MEDICAL TOXICOLOGY OF OCCUPATIONAL AND ENVIRONMENTAL EXPOSURES

Volume 1

Metals and Metalloids: Clinical Assessment, Diagnostic Tests, and Therapeutics

DONALD G. BARCELOUX, MD, FAACT, FACMT, FACEP

Consultant, Medical Toxicology
Donald G. Barceloux, M.D., Inc.

Emeritus Physician
Department of Emergency Medicine
Pomona Valley Hospital Medical Center
Pomona, California

Emeritus Partner, Vituity
Emeryville, California

Clinical Professor of Medicine, 2002–2023
Department of Emergency Medicine
Olive View/University of California at Los Angeles Medical Center
Sylmar, California

Edited by

ROBERT B. PALMER, PhD, DABAT, FAACT

Rocky Mountain Poison and Drug Safety
Denver, Colorado

Section of Medical Toxicology
Department of Emergency Medicine
University of Colorado School of Medicine
Aurora, Colorado

Toxicology Associates, PLLC
Littleton, Colorado

To My Wife, Kimberly,
Fifty years ago, a chance meeting in the Rome Train Station led to a life full of love, companionship, and a conversation that has continued through all these years. Your counsel and support made all the difference and life worthwhile.

To my adult children (Colin and Shannon) and their spouses (Taylor and Michael),
I am proud of your accomplishments, compassion, resilience, and the knowledge the world is a better place because of your presence.

Donald G. Barceloux, MD

To My Wife, Karen,
We intended to try to benefit the professional organizations through those endless committee and board meetings. Little did I know I would be the true beneficiary. Your love, kindness, and friendship, not to mention sage counsel, far exceed anything I could have ever hoped for.

To my daughter Abigail, who knows far more about metals chemistry than I ever will, and her husband, Michael. Your accomplishments are immense. But the real joy is the two of you falling for one another – beginning far too literally with a skydiving adventure.

FOREWORD

The multivolume *Medical Toxicology of Occupational and Environmental Exposures* covering metals, radiation, and cancer is the eagerly awaited third instalment in the seminal series of medical toxicology textbooks written by Dr. Donald G. Barceloux. The first two books focused on natural substances and drugs of abuse, respectively, and have quickly established themselves as reference works in their respective fields. The comprehensive coverage of topics coupled with a consistent and easy-to-follow organization of content have made them indispensable companions of physicians and researchers alike. The newest addition to the series, created by Dr. Barceloux and edited by Dr. Robert B. Palmer, is a worthy successor to the first two books. Once again, the focus is on naturally occurring and man-made toxic threats that all medical toxicologists will have heard of but few will have had first-hand experience with. This is precisely what makes this work so valuable.

The first volume literally comprises an A–Z of all there is to know about the clinical toxicology of metals and metalloids, from aluminum to zirconium. The 36 chapters naturally include well-known toxic metals such as arsenic, cadmium, lead, and mercury on which there is a wealth of clinical and monitoring data available. Summarizing and organizing this information makes these chapters almost textbooks in their own right, covering their subjects in a breadth and depth rarely seen in other publications. This is exemplified by the chapter on arsenic which not only covers the well-known toxic inorganic arsenicals but also includes sections on gallium arsenide, organic arsenic, and arsine gas. Even chapters on metals that are rarely encountered in clinical practice offer a wealth of information, e.g. the chapter on beryllium boasts 167 references. And who would know where to look for information on the toxicokinetics of rare earths, or whether tellurium is a human teratogen? It is the attention to this kind of detail that sets *Medical Toxicology of Occupational and Environmental Exposures: Metals and Metalloids* apart.

In contrast to standard textbooks on clinical toxicology, *Medical Toxicology of Occupational and Environmental Exposures: Metals and Metalloids* is not only aimed at those working in the treatment of the poisoned patient. As the most comprehensive source of information in its field, it will equally be an invaluable reference for occupational physicians and hygienists as well as scientists and researchers in environmental health disciplines. Indeed, anyone concerned with the human health risk assessment and risk management of exposure to metals and metalloids, whether they work in regulatory agencies, industry, or universities, will benefit from this truly interdisciplinary work that will stand the test of time.

