine). These biomarkers indicate the chemical reached a toxicologically significant site and produced damage to critical macromolecular targets. The advantage of biomarkers of effective dose is their independence from interindividual differences in metabolism. The determination of an effective dose for carcinogens often involves measuring DNA changes in body fluids. Methods for the detection of the effective dose may be chemically specific (e.g., hemoglobin, protein or DNA adducts) or a nonselective measure (e.g., rate of DNA repair, oxidative DNA damage, adduct formation).[30] The carcinogen-DNA adducts result from the covalent binding of electrophilic chemicals with DNA; this interaction is a necessary but not sufficient condition for the initiation of cancer. DNA adducts indicate chemical-induced mutagenicity and an elevated cancer risk. However, carcinogen-protein adducts, particularly Hb adducts (e.g., alkylating agents, aromatic amines, nitroaromatic compounds), are surrogates for carcinogen-DNA covalent binding and effective dose when detectable in body fluids; estimates for cancer risks are more accurate based on these adducts than measuring genotoxic substances and their metabolites in human body fluids.[31] Nonselective measures of the effective dose (e.g.,^{32}P postlabeling assays, immunoassays) indicate the occurrence of a reaction at the target site; the test does not provide information regarding the structure or nature of the chemical interaction. These techniques are very sensitive for DNA adduction monitoring and correlate on a group level; however, these tests lack specificity, do not reflect the current cancer status, and do not correlate well on an individual level.[32,33]

Macromolecular (i.e., DNA, protein) adduct levels depend on several factors, including the amount of external contamination, absorption and distribution of the carcinogen, metabolic activation of the carcinogen, stability of the carcinogens or metabolites and their adducts, and DNA replication and repair.[34] Interpretation of macromolecular adduct data is complicated when the carcinogen requires metabolic activation or produces different adduct concentrations in the target organs than in body fluids. Methods for detecting DNA and protein adducts include the following: synchronous fluorescence spectrophotometry; high-performance liquid chromatography with electrochemical or fluorescent detection; gas chromatography/mass spectrometry; liquid chromatography/tandem mass spectrometry; immunoassays using polyclonal or monoclonal antibodies; and ^{32}P-postlabeling. The latter two techniques are the most common and sensitive methods, but the ability to identify a particular type of adduct using strict structural criteria (i.e., specificity) remains problematic.[35] Monoclonal antibodies offer greater specificity than ^{32}P-postlabeling, but substantial cross-reactivity still occurs with these antibodies.

DNA Adducts

DNA adducts are molecular dosimeters (biomarkers of exposure) and measures of the genotoxic potential of chemicals (biomarkers of effect).[36] Some DNA adducts produce mutations, whereas others do not; furthermore, some DNA adducts occur in healthy persons because of lipid peroxidation. Carcinogen-DNA adducts are detectable by current laboratory techniques involving a variety of agents, including aflatoxin B_1, vinyl chloride, aromatic compounds, 8-methoxypsoralen, cisplatin, melphalan, and UV light. Monitoring DNA adducts in the work environment primarily involves workers exposed to PAHs; dihydrodiol epoxide metabolites of these compounds form the adducts. A study of foundry workers demonstrated a good correlation between ambient air levels of polycyclic aromatic hydrocarbons (PAHs) and PAH-DNA adducts in workers; however, the adduct concentrations of local controls living near the cokeries were similar to those of workers rather than rural controls.[37,38] Extensive interindividual variation in PAH-DNA binding complicates the interpretation of these studies and the ability of these tests to separate environmental, occupational, and background contributions to measured PAH-DNA adduct concentrations. Factors contributing to the large interindividual variation include work habits, safety equipment use, diet (broiled, barbecued, smoked meat, or fish), smoking, outdoor exposure (forest fires, coke production, motor vehicle exhaust, coal combustion), and age.[39]

A consistent decrease in PAH-DNA adduct concentrations occurs within several weeks; therefore, samples should be collected during a period of constant PAH exposure.[40] Interindividual variations in the background macromolecular adduct concentrations depend primarily on differences in carcinogen toxicokinetics (e.g., absorption, metabolism) and the efficiency of DNA repair processes; genetic polymorphisms explain only part of the interindividual variation.[34,41] The formation and persistence of adducts also vary within different organs and different cell types within the same organ. Most tissues contain multiple cell types that differ in their ability to form DNA reactive species and produce DNA adducts. The presence of differences in the background adduct concentrations and interindividual variation suggests biological monitoring has advantages over environmental monitoring of large populations.[42,43] The major issue concerning DNA adducts at the present time is the clinical prognostic value of the presence of damaged DNA. Certain individuals possess heritable genes that increase cancer risk (e.g., *MSH2* gene for colon cancer, *BRCA1/2* gene for breast cancer). Although breast cancer is relatively common, only about 5–10% of breast cancer cases result from the inheritance of highly penetrant cancer susceptibility genes. The cloning of the *BRCA1/2* genes indicates these genes contain over 1,000 mutations with no test detecting all mutations in *BRCA1* or *BRCA2* genes. The presence of these gene mutations confers a seriously increased risk of breast and ovarian cancers in women with these mutations;[44] consequently, the National Comprehensive Cancer Network guidelines recommend criteria/family history-based *BRCA1*/*BRCA2* testing in women meeting these guidelines. The issue of screening the general population of women for breast and ovarian risk factors (*BRCA1/2, RAD51C/D, BRIP1, PALB2*) remains unresolved.[45,46]

Protein Adducts

Similar to DNA adducts, the suitability of a carcinogen-protein adduct depends on the degree of carcinogen-protein adduct binding, the background DNA adduct concentrations, and the stability of the DNA adducts. In some instances, carcinogen-protein adducts are satisfactory surrogates for DNA binding. The most commonly studied classes of proteins are hemoglobin and albumin. The use of hemoglobin for dose monitoring offers several advantages over DNA adducts, including a specific lifespan not affected by repair processes, accessibility, and reliable methods of chemical identification.[47] For adducts attached to hemoglobin and albumin in the blood, the information about past exposure to carcinogens is limited by the half-life (125 days, 25 days, respectively) of these two compounds. 4-Aminobiphenyl is a human bladder carcinogen that forms a large amount of hemoglobin adducts; urinary concentrations of 4-aminobiphenyl correlate with tobacco smoke exposure. Although preliminary studies of tobacco smokers indicated a 3–5-fold increases in hemoglobin adducts of 4-aminobiphenyl,[48] the biomarker of effective dose (4-aminobiphenyl-Hb adducts) weakly correlates with the biomarker of internal dose (urinary 4-aminobiphenyl) as a result of variations in accumulation and elimination rates.[49] To the extent that protein adducts quantify genotoxicity in the target organ, these adducts will reflect the magnitude of the process of initiation. If initiation is the rate-limiting step in the development of carcinogenesis following carcinogen exposure, the adduct concentrations should estimate the relative cancer risk; however, if later stages (promotion) are more important than initiation, then molecular adduct concentrations will not be proportional to the cancer risk.

Early Biological Effect

Biomarkers of response range from simple measures (weight, histopathology, mortality) to sophisticated determination of isoenzyme induction and molecular genetics/epigenetics. These biomarkers predict the development of subsequent health impairments, including subcellular histological abnormalities and clinical functional changes in gene expression. The value of a biomarker of response depends on the sensitivity and specificity of the test for the presence of toxicologically significant changes. Biomarkers of early biological effects include cytogenic techniques and oncogene protein products. These biomarkers of early biological effects detect **irreversible** damage to the genome or epigenome in contrast with biomarkers of the biologically effective dose (carcinogenic-DNA, carcinogenic-protein adducts) that reflect a potentially repairable interaction with critical macromolecules. Both biomarker types provide a summation of the biological processes that result from a carcinogenic exposure; however, carcinogen-DNA and carcinogen-protein adducts are **chemical**-specific markers, whereas biomarkers of biological effect (cytogenic and oncogene protein products) are nonspecific markers of the response of an organism to all carcinogens.

Markers of biological effect detect the changes in the target cells that commit the cell to the development of malignant disease. These markers have difficulty distinguishing background by-products of the DNA repair process from products of the initiation and promotion stages of carcinogenesis. In contrast to studies on radiation that indicate the presence of dicentric chromosomes is a specific marker of effect, studies with chemicals have not identified a unique chromosome marker. The advantage of monitoring workers with biomarkers of biological effects is the use of a single test, in contrast to chemical-specific biomarkers (e.g., adducts) that require a test for each carcinogen. Data from chromosome studies on the effects of chemicals must be interpreted on a group basis rather than as a specific marker of chemical exposure pending further research. Although molecular epidemiology studies have identified many promising biomarkers, including alteration of gene expression and DNA methylation, these newer biomarkers require validation and documentation of their role in causing cancer.[50]

Cytogenic Techniques

Cytogenic techniques identify and quantify chromosomal changes, including abnormalities of chromosome numbers, breakage, rearrangements, and exchanges. **Chromatid** aberrations include chromatid breaks, exchanges, and intra-exchanges, whereas **chromosomal** aberrations include acentric fragments, dicentric chromosomes, and ring chromosomes. Cytogenic techniques include sister chromatid exchanges, micronucleus tests (fragments of nuclear material present in the cytoplasm after mitosis), and measurements of single-strand breaks in lymphocyte DNA or DNA hyperploidy. The micronucleus and chromosomal aberrations assays in peripheral blood lymphocytes and exfoliated epithelial cells gradually replaced sister chromatid exchange tests as the most frequently used cytogenetic endpoints in human population studies.[51] Chromosomal aberrations and micronucleus assays are common biomarkers of genotoxicity in workers exposed to radiation, organic chemicals (benzene, styrene, ethylene oxide, polycyclic aromatic hydrocarbons), and metals (uranium, chromium, lead, nickel, pesticides, antineoplastic drugs). Although many human carcinogens increase chromosomal damage in persons exposed to these chemicals,[52] interindividual variation and the complexity of changes involved with the multistage process of carcinogenesis complicate the establishment of a direct causal relationship between specific levels of chromosomal aberrations and cancer risks.

Several studies comparing groups with high and low micronucleus and chromosomal (but not chromatid) aberration frequencies in healthy subjects suggest a significant association between increased frequencies and cancer risk (i.e., early events in carcinogenesis);[53] however, interindividual variability and preventive strategies in high-risk groups require further study.[54] Intra- and interindividual variations occur in baseline frequencies of cytogenetic end points in lymphocytes from human populations with a significant portion of the variation resulting from personal characteristics (e.g., sex, smoking, environmental/occupational exposures). Age is an important confounding factor in determining the results from cytogenic studies resulting from age-related increases in micronucleus (MN) and chromosomal aberration (CA) frequencies. In Poisson regression analysis of 2,000 MN tests, the frequency ratio comparing the 50–59-year-old subgroup with the 1–19-year-old subgroup was 1.97 (95% CI: 1.43–2.71); the MN frequency ratios remained similar comparing older subgroups (>59 years) with the young subgroup.[55] Results for CA assays were similar, except the frequency ratios continued to increase in subgroups of >59-year-olds. Although the presence of a positive association between a chemical exposure and CA or MN frequency may suggest an increased cancer risk, a null association does not exclude a carcinogenic exposure

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. if the mechanism of action operates through processes that do not currently produce CAs or micronuclei (e.g., epigenetic or receptor pathways). Unstable CAs and micronuclei usually persist for a few months, whereas translocations could exist for years.[56]

Oncogene/Tumor Suppressor Protein Products

Activation of oncogenes results from gene mutations, chromosomal breaks, and rearrangements of chromosomes. Immunoblotting or polymerase chain reaction techniques can detect the activation of oncogenes following exposure to environmental carcinogens (e.g., benzo[*a*]pyrene, *N*-nitroso compounds, PAH).[57,58] The *RAS* gene is a potential early marker of carcinogenicity along with the *p21* protein product of this gene because of the important role this gene plays in the control of cell proliferation. A small study of 40 volunteers without exposure to known carcinogens other than smoke indicated that smoking is unlikely to confound human monitoring studies using oncoprotein levels.[59]

A variety of different cancer types contain mutations of the TP53 gene, which codes for the tumor suppressor protein p53.[60] Tumorigenesis typically involves only a relatively small number of mutations. Although most mutations in tumors are unlikely to affect the initiation or progression of cancer particularly mutations affecting the third codon base,[61] high-throughput sequencing of cancer genomes indicates certain mutations frequently occur in specific tumors as fingerprints of the impact of environmental factors.[62] Most tumor-specific mutational signatures have two or more signatures. Sequence analysis of TP53 gene mutations in UV-induced nonmelanoma skin cancers (basal/squamous cell carcinomas) indicates a substantial percentage (e.g., >50%) of these skin cancers are associated with C → T transitions at dipyrimidine sites including CC → TT tandem mutations.[63] Lung cancers frequently contain TP53 mutations characterized by G → T transversions, particularly in tumors associated with exposure to tobacco smoke and benzo[*a*]pyrene.[64] Aristolochic acid forms DNA adducts at adenine bases after metabolic activation. A → T mutations comprise >70% of the mutations in aristolochic acid-induced urothelial cell carcinomas, with the A → T transversion being a characteristic mutation of aristolochic acid in experimental systems.[65,66]

Patients living in areas with high aflatoxin levels are more likely to have TP53 mutations (e.g., codon 249 G > T transversions) compared with patients living in areas with low aflatoxin concentrations;[67] however, multiple genetic and epigenetic changes are involved in the molecular pathogenesis of hepatocellular cancer (HCC) beside somatic mutations in the TP53 tumor suppressor gene, including activation of the Wnt signaling pathway involved with apoptosis complicating the use of this biomarker alone as a surrogate for HCC risks.[68,69] Additionally, the prevalence of TP53 mutations varies significantly between various geographical locations and tumor types. In a Chinese case-series of hepatocellular carcinoma, the prevalence of this mutation ranged from 36–54%, whereas the prevalence of a codon-249 TP53 mutation in patients with hepatocellular carcinoma was much lower in Egypt.[70,71] The apparent association of p53-specific mutations with aflatoxin probably results from the selective advantage of HBV-mutated cells rather than a causal event in the pathological process of aflatoxin-induced HCC. Numerous issues complicate the use of human cancer gene fingerprints including the following: 1) multifactorial process of human cancer, 2) individual variation in DNA repair mechanism, 3) confounding of biological (e.g., grading, staging) and clinical (e.g., treatment) factors, 4) variation in temporal sequences in the activation and deactivation of cancer genes, 5) high frequency of cancer gene mutations from genomic instability unrelated to an exposure, and 6) several different carcinogens may induce the same TP53 mutations.[50]

Cell-Free Circulating Tumor DNA

Most circulating cell-free DNA (cfDNA) in the blood stream results from the rupture of nonmalignant, germline cells, whereas the subset (ctDNA) of cfDNA derives from tumor-specific DNA abnormalities. Next-generation sequencing provides high-throughput analysis of cfDNA in circulating blood to detect ctDNA using a digital polymerase chain reaction to amplify cfDNA fragments and quantify specific alterations in ctDNA; typically, the latter represents <1% of the circulating cell-free DNA.[72] The Cobas EGFR Mutation Assay is a US Food and Drug Administration (FDA)-approved ctDNA analytical technique to initially genotype tumors in lung cancer patients when adequate amounts of tissue are unavailable to characterize the tumor tissue.[73] Other potential uses for this biomarker in addition to noninvasive cancer detection and characterization include monitoring of disease relapse, prediction of tumor response, and detection of tumor resistance.