PREFACE

This volume, *Metals and Metalloids*, in the multivolume *Medical Toxicology of Occupational and Environmental Exposures* is a continuation of the *Medical Toxicology Series* that began with *Medical Toxicology of Natural Substances: Foods, Fungi, Medicinal Herbs, Plants, and Venomous Animals* and *Medical Toxicology of Drug Abuse: Synthesized Chemicals and Psychoactive Plants*. The *Medical Toxicology Series* provides in-depth, evidence-based coverage of the most important human toxins. Similar to the rest of the *Medical Toxicology Series*, the goal of this volume is the creation of a comprehensive and convenient reference to answer questions regarding medical toxicology issues. The volume on *Metals and Metalloids* presents the basic and clinical science associated with exposure to these elements and their compounds.

The reader will recognize the similarities of the template in this volume with the template in previous books in the *Medical Toxicology Series*. This organizational consistency allows easy location of the appropriate information necessary for decisions regarding properties, sources, effects, regulation, and management of toxic exposures to metals and metalloids. General section headings include history, identifying information, physical characteristics, exposure, environmental fate, dose effect, toxicokinetics, histopathology, clinical response, diagnostic testing, health surveillance, and treatment.

Medical toxicology is a field often dependent on relatively weak scientific evidence (case reports, case series, retrospective analyses), resulting in the increased risk of perpetuating equivocal treatment regimens and even folklore. This volume provides the relevant evidence base to determine the clinical consequences, treatment, and safety measures important for the reduction of injury from excessive exposures to metals and metalloids. References are documented to validate the information and provide sources for further inquiry. Although this unique volume provides a medical toxicologist's perspective for exposures to metals and metalloids, the coverage contains input from a variety of disciplines including other clinical specialties, public health physicians, and research scientists. Since guidelines and regulations change with time, the organizations' websites should be consulted for any updates of specific guidelines and regulations.

The choice of topics in this volume reflects our desire to expand communication between medical toxicologists and practitioners in related fields. Our hope remains that this interdisciplinary, evidence-based approach will increase communication between traditional clinical settings and fields aligned with medical toxicology including those in laboratories, academic settings, and regulatory agencies. We anticipate this approach will encourage more inquiry into the pathophysiology, clinical effects, biomarkers, treatment, and prevention of illnesses related to metal and metalloid exposures.

ACKNOWLEDGMENTS

I thank the following colleagues for their contributions to the quality, depth, and accuracy of *Medical Toxicology of Occupational and Environmental Exposures: Metals and Metalloids*.

John Wiley & Sons' Staff

Dr. Andreas Sendtko, Senior Managing Editor, Physical Sciences Books, whose dedication and patient guidance guaranteed the accuracy of the printing process and the quality of these books.

Bob Esposito, former Senior Editor, made our Medical Toxicology Book Series a reality by believing in the importance of a highly detailed, structured series covering the expanding field of Medical Toxicology.

Jeyabalan Jeyaraj and Jananee Sekar did an outstanding job of copyediting.

Summers Scholl, Executive Editor, was instrumental in bringing the Medical Toxicology Series to our audience.

Pomona Valley Hospital Medical Center

I admire the dedication and perseverance of the physicians, nurses, and the Emergency Department staff in times complicated by COVID-19, difficult medical problems, and complex social issues. In particular, I appreciate the support of the physician staff including Howard Friedman; Ivan Schatz; Richard Dorosh; Ken Nakamoto, past Vice President of Medical Affairs; Ken Moore, former Medical Director Emergency Department; and James Kim, Medical Director, Emergency Department.

UCLA Emergency Department Colleagues

I appreciate all our colleagues who shared their expertise and clinical experience at UCLA Conferences, especially Gregory W. Hendey, MD, Department Chair; Steven Lai, MD, Assistant Program Director, Olive View-UCLA; Richelle J. Cooper, MD, UCLA Emergency Department Research Director; Lynne B. McCullough, MD, UCLA ED Medical Director; Pamela Dyne, MD, Associate Program Director, Olive View-UCLA; Michael Levine, MD, Toxicology; Cynthia Koh, MD; Eric A. Savitsky, MD; Luis Lovato, MD, Informatics; and Matthew Waxman, MD.

UCLA Librarians

Writing a book series is not possible without the support of the UCLA Biomedical Library, especially Juan Jaime, Access Services Manager, UCLA Science Libraries.