Epigenetic

The epigenome is the combination of epigenetic information including DNA methylation, histone modification (e.g., acetylation, methylation, phosphorylation), nucleosome positioning, chromatin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

modification, and miRNA expression. Dysregulation of the epigenome involves the following: 1) DNA alteration and histone modification, 2) changes in somatic epigenetic proteins, and 3) altered expression of epigenetic proteins, resulting in a vast array of potential biomarkers.[74] Potential epigenetic markers of cancer diagnosis and prognosis include DNA methylation, histone modification patterns, and miRNAs. Of these potential biomarkers, DNA methylation is the best studied involving DNA methylation (5-methylcytosine) at the CpG dinucleotides, primarily concentrated in the CpG islands within core promoter regions or the first exon.[75] DNA methylation biomarkers include quantitative methylation-specific PCR, a 1-step methylation-specific polymerase chain reaction assay, and MethyLight assay. Potential biomarkers of cancer genes include methylation of *BRCA1* gene in breast cancer, *MGMT* gene in glioblastoma, and *MLH1* gene in colon cancer. *SEPT9* is the first USFDA-approved, blood-based methylated biomarker for colon cancer diagnosis.[76] Post-transcriptional gene regulation by miRNAs includes editing, splicing, transport, storage, and translation of mRNA through downregulation of gene expression by complementary binding to the 3′-UTR region of the target genes.[77] The dicer gene codes for an enzyme that cleaves dsRNA and pre-miRNA into small interfering RNA and miRNA, which are essential for development of the female reproductive tract. Dysregulation of miRNAs (e.g., *miR*-379, *miR*-15b, *miR*-691, *miR*-872, *miR*-1897) is associated with ovarian toxicity and potentially mitogen-activated protein kinase signaling pathways involved in cancer.[78]

In 2007, the American Academy of Cancer Research began collaboration on biomarker research by forming the AACR-FDA-NCI Cancer Biomarkers Collaborative with the US Food and Drug Administration (FDA) and National Cancer Institute (NCI). The purpose of the collaboration was to accelerate the translation of cancer therapeutics into the clinic by shaping the processes for the effective development of validated biomarkers and to use the clinical trials to maximize patient benefit.[79] The CBC identified and provided recommendations for eight critical areas for the development of biomarkers for the rapidly expanding field of epigenetic modification associated with cancer including biospecimens (i.e., quality of sample material), analytical performance, bioinformatics, and collaboration with data sharing. Identification of accurate epigenetic biomarkers awaits further validation studies.

Susceptibility

Some individuals are more susceptible to environmental exposures that result from genetic predisposition or other factors (age, gender, ethnicity, health impairment, nutritional deficiencies). Genetic variation may modulate the susceptibility of an individual to a toxin (e.g., differences in the toxicokinetics of the specific chemical).[80] Genes vary in their penetrance (i.e., the frequency of the expression of a specific genotype given a certain environmental condition). The most important sources of variability involve variations in DNA repair and metabolic genes (polycyclic aromatic hydrocarbon-associated lung cancer).[11,81] The ability to acetylate aromatic amines, hydrazines, and sulfonamides is genetically determined; ethnicity has a significant impact on the number of individuals with a specific acetylator phenotype. Cytochrome P450 enzymes activate a wide range of environmental carcinogens to reactive intermediates; however, amounts of these enzymes vary substantially between individuals. Urinary caffeine is a biomarker for the activity of CYP1A2 that catalyzes the *N*-oxidation of several aromatic and heterocyclic amines to reactive carcinogens.[82] Most genes act in a sequence or cascade. Although a large number of studies examine the role of signal nucleotide polymorphisms (SNPs), relatively few SNPs are clearly associated with increased cancer risks across different populations (e.g., methylenetetrahydrofolate reductase [*MTHFT* gene] deficiency and colorectal cancer).[83]

Chapter 53

RESPIRATORY TRACT

Lung cancer is the leading cause of cancer-related deaths among men and women in the United States, with 5-year survival rates remaining very low despite some improvement recently. From 2014–2018, the overall 5-year survival rate increased from 21–25%. Other less common tumors of the respiratory tract include sinonasal cancer, laryngeal cancer, and mesotheliomas. Table 53.1 lists the strength of the human evidence (i.e., sufficient, limited) for carcinogenic agents and processes associated with respiratory tract cancers based on evaluations by the International Agency for Research on Cancer (IARC).[1,2] The carcinogenic potential of these agents/processes varies within their respective categories. The actual risks are determined by individual risk factors (e.g., dose, exposure duration, host susceptibility, cocarcinogens).

LUNG

Lung cancer was rare before the 20th century; later in the 1920s, epidemiological evidence of an association between lung cancer and smoking emerged.[3] In the United States and Europe, the age-adjusted lung cancer incidence increased substantially 1950s–1980s with ~237,000 new cases of lung cancer diagnosed yearly in the United States. Currently, tobacco smoking accounts for ~85% of lung cancers.[4,5] Given the 10- to 30-year latent period for lung cancer, increased lung cancer incidence during this time reflects changes occurring in the early 1940s–early 1960s.[6] Lung cancer rates vary dramatically by geographic and demographic characteristics (e.g., age, sex, ethnicity, location, socioeconomic status), resulting primarily from differences in smoking patterns.[7] Lung cancer incidence and mortality rates are similar because of low survival rates following diagnosis, particularly for advanced stages of lung cancer. Only ~15% of lung cancer cases are diagnosed in early stages when the prognosis is much better.[8] The long delay between smoking initiation and clinically apparent lung cancer results in rare presentations prior to 30 years of age; the peak rates at diagnosis develop at a median age of ~70 years. The incidence of smoking-induced lung cancer declines after the age of 80 years.[9]

CARCINOGENESIS

Lung cancer is a very heterogeneous disease consisting of many somatic mutations affecting multiple signaling pathways. Compared with 30–60 somatic mutations in most solid tumors, genome-wide gene sequencing analyses indicate a lung tumor contains ~150 somatic mutations along with chromosomal translocations/fusions and somatic copy number alterations (deletions, gains) producing subsequent disruption of signaling pathways.[10] Tobacco smoke strongly influences the development of lung cancer with a somatic mutation rate of ~10-fold higher in lung tumors from smokers than nonsmokers.[11] Although most of these changes revert to normal baseline in former smokers, some alterations are irreversible and persistent.[12] The variety of histopathological types of lung cancer also reflects the very large tumor heterogeneity and differences in molecular pathogenesis (driver genes) noted in the Cancer Genome Atlas (TCGA databases).[13]

TABLE 53.1. International Agency for Research on Cancer (IARC) classification of respiratory tract cancer sites by sufficient and limited evidence of human carcinogenicity. (Adapted from Cogliano et al. and IARC).[1,2]

Anatomic Site	Carcinogens with *Sufficient* Human Evidence (Group 1)	Carcinogens with *Limited* Human Evidence (Group 2A or 2B)
Nasal cavity and paranasal sinuses	Isopropyl alcohol production, leather dust, nickel compounds, radium-226 and its decay products, radium-228 and its decay products, tobacco smoking, wood dust	Carpentry and joinery, hexavalent chromium compounds, formaldehyde, textile manufacturing
Larynx	Acetaldehyde associated with alcoholic beverage use, acid mists, strong inorganic, alcoholic beverages, asbestos (all forms), tobacco smoking	Human papillomavirus type 16, rubber production industry, sulfur mustard, tobacco smoke, secondhand
Lung	Acheson process, occupational exposures, aluminum production, arsenic and inorganic arsenic compounds, asbestos (all forms), beryllium and beryllium compounds, bis(chloromethyl)ether; chloromethyl methyl ether (technical grade), cadmium and cadmium compounds, chromium (6^+) compounds, coal, indoor (household emissions from combustion) coal gasification, coal-tar pitch, coke production, engine exhaust, diesel, hematite mining (underground), iron and steel founding, MOPP (vincristine-prednisone-nitrogen mustard procarbazine mixture), nickel compounds, outdoor air pollution, painting, particulate matter in outdoor air pollution, plutonium, radon-222 and its decay products, rubber production industry, silica dust, crystalline, soot, sulfur mustard, tobacco smoke, secondhand, tobacco smoking, welding fumes, X- and γ-radiation	Acid mists, strong inorganic art glass, glass containers, and pressed ware manufacturing, benzene, biomass fuel household combustion (indoor emissions from mostly wood), bitumens, occupational exposure (oxidized bitumens and emissions during roofing and mastic asphalt work), carbon electrode manufacture, α-chlorinated toluene and benzoyl chloride (combined exposures), cobalt metal with tungsten carbide, creosotes, diazinon, fibrous silicon carbide, frying (emissions from high-temperature), hydrazine, insecticides, non-arsenical (occupational exposures during spraying and application), printing processes, 2,3,7,8-tetrachlorodibenzo-*p*-dioxin
Mesothelioma	Asbestos, painting, erionite, fluoro-edenite	Polyoma virus SV40 (simian virus 40)[a]

[a] cocarcinogen.

The most frequently mutated cancer driver gene in lung cancer is the tumor suppressor gene p53 (*TP53*) ranging from 50% in adenocarcinomas to 86% in small cell lung cancer based on the cBioPortal for Cancer Genomics database (http://www.cbioportal.org). For adenocarcinoma tumors, the next four most common driver genes are *LRP1B* (low-density lipoprotein receptor related protein 1B), *KRAS* (Kirsten rat sarcoma viral oncogene homolog), *EGFR* (epidermal growth factor receptor), and *KEAP1* (kelch-like ECH-associated protein 1). The next most common driver genes in squamous cell carcinoma lung tumors are *LRP1B*, *KMT2D* (lysine methyltransferase 2D, *KMTD2*), *PCLO* (piccolo presynaptic cytomatrix protein), and *KMT2C* (lysine methyltransferase 2C) compared with *RB1* (retinoblastoma transcriptional corepressor 1), *LRP1B*, *PCLO*, and the tumor suppressor *FAT4* (FAT atypical cadherin 4) in small cell carcinoma. Table 53.2 compares the percentage of the 10 most common mutations in profiled samples of adenocarcinoma, squamous cell carcinoma, and small cell lung cancer samples contained in the cBioPortal for Cancer Genomics database. Intratumor heterogeneity also occurs with a majority of mutations often not distributed uniformly across the tumor; mutational discordance also exists between primary tumors and their metastases.[14,15]

Adenocarcinoma

A prominent subset of adenocarcinomas develops from the progression of preinvasive atypical adenomatous hyperplasia followed by intermediate lesion of adenocarcinoma *in situ*, minimally invasive adenocarcinoma, and ultimately overt invasive adenocarcinoma with a lepidic pattern lining preexisting alveolar walls.[16] Atypical adenomatous hyperplasia is the presumed origin of lung adenocarcinoma; ~30–40% of these lesions contain mutations of *KRAS* (codon 12) genes.[17,18] This small (<0.5 cm), slow-growing, noninvasive lesion typically occurs in the peripheral lung near the pleura. Telomere shortening and DNA damage responses are early lung carcinogenesis events with the expression of these damage response proteins and mRNA

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. TABLE 53.2. Comparison of the most frequent (percentage) somatic mutations in adenocarcinoma, squamous cell carcinoma, and small cell lung cancer samples within the cBioPortal for Cancer Genomics database (http://www.cbioportal.org). The number in parentheses represents the number of profiled samples for each histological type of lung cancer. These data reflect sampling in Western countries; the mutational status of populations depends on the distribution of ethnic groups within the database. Consequently, the frequency of mutations varies between databases.

Gene Mutations	Adenocarcinoma (2,322)[a]	Squamous Cell (841)[a]	Small Cell (210)[a]
TP53	50.3	83.0	86.2

[a] Profiled samples.

encoding telomere-specific DNA-binding proteins (*TERF1* and *TERF2*) associated with the progression from atypical adenomatous hyperplasia to adenocarcinoma *in situ*. The latter lesion is a slightly larger (i.e., ≤3 cm), localized preinvasive lesion with densely packed atypical cells, greater cell–cell contact, and an abrupt transition to normal adjacent pneumocytes. Minimally invasive adenocarcinoma is a small adenocarcinoma (≤3 cm) with a predominately nonmucinous lepidic pattern; the invasive structure is <5 mm. Adenocarcinomas have distinct genomic alterations that separate these tumors from other lung cancers (e.g., squamous cell carcinoma, small cell carcinoma).[19] Major driver genes include *TP53*, *EGFR*, *KRAS*, *BRAF, NF1* (neurofibromin 1), *MET* (*MET* protooncogene, receptor tyrosine kinase), and *RIT* (Ras like without CAAX 1). Recurrent somatic copy number alterations include deletions of *CDKN2A*, *LP1B*, and *PTPRD* along with amplifications of *EGFR*, *ERBB2*, *KRAS*, *MDM2*, and *MET* involved with telomeric DNA, organogenesis (*NKX2-1*), and cell division (*MYC*). Signaling pathways affected by these genetic alterations include RTK/RAS/RAF, mTOR, JAK–STAT, cell cycle regulation, DNA repair, and epigenetic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. deregulation. The latter includes differential DNA methylation profiles, histone modification, and altered miRNA expression (oncogene upregulation, tumor suppressor gene silencing).[20] Highly expressed miRNAs in adenocarcinomas include miR-29b, miR-29c, miR-100, miR-125a-5p, and let-7e; miR-124a is specific to adenocarcinomas.[21,22]

The presence of chronic tobacco smoking impacts the pathogenesis of adenocarcinoma with the KRAS pathway (rat sarcoma viral oncogene) more prominent in smokers, whereas the EGFR (epidermal growth factor receptor) pathway is present in ~50% of adenocarcinoma tumors from nonsmokers.[23] KRAS mutations alone are insufficient to drive carcinogenesis. Inactivation of oncogene-induced senescence (e.g., *TP53*, *CDKN2A*) promotes tumor growth in KRAS-mutated adenocarcinomas by limiting senescence. The frequency of KRAS mutations progressively declines from 33% in atypical adenomatous hyperplasia to 0% in well-differentiated invasive adenocarcinomas and 17% in poorly differentiated invasive adenocarcinomas.[24] In contrast, the frequency of EGFR mutations remains similar during this progression.

Other molecular abnormalities in this premalignant lesion include loss of heterozygosity in chromosomes 3p, 9p (*CDKN2A*), 9q (*TSC1*, tuberous sclerosis complex 1), 17p (*TP53*), and 17q. Overexpression of survivin (apoptosis protein family inhibitor), CCND1 (cyclin D1), and ERBB2 oncoproteins occurs along with downregulation of serine/threonine kinase 11 (STK11, a tumor suppressor). Epigenetic alterations include DNA methylation of *CDKN2A* (p16) and *PTPRN2*. Progression of atypical adenomatous hyperplasia to adenocarcinoma in nonsmokers is associated with *EGFR* oncogene and TTF-1 amplification along with increasing frequency of TP53 mutations.[25] The BRAF mutation enhances tumor initiation and progression via activation of the ERK(MAPK1) pathway. *BRAF* gene is a member of the *RAF* gene family that encodes a serine/threonine protein kinase by activating RAS downstream. BRAF mutations occur primarily in early preinvasive adenocarcinoma lesions in nonsmokers.[26]

Squamous Cell Carcinoma

Early changes in the pathogenesis of squamous cell carcinomas include alteration of 3p chromosome sites and 9p21 (*CDKN2A*) in normally appearing bronchial epithelia along with increasing DNA methylation of *CDKN2A* as the premalignant lesion progresses.[27] Amplification of the *SOX2* oncogene (3q26.3) and overexpression of endothelial growth factor (*VEGF*) and *VEGF* receptors (*VEGFR*) support angiogenesis and promote tumor survival.

Small Cell Carcinoma

The pathogenesis of small cell lung cancer is not associated with phenotypically identifiable preneoplastic lesions; however, a very high incidence of alterations in epithelia occurs in histologically normal epithelium, suggesting the cells of origin may be normal or slightly abnormal bronchial epithelium.[23] In genetically engineered mouse models, small cell lung cancer is associated with *TP53* and *RB1* oncogene overexpression, resulting in hedgehog signaling pathway activation.[28] Integrative genome analyses in humans suggest key somatic drivers include TP53 and RB1 mutations as well as histone modifiers (*CREBBP*, *EP300*, *MLL*) and mutations of *FGFR1* oncogenes.[29]

EXPOSURE

Lung cancer incidence trends follow the pattern of tobacco consumption. However, the increased lung cancer incidence in nonsmokers suggests the possibility that other environmental or occupational factors will become more important etiological agents for lung cancer in the future, assuming the present decrease in overall tobacco consumption continues.[30] The contribution of outdoor and indoor pollutants (e.g., radon, formaldehyde, asbestos) is more difficult to assess, in part because of the strong confounding of smoking. Additionally, exposure to these potential carcinogens is typically much lower than the carcinogens in tobacco smoke.[31] At these exposure levels, ascertainment of true cases, accurate exposure measurement, and careful control of confounding variables are necessary to detect the attributable risk of pollutants. Host predisposition, the influence of microclimates on individual exposure, the interaction of carcinogens, and changes in exposure (e.g., job, residence) over the lifetime of an individual modify the ability of a study to detect an increased cancer incidence in the study population.[32]

Occupation

Attributable Risks

The average attributable risk of occupational exposure to lung cancer in men ranges from ~5–15%.[33,34] In 1981, Doll and Peto attributed 15% of the lung cancers among American men to occupational exposure.[35]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

A review of all case-control studies on lung cancer using age/smoking-adjusted estimates of relative risk reported that the attributable risk from occupational exposure depends on the prevalence of exposure within the population and the dose received by individual workers.[36] The attributable risk ranged from 1–40% in certain workers with high ionizing radiation exposure. A case-referent study of lung cancer in Swedish men estimated the attributable lung cancer risk from occupational exposure to combustion products including diesel exhaust and asbestos was ~9.5%.[37] In a case-control study of Italian lung cancer patients and local controls, the estimated percentage (population attributable fraction) of all occupationally related lung cancers in men was ~5% (range, 2.0–7.8%) based on self-reported exposure to known human lung carcinogens.[38] The risk of developing lung cancer in women following occupational exposures is relatively low compared with men.[39] In a case-control study of workers in Central and Eastern Europe, the attributable fraction of occupationally related lung cancer using Miettinen's formula was 7.9% in men and 1.4% in women.[40] The highest attributable fraction for men was squamous cell carcinoma (11.4%) and for women was small cell carcinoma (7.1%). Silica and metals accounted for most of the attributable fraction of occupationally related lung cancers.

Histological Types

There are limited data on the specific subtypes of lung cancer associated with known human lung carcinogens (e.g., some metals, benzene, asbestos).[41] Age is a confounding variable for studies correlating chemical exposures with histological lung cancer types because the distribution of lung cancers into histological types depends on age. Exposure to asbestos increases the incidence of all three histological lung cancer types,[42] whereas many other carcinogens demonstrate a predilection to a specific histological type. Each histological lung cancer type has a multifactorial etiology including smoking, occupation, and environmental exposures.[43] Smoking patterns account for only part of the difference in the prevalence of these different histological types.[44] Adenocarcinoma predominates in younger men, women nonsmokers, and arsenic-exposed copper smelter workers.[45]

Carcinogens

Occupational lung carcinogens include arsenic, asbestos, beryllium, cadmium, chloromethyl ethers, hexavalent chromium, nickel, radon, silica, and vinyl chloride. Of all occupational carcinogens, asbestos exposure accounts for the highest population attributable fraction of lung cancer.[46] Cancer registry-based, case-control studies suggest workers at increased lung cancer risk include wood-processing plant operators (OR 4.63; 95% CI: 1.05–20.29)[47] and meat/poultry workers from food animal oncogenic viruses (~30%);[48,49] however, the wide confidence intervals, imprecise estimates, and insufficient epidemiological data to exclude confounding prevent the establishment of a causal association for these workers. The Nordic Cohort Study on work-related cancers reported a reduced standardized incidence ratio (SIR) for lung cancer in wood workers (SIR = 93, 95% CI: 90–95) and a modestly elevated SIR in food manufacture workers (SIR = 117, 95% CI: 111–122) that included meat workers with other food preparers (e.g., dairy, bakers, grain millers).[5]

Asbestos accounts for substantial occupational cancer deaths in the United States. The estimated annual number of deaths attributed to asbestos exposure peaked in 1992 with a proportionate decline in the ratio of lung cancer/mesothelioma deaths since that time.[50,51] Occupations associated with increased lung cancer risk in the ICARE study included painters and welders, particularly gas welders.[52] Occasional welding was not associated with an increased lung cancer risk. A systematic review of lung cancer studies in refinery workers reported 27 studies with only 1 study demonstrating a statistically significant elevation of lung cancer rates in refinery workers.[53] The summary RR for lung cancer using the random effects model was 0.81 (95% CI: 0.76–0.86) with substantial heterogeneity (I^2 = 72%, $P > 0.001$).

Although some case reports associate vegetable dust exposure with lung cancer,[54] most observational studies of workers with high endotoxin exposure (agriculture, cotton textile) demonstrate reduced lung cancer risks and little association between hypersensitivity lung disease and lung cancer,[55] particularly active dairy (but not row crop/orchard) farmers[56] and cardroom sorters/weavers in the textile industry.[57] The lack of accurate endotoxin concentrations and substantial heterogeneity between studies limit conclusions regarding the role of endotoxin exposure; however, a systematic review and meta-analysis of cohort and case-control studies of agricultural and cotton textile workers exposed to high concentrations of endotoxin-contaminated organic dust generally support reduced lung cancer risks in these two industries. The summary lung cancer risks were 0.62 (95% CI: 0.52–0.75) and 0.72 (95% CI: 0.57–0.90), respectively.[58]

Industries

The IARC lists aluminum production, coal gasification, and coke production as occupations associated with increased lung cancer risks.[2] A meta-analysis of 24 cohort studies involving 296,810 workers reported a statistically significant, modestly increased lung cancer risk in the coal/coke and related product industries (metaRR = 1.55, 95% CI: 1.01–2.37) and the iron/steel foundry industry (metaRR = 1.52, 95% CI: 1.05–2.20), but not in the iron/steel foundry (metaRR = 1.13, 95% CI: 0.88–1.33) or aluminum production industries (metaRR = 1.29, 95% CI: 0.96–1.33).[59] Wide variation in smoking habits and PAHs exposure occurred among the cohort studies with only 12 of the 24 studies reporting smoking status and 10 reporting smoking-adjusted data. In a meta-analysis of cohort studies using weighted average SMRs and random effects modeling, the overall SMR for lung cancer ranged from 1.05 for the iron/steel foundry industry (pooled RR = 1.31, 95% CI: 1.07–1.61, $n = 13$ studies, $P_{\text{heterogeneity}} = <0.0001$) to 1.12 for asphalt workers (pooled RR = 1.59, 95% CI: 0.68–3.76, $n = 3$ studies, $P_{\text{heterogeneity}} = <0.0001$) and 1.14 for aluminum production (pooled RR = 1.07, 95% CI: 0.93–1.23, $n = 10$ studies, $P_{\text{heterogeneity}} = <0.0001$).[60]

Chemicals

Exposure to organic solvents probably does not contribute significantly to occupational lung cancer risks. Although the presence of large numbers of substances in the work environment complicates the determination of the contributions of individual solvents to lung cancer risks, a French multicenter, population-based case-control (ICARE) study of 2,276 male lung cancer cases and age-matched 2,780 controls did not detect evidence of lung carcinogenicity from the solvents studied using stepwise logistic regressions with a Bayesian approach.[61] Exposure assessment involved questionnaires and job-exposure matrices separating solvent exposures into clusters including alcohol, benzene, carbon tetrachloride, chloroform, diethyl ether, ethylene glycol, gasoline, kerosene/diesel oil/fuel oils, ketones/esters, methylene chloride, mineral spirits and other light aromatic fractions (white spirits), special boiling point spirits and other aliphatic petroleum-based solvents, tetrachloroethylene, tetrahydrofuran, and trichloroethylene.

Using benzene soluble matter (BSM) as the surrogate for exposure to polycyclic aromatic hydrocarbons, some,[62,63,64] but not all,[65,66] epidemiological studies of exposed workers demonstrate modest, statistically significant, dose-dependent increases in the lung cancer risks above concentrations of 10 μg BSM/m^3/year. The lack of accurate historical data on the chemical concentrations and the difficulty identifying a truly nonexposed group limit the conclusions regarding quantification of the lung cancer risk.

The association between occupational formaldehyde exposure and lung cancer is weak and inconsistent with a comprehensive review of cancer in industry workers and professionals reporting no appreciable excess risk of lung cancer in these groups.[67] The overall pooled relative risks of lung cancer mortality were statistically nonsignificant in industry workers (RR = 1.06, 95% CI: 0.92–1.23, $n = 6$ cohort studies, $P_{\text{heterogeneity}} = 0.0019$) and inverse in professionals (RR = 0.63, 95% CI: 0.47–0.84, $n = 8$ cohort studies, $P_{\text{heterogeneity}} = <0.0001$). In a meta-analysis of 31 case-control, nested case-control, cohort, proportional mortality, and proportional incidence studies on occupational formaldehyde exposures using random effects models, the overall pooled risk estimate for lung cancer comparing exposed workers with unexposed controls was consistent with the null (pooled RR = 1.04, 95% CI: 0.97–1.12).[68] The risk estimate increased with study quality as evaluated by the Newcastle-Ottawa/scale (pooled RR = 1.13, 95% CI: 1.08–1.19, $I^2 = 40.2\%$, $P_{\text{heterogeneity}} = 0.066$); the risk estimates also increased with higher formaldehyde exposures but were statistically nonsignificant (pooled RR = 1.19, 95% CI: 0.96–1.46). Only 1/3 of the studies adjusted for smoking; however, a subanalysis comparing adjusted and non-adjusted studies did not detect a significant difference in the risk estimates. The lung cancer risks were higher in fiberglass industry workers compared with professionally exposed workers (pathologists, embalmers) and wood industry workers.

Sulfur Mustard (Mustard Gas) Mustard gas was one of the first chemical warfare agents introduced in World War I and the first chemotherapeutic agent used to treat cancer patients. The use of mustard gas produced a detectable increase in lung cancer in British veterans, although a small increased risk (i.e., ~1.5) appeared in American veterans. The results of these studies are inconclusive because of the poorly documented exposure and confounding of smoking.[69] A cohort of Japanese workers producing mustard gas during World War II experienced a 3-fold increase in lung cancer incidence compared with the local controls after considering smoking history.[70] A majority of these cases involved squamous cell carcinomas and undifferentiated carcinomas, whereas adenocarcinomas and small cell carcinomas were rare.[71] The latent period usually exceeds 20 years.[72] From 1929–1945, a prospective Japanese study evaluated lung cancer risks in a cohort of workers from a poisonous gas factory in Okuno-jima,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Hiroshima Prefecture, Japan, exposed to mustard gas ($n = 480$), lewisite ($n = 55$), and/or diphenylcyanoarsine ($n = 178$).[73] The control group contained 969 manufacturing workers unexposed to these gases. A 1-year exposure to mustard gas in workers ≤18 years of age reduced the age at lung cancer diagnosis by 4.9 years (95% CI: 1.7–7.9 years) compared with controls. The effect declined with age. For workers of >18 years of age, the average age at diagnosis decreased by 3.2 years (1.2–5.5 years).

Chloromethyl Methyl Ether Chloromethyl methyl ether (CMME) and bis(chloromethyl)ether (BCME) are volatile colorless liquids recognized as established animal carcinogens. BCME is a contaminant of CMME and a much more potent animal carcinogen than CMME.[74] The relative risk of developing lung cancer increases with cumulative CMME exposure, reaching 10 in heavily exposed workers.[75] Maximal risk occurs ~15–20 years after exposure; however, heavy CMME exposure shortens the latent period.[76] The mean latent period from the onset of exposure to death for 59 moderately (10–<20 years) and heavily (>20 years) exposed workers was 21–25 years; the latent period was inversely related to cumulative exposure.[77] The exposure category was calculated by multiplying the estimated time-weighted average and the exposure time in years. In a French cohort study of a factory using technical-grade chloromethyl methyl ether in the manufacture of anion exchange resins, the mean time from first exposure to lung cancer diagnosis was 13 years (95% CI: 8–18 years), whereas cumulative dose was not correlated to induction time.[78] The rate ratio for lung cancer among potentially exposed workers was 5.0 (95% CI: 2.0–12.3) compared with nonexposed workers at the same plant; the incidence of lung cancer in the exposed workers was dose related. Small cell carcinoma accounts for ~80% of the lung cancers associated with CMME exposure.[77,79]

Diesel Exhaust

Although the IARC classified diesel exhaust as a human carcinogen in 2012 based primarily on the Diesel Exhaust in Miners Study and nested case-control studies of eight US nonmetal mines, the association between diesel exhaust and lung cancer remains controversial because of concerns regarding selection bias (low participation rates), exposure misclassification (insufficient latency based on job title), confounding (e.g., radon co-exposure), inconsistent exposure-response trends, and posteriori adjustment bias.[80,81,82] The cohort mortality study of 12,315 workers exposed to diesel exhaust at US nonmetal mining facilities reported a standardized mortality ratio for lung cancer of 1.26 (95% CI: 1.09–1.44).[83] The lung cancer mortality hazard ratios increased with increasing 15-year lagged cumulative estimates of respirable, elemental carbon exposure for ever-underground workers. The hazard ratio for lung cancer mortality was increased (HR = 5.01, 95% CI: 1.97–12.76) in ever-underground workers with ≥5 years of tenure to respirable elemental carbon ≤640–<1,280 μg/m^3/year compared with controls (0–<20 μg/m^3/year). However, the hazard ratio was not dose-dependent, as the HR for exposures ≥1,280 μg/m^3/year was not statistically significantly different than the control category (HR = 2.39, 95% CI: 0.82–6.94, $n = 14$ deaths, $P = 0.109$). The wide confidence interval suggests imprecise estimates.

Metals and Metalloids

The IARC lists types of five metals (arsenic, beryllium, cadmium, chromium, nickel) as human (Group 1) lung carcinogens. The classification of these metals is based primarily on the strength of the epidemiological data rather than an estimation of the carcinogenic potency of each metal.[84] For arsenic, beryllium, and cadmium, this classification applies to metallic compounds as a whole and not necessarily to individual species within the group of metallic compounds. There are very substantial differences in the physiochemical properties of individual species of the same metal that affect the carcinogenic potency of a specific species. Metallic chromium and metallic nickel are not included in the Group 1 classification. Some forms of arsenic (trivalent), chromium (hexavalent), and nickel (oxide, subsulfide) are well-established lung carcinogens.[85]

Arsenic Several epidemiological studies correlate exposure to arsenic trioxide in smelters[86] and arsenic-containing pesticides,[87] with a dose-related increase in lung cancer risks up to 10-fold in heavily exposed smelter workers[88] and 3-fold in arsenic-exposed pesticide workers. In a study of smelter workers exposed to arsenic, a relative excess of adenocarcinomas and a slight excess of small cell (previously named oat cell) carcinomas appeared.[89] The contribution of smoking to the appearance of lung cancer was almost multiplicative in a study of smelter workers;[90] however, the influence of smoking was less dramatic in another study.[91] Studies on the effect of air contamination with arsenic are inconsistent, and studies associating an increased lung cancer incidence with living near a smelter require further confirmation.[92,93,94] The carcinogenicity of arsenic compounds may result, at least in part, from the inhibition of DNA repair processes.[95]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

BERYLLIUM The epidemiological evidence for the carcinogenicity of beryllium is based on the US Beryllium Case Registry and studies of seven US manufacturing plants. Although criticized for lack of control over smoking, selection bias, poor dose-response relationships, and underestimation of expected lung cancer deaths,[96] several cohort studies of beryllium workers demonstrated excess mortality from lung cancer with a relative risk of 1.4–1.6.[97,98] However, the excess lung cancer risk was confined primarily to workers developing acute beryllium disease after short-term exposure (<1–5 years) rather than workers with a long-duration, high-intensity beryllium exposure. An analysis of the US Registry demonstrated an ~2-fold excess lung cancer risk in workers with acute beryllium disease and a 50% excess in workers with chronic disease;[99] however, the causal association between beryllium exposure and increased lung cancer risk remains controversial because of the lack of a clear dose-response and potential confounding from the relatively small increased cancer risk.[100,101]

CADMIUM The human data establishing a relationship between cadmium exposure and lung cancer are limited because of confounding variables (smoking, nickel and/or arsenic exposure) complicate the interpretation of positive studies. Some,[102] but not all,[103,104] studies of cadmium workers demonstrate a significant increase (average ~10–50%) in lung cancer mortality in cadmium-exposed workers. A retrospective cohort mortality study of 606 white, male workers at a cadmium smelter demonstrates marginal statistically significant excess lung cancer mortality (SMR = 149, 95% CI: 95–222) among workers exposed to cadmium based on a modified life-table analysis to estimate working lifetime risks (45 years).[105] This increase was dose-related. For workers in the highest cadmium exposure group, the SMR was 272 (95% CI: 123–513, $P < 0.05$).