DONALD G. BARCELOUX, MD

Chapter 1

ALUMINUM

HISTORY

Although the identification of aluminum as a metal occurred in 1827, the Romans used alum (hydrated aluminum sulfate) for the purification of water and the preparation and staining of hides.[1] In Europe, the commercial production of aluminum as a metallic pigment began shortly after the development of the Hall–Heroult electrolytic process in 1886. This process became the major industrial process for smelting aluminum by dissolving aluminum oxide (alumina from bauxite ore) in molten cryolite and electrolyzing the molten salt bath.[2] The first reported case associating aluminum toxicity with memory loss, ataxia, tremor, and muscle tics occurred in 1921.[3] Massive exposure to finely divided pyrotechnical aluminum flake powders during World War II in Germany caused fibrotic lung disease (aluminosis); ~20 years later, McLaughlin et al. reported the case of a ball mill operator with an occupational exposure to aluminum and aluminum oxide (Al_2O_3) during the production of flake powders; he presented with pulmonary fibrosis and encephalopathy (poor memory, speech disorder, myoclonic jerks, convulsion, focal weakness).[4]

In the middle of the 20th century (1944–1979), aluminum powder (e.g., McIntyre powder) was released in mines as a prophylactic agent to coat silica particles and prevent silicon-induced fibrotic reactions. Mortality studies of Australian cohorts exposed to aluminum dust prophylactically did not support the effectiveness of aluminum as a protective agent for silicosis.[5] This study suggested the possibility of increased risk of cardiovascular disease and Alzheimer's disease in the exposed cohort; however, the increase was small (SMR = 1.38) and not statistically significant with wide confidence intervals. An analysis of postmortem aluminum concentrations suggested pulmonary aluminum concentrations were similar in eight workers receiving McIntyre Powder and occupationally exposed workers.[6] The medical use of aluminum increased significantly in the 1950s when aluminum was prescribed as a phosphate binder to patients with chronic renal failure. By 1972, Alfrey et al. recognized an encephalopathy in patients on dialysis characterized by progressive dementia, myoclonus, facial grimacing, diffuse pain, and seizures.[7] This epidemic of dialysis dementia vanished when excess aluminum was eliminated from the dialysate.[8] In the early 1980s, a syndrome of encephalopathy, metabolic bone disease, and microcytic anemia occurred in dialysis-dependent children receiving aluminum-containing antacids.[9] Calcium carbonate gradually replaced aluminum-containing antacids in patients with chronic renal failure because of the lack of toxicity and the superior binding of calcium carbonate to phosphates compared with aluminum.[10] Parenteral solutions (e.g., total parenteral nutrition) were recognized as sources of aluminum loading, particularly in children; in 1990, the US FDA recommended that the aluminum concentration of these solutions not exceed 25 μg/L followed in 2004 by a daily recommended intake of 5 μg/kg.

PHYSIOCHEMICAL PROPERTIES

Aluminum is the third most abundant element in the earth's crust after oxygen and silicon, comprising about

8% of the earth's crust and belonging to Group 13 (Group IIIa) along with boron, gallium, indium, and thallium.[11] Most aluminum compounds are solids with high melting points. Pure aluminum is a light, malleable, silvery-white metal that easily conducts both heat and electricity; however, the high reactivity of aluminum limits the existence of the metallic state in the earth's crust. The only natural oxidation state of aluminum is Al^{3+} with an ionic radius and chemical behavior similar to Fe^{3+}. Because aluminum has a small radius and an avid affinity for oxygen, this metal exists almost exclusively as aluminum oxides (bauxite) or aluminosilicate compounds (clays, feldspars, and micas). The resistance of aluminum to corrosion results from the rapid formation of aluminum oxide following exposure to oxygen, water, or other oxidants.