CHROMIUM Hexavalent chromium (chromates, chromic acid) is a well-established lung carcinogen. Water-soluble hexavalent chromium compounds are particularly carcinogenic with zinc chromate being the most potent chromate carcinogen. Trivalent chromium does not penetrate cells; therefore, these compounds are not genotoxic. Depending on the study population, exposure duration/concentration, and study design, epidemiological studies of primary chromate production process and chromate pigment industry demonstrate highly variable excess lung cancer risks ranging slightly from >1–50-fold.[106,107] Chromium pigments are usually hexavalent typically containing zinc, strontium, and lead chromates. The most common histological type of lung cancer in chromate workers is squamous cell carcinoma followed by small cell carcinoma, usually located in the central bronchus.[108]

The risk of developing lung cancer is smaller in the chrome plating and stainless-steel welding industries. The Cr^{6+} concentration in stainless-steel welding fumes and ambient air of chromate industry workers developing lung tumors is similar. Some epidemiological studies detected a 30–40% increased lung cancer incidence among stainless-steel welders compared with unexposed controls;[109,110] however, a substantial portion of the increased lung cancer risk may be attributable to co-exposure to confounders (e.g., asbestos, smoking) or unidentified carcinogens.[111] Mild steel welders have negligible exposure to chromium and nickel; however, some European studies suggest an increased relative lung cancer risk among these welders. In a Finnish cohort study of welders born during 1906–1945, the relative risk of squamous cell lung cancer in the highest exposure category based on the Finnish job-exposure matrix as judged by 20 experts at the Finnish Institute of Occupational Health was 1.55 (95% CI: 1.08–2.24). The results were adjusted for a 20-year latency period for cumulative exposure and confounders (smoking, asbestos, silica dust, socioeconomic status).[112] There was no excess risk of small cell lung cancer in this cohort.

The standardized incidence ratio for lung cancer was higher in mild steel welders than in stainless-steel welders, despite relatively higher exposure to hexavalent chromium in the latter group. Chromium trioxide is a potential carcinogen in the chrome plating industry; a retrospective cohort study of 116 hard chrome platers and 62 bright chrome platers demonstrated an excess number of lung cancer deaths (observed = 3 deaths, expected = 0.6, latency period >10 years); however, the results were not adjusted for confounders.[113] The airborne chromium trioxide concentrations were substantially higher in hard chrome than bright chrome plating. In a prospective cohort study of 626 Japanese chromium platers, the standardized lung cancer mortality of the exposed group was borderline statistically significant (SMR = 1.46, 95% CI: 0.98–2.04, $n = 28$ cases) using nonexposed workers as referents.[114]

NICKEL Exposure to insoluble nickel compounds (e.g., subsulfide, oxide) produces an increased lung cancer risk in workers involved in the nickel refining industries, particularly with roasting, sintering, and calcining of ores.[115,116,117] The prior use of sulfuric acid contaminated with arsenic complicated the exposure assessment of older workers in these studies.[118] The risk of lung cancer in nickel mining and industries using nickel is less well defined. Excess mortality from respiratory tract cancers

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

was not detected in studies of mortality in workers exposed to metallic nickel in nickel alloy plants[119] or gaseous diffusion plants.[120]

Fibers

Asbestos Asbestos exposures are well-known causes of malignant mesotheliomas, lung cancer, and pneumoconiosis.[121] In ancient times, asbestos use was very limited (e.g., weaving material for napkins, cooking, and storage pots); however, asbestos exposure dramatically increased during the early 20th century from the use of asbestos as a durable heat- and corrosion-resistant material in water and combustion pipes, car brakes/gaskets, house construction, and shipbuilding. Of an estimated 10,000–12,000 lung cancer cases/year attributed to occupational carcinogens, >½ of these cases were associated with asbestos exposure.[122] Risk factors for tumor induction in the respiratory tract include fiber origin and physical characteristics, cumulative exposure (i.e., duration, dose), latent period, smoking history, and confounding from other occupational and environmental carcinogens.[123] At low asbestos concentrations, the relationship between intensity and lung cancer risks is nonlinear. The validity of risk estimates depends on the appropriateness of the risk model, exposure measures, and control of confounding variables.[124] Individuals with radiological or pathological evidence of asbestosis have the greatest risk of developing lung cancer, with lung cancer developing primarily in patients with well-documented asbestosis.[125,126] The issue of whether asbestos-induced lung cancer develops in the absence of asbestosis remains controversial.[127,128] The presence of asbestosis indicates a relatively large cumulative asbestos dose because the threshold dose of 25–105 fibers/mL/year for asbestosis occurs almost exclusively in workers with heavy occupational exposures (asbestos insulators, miners, millers, textile workers).[129] About 30–40% of patients with well-documented asbestosis will die from lung cancer, whereas ~10% of this population will die from mesothelioma.[50,130]

Classification. Asbestos consists of two main forms of hydrated fibrous silicate minerals (i.e., serpentine, amphibole) that share common properties of flexibility, high tensile strength, and resistance to heat and chemicals. Table 53.3 outlines the common types of commercial asbestos, other silicate fibers, and man-made vitreous fibers.[131] Chrysotile is the principal variety of asbestos fiber, whereas other varieties (actinolite, amosite, anthophyllite, crocidolite, tremolite) account for <2% of commercial production.[132] Previously, these latter varieties accounted for ~10% of commercial asbestos production. Environmental asbestos exposure usually results from the presence of tremolite in local geological formations (French Corsica and New Caledonia, Cyprus, central and eastern Turkey).[133]

Dose-Response. For occupational asbestos exposures, the exposure-response relationships for lung cancer are linear and cumulative; however, these relationships also depend on the industrial process and type of asbestos fiber.[134] The relative risk is much smaller (i.e., 10–30 times) for workers in chrysotile mining and milling than other types of asbestos fibers.[135] Cohort studies of workers exposed to processed asbestos fibers in the insulation and textile industries demonstrate a steeper exposure-response curve compared with the risk (i.e., relative risk of 0.1%/year) associated with workers exposed to asbestos contained within a matrix, mining, or asbestos cement manufacturing.[121,136] Overall, relative lung cancer risks in studies of workers in asbestos cement production are not usually elevated.

Although the dose-response data in occupational cohorts appear linear at high asbestos concentrations,

TABLE 53.3. Major fiber categories include asbestos, other silicate fibers, and man-made vitreous fibers (synthetic or manufactured vitreous fibers). The main asbestos fibers are serpentine and amphiboles, whereas man-made vitreous fibers are divided into filaments and wools. The latter are noncrystalline fibers produced from inorganic fibrous material (e.g., inorganic oxides, glass, minerals, rock, slag).

Asbestos Groups	Asbestos Types	Other Silicate Fibers	Man-Made Vitreous Fibers	Vitreous Fiber Types
Serpentine	Chrysotile (white asbestos)	Attapulgite, erionite, sepiolite, talc, vermiculite, wollastonite	Filaments	Continuous glass filament
Amphiboles	Actinolite,[a] amosite (brown asbestos or cummingtonite-grunerite), anthophyllite,[a] crocidolite (blue asbestos or riebeckite), tremolite[a]		Wools	Glass wool, refractory ceramic fibers, rock (stone) wool, slag wool, other fibers (e.g., alkaline earth silicate wools, high-alumina, low-silica wools)

[a] Little commercial value, primarily found as contaminants.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the extrapolation of a linear dose-response to environmental asbestos levels remains controversial.[137,138,139] Follow-up cohort studies in a British friction materials factory[140] and Australian crocidolite miners[141] did not detect an increased lung cancer relative risk in workers employed for <2 years. The odds ratio increased with employment duration after this time period to 2.2 (95% CI: 1.1–4.5) for employment ≥5 years. The major difficulty in determining the presence of a threshold results from the lack of accurate exposure data in occupational and community cohorts. In occupational exposures, duration of employment may be a much stronger component of cumulative exposure than dust concentrations, whereas fibers are typically short and poorly characterized in environmental settings. Cigarette smoking produces an almost multiplicative effect on the incidence of asbestos-related lung cancer. One cohort study of amosite workers followed from 1941–1977 demonstrated an 80-fold increase in lung cancer incidence among smoking workers.[142]

Histological Type. The histological types of lung cancer associated with asbestos and non-asbestos exposed cigarette smokers are similar; however, the frequency of histological types varies depending on the smoking history.[143] In a nested case-control study of 71 lung cancer cases among Australian crocidolite workers, the distribution of histological patterns was: 1) adenocarcinoma, 31%; 2) squamous cell carcinoma, 27%; 3) small cell carcinoma, 18%; 4) large cell carcinoma, 11%; and 5) unclassified, 13%.[144] The median cumulative exposure to crocidolite was 6 fibers/mL/year. After adjustment for smoking, commonly associated with squamous cell carcinoma, increasing crocidolite exposure produced a relatively greater increase in incidence of squamous cell carcinoma than adenocarcinoma. A Danish study of asbestos workers exposed primarily to chrysotile found a stronger relationship between asbestos exposure and adenocarcinoma than squamous cell carcinoma.[145] Lower lobe lung cancers predominate in asbestos workers, whereas upper lobe tumors dominate smoking-related lung cancers without asbestos exposure.[146] Pleural plaques are a marker of asbestos exposure rather than an independent marker for increased lung cancer risks.[129]

Silica and Other Silicates. The International Agency for Research on Cancer (IARC) concluded in 1987 that the evidence for the carcinogenicity of crystalline silica in experimental animals was sufficient but the evidence for cancer in humans was limited.[69] In 1997, the IARC changed the classification of crystalline silica to Group 1 (human carcinogen) based,[147] in part, on an increasing dose-response gradient in some studies with rate ratios up to 5.35 (95% CI: 2.23–12.8) for the highest crystalline silica exposure category (≥5.0 mg/m^3, 15-year latent period).[148] Other studies demonstrated no dose-response relationship,[149] particularly in studies of crystalline silica-exposed workers without silicosis.[150] Epidemiological studies of workers exposed to crystalline silica demonstrate variable findings with both positive and negative results on the association of silica exposure with lung cancer. The overall risk estimates from the positive studies are low (i.e., <2), and the risk of developing lung cancer appears concentrated in workers exposed to high silica concentrations that produce silicosis.[151] A meta-analysis of studies on silicosis indicates an ~2-fold increased lung cancer risk compared with the general population.[152] Frequently, exposure to other carcinogens (e.g., smoking, radon, asbestos, benzene) confounds the interpretation of these studies with inconsistent relationships between latent period, exposure duration, and quantitative exposure estimates. Smoking is a very strong confounding variable in studies on silica exposure; some positive studies are consistent with a multiplicative effect of smoking and dust exposure on the induction of lung cancer in silica-exposed workers.[153]

Epidemiological studies of exposures to other silicates are limited by difficulty identifying study populations with adequate size, latent period, and limited exposure to other carcinogens. Exposure of talc workers to tremolite and anthophyllite-contaminated talc as well as exposure of miners to tremolite-contaminated vermiculite produces increased lung cancer incidence; however, small studies of workers exposed only to trace contamination by asbestos demonstrate relatively small increased lung cancer risks.[123,154] Although data are limited, small studies of workers exposed to attapulgite, sepiolite, and wollastonite have not demonstrated a clear lung cancer excess.[123]

Man-Made Vitreous Fibers. A statistically significant elevation of standardized mortality ratios (SMRs) occurred in large epidemiological studies of rock/slag wool production workers in the United States (SMR = 134, n = 60 deaths)[155] and Europe (SMR = 124, n = 81 deaths).[156] These studies did not detect lung cancer excesses in glass wool or glass fiber (continuous filament) workers. In the European study, the excess lung cancer incidence was concentrated in the early technological phase of fiber production; this excess did not appear in workers employed in the later technological phase of fiber production following the introduction of dust-suppressing agents. Although there were insufficient data to estimate the qualitative lung cancer risk

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. in the general population from exposure to man-made fiber, the World Health Organization concluded risks to the general population are several orders of magnitude below the risk of current occupational exposures.[157] Case-control studies of environmental and occupational exposure to man-made vitreous fibers do not support a consistently increased lung cancer risk.[158,159] In a systematic review and meta-analysis of lung cancer risks in man-made fiber workers, the summary relative risk (RR) was 1.21 (95% CI: 1.11–1.32, n = 1,662 cases).[160] The RR in studies of production workers was 1.26 (95% CI: 1.10–1.44), similar to the risks in rock and glass wool workers with statistically nonsignificant elevations of risks in end users [RR = 1.06 (95% CI: 0.77–1.48) and 1.18 (95% CI: 0.98–1.42)] in community-based studies.

Ionizing Radiation

Radon is a natural decay product of radium 226 and uranium 238, which exists as a ubiquitous gas in soil and rock with highly variable concentrations. This radionuclide has a half-life of 3.82 days with the radon decay products (radon daughters) including the α-emitting polonium 218 and polonium 214. The α-particles are highly damaging to respiratory epithelium. Epidemiology studies demonstrate a linear relationship between radon exposure and lung cancer risk in underground miners.[161] Underground uranium miners with >5 years of employment experience an ~10-fold increase in lung cancer incidence.[162] The actual lung cancer risk depends on cumulative radon exposure. Small cell undifferentiated carcinomas are the most common histological type of radiation-induced lung cancer.[163] Although an increased lung cancer risk occurs in nonsmoking Indian miners,[164] analysis of lung cancer mortality data in Colorado uranium miners suggests a multiplicative effect on the development of lung cancer between cumulative radon exposure and pack years of smoking.[165]

Environment

Environmental asbestos exposures are typically much lower than those in occupational settings; consequently, most lung cancer cases are related to occupational rather than environmental exposure. Lung cancer risks depend on the concentration and type of asbestos fibers. Epidemiological evidence associating passive asbestos exposure in buildings with lung cancer is weak with the exception of para-occupational exposure.[166] Mortality studies of populations surrounding point sources of asbestos have not demonstrated a statistically significant increase in mortality from lung cancer when occupationally exposed workers are excluded from the study population.[167] Epidemiological evidence suggests the balance between carcinogens and agents that stimulate defense mechanisms affects the risk of environmentally induced lung cancer.[168] Several epidemiological studies indicate workers exposed to dust containing bacterial endotoxins demonstrated a lower lung cancer incidence than controls.[169]

Outdoor Air

Outdoor pollution is a complex mixture of gases and particles, including soot, dust, metals, fibers, polycyclic aromatic hydrocarbons, aromatic amines, endotoxins, bacterial produces, and fungi. Associations between estimated air pollutant concentrations and lung cancer incidence/mortality typically involve exposure to nitrogen dioxide (NO_2), nitric oxide (NO), and/or PM_{10}/$PM_{2.5}$, whereas the associations between sulfur dioxide (SO_2) and these outcomes are usually weak and statistically nonsignificant.[170] An issue of concern is the presence of small particulate matter from vehicle exhaust, which is typically classified as fine particles with an aerodynamic diameter of ≤2.5 μm ($PM_{2.5}$) and inhalable particles with an aerodynamic diameter of ≤10 μm (PM_{10}). The mechanism of action involves genomic instability and alteration of DNA replication, DNA repair, cell-cycle progression, and chromosomal segregation.[171] The IARC designated particulate matter in air pollution as a human carcinogen (Group 1) based on the relationship of particulate matter to lung cancer risk.[172] The concentration of mutagens is typically higher in the $PM_{2.5}$ than PM_{10} fraction, whereas the PM_{10} fraction contains the $PM_{2.5}$ fraction plus relatively higher amounts of biological and mineral nanoparticles.[173] Consistent with analysis of data from the American Cancer Society Cancer Prevention II study using linked metropolitan air pollution data,[174] most positive studies associating air pollution with lung cancer demonstrate increased overall relative risks of <10% with each increment of 10 μg/m^3. In a systematic review and meta-analysis of incidence and mortality studies analyzing lung cancer relative risks associated with particulate matter exposure per 10 μg/m^3 increments, the overall summary relative risk meta-estimates were 1.09 (95% CI: 1.04–1.14, n = 14 studies, I^2 = 53.0%, P = 0.010) for $PM_{2.5}$ and 1.08 (95% CI: 1.00–1.17, n = 9 studies, I^2 = 74.6%, P = 0.000) for PM_{10}.[175] The funnel plot was asymmetric with substantial heterogeneity. The analysis demonstrated overall meta-estimate of adenocarcinoma for $PM_{2.5}$ of 1.40 (95% CI: 1.07–1.83, n = 3 studies); however, evidence for an association with squamous cell carcinoma was weak (1.11, 95% CI: 0.72–1.72, n = 2 studies).

For meta-estimates involving smoking status and the lung cancer, relative risks associated with $PM_{2.5}$ were strongest for former smokers (1.44, 95% CI: 1.04–2.01) and weaker for never-smokers (1.18, 95% CI: 1.00–1.39) and current smokers (1.06, 95% CI: 0.97–1.15).

Indoor Air

Potential lung carcinogens in indoor air pollution include cooking fumes, radon, and environmental tobacco smoke. The strength of these associations with lung cancer is much weaker than that of mainstream tobacco smoke.

Environmental Tobacco Smoke

The lung cancer risk estimates from exposure to environmental tobacco smoke (ETS) are much smaller and more inconsistent than those from inhaling mainstream smoke, reflecting, in part, the difficulty in accurately measuring ETS (passive) smoke exposure. Overall, increased lung cancer risk for nonsmokers is relatively small (i.e., ~20%) compared with mainstream tobacco smoke. In a meta-analysis of 35 case-control and 5 cohort studies, the relative lung cancer risk in nonsmoking women ever-exposed to a smoking spouse was 1.20 (95% CI: 1.12–1.29).[176] The pooled relative risk was 1.19 (95% CI: 1.10–1.29) for case-control studies and 1.29 (95% CI: 1.04–1.62) for cohort studies, with increasing risk as ETS exposure increased. The prospective, multicenter US Women's Health Initiative Observational cohort study of 76,304 postmenopausal women (participation rate: 81%, age: 50–79 years) following a mean of 10.5 years identified 901 lung cancer cases.[177] Using Cox proportional hazards models and 152 never-smokers as referents, the lung cancer incidence was highest in current smokers ($HR_{multivariable\ adjusted}$ = 13.44, 95% CI: 10.80–16.75, n = 218 cases) and former smokers ($HR_{multivariable\ adjusted}$ = 4.20, 95% CI: 3.48–5.08, n = 531 cases). Among never-smokers, lung cancer incidence was not increased, comparing any passive smoking exposure with none ($HR_{multivariable\ adjusted}$ = 0.88, 95% CI: 0.52–1.49, n = 16 unexposed cases/136 ever-exposed cases); however, the lung cancer risk was marginally significant in women with ≥30 years of passive adult smoke exposure ($HR_{multivariable\ adjusted}$ = 1.61, 95% CI: 1.00–2.58, n = 32 cases).

Similar to mainstream tobacco smoke and lung cancer, the risks are highest for small cell lung cancers and lowest for adenocarcinomas. In an analysis of 18 case-control studies in the International Lung Cancer Consortium, the odds ratio for lung cancer in never-smokers comparing ever- and never-ETS exposure was 1.31 (95% CI: 1.17–1.45) for all histological subtypes combined.[178] The OR was 1.26 (95% CI: 1.10–1.44) for adenocarcinoma and 3.09 (95% CI: 1.62–5.89) for small cell lung cancer. The association was not statistically significant for squamous cell carcinoma (OR = 1.41, 95% CI: 0.99–1.99) or large cell lung cancer (OR = 1.48, 95% CI: 0.89–2.45); the association of ETS with lung cancer was greater for small than non-small cell lung cancer (OR = 2.11, 95% CI: 1.11–4.04).

In a Japanese systematic review and meta-analysis of four cohort and five case-control studies examining ETS exposure during adulthood and lung cancer, most populations studied demonstrated increased lung cancer risks from ETS exposure.[179] The pooled relative risk of lung cancer was 1.28 (95% CI: 1.10–1.48) comparing nonsmoking individuals (i.e., mostly women) with smoking and nonsmoking spouses. After adjustment, the funnel plot did not display significant publication bias. Examination of dose-response relationships suggested an increased lung cancer risk when comparing nonsmoking women living with current rather than former smokers; however, the frequency of ETS exposure or the number of household smokers did not clearly affect lung cancer risk. Long-term lung cancer risks following chronic exposure to inhaling hookah or e-cigarette smoke remain poorly defined.

Radon

Radon is a well-established lung carcinogen with highly variable exposures throughout the world. A meta-analysis of 13 European case-control studies involving 7,148 persons with lung cancer and 14,208 controls reported excess relative lung cancer risk per 100 Bq/m^3 increase in observed radon concentration of 8% (95% CI: 3–16%, $P = 0.0007$) after control for confounding.[180] Radon exposure was based on self-reported smoking history and long-term radon gas measurements of residential radon concentrations. After removing bias induced by random uncertainties related to radon exposure assessment, estimated risks at 0 Bq/m^3, 100 Bq/m^3, and 400 Bq/m^3 for lifelong nonsmokers compared with unexposed lifelong nonsmokers were 1.0, 1.2, and 1.6, respectively. The risks of radon and cigarette smoking were synergistic. A review of five North American studies on residential radon exposure demonstrated conflicting results on exposure-response relationships, statistical significance, and trends, with some studies reporting similar excess relative risks (ERRs) as the European meta-analysis (e.g., overall ERR = 0.24 (95% CI: −0.07–0.55 for nonsmokers with substantial heterogeneity).[181]

Indoor Heating

The IARC classifies indoor coal emissions from combustion during heating and cooking as a human carcinogen (Group 1), whereas emissions from biomass combustion (wood, twigs, crop residues) are listed as probable human carcinogens (Group 2A). In a pooled analysis of 7 studies from the International Lung Cancer Consortium involving 5,105 lung cancer cases and 6,535 nonsolid-fuel using controls (oil, gas, electricity), the lung cancer risk was elevated in predominant coal users (OR = 1.64, 95% CI: 1.49–1.81) and predominant wood users in North American and European countries (OR = 1.21, 95% CI: 1.06–1.38).[182] The odds ratio for predominant coal users in Asia was higher and less precise than in other parts of the world (OR = 4.93, 95% CI: 3.73–6.52). A systematic review and meta-analysis of 8,221 lung cancer cases and 11,342 controls from 13 case-control studies on biomass cooking and/or heating reported an odds ratio of 1.17 (95% CI: 1.01–1.37) for lung cancer risk associated with biomass cooking and/or heating compared with controls.[183] Restricting data to studies with adequate adjustment and a clean reference category demonstrated an odds ratio of 1.21 (95% CI: 1.05–1.39) for men (two reports, compiling five studies) and 1.95 (95% CI: 1.16–3.27) for women (five reports, compiling data from eight studies). The exposure-response trends reflected the higher exposures of women from developing countries.

Ionizing Radiation

Data from Hiroshima and Nagasaki atomic bomb survivors indicate lung cancer incidence increases in a linear dose-response relationship to ionizing radiation.[184] Low-dose radiation effects from X-ray or computed tomography differ from the single, high-dose exposure received by the atomic bomb survivor, requiring extrapolation of the high-dose data below the range of observation.[185,186] Initiation processes dominate the risk of radiation exposure in younger individuals, whereas promotion of preexisting premalignant cells predominately influences cancer risks after radiation exposure in later years. Hence, cancer site-dependent balance between initiation and promotion determines the dependence of cancer risk on age at radiation exposure with radiation-induced cancer risks persisting into middle age.[187]

Lifestyle

Although alcohol consumption,[188] marijuana smoking, diet,[189] estrogen use, and some infections (human papillomavirus, HIV, Epstein–Barr virus) are suggested risk factors for lung cancer, current evidence is insufficient to establish a clear association between lung cancer and these potential risk factors.[190] A systematic review of lung cancer risks and alcohol consumption among the Japanese population identified seven cohort and two case-control studies with only five of these studies adjusting for smoking.[191] One cohort study reported a statistically significant increased lung cancer risk in daily-drinking women (RR = 2.53, 90% CI: 1.59–4.03, $P = 0.011$) compared with nondrinkers; however, the association became statistically nonsignificant after adjustment for smoking. Another two studies reported weak positive risks, whereas five studies reported no significantly increased lung cancer risk. Obesity is not strongly associated with lung cancer; some studies suggest an inverse association with BMI and a modestly increased risk for measures of central obesity (waist circumference, waist-to-hip ratio). A pooled analysis of 12 prospective cohort studies in the United States, Europe, and Asia identified 23,732 incidence lung cancer cases during an average 11.9 years of follow-up for 1,636,357 participants.[192] Using Cox proportional hazard regression and BMI of 23–24.99 kg/m^2 as referents, the BMI was modestly inverse and statistically significant for lung cancer risks in obese participants with BMI 30–34.99 kg/m^2 (adjusted HR = 0.81, 95% CI: 0.75–0.87, n = 1,100 cases) during 5–10 years of follow-up, but statistically nonsignificant for >10 years of follow-up. Similarly, for very obese participants (BMI = >35 kg/m^2), the adjusted HR was 0.81 (95% CI: 0.72–0.90, n = 382 cases) during 5–10 years of follow-up, but statistically nonsignificant for >10 years of follow-up (adjusted HR = 0.92, 95% CI: 0.77–1.09, n = 145 cases). In general, lung cancer risks were marginally increased for central measures of obesity (e.g., adjusted HR = 1.15, 95% CI: 1.00–1.33, n = 682 cases) for the highest category of waist-to-hip ratio during >10 years of follow-up. In the American Cancer Society Cancer Prevention Study-II Nutrition Cohort of 162,679 men and women, physical activity was not associated with lung cancer risk within any smoking strata, except for former smokers of 10 years since quitting (RR = 0.77, 95% CI: 0.67–0.90 for >17.5 MET-hours/week).[193] Waist circumference was not associated with lung cancer risk in any smoking category.

Tobacco Smoking

Approximately 15% of smokers develop lung cancer, whereas 10–15% of lung cancers occur in never-smokers.[194] Tobacco consumption accounts for 80–85% of US lung cancer deaths.[9,195] In 1964, the US Surgeon General's Report noted a 9–10-fold greater lung cancer

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

risk comparing average male smokers with nonsmoking men.[196] The risk of developing lung cancer strongly correlates to cumulative smoking dose with an odds ratio of ~16 for male smokers with >40 pack-years smoking history.[66] Smoking declines with age; in the United States, current smokers account for ~5% of 75-year-olds compared with 21.5% of 18–44-year-olds.[197] The smoking rate continues to decline. The high lung cancer incidence in the general population attributable to smoking complicates the interpretation of studies examining causes unrelated to smoking. Because smoking is a very strong risk factor, cohorts must carefully categorize smoking history to avoid misclassification bias. Although cessation of smoking reduces lung cancer risks, the risk of cancer never returns to baseline levels.[198]

Although current tobacco smoking increases the risks of all four major histological lung cancer subtypes, the association is stronger for squamous cell carcinomas and small cell lung cancer than large cell lung cancer or adenocarcinomas.[199] Controls were hospital patients without a history of tobacco-related diseases. Most lung carcinomas including adenocarcinomas develop in the lungs of smokers with chronic obstructive pulmonary disease;[200] almost all (i.e., 98%) of the lung cancers in COPD patients are non-small cell lung tumors.[201] Although some case-control studies suggest an increased risk of large cell carcinomas in smokers,[202] poor exposure data, revisions of histological classifications, and wide confidence intervals indicate the potential for substantial misclassification and imprecise odds ratios. In a hospital-based case-control study of 851 male and 507 female lung cancer cases along with age/race-matched controls (888 men, 608 women), the adjusted odds ratio of lung cancer in current smokers of ≥30 cigarettes/day was highest for small cell carcinoma (OR = 5.5, 95% CI: 1.6–18.2, n = 40 cases), squamous cell carcinoma (OR = 2.3, 95% CI: 1.3–3.9, n = 100 cases), and adenocarcinoma (OR = 1.9, 95% CI: 1.1–3.2, n = 99 cases).[203] The results for large cell carcinoma were null (OR = 1.0, 95% CI: 0.5–2.3, n = 29 cases).

Marijuana Smoking

The results on chronic marijuana smoking and lung cancer are inconsistent. Although the possibility of potential adverse effect for heavy consumption was not excluded, pooled analyses from six case-control studies within the International Lung Cancer Consortium detected little evidence for an increased lung cancer risk among habitual or long-term cannabis smokers; the pooled OR for habitual versus non-habitual or never-users was 0.96 (95% CI: 0.66–1.38).[204] A meta-analysis of eight observational studies (five case-control, one cross-sectional, one prospective, one retrospective cohort) was unable to pool data for lung cancer because of inadequate adjustment, confounding by few marijuana-only smokers, and poor exposure assessment.[205]

Diet

Diet is not strongly associated with increased lung cancer risks. Previously, β-carotene was a prime candidate for lung cancer chemoprevention; however, subsequent studies demonstrated an increased lung cancer incidence following the administration of β-carotene alone or combined with vitamin E (α-tocopherol) or retinyl palmitate.[206] Although large-scale chemoprevention studies on vitamin supplementation were negative, most health professionals recommend a balanced diet of fruits and vegetables including β-carotene. After adjusted for smoking history and other covariates, the NIH-AARP study of 472,081 participants aged 50–71 years did not demonstrate a relationship between total fruit/vegetable consumption and reduced lung cancer incident in 6,035 lung cancer cases.[207] The study detected no evidence of a dose-response trend. The randomized, double-blind, placebo-controlled Beta-Carotene and Retinol Efficacy Trial (CARET) was terminated 21 months early when vitamin A and/or β-carotene supplementation produced a clear lack of efficacy and substantial evidence of harm.[208] The Physicians' Health Study of 22,071 male physicians followed over 12 years demonstrated no benefit (RR = 0.9, 95% CI: 0.7–1.2) or harm from β-carotene supplementation on lung cancer rates.[209]

Medications

Women are more likely to develop adenocarcinomas at a younger age of diagnosis compared with men, suggesting potential reproductive and hormonal risk factors; however, observational studies are conflicting and lack a clear consensus on the effect of female hormones on lung cancer risks. Most epidemiology studies do not support a clear association between lung cancer and hormone replacement therapy or oral contraceptives.[210,211] Although female hormones may influence lung carcinogenesis, the effect is probably modest varying by histological subtype and smoking status. The Italian Environment and Genetics in Lung Cancer Etiology is a population-based study consisting of 407 women lung cancer cases (91% participation rate) and 499 age/residence/smoking/education/BMI-matched controls (99% participation rate).[212] Using never-users

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

as referents, the lung cancer risk in ever-users of hormone replacement therapy was inverse and statistically significant (adjusted OR = 0.61, 95% CI: 0.39–0.95, $n = 63$ cases/112 controls); however, the trend for duration of use was not significant ($P_{trend} = 0.11$). Similarly, lung cancer risk for ever-oral contraceptive users was inverse (adjusted OR = 0.60, 95% CI: 0.39–0.93, $n = 101$ cases/132 controls) with no significant dose-response relationship ($P_{trend} = 0.09$). The study suggested longer reproductive periods (i.e., prolonged endogenous estrogen production) are associated with reduced lung cancer risks (≥51 years: adjusted OR = 0.49, 95% CI: 0.31–0.79, $P_{trend} = 0.003$).