The pH determines the solubility of aluminum compounds; therefore, the physiological milieu strongly affects the affinity of Al^{3+} for hydroxide ions and the subsequent precipitation of the complex. Only small amounts of free aluminum exist in solutions within pH 6.5–7.4. Aluminum salts of chloride, nitrate, and sulfate are water-soluble, whereas metallic aluminum, aluminum oxide, and other aluminum salts (hydroxide, phosphate, silicate) are very poorly water-soluble. Aluminum hydroxides and aluminum phosphates are some of the least soluble aluminum salts, but both compounds contribute to aluminum exposure.[12] Aluminum oxide nanoparticles (<100 μm) more easily diffuse across biological membranes than larger particles.[13] At pH 7.0, the solubility of aluminum hydroxide and aluminum sulfate is limited (2.5 mg/L);[14] however, the solubility of aluminum salts increases as the pH deviates from neutral. Aluminum hydroxide binds hydrogen ions in an acid medium, whereas aluminum hydroxide releases hydrogen ions in an alkaline medium. In acidic aqueous conditions of the stomach (i.e., pH 2), aluminum occurs primarily as a monomolecular hexahydrate, $Al(H_2O)_6$, which is the "free" form of Al^{3+}. As pH increases to near-neutral conditions in the intestines, the insoluble precipitate (aluminum hydroxide, $Al(OH)_3$) forms. Table 1.1 lists the physical properties and identifying information of aluminum and common aluminum salts.

EXPOSURE

Commercial Processes

Aluminum exists naturally in bauxite, cryolite, feldspars, micas, and silicates. The major source of commercial aluminum is bauxite; this mineral contains aluminum hydroxide, silica, ferrous oxide, and smaller amounts of cryolite (Na_3AlF_6). The production of this metal via electrolytic reduction of the raw material involves the following: 1) the refining of bauxite (Bayer Process) under high temperature, pressure, and strong caustic solution to form alumina (aluminum oxide), 2) the electrolytic reduction of the hydrate by the Hall–Heroult process to produce aluminum in the reduction cells (pots), and 3) the casting of aluminum into ingots. During this chemical process, the aluminum leaches from the bauxite as sediment containing aluminum oxide (alumina). During the electrolysis of molten cryolite, the electrothermal process produces pure aluminum that precipitates on carbon cathodes in the furnace of a carbon-lined steel reservoir. Typically, ~200 pots are arranged in potlines within buildings called pot-rooms. Prebake technology has gradually replaced the older Søderberg pots, resulting in more efficient hooding, improved fume extraction, and reduced exposure to a variety of dust, fumes, and gases. Potential exposures to chemicals during the electrolysis of aluminum include tar oils, polyaromatic hydrocarbons (3,4-benzo(*a*)pyrene),[15] carbon monoxide, sulfur dioxide, and airborne fluorides (F^-, HF, sodium aluminum tetrafluoride).[16] In a study of 17,089 aluminum smelter workers followed from 1950–2004, the incidence of lung, bladder, and buccal cancer increased significantly ($P < 0.001$) with exposure to benzo(a)pyrene.[17]

Uses

Aluminum is an extremely versatile metal with myriad of uses as a structural material in the manufacture of food containers, insulating materials, automobile and airplane manufacturing, machinery, electrical products, and cooking utensils. Because pure aluminum lacks strength, most aluminum used in metallurgy involves the production of aluminum-based alloy castings and wrought aluminum products. The wire form of aluminum is used in welding, whereas the powder form is a constituent of paints, pyrotechnic flakes, and solid rocket propellants. Other applications for aluminum compounds include the following: antacids (hydroxide, phosphate), deodorants (chloride hexahydrate, hydroxide, phosphate, carbonate, silicate), abrasives (trioxide), petroleum cracking (anhydrous chloride), water purification (sulfate, alums), leavening agent (acidic sodium phosphate), grain fumigant (aluminum phosphide), emulsifying agent (basic sodium phosphate), acidifying agent (sulfate), anti-caking agent

(silicate), color additives (aluminum lakes), the brewing and paper industry (bentonite, zeolite), the catalyst for the manufacture of rubber and wood preservatives (chloride), glass and ceramic production (borate), soap and paint industry, and food processing. Alum is a series of double sulfate salts of monovalent cations (i.e., principally aluminum, potassium, other aluminum sulfates) used to reduce the turbidity of drinking water. The sulfate of aluminum dissolves in water to form aluminum hydroxide, resulting in precipitation along with suspended organic matter. Aluminum chloride ($AlCl_3$) is a skin and mucous membrane irritant used as a fine powder in the petroleum cracking and polyisoprene production industries. Military applications have the greatest potential for aluminum nanoparticles, particularly coatings, fuels, and propellants.

Sources

The primary sources of exposure to this common metal for the general population are natural rather than anthropogenic processes.[11] In the environment,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

aluminum is always found in combination with other elements (aluminosilicates, oxides, hydroxides). Exposure to Al occurs daily, primarily via food (<10 mg) and drinking water (<1 mg).[18] The inhalation of airborne dust particles provides a much smaller contribution to the daily intake of Al (<0.1 mg/day). Potential sources of relative higher Al exposure for the general population include the use of aluminum-containing consumer products (e.g., antiperspirants, antacids, cosmetics). Exposure of the general population to anthropogenic sources of aluminum is primarily indirect. These sources include increasing dissolution of aluminum in the soil as a result of acidification from acid rain and enhanced wind and water erosion from cultivated land.[19]

Air

Aluminum exists in air primarily as aluminosilicates associated with particulate matter. The primary source of aluminum in the atmosphere is dust from the erosion of ores and rock material on the surface of the earth as well as volcanic activity. Only ~13% of the aluminum present in the atmosphere is released from anthropogenic sources with the major contributors being aluminum smelting, coal combustion, and commercial production of fuel and ores.[20] In urban environments, vehicle exhaust accounts for ~1–9% of the aluminum released into the ambient air.[21] Aluminum concentrations in urban air range from 0.4–10 ng/m^3 compared with background levels of 0.005–0.18 ng/m^3 in rural areas.[22,23] Aluminum concentrations in ambient air samples from aluminum plants are several orders of magnitude higher than in typical urban settings. In a study of 235 workers employed at 15 US plants producing various aluminum products, the median concentration of respirable and total aluminum in personal breathing samples was 25 μg/m^3 and 100 μg/m^3, respectively.[24] The percentage of particles deposited in the lungs depends on particle size; typically, about 20% of particles in the range of 0.1–0.3 μm are deposited in the alveolar region. In contrast to sparingly soluble Al particles, hygroscopic water-soluble Al salts may increase in size in the humid environment of the respiratory tract, thereby decreasing the deposition of inhaled Al particulates in the alveolar region. Higher ambient Al concentrations may occur during aluminum smelting (mean = 310 μg/m^3, range 40–900 μg/m^3 in 7 UK secondary smelters),[25] metal inert-gas (MIG) welding of aluminum cylinders (2,900 μg/m^3),[26] plants producing large flakes of pyrotechnical Al powder (5,000–21,000 μg/m^3),[27] and corundum (aluminum oxide) processing (1,600–7,400 μm^3).[28] Experimental studies suggest that fumes from MIG welding of aluminum may contain ozone up to 250 μg/m^3, potentially affecting lung function.[29]

Soil

The content of aluminum in the soil varies widely in different locations as a result of several factors (e.g., pH, volcanic activity). Aluminum is the third most abundant element with soil concentrations ranging from 700–100,000 mg/kg.[30] The aluminum concentration in urban street dust ranges from 3.7–11.6 μg/kg.[19] Most Al resides in bauxite rocks (hydrous aluminum oxides) or soil as insoluble Al silicates (e.g., feldspars, micas). Aluminum in the soil complexes with sodium and fluoride (cryolite). Weathering results in the formation of aluminum hydroxide.

Water

Although aluminum is ubiquitous in natural waters, the Al concentration in surface water is usually low (<0.1 mg Al/L) because aluminum solubility is very low in water with a pH >5.5. High humic acid content and acid precipitation increase aluminum content of groundwater. Ash from volcanic eruptions (e.g., Mt. Saint Helens) may increase Al concentrations in water up to 1 mg/L.[31] Aluminum concentrations in the ocean are much lower (i.e., <0.001 mg/L) than in lakes or streams.

High aluminum concentrations develop only when the pH is <5; this situation is unusual because the pH of naturally occurring water typically ranges from 6–9.[30] The median aluminum concentration in drinking water is highly variable ranging up to ~1 ppm.[32] Higher Al concentrations occur in water from treatment facilities using aluminum sulfate (alum) as a flocculent. In a study of US drinking water samples, the median Al concentration from facilities using alum was 0.224 mg/L compared with 0.043 mg/L for water samples that did not contain alum as a flocculent.[32]

Diet

Aluminum Intake

The primary (i.e., ~90–95%) source of aluminum for the general population is food, particularly food additives (e.g., acidifiers, buffers, emulsifiers, anti-caking agents, leavening agents, stabilizers, thickeners) in grain products, salt, and processed cheese.[33] Most adults ingest <15–24 mg of Al daily with ~1–10 mg derived from natural sources. Aluminum-containing medication and food additives account for ~5–7 mg.[19,34] The mean daily intake of Al from food in Bombay, India, was