Diseases

Chronic Obstructive Pulmonary Disease

The prevalence of COPD in lung cancer patients ranges from ~28 to 51%.[213,214] Although chronic obstructive pulmonary disease (COPD) and lung cancer have a common risk factor (cigarette smoking), COPD is probably an independent risk factor for lung cancer in current, former, and never-smokers, depending on the type and severity of COPD.[215,216] Overall, increased lung cancer risk is ~1.25–2.5-fold higher in patients with COPD than in those without COPD.[217,218] In an analysis of pooled data from seven European and Canadian case-control studies involving 12,739 cases and 14,945 controls, a past history of chronic bronchitis and emphysema was positively associated with lung cancer independent of smoking history.[219] The odds ratio for lung cancer in men was 1.33 (95% CI: 1.20–1.48) for chronic bronchitis and 1.50 (95% CI: 1.21–1.87) for emphysema using subjects without a history of past respiratory disease as referents. The medical history was self-reported with potential for recall bias and misclassification. Pathways identified as potentially producing an association between COPD and lung cancer include oxidative stress, inflammation, and extracellular matrix proteolysis. The presence of COPD worsens lung cancer prognosis because of increased morbidity and mortality.[220]

Idiopathic pulmonary fibrosis is a chronic, nonmalignant disease with a grave prognosis from progressive fibrosis of pulmonary tissues. Although some studies do not confirm an association between lung cancer and idiopathic pulmonary fibrosis (IPF),[221,222] systematic reviews indicate the current evidence supports a positive association between IPF and lung cancer. The results from these studies demonstrate highly variable relative risks, wide confidence intervals, and substantial heterogeneity.[223,224] In an analysis of a UK longitudinal computerized primary care dataset (Health Improvement Network), the overall lung cancer incidence was elevated in patients with IPF (rate ratio = 4.95, 95% CI: 3.00–8.18) compared with the general UK population.[225] The results were adjusted for age, gender, and self-reported smoking history. Other studies reported higher rate ratios. In a population-based cohort study involving 890 subjects with cryptogenic fibrosing alveolitis (idiopathic pulmonary fibrosis) and 5,884 control subjects from the United Kingdom General Practice Research Database, the RR was 8.25 (95% CI: 4.70–11.48, $P < 0.001$) after adjustment for smoking history.[226]

Infectious Agents

The role of infectious organisms as causal agents in the development of lung cancer remains unclear, with marginal evidence for a variety of these organisms (e.g., human papillomavirus, Epstein–Barr virus, *Chlamydia pneumonia*, HIV, pulmonary tuberculosis). In a Danish study of 1,747 cancers in 15,024 patients with active tuberculosis following a median of 8.5 years, the standardized incidence ratio (SIR) was 1.52 (95% CI: 1.45–1.59) for all cancers and 3.40 (95% CI: 3.09–3.74) for lung cancer.[227] Although tuberculosis was associated with an increased lung cancer incidence, the presence of tuberculosis was a marker of occult lung cancer and several nonpulmonary cancers. A prospective cohort study followed 1,607,710 Korean adults up to 16 years; the presence of tuberculosis was significantly associated with an elevated lung cancer incidence after controlling for cigarette smoking, age, and other covariates.[228] The hazard ratio was 1.37 (95% CI: 1.29–1.45) in men and 1.49 (95% CI: 1.28–1.74) in women. For mortality, the HR was 1.43 (95% CI: 1.34–1.52) in men and 1.53 (95% CI: 1.28–1.83) in women. In a meta-analysis of 37 case-control and 4 cohort studies using random effects models, the association with a history of tuberculosis was statistically significant after adjustment for smoking for adenocarcinoma (adjusted RR = 1.60, 95% CI: 1.24–2.05), but not for squamous cell carcinoma (meta RR = 1.30, 95% CI: 0.85–1.99) or small cell lung cancer (meta RR = 0.79, 95% CI: 0.25–2.55).[229] The overall meta RR for lung cancer and a history of tuberculosis across all global studies was 1.74 (95% CI: 1.48–2.03, $n = 11$ studies, $I^2 = 59.2\%$, $P_{heterogeneity} = 0.00\%$) with moderate heterogeneity.

HPV in lung tumors ranges widely between geographical regions, sex, and histological type, resulting in conflicting outcomes. In a meta-analysis of HPV16 and HPV18 presence in primary lung cancers from 2,435 subjects reported in 37 published studies, the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

overall HPV prevalence ranged from 0.0–78.3%, with large heterogeneity across geographical regions and histological tissue types.[230] An international pooled analysis of 27 cross-sectional studies containing tumors from 3,249 patients evaluated HPV DNA prevalence in these lung tumors.[231] The highest adjusted prevalence of HPV16/18 occurred in South and Central America (22%), followed by Asia (5%), North America (4%), and Europe (3%). The lung cancer risk in HIV-positive populations also varies with geographical region, with lung cancer being a common non-AIDS-defining malignancy among HIV-infected patients compared with the general population. In a review of 65 publications, the standardized incidence ratio (SIR) or incident rate ratio (IRR) for lung cancer in HIV-positive patients ranged from 0.7–6.9 in the United States, 1.5–3.4 in Europe, and 5.0 in Africa.[232]

HISTOLOGY

Classification

The major histological types of malignant epithelial and neuroendocrine lung tumors as defined by the World Health Organization (WHO) in 2015 include: 1) adenocarcinomas, 2) squamous cell carcinomas, and 3) neuroendocrine tumors (e.g., small cell carcinoma, large cell carcinoma, carcinoid), as listed in Table 53.4.[233] Squamous cell and small cell carcinomas are typically central lesions arising from epithelium in proximal bronchi, whereas adenocarcinomas frequently appear in the peripheral portions of the lung. Non-small cell lung carcinoma refers to the heterogeneous group of histological lung cancer types other than highly malignant small cell lung cancer that includes squamous cell carcinomas, adenocarcinomas, true large cell neuroendocrine carcinomas, and more poorly differentiated variants.[234] The variety of histopathological types reflects very large tumor heterogeneity from different cells of origin and differentiation pathways.[15]

Adenocarcinomas

The suspected cells of origin for lung adenocarcinomas are epithelial cells lining peripheral small bronchi, bronchioles, or alveoli (e.g., Clara cells);[235] however, some evidence suggests the surfactant protein C expressing AT2 (alveolar type II) cells are potential cells of origin in more central locations.[236] As noted in Table 53.4, premalignant lesions include benign atypical adenomatous hyperplasia and minimally invasive adenocarcinoma *in situ* (mucinous or nonmucinous). The latter typically consists of nonmucinous type II pneumocytes or Clara cells and rarely mucinous resembling goblet cells. Lepidic refers to the noninvasive component of an invasive adenocarcinoma. Pathologically, lepidic adenocarcinomas are tumor cells proliferating along the surface of intact alveolar walls without stromal or vascular invasion; these lesions do not metastasize when locally resected. Most studies indicate lepidic adenocarcinomas are low-grade, whereas acinar and

TABLE 53.4. Histological types and subtypes of epithelial and neuroendocrine lung tumors from the 2015 World Health Organization (WHO) classification of lung tumors. This classification also includes 12 mesenchymal tumor subtypes (e.g., pulmonary hamartoma, chondroma), six lymphohistiocytic tumor subtypes (e.g., extranodal marginal zone lymphomas of mucosa-associated lymphoid tissue, MALT lymphoma), four tumors of ectopic origin (e.g., mature/immature teratoma), and metastatic tumors not listed in this table. (Adapted from Travis et al.).[233]

Histological Type	Subtypes	Malignant Potential
Adenocarcinoma	Lepidic, acinar, papillary, micropapillary, solid, invasive mucinous, colloid, fetal, enteric, minimally invasive (nonmucinous, mucinous).	Malignant
	Preinvasive lesions – atypical adenomatous hyperplasia and adenocarcinoma *in situ* (mucinous, nonmucinous).	Benign *In situ*
Squamous cell carcinoma	Keratinizing squamous cell carcinoma, nonkeratinizing squamous cell carcinoma, basaloid squamous cell carcinoma.	Malignant
	Preinvasive lesion – squamous cell carcinoma *in situ*.	*In situ*
Neuroendocrine tumors	Small cell carcinoma (combined), large cell neuroendocrine carcinoma (combined), carcinoid tumors (typical, atypical), large cell carcinoma, adenosquamous carcinoma, sarcomatoid carcinomas (pleomorphic, spindle cell, giant cell, carcinosarcoma, pulmonary blastoma), other/unclassified (lymphoepithelioma-like carcinoma, NT carcinoma), salivary gland-type (mucoepidermoid carcinoma, adenoid cystic carcinoma, epithelial-myoepithelial carcinoma).	Malignant
	Salivary gland-type pleomorphic adenoma, papillomas [squamous cell (exophytic/inverted), glandular, mixed squamous/glandular], adenomas (sclerosing pneumocytoma, alveolar, papillary, mucinous cystadenoma, mucous gland adenoma).	Benign

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

papillary tumors are intermediate-grade and solid or micropapillary adenocarcinomas are high-grade.[237] Bronchioalveolar carcinoma and clear cell/signet ring adenocarcinomas are discontinued terms.[233] Former large cell carcinomas with pneumocyte marker expression (i.e., TTF-1 and/or Napsin A biomarkers) are now considered solid adenocarcinomas.

Squamous Cell Carcinoma

In Western, industrialized countries during the early 1990s, squamous cell carcinoma was the most common histological lung cancer type in smokers followed by adenocarcinoma and small cell carcinoma;[238,239] however, the predominance of squamous cell carcinoma declined in the last few decades while the prevalence of adenocarcinoma increased.[240] Smoking is typically more strongly associated with central lung tumors (squamous cell carcinoma, small cell carcinoma) than more peripheral lung cancer types (adenocarcinoma, large cell carcinoma). Pluripotent basal cells in the respiratory epithelia of the large airways of smokers are suspected cells of origin for metaplastic and dysplastic squamous cells.[241] The dose-response between smoking and squamous cell carcinoma was stronger in women than men.[203] In contrast to the previous 2004 WHO classification of squamous cell carcinomas, clear cell change is a cytological feature of both keratinizing and nonkeratinizing squamous cell carcinomas rather than a separate subtype. The diagnosis of surgically resected nonkeratinizing squamous cell requires positive squamous cell biomarkers (e.g., p40, p63) in the absence of unequivocal keratinization. As noted in Table 53.4, squamous cell carcinoma subtypes include keratinizing, nonkeratinizing, and basaloid, with the prognostic significance of these subtypes unclear.[242,243]

Neuroendocrine Tumors

Neuroendocrine tumors comprise a heterogeneous group of neoplasms ranging from well-differentiated bronchial carcinoids with a low mitotic rate to highly malignant, rapidly proliferating, poorly differentiated small cell lung cancer and large cell neuroendocrine carcinomas.[244] Carcinoids frequently occur in never-smokers, whereas small cell lung cancer and large cell neuroendocrine carcinomas usually develop in smokers.

Small Cell Carcinomas

Small cell carcinoma is the most common neuroendocrine lung tumor, particularly in younger patients, accounting for ~10–15% of invasive lung cancers; however, the US incidence decreased over the last several decades as smoking declined in the United States.[245] Histological features distinguishing small cell lung cancer from large cell neuroendocrine carcinomas include cell size and absent/inconspicuous nucleoli. Over 90% of small cell lung cancer tumors contain one of several neuroendocrine biomarkers (neural cell adhesion molecule, CD56; synaptophysin; chromogranin A). This tumor is the most malignant type of lung cancer, proliferating very rapidly (i.e., ~80-day doubling time)[246] and metastasizing early. The cell of origin is probably the pulmonary neuroendocrine cell (bronchial Kulchitsky-type cell) that is the first epithelial cells to form and differentiate during the earliest stages of lung development; however, the alveolar type II cell is also a potential cell of origin.[244]

Large Cell Carcinomas

This histological type is a rare tumor (i.e., <3% of invasive lung tumors). The 2015 WHO classification significantly revised the subtypes of large cell carcinomas using immunohistochemical biomarkers (the pneumocyte marker, TTF-1; p40). Several large cell carcinoma variants were reclassified into other categories, including basaloid carcinoma (squamous cell carcinoma subtype), lymphoepithelioma-like carcinoma (other and unclassified carcinoma), clear cell carcinoma/rhabdoid phenotype (cytological feature rather than specific histological subtype), and solid carcinomas (solid adenocarcinoma with TTF-1^+ or nonkeratinizing squamous cell carcinoma when p40 positive).[233] Significant histological, epidemiological, genetic, and clinical differences exist between typical/atypical carcinoid tumors and other neuroendocrine carcinomas (e.g., high-grade small cell lung carcinomas, large cell neuroendocrine carcinomas), including younger age, little association with smoking, fewer genetic abnormalities, and better prognosis.[247]

HOST SUSCEPTIBILITY

Nonsmoking individuals (i.e., <100 cigarettes/lifetime) account for about 15–20% of lung cancer patients. Risk factors include exposure to radon, asbestos, air pollution, and environmental tobacco smoke as well as a first-degree family member with lung cancer. The development of *ALK* gene rearrangements and EGFR mutations increase the lung cancer risks in these patients. Lung cancer incidence appears higher in nonsmoking women than in nonsmoking men. In a hospital-based, case-control study of 1,889 lung cancer patients and 2,070 controls, the portion of never-smoking patients with lung cancer was almost

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

twice as high for women than men.[248] Potential factors contributing to an increased lung cancer risk include strong family history of lung cancer, chronic obstructive pulmonary disease, fibrotic disorders (asbestosis, idiopathic pulmonary fibrosis, silicosis), and tuberculosis. On a molecular level, more women than men have proportionally increased tobacco-related mutations (G → T transversion in the TP53 and KRAS) and EGFR gene mutations; the latter being a protype receptor tyrosine kinase epidermal growth factor receptor.[249] Substantial epidemiological evidence supports a ~2-fold increased lung cancer risk in smoking relatives with a family history of lung cancer using smoking relatives without a family lung cancer history as controls, particularly when lung cancer is diagnosed at a relatively young age (i.e., <60 years) and involves multiple family members.[250,251] The lung cancer risks increase (i.e., 2–4-fold) for first-degree relatives with lung cancer after adjusting for other risk factors (sex, age, occupation, COPD, smoking history).[194] Genetic susceptibility may result from rare, high penetrance genes in multiple locations (e.g., 6q23–25, 18p11.23, 2p22.2, 14q13.1, 16p13, 20q13.11)[252] or common, low penetrance genes (chromosomes 15q25, 6p21, 5p15). Although the lung cancer risk increases in individuals with a family history of lung cancer, irrespective of smoking status,[253] the addition of a smoking history to a family with genetic susceptibility substantially elevates lung cancer risks (e.g., 3-fold in persons with genetic susceptibility from 6q23–25).[254] Mechanisms of action for genetic susceptibility include polymorphisms in metabolic activation/detoxification of chemical carcinogens, chronic inflammation pathways, and alteration of DNA repair enzymes.[129]

CLINICAL FEATURES

Lung cancer commonly begins appearing clinically in the 6th and 7th decade of life; the mean age at diagnosis is ~71 years and the diagnosis of cancer in persons under 20 years is highly unusual.[129] The male/female lung cancer ratio was ~1.5 in the 1990s.[200] The trend for the last decade indicated lung cancer rates increased in women and never-smokers with adenocarcinomas representing a larger portion of the non-small cell lung cancers (NSCLCs).[255] In men, the diagnosis of NSCLC usually occurs at an advanced stage. The latent period for the clinical diagnosis of lung cancer following asbestos exposure typically ranges from 15–40 years.[256] The latent period decreases with increasing asbestos dose and younger age at exposure.