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

~6 mg with the total daily intake from inhalation and ingestion ranging ~2–12 mg.[35] The poor absorption of aluminum from the gastrointestinal tract limits daily Al absorption to ~0.3–0.5% of the daily intake.[36] Drinking water accounts for the small amount of the remaining Al exposure because the bioavailability of Al in drinking water is low (<1%).[37] Drinking water typically contributes <1–5% of the total daily Al intake by the general population.[38,39]

Foodstuffs

Aluminum (metallic aluminum, aluminum sulfate, sodium aluminum phosphate) is an approved food additive in the United States and the United Kingdom. Aluminum sodium silicate helps smooth icing on cakes in concentrations up to 1.5%.[40] These aluminum additives are more important sources of aluminum intake in the United States than in Europe.[33] Aluminum occurs naturally in tea and some vegetables. Sources of aluminum in food include processed cheese, cornbread, bay, herbs, spices, tea, some soy-based milk products, baking powder (prepared cake mixes), pancake mixes, self-rising flour, and pickled vegetables.[41] In a study of German foods, the order of increasing aluminum content was as follows: beverages, food of animal origin, and food of plant origin.[42] Table 1.2 lists the aluminum concentrations of some selected foods.

The aluminum content of beverages from aluminum cans is generally higher (noncola drinks, 33.4 μmol/L; cola drinks, 24.4 μmol/L) than that of beverages from bottles (5.6–8.9 μmol/L).[43] Both pH and container type influence the aluminum content in beverages with a pH of about 3.8 being the optimum pH for the transfer of Al from the container to the liquid. The aluminum content in a survey of beer containers was greatest in draft beer and least in beer bottles.[44] Dietary citric acid increases the absorption of oral aluminum loads (e.g., antacids) as a result of the formation of the more soluble Al-citrate complexes.[45] Because aluminum is abundant in the soil, some foods (e.g., carrots) may contain high Al concentrations (1,520–4,050 μg/100 g).[46]

Containers and Heating

Although cooking acidic food (tomatoes) in uncoated aluminum utensils or placing acidic food (vinegar, fruit

TABLE 1.2. Estimated aluminum concentration in selected foods. (Adapted from Soni et al.).[11]

Food Type	Aluminum Concentration (mg/100 g)	Food Type	Aluminum Concentration (mg/100 g)
Animal Products		*Vegetables*

juice, lemons) in aluminum containers can increase the amount of aluminum in the food, the increase does not usually appear sufficient to cause adverse effects.[47,48] Cooking in aluminum containers causes a statistically significant increase in the Al content of some foods; cooking rhubarb in an aluminum saucepan increased the aluminum content in the meal from 0.1–25 mg.[23] A Swedish cross-sectional study suggested the use of aluminum utensils add 2 mg daily Al intake.[49] The mean Al intake from the diets of 105 Swedish women was 13 mg (range, 1.2–99 mg) compared with 7.8 mg (range, 1.2–24 mg) in 41 diets with little or no use of aluminum. In a study of Belgian adults, the estimated contribution of kitchenware to the diet was 7-fold less than that of food based on leaching models for food contact materials and surface area determined by in-house validation surveys.[50] A case report associated the chronic injection of an oral methadone solution heated in an aluminum pot with Al toxicity (admission Al = 180 μg/L) in an intravenous methadone addict with mild to moderate renal failure.[51] The symptoms of aluminum toxicity (seizures, ataxia, dysarthria, cognitive decline) occurred after ~3–4 years of regular intravenous injections; determination of causation is limited by the use of multiple drugs of abuse. Rarely, a delayed, toxic (spongiform) leukoencephalopathy manifested by apathy, cerebellar signs, confusion develops after inhalation of pyrolysates from heating heroin on aluminum foil ("chasing the dragon"). A 46-year-old woman with heroin dependence presented with acute behavioral changes and MRI images consistent with toxic encephalopathy.[52] Later, she developed difficulty making decisions (abulia), catatonia, and akinetic mutism before recovering.