Lung parenchyma contains no pain sensory fibers. Consequently, many lung cancer patients present with an asymptomatic lung lesion discovered incidentally during radiological imaging. Clinical features of lung tumors include fatigue, dyspnea, pleuritic chest pain, cough, wheezing, and hemoptysis, depending on the presence of local/distant invasion, lung dysfunction, and tumor type/location/size. One-year mortality rates remain higher in men (56.6%) than women (50.9%). Small cell lung cancer is the most lethal lung cancer subtype with a 95% mortality rate; almost cases occur in heavily smoking patients (>30 pack-years) aged 60–80 years.[257] The 5-year survival rate for small cell lung cancer is substantially lower than for large cell neuroendocrine carcinomas (13–57%).[258] Current staging of NSCLC ranges from IA (≤3 cm, no regional metastasis) to IV (any tumor size with distant metastasis); the 5-year survival ranges from 50–2%, respectively.[259] Incidence-based NSCLC lung cancer mortality over the last few years has decreased over twice as fast as NSCLC incidence, reflecting the effectiveness of targeted therapies and immunotherapies (e.g., anaplastic lymphoma kinase, epidermal growth factor receptor).[260] During the same time period, small cell lung cancer incidence-based mortality has remained relatively flat until recently following advances in molecular profiling, immunotherapies, and targeted therapies. The 5-year overall survival rate in the US is 12–30% depending on whether (limited stage) or not (extensive stage) the disease can be treated within a radiation field confined to one hemithorax exclusive of contralateral mediastinal or supraclavicular nodes.[245]

MESOTHELIOMA

Although the association between asbestos exposure and lung cancer was reported in the early 1920s,[261] discovery of the relationship between asbestos and pleural mesothelioma did not occur until 1960, when J. C. Wagner et al. documented the high prevalence of mesotheliomas in residents and workers employed and/or living near South African crocidolite (amphibole) asbestos mines in Northwest Cape Province.[262] Eight case-control studies published from 1965–1975 on 657 mesothelioma cases from asbestos exposures in shipyards, factories, heating trades, and insulation manufacturing provided confirmation with relative mesothelioma risks ranging from 2.3–7.0.[263] Over the last several decades, the asbestos exposures of workers with malignant mesothelioma have shifted from asbestos workers handling raw asbestos material to end users typically installing or handling asbestos products.[264]

The importation and use of asbestos closely correlate with mesothelioma incidence.[265] Worldwide,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

estimated crude incidence mesothelioma rates range from 0.15 cases/1,000 person/year for cumulative exposure of <3,530 million particles/m^3/year (<100 million particles/ft^3/year) to 0.97 cases/1,000 person/year for cumulative exposure of >10,590 million particles/m^3/year.[135] Based on a mean latency of 40 years and historical asbestos use data, the projected peak mesothelioma incidence in the United States and Western Europe is near 2020.[266,267] The annual number of US mesothelioma cases is ~1,500–2,000 (~1/20,000,000 inhabitants) compared with ~30,000 cases worldwide.[268,269]

Observational studies on occupational asbestos exposures indicate that attributable risks for malignant pleural mesothelioma in developed countries vary by geographical location.[270] Male urban and rural mesothelioma rates increased in the 1980s and 1990s, followed by leveling and subsequently decreasing rates as declining asbestos production shifted occupational asbestos exposures from manufacturing to end uses, whereas female urban and rural mesothelioma rates remained relatively stable during this period.[271,272] Trend analyses indicate female urban and rural mesothelioma incidence rates remain ~5–6-fold lower than male urban and rural incidence rates, consistent with historical occupational asbestos exposures based on US SEER data. The lower mesothelioma rates in rural areas reflect the ~10-fold increased asbestos fiber concentrations in urban environments; the exact environmental asbestos concentrations are difficult to estimate given the differences in sensitivity and specificity of analytical techniques.

CARCINOGENESIS

Most mesotheliomas are associated with chronic asbestos exposure. Although chromosome 14q11 losses occur frequently in asbestos-related mesothelioma displaying macrophage-driven inflammation and reactive oxygen species-induced DNA damage,[273] no unique signature gene abnormality has been identified. Overall, the recurrent mutation load is limited compared with the high chromosomal aberration rate and subsequent gene copy number alterations, primarily chromosomal deletions (e.g., *BAP1*, 3p21.1; *CDKN2A*, 9p21.3; *NF2*, 22q12.2; *SETD2*, 3p21.31).[274] The composition and location of common genetic abnormalities vary substantially between and within tumors, resulting in both intra- and inter-tumor heterogeneity as well as the development of resistant clones.[275] Despite the wide heterogeneity between mesothelioma tumors, genetic alterations in mesotheliomas are limited compared with most other tumor types; the actual number of alterations depends on the sequencing technique used.

The most frequent driver gene mutations associated with mesotheliomas involve tumor suppressor genes, including *BAP1* (BRAC1-associated protein 1), *NF2* (neurofibromin type 2), and *CDKN2A* (cyclin-dependent kinase 2A).[276] In an examination of 42 mesotheliomas (55% pleural, 26% peritoneal, 5% pericardial, 14% unknown) referred to a clinical laboratory for analysis with next-generation sequencing, no two patients displayed identical molecular portfolios.[277] In this study, the most common aberrations occurred in the *BAP1* gene (47.6%), *NF2* gene (38.1%), *CDKN2A/B* loss (35.7%), and *TP53* aberrations (16.7%). Among 23 pleural mesothelioma patients in this study, *BAP1* was the most commonly altered gene (60.9%) followed by *CDKN2A/B* loss (52.2%), *NF2* loss (34.8%), and *TP53* (17.4%), whereas the most frequently altered genes in 11 peritoneal mesotheliomas were *NF2* (36.4%) and *BAP1* (27.3%).

Recurrent mutations of genes other than tumor suppressors involve the epigenetic regulators of histone methyl transferases (*SETD2*, *SETDB1*), ATP-dependent DEAD-box RNA helicases (*DDX3X*, *DDX51*), serine/threonine kinase-like (*ULK2*), and ryanodine receptor proteins (*RYR2*). The total number of protein-altering gene mutations in 216 mesotheliomas averaged 24 ± 11/tumor using exome sequencing.[278] In pleural mesotheliomas from this study, the most frequently altered signaling pathways involved Hippo, histone methylation, RNA helicases, mTOR, and p53. Mutation of *BAP1* (chromosome 3p21) is a tumor suppressor mutation present in 20–61% of mesotheliomas depending on the sequencing method. *CDKN2A* (chromosome 9p21) regulates the G_1 cell cycle progression by expressing $p16^{INK4A}$ and $p14^{ARF}$ proteins that suppress cyclin-dependent kinase 4/6 complexes (*CDK4*, *CDK6*). The loss of p14 protein is not unique to mesotheliomas. The *NF2* gene encodes the merlin protein that regulates multiple signaling pathways involved with cell proliferation (e.g., Hippo, hedgehog) and cell adhesion. Other less involved pathways include RAF/MEK-extracellular signal-regulated kinase and phosphoinositide-3 kinase (PI3K/AKT), mTOR, and Wnt.[279] *BAP1* gene encodes a nuclear deubiquitinase involved with chromatin remodeling, tumor suppression (*BARD1*, *BRCA1*-associated RING domain 1), and transcription regulation (*HCFC1*, host cell factor C1), which are important during cell proliferation, differentiation, and DNA damage repair. TP53 mutations are less frequent. Mutations in oncogenes (e.g., *BRAF*, *EGFR*, *KRAS*, *PIK3CA*) and mutations in the *TERT* promoter gene are infrequent, except for the latter in sarcomatoid mesothelioma.[280]

EXPOSURE

Substances causally associated with mesotheliomas include asbestos, natural nonasbestos fibers, and probably ionizing radiation. The monkey polyoma virus (simian virus 40, SV40) is an animal carcinogen associated with pericardial rodent mesotheliomas; however, epidemiological data are insufficient to support causality in humans. Simian virus 40 (SV40) is a member of small, double-stranded DNA polyoma viruses that were widely disseminated in Salk polio vaccines during the 1950s–1960s. Although up to 60% of human mesotheliomas contain SV40 DNA, the presence of SV40 infections is not associated with increased mesothelioma incidence.[281] The IARC lists S40 viruses as potential risk factors for mesotheliomas (limited human epidemiology evidence); however, the role of SV40 in mesothelioma pathogenesis remains unproven.[282] Although SV40 is a carcinogenic virus in experimental and animal models, evidence for an association between mesothelioma and SV40 infection in humans is limited. From 1956–1962, ~1/3 of the UK population received SV40-contaminated polio vaccine. A pathological study evaluated tumor and background lung tissue microarrays from archival surgical specimens of 127 pleural mesothelioma cases collected during 1998–2005 using a highly sensitive and specific SV40 Tag RNA *in situ* hybridization detection method.[283] These samples represented birth cohorts overlapping the period 1950–1960 during the administration of the contaminated vaccines. None of these tumors had evidence of SV40 infection, whereas the positive and negative controls were appropriately positive and negative, respectively.

The potential role of high-aspect-ratio nanoparticles (HARN) in the formation of mesotheliomas remains undefined.[284] Currently, no synthetic mineral fibers are causally linked to mesotheliomas; however, carbon nanotubes demonstrate similar shape and cytotoxicity as asbestos and produce malignant mesothelioma in some rodent studies.[285,286] Mesotheliomas are not related to smoking, presumably because tobacco carcinogens do not diffuse into the pleural or peritoneal mesothelium.[287]

Asbestos

Asbestos exposure is the major risk factor for malignant pleural mesothelioma, with ~80% of mesothelioma cases having an asbestos exposure history, typically with a long latency period (i.e., 30–50 years);[288] however, mesothelioma develops in a small minority of asbestos-exposed persons. A population-based study on 437 incident mesothelioma cases and 874 unexposed controls suggests a dose-response relationship between pleural mesothelioma and occupational asbestos exposure based on a retrospective asbestos exposure analysis by two blinded expert hygienists.[289] For men with an estimated cumulative asbestos exposure of <0.1 fibers/mL/year, the odds ratio for pleural mesothelioma was 4.0 (99% CI: 1.9–8.3, $n = 54$ exposed cases/181 unexposed control cases) compared with an OR of 67 (99% CI: 25.6–175.1, $n = 97$ exposed cases/27 control cases) for men, with an estimated cumulative asbestos exposure of >10 fibers/mL/year. The population-attributable risk of mesothelioma for any asbestos exposure was 87.3% (99% CI: 78.9–95.7%) for men and 64.8% (99% CI: 45.4–84.3%) for women. The wide confidence intervals suggest imprecise estimates.

Approximately 5–20% of mesothelioma patients have no self-reported history of asbestos exposure.[285] Over 9 years, a hospital-based case-control study enrolled 38 mesothelioma cases and 134 controls (65 with nonasbestos-related cancers, 69 medical controls); the expected number of mesothelioma cases was 50 over 3–4 years.[290] The mesothelioma risk was borderline statistically significantly elevated for no known reason but likely occupational asbestos exposure (OR = 3.1, 95% CI: 1.0–9.6). Exposure was based on an interviewer-administered questionnaire covering 47 substances; however, no specific substance or group of substances had a statistically significant association with mesothelioma as coded by an expert industrial hygienist blinded to the respondent's diagnosis. The risk of developing mesothelioma depends more on the time since asbestos exposure began than the dose (i.e., increased dose does not shorten the latency period); smoking is not a significant risk factor for mesothelioma or asbestos-induced tumors.[291,292] These tumors may occur in the absence of asbestosis.[293]

In a UK study of 622 mesothelioma patients (512 men, 110 women) and 1,420 population-based controls using unconditional logistic regression, the estimated excess mesothelioma risk attributed to domestic (nonoccupational) asbestos exposure to a high-risk asbestos worker before age 30 years was doubled in Britons born in the 1940s for men (OR = 2.1, 95% CI: 1.0–4.5, $n = 13$ cases/98 controls) and women (OR = 1.9, 95% CI: 1.1–3.2, $n = 37$ cases/86 controls). This excess risk corresponded to a lifetime mesothelioma risk of ~1/1,000.[294] Approximately 14% of 512 male and 62% of 110 female mesothelioma cases were attributed to neither occupational nor domestic asbestos exposures; the authors opined that these cases presumably resulted from ambient or unreported asbestos exposures, natural causes,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

or unknown factors. The study reported no increased risk in men or women living within 1 mile of a potential asbestos environmental hazard (shipyard, asbestos factory, power plant, disposal site) before 30 years of age; however, the risk was positive, statistically nonsignificant, and imprecise for living near a potential source for ≥20 years (OR = 3.3, 95% CI: 0.7–14.8, n = 3 cases/6 controls). No historical environmental measurements were available. In an analysis of the Italian National Register of Mesotheliomas, domestic (living with occupationally exposed asbestos worker) and environmental asbestos exposures (residence near an asbestos pollution source) accounted for 4.9% and 4.4% of the total mesothelioma cases, respectively.[295] Nonoccupational sources were asbestos cement plants, shipbuilding/repair, and soil contamination (i.e., Biancavilla area in Sicily). The Italian standardized incidence rates for pleural mesothelioma are 3.84/100,000 in men and 1.45/100,000 in women; ~93% of these cases occur in men.[296]

Classification

Asbestos is a commercial name defining a family of six natural silicate mineral fibers. These fibers are <3 μm thick and >5 μm long, with an aspect (length/diameter) ratio of >3. Noncommercial, non-asbestiform amphiboles include richterite, winchite, and tremolite. Mesothelioma potency depends on biopersistence, diameter, and length, with fibers <0.1 μm thick and >5 μm long being the most potent.[297]

Amphibole Asbestos

Although all asbestos types can cause mesotheliomas, these tumors are primarily associated with amphibole-type asbestos (e.g., crocidolite, amosite), with serpentine-induced mesotheliomas (i.e., chrysotile) much less frequent.[123] The carcinogenic potency required to produce mesotheliomas is significantly greater (~2–10-fold) for crocidolite than amosite or mixtures of amosite and chrysotile when comparing amphibole mining in South Africa and Australia with chrysotile mines and mills in Canada and Italy.[263,298] Based on tremolite-contaminated Quebec and Libby Mine data on crocidolite, amosite, and tremolite exposures, these amphiboles account for most mesothelioma cases, with tremolite contamination (typically <1%) accounting for some of the cases associated with chrysotile.[263] Substantial uncertainty surrounds estimates comparing chrysotile, amosite, and crocidolite asbestos potency producing pleural/peritoneal mesotheliomas. The 2000 Hodgson-Darnton model predicts a ratio of 1:100:500, respectively, based on the percent of all expected deaths caused by mesothelioma per fiber/cc/year following initial exposure at age 30 per unit of cumulative exposure (e.g., fiber/cc/year).[137] The relative potency of chrysotile/amosite/crocidolite was similar (1:83:376) in a 2018 update of the 2000 Hodgson-Darnton model by Garabrant and Pastula.[299] The potency of Libby fibers for mesothelioma was ~23-fold higher than chrysotile and 3.5-fold smaller than amosite. Talc and gold mining non-asbestiform elongate mineral particles were not associated with mesothelioma. Environmental amphibole asbestos exposures associated with the development of mesothelioma include whitewashing Greek houses with soft tremolite[300] and tilling crocidolite-containing soil by Chinese farmers.[301]

Serpentine (Chrysotile) Asbestos

Occupational chrysotile exposure does not consistently increase mesothelioma risks, with chrysotile fibers commonly used in mining and milling producing a much lower mesothelioma incidence than amphibole asbestos material commonly present in manufacturing and insulation industries.[302,303] A hospital-based, South African study of 119 mesothelioma cases and 103 medical controls did not identify any chrysotile-induced mesothelioma cases from occupational or environmental chrysotile exposures.[304] Although recently manufactured asbestos contains primarily chrysotile, *potential* exposure to these mesothelioma-producing minerals continues because substantial quantities of amphiboles remain in building insulation.[123] Workers installing and/or repairing car and truck brakes have potential asbestos exposure, primarily chrysotile asbestos; however, epidemiology studies do not provide significant support for increased mesothelioma risks in automotive friction product (i.e., brake) workers.[305,306]

Nonasbestos Fibers

Natural, elongated nonasbestos mineral particles associated with the occurrence of mesothelioma include erionite, fluoro-edenite, richterite, and winchite; the IARC considers erionite and fluoro-edenite as human carcinogens (Group 1) based on sufficient evidence in humans.[307,308] The true risk of developing mesothelioma is less well defined for the latter natural fibers than asbestos because of the extreme rarity of these tumors and the limited power/precision of applicable epidemiology studies. Although silica is not associated with elevated malignant mesothelioma risks, the effect of simultaneous exposure to asbestos and silica remains unclear.[270] There is no significant epidemiological evidence of an association in these studies between

mesothelioma and exposure to any man-made mineral fibers reflecting the relatively short biopersistence of these fibers compared with amphibole fibers.[309,310] Pure talc is not a recognized human carcinogen; however, some geological talc deposits may contain other silicates (e.g., tremolite, anthophyllite). Analysis of pooled data from four European cosmetic talc miner and miller cohorts totaling 113,344 person-years of observation did not support an association between cosmetic talc and pleural cancer/mesothelioma.[311] The study identified no incident cases of pleural cancer or mesothelioma (three cases expected) with a 79% power to detect a 3-fold increased incidence.