Infant Formula

In general, the aluminum content of human breast milk and cow milk is very low (<0.05 mg/L).[53] Risks of aluminum toxicity are documented only for infants with renal failure exposed to high aluminum concentrations from drugs or dialysate fluid and preterm infants receiving high Al-containing parenteral nutrition.[54] The mean aluminum concentration in breast milk in one study was 49 μg/L, whereas the Al concentration of most baby formulas is <500 μg/L.[55] The aluminum concentration is ~10–20-fold higher in cow milk and ~100-fold greater in soy-based formulas than breast milk.[56] A study of seven infants with renal failure suggests that low-phosphorous infant formula produces no greater risk of aluminum toxicity than ingestion of a regular diet.[57]

Medical Therapy

Antacids

The use of maximum recommended daily doses of aluminum hydroxide-containing antacids substantially increases the daily aluminum intake up to 5 g.[58] Aluminum hydroxide antacids contain ~32 g Al/L. Under normal circumstances, poor absorption prevents aluminum toxicity; however, aluminum encephalopathy has occurred in uremic patients given large amounts of aluminum-containing antacids.[9] The administration of citrate in the form of calcium salts,[59] effervescent analgesic tablets,[60] or Shohl's solution[61] markedly increases aluminum absorption; the co-administration of citrate and aluminum-containing antacids may produce aluminum encephalopathy in dialysis patients.

Sucralfate

Sucralfate is a basic aluminum salt that contains 21% aluminum by weight. The bioavailability of aluminum in sucralfate increases at low pH, but aluminum absorption of this product in patients with normal renal function is not clinically significant.[62] A 21-day course of 4 g sucralfate daily significantly increased the serum aluminum level in 6 patients with chronic renal failure to 0.83 ± 0.48 μmol/L compared with patients without renal failure (0.24 ± 0.17 μmol/L).[63] Case studies suggest that the administration of sucralfate to patients with renal failure may produce an aluminum encephalopathy.[64,65]

Intravenous Solutions

Increased aluminum and osteomalacia may occur in patients receiving long-term total parenteral nutrition (TPN), even in patients with normal renal function.[66] The replacement of casein with amino acids substantially reduced the stainable aluminum on the surface of mineralized bone.[67] Infusions of purified albumin during plasmapheresis may increase plasma aluminum concentrations 5-fold,[68] although the clinical significance of this exposure to aluminum remains unclear. An acute encephalopathy developed in patients with renal dysfunction after the administration of intravesical irrigations of alum (ammonium aluminum sulfate) for severe urinary hemorrhage.[69,70,71,72]

Dialysis Fluid

Significant amounts of aluminum may diffuse across the dialysis membrane with plasma Al concentrations >10 μg/L potentially occurring during hemodialysis.[73] Because aluminum binds to nondialyzable plasma

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

constituents, little aluminum typically passes into the dialysate.[74] Consequently, aluminum accumulates in the plasma of dialysis patients during hemodialysis. Techniques (e.g., reverse osmosis, deionization) almost eliminate aluminum from the dialysate.

ENVIRONMENTAL FATE

As an element, Al does not degrade in the environment. This element is highly reactive; consequently, aluminum does not exist as a free metal in nature.[23] Aluminum enters the air from the erosion of soil and combustion of coal, primarily as aluminosilicates associated with particulate matter. Transport of aluminum to soil occurs primarily through the deposition from the atmosphere. Aluminum exists naturally only in the trivalent oxidation state. Consequently, the fate of aluminum in the soil and water depends upon the chemical interactions of anions and water as well as the physical characteristics of the local environment (underlying geological materials, hydrological flow paths, soil–water interactions).[19] The presence of high concentrations of dissolved organic matter (i.e., fulvic acid) increases the amount of dissolved aluminum in streams and lakes. At pH >5.5, aluminum exists predominately in the undissolved form (i.e., gibbsite (aluminum hydroxide) and aluminosilicates). The mobility of Al in the soil increases as the pH decreases. Adsorption of Al into clay may limit mobility. Bioconcentration of Al in plants is limited, although Al uptake increases in a few plants (e.g., tea) grown on acidic soil. Because of the toxicity of aluminum to aquatic animals, Al does not bioaccumulate in the food chain.[23]

DOSE EFFECT

Because absorption of aluminum from the gastrointestinal tract is poor and aluminum excretion is rapid, the ingestion of aluminum compounds seldom produces toxicity unless renal dysfunction causes the accumulation of aluminum in the body. Healthy individuals on normal diets sustain little risk of aluminum toxicity including those cooking with aluminum pans.[75,76] Susceptible patients include patients with renal failure and premature infants receiving parenteral nutrition.[77] There is little risk of acute aluminum toxicity. The administration of 40 mg Al/kg/day as montmorillonite (loosely bound clay minerals containing hydrated aluminum silicates) to healthy adults for up to 90 days was not associated with any adverse effects.[78]