Erionite

Erionite is a fibrous form of the zeolite mineral group contaminated with tremolite asbestos that occurs in relatively high concentrations in volcanic rocks from certain Cappadocian villages in Turkey, central Mexico, and the western United States. The mesothelioma incidence in former villagers is elevated without occupational asbestos exposure.[285,312] In a prospective study of 891 residents of 2 exposed and 1 nearby control villages followed for 23 years, the standardized pleural mesothelioma mortality rate was 485 (95% CI: 395–590).[313] Mesotheliomas accounted for 119 of the 372 deaths (44.5%) in the exposed villages during the follow-up period compared with 2 deaths in the control village. Pleural and peritoneal mesotheliomas accounted for 86% and 14% of the mesothelioma-associated deaths, respectively.

Fluoro-edenite

Fluoro-edenite is a newly defined fibrous amphibole similar to actinolite-tremolite mineral species that exists in a volcanic area of the eastern Sicilian city of Biancavilla near Mt Etna;[314] exposure of the local population resulted from the use of material from stone quarries near Monte Calvario to pave roads and build houses. Examination of mortality data from this area demonstrated a geographical cluster of pleural mesothelioma cases.[315]

Ionizing Radiation

Occupational exposure to ionizing radiation occurs in aircrews, Chernobyl cleanup workforce, nuclear weapons test participants, nuclear industry workers, and underground hard-rock miners. The association between ionizing radiation and mesothelioma is strongest for exposures to α-particle emitting radiocontrast agents (i.e., Thorotrast exposure, 1930–1955) and local areas of skin irradiated by high doses of therapeutic radiation.[316]

Thorotrast

Thorotrast is an insoluble radionucleotide that is very poorly excreted after intravenous injection and diffusely distributed to most tissues including the pleural and peritoneal pleura. In the German Thorotrast study comprising 2,326 patients and 1,890 controls followed since 1968, mesotheliomas developed in 9 patients (5 pleural, 4 peritoneal) and no controls (RR not calculated).[317] In a Danish hospital-based study of 999 neurology patients administered Thorotrast for cerebral angiography in 1935–1947, the SMR for peritoneal mesothelioma was 11.54 (95% CI: 3.10–29.54, $n = 4$ cases/0 controls) and 4.05 (95% CI: 0.05–22.51, $n = 1$ case/1 controls) for pleural mesothelioma.[318] Subsequently, the authors reported two peritoneal and one pleural mesothelioma misclassified as other tumors.[319]

Therapeutic Radiation

Overall, epidemiological evidence is supportive of a causal link between therapeutic ionizing radiation and mesothelioma, including numerous case reports and comparisons with standardized incidence/mortality rates; however, poor statistical power from the low incidence of mesothelioma, potential misclassification from the nonuniform reporting of mesothelioma before the ICD-10 reclassified mesotheliomas into a separate category in 1999, long latency periods up to 40 years, and the confounding of asbestos limit firm conclusions, particularly for nuclear industry workers.[320] Although some studies show elevated peritoneal and pleural mesothelioma rates with wide confidence intervals following irradiation for Hodgkin lymphoma, non-Hodgkin lymphoma, and breast cancer,[321,322] several observational studies of therapeutically irradiated patients do not demonstrate statistically significant increases in these rates.[316,323] An analysis of data from the SEER database for mesothelioma incidence identified 21,881 patients with Hodgkin lymphoma (HL) and 101,001 patients with non-Hodgkin lymphoma (NHL). The SIR for mesothelioma in male HL patients with radiation exposure was statistically significant (SIR = 6.59, 95% CI: 1.79–16.87, $n = 4$ cases), but not in female HL patients with radiation exposure.[321] For male and female NHL survivors combined, the overall SIR was statistically significant (SIR = 2.24; 95% CI: 1.07–4.12, $n = 10$ cases); however, the SIR for mesothelioma was statistically nonsignificant in male (SIR = 1.91, 95% CI: 0.77–3.93, $n = 7$ cases) and female NHL patients

(SIR = 3.75, 95% CI: 0.77–10.95, $n = 3$ cases). The mean follow-up period was ~11 years for Hodgkin lymphoma (HL) and ~5 years for NHL. In a Dutch study of 2,567 five-year survivors of Hodgkin lymphoma, 13 developed mesotheliomas during a median follow-up of 18.1 years (SIR = 25.7, 95% CI: 13.7–44.0, $n = 13$ cases).[322] Among HL patients receiving radiotherapy, the SIR was 29.4, (95% CI: 15.7–50.4, $n = 13$).

Nuclear Industry Workers

Observational studies of nuclear industry workers exposed to relatively low ionizing radiation doses report fewer statistically significant associations with mesothelioma than patients receiving Thorotrast or local, high-dose therapeutic ionizing radiation. In a review of 17 relevant epidemiology studies on pleural mesothelioma risks among mostly nuclear industry workers, 15 reported mostly modest positive results; however, of the 12 studies containing a dose-response analysis, only 1 study reported a statistically significant association between the radiation dose and pleural mesothelioma.[324] This follow-up UK cohort study of 19,454 radiation and non-radiation exposed workers ever-employed at the Springfields uranium production facility from 1968–1995 examined pleural cancer incidence and mortality. Although there was no excess of pleural cancers (presumably mostly mesotheliomas) at Springfields ($SMR_{\text{radiation workers}} = 67$, $SMR_{\text{nonradiation workers}} = 0$), pleural cancer registrations displayed significant trend statistics (simulated $P \leq 0.033$) when the dose was lagged by 0, 2, 10, 15, and 20 years, respectively. However, the result depended on only one registration. The mean follow-up was 24.6 years. The 15-country retrospective cohort study of 407,391 nuclear industry workers monitored individuals for external radiation.[325] The estimated ERR/Sv was high, but statistically nonsignificant and imprecise (ERR/Sv = 5.28, 90% CI: <0–39.9, $n = 39$ deaths), with no significant trend with ionizing radiation dose ($P_{\text{trend}} = 0.45$); the relative risk of pleural cancer at 100 Sv cumulative dose was 1.53 based on a linear excess relative risk model. None of these studies adequately evaluated asbestos exposures.[320]

The Rocketdyne (Atomics International) mortality study evaluated mortality data on 46,970 workers employed from 1948–1999, including 5,801 radiation-exposed workers (2,232 monitored for radionuclide intake) and 41,169 workers engaged in nonradiation-associated activities.[326] The mean external radiation dose was 13.5 mSv (maximum 1 Sv), whereas the total mean lung dose was 19.0 mSv (maximum 3.6 Sv). The mean follow-up was 33.9 years. Radiation exposure was not associated with increased mesothelioma (pleural/peritoneal cancer) risks based on two deaths (SMR = 0.63, 95% CI: 0.08–2.29, $n = 2$ obs/3.2 exp) with no evidence of a dose-response ($P_{\text{trend}} = 0.33$). The US Mallinckrodt Chemical Works (uranium processing facility) study consists of 2,514 white male workers employed from 1942–1966 and followed through 2012 ($\text{Mean}_{\text{followup}} = 43.3$ years, $\text{Mean}_{\text{duration employment}} = 5.2$ years).[327] Organ/tissue-specific dose reconstruction of external and internal sources provided radiation exposure estimates. Assuming a dose-weighting factor of 1 for absorbed internal radiation doses, the mean lung dose was 27.1 mGy (maximum 416 mGy). The SMR for pleural and peritoneal cancer (presumably, mesothelioma) was 0.95 (95% CI: 0.11–3.41, $n = 2$ deaths). Small case numbers preclude definitive conclusions regarding associations with occupational radiation and mesothelioma risks, particularly with potential asbestos confounding.

HISTOLOGY

Mesotheliomas are very rare pleural (~70–80%), less commonly peritoneal (10–20%), and rarely pericardial and scrotal/tunica vaginalis (<5%) tumors that arise from the neoplastic transformation of multipotential, self-renewing mesothelial cells.[328] The pleura is a 5-layer covering of the thoracic cavity with a single layer of mesothelial cells involved with inflammatory reactions and phagocytosis. Pleural mesotheliomas arise in the lining of the pleura from malignant transformation of mesothelial cells as a result of constant inflammation from asbestos fibers and the subsequent formation of reactive oxygen species, attraction of macrophages, and direct interference with mitotic spindles.[329] Inhaled fibers enter the parietal pleura retrogradely through the lymphatics or pass through the alveoli, visceral pleura, and pleural space to the parietal pleura.[330]

The 2015 World Health Organization classification of tumors did not change mesothelioma subtypes from the 2004 WHO classification. Epithelial mesothelioma consisting of cuboidal cells is the most common histological subtype of mesotheliomas (50–60%), whereas sarcomatous mesothelioma with spindle-like cells (10–20%) and biphasic (mixed) subtypes (25–35%) are less common.[331] Desmoplastic forms are rare (1–2%). Epithelial tumors contain large spherical cells that form solid masses and columns in local lymphatics and may resemble adenocarcinomas, whereas sarcomatoid tumors consist of ovoid-to-spindle-shaped cells resembling fibrosarcomas that arise in deep connective tissue. The main differential diagnosis for epithelioid mesothelioma

is metastatic carcinoma, particularly adenocarcinoma. Although pleural plaques occur in parietal pleura and are strongly associated with asbestos exposure, the presence of pleural plaques as an independent risk factor for malignant mesothelioma remains controversial. A French 7-year follow-up study of 5,287 male participants with chest CT scan suggest an elevated mesothelioma risk in subjects with pleural plaques (adjusted HR = 6.8, 95% CI: 2.2–21.4, n = 17);[332] however, the large confidence interval indicates an imprecise measure of risk. Next-generation sequencing and cytogenic studies indicate mesotheliomas contain massive genomic damage with highly complex and variable chromosomal aberrations; no polymorphisms in a single gene or signature of genes reproducibly occurs in most mesotheliomas using current technology.[333]

HOST SUSCEPTIBILITY

Mesotheliomas develop in a minority of asbestos-exposed individuals. The relatively low occurrence (i.e., 5–10%) of mesothelioma following prolonged asbestos exposure and the linkage of certain families with elevated mesothelioma risks suggest the existence of some recessive genetic susceptibility; however, the specific proportion attributable to genetic susceptibility is difficult to estimate because of the strong confounding effects and ubiquity of asbestos exposure in familial cases.[334,335] Although germline BAP1 mutations commonly occur in familial mesotheliomas, germline BAP1 mutations in sporadic mesotheliomas are infrequent. In a study of germline BAP1 mutation status of 150 mesothelioma patients with a family history of cancer, 50 asbestos-exposed control individuals with a family history of cancers other than mesothelioma, and 153 asbestos-exposed individuals without familial cancer, 9 (6% of 150) mesothelioma cases with a family history of cancer had BAP1 alterations compared with none of the controls.[336] Five of the nine cases were peritoneal mesotheliomas. BAP1 mutation carriers developed mesothelioma at an earlier age, but long-term survival was higher in carriers than noncarriers.

Turkish pedigree and mineralogical studies indicate malignant mesothelioma occurs following erionite exposure in genetically predisposed individuals,[337] whereas a study of former workers and residents exposed to crocidolite at Wittenoom, Western Australia, demonstrated a modestly increased risk ratio for mesothelioma in blood relatives of 1.9 (95% CI: 1.3–2.9, P = 0.002).[338] However, a genome-wide association study for malignant mesothelioma risk did not demonstrate consistent genetic abnormalities between Australian cases (*SDK1*, *CRTAM*, *RAS-GRF2* genes, 2p12 chromosome) and Italian/Japanese studies (tumor suppressor gene *BAP1*, *BRCA1*-associated protein 1).[339] The *BAP1* gene (chromosome 3p21) expresses a nuclear protein (BAP1) involved in transcriptional and chromatin regulation along with multiple pathways that regulate cell cycle checkpoints, cell differentiation, and apoptosis.[340] Approximately 30–60% of mesotheliomas contain loss or deletion of regions in chromosome 3p21. Subsequent studies of families with malignant mesothelioma syndrome suggest the occurrence of this tumor involves genes other than *BAP1* (e.g., DNA repair genes).[341,342] Oncogene mutations are infrequent in malignant pleural mesotheliomas. A Turkish study of 142 consecutive cases of histopathologically confirmed malignant pleural mesothelioma associated with almost exclusively environmental asbestos exposure did not detect a relationship between asbestos fiber type and age or exposure period; 5 of 131 (3.8%) patients had a family history of mesothelioma.[343] The study did not separate erionite from asbestos exposure.

Children may be particularly susceptible to developing mesotheliomas. In a study of Western Australian adults exposed to crocidolite asbestos before the age of 15 years, the standardized incidence ratio of mesothelioma was very substantially elevated among men (SIR = 44.54, 95% CI: 29.83–63.98) and women (SIR = 70.05, 95% CI: 36.20–122.37) compared with the general population.[344]

CLINICAL FEATURES

Pleural mesotheliomas account for most mesothelioma cases, with peritoneal mesotheliomas occurring in most other mesothelioma cases.[345] In most epidemiological studies, mesothelioma develops more commonly in men than women, except in occupations dominated by women.[346] The mean latency period between the initial asbestos exposure and death typically averages ~35–45 years, with a range of 20–60 years. In a study of 557 Italian patients with the diagnosis of malignant mesothelioma, the latency period between first asbestos exposure and death ranged from 14–75 years with a mean of ~49 years.[347] Clinically apparent mesothelioma is rare before 45 years of age, with diagnosis of mesothelioma in this age group representing 2.4% of total cases in the Italian National Register of Mesotheliomas.[296] In a case series of 614 UK asbestos workers dying of mesothelioma between 1978 and 2005, the median latency defined as the time between first occupational asbestos exposure and mesothelioma-induced death was