TOXICOKINETICS

Absorption

Oral

Factors that affect the absorption of aluminum include the bioavailability of the specific aluminum salt administered, the effect of pH on aluminum speciation and solubility, and dietary factors. Volunteer studies indicate that adults with normal renal function absorb between 0.1–1% of an oral dose of aluminum following ingestion depending on the solubility of the specific aluminum compound and the presence of complexing agents (organic acids, amino acids, silicates, carbohydrates, nucleotides, phosphates).[31,79] The presence of carboxylic acids (e.g., citric, lactic) enhances the absorption of aluminum, whereas the presence of phosphate or dissolved silicate decreases the absorption of aluminum.[23] Most of the gastrointestinal absorption of aluminum occurs in the acid media of the stomach, whereas very little absorption occurs in the duodenum. The poor bioavailability of aluminum significantly limits the oral toxicity of aluminum, particularly water-insoluble, hydrated aluminum silicates.

The bioavailability of aluminum from drinking water averages ~0.3% compared with an average bioavailability of ~0.1% from food;[80] the presence of food, calcium, or magnesium does not alter the bioavailability of aluminum in drinking water.[81] Unabsorbed aluminum hydroxide combines with phosphates in the gastrointestinal tract; the resultant aluminum phosphates are insoluble and excreted in the feces. Animal experiments confirm the limited bioavailability (i.e., 0.27–2.18%) of aluminum salts (e.g., borate, chloride, citrate, glycinate, hydroxide, lactate, sucralfate) in solutions with pH ranging from 1.7–7.0.[82] In studies of fasted rats gavaged with doses of aluminum citrate normally present in the diet, the absorption of aluminum ranged from ~2–5%.[83]

Pulmonary

In contrast to the oral route of Al exposure in the general population, inhalation is the primary route of occupational exposure to aluminum. Pulmonary absorption of aluminum varies between aluminum processes depending on solubility and particle size. Typically, aluminum-containing welding fumes consist of particles <1 μm in diameter, whereas the particles in aluminum flake powders vary from 5–200 μm in diameter and 0.05–1 μm in thickness.[84] Studies of workers exposed to welding fumes suggest that some absorption of aluminum (i.e., ~2%) occurs following the inhalation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of aluminum compounds based on increased urinary excretion of aluminum;[85] however, elevated plasma aluminum concentrations are usually small and the clinical significance of these concentrations appears limited. Based on limited industrial data, the bioavailability of soluble airborne Al is ~1.5–2% as a result of the conversion of Al to less soluble forms (aluminum oxides) in aqueous tissues.[24,80] A Scandinavian study of five aluminum sulfate workers suggests exposure to soluble Al at an aluminum sulfate plant may result in higher aluminum absorption (i.e., ~7%).[86] The mean, 8-hour time–weighted average aluminum concentration was 0.13 mg/m^3 with a range of 0.02–0.5 mg/m^3.

Dermal

Few data exist on dermal aluminum absorption; however, intact skin apparently acts as a barrier to aluminum absorption.[87] A case report of a 43-year-old woman using an aluminum chlorohydrate-containing antiperspirant daily for 4 years suggested some dermal aluminum absorption occurs based on an initial plasma aluminum concentration of ~10 µg/dL (normal reference range of <1 µg/dL) prior to cessation of deodorant use.[88] Limited studies of the dermal application of ^{26}Al chlorohydrate on human volunteers indicate that the bioavailability of Al in this form does not exceed 0.012%.[89] In an *in vitro* study of human donor skin, transdermal Al absorption was very small (i.e., ≤0.07% of the deposited aluminum) with a mean absorption rate of 1.8 µg/cm^2 for the aerosol base and 0.5 µg/cm^2 for the roll-on type antiperspirant.[90] The measured uptake was significantly higher on stripped skin (11.50 µg/cm^2) than normal donor skin (1.81 µg/cm^2).

Distribution

The amount of aluminum bound to serum proteins increases with increasing blood aluminum concentrations ranging 54–92% between serum Al concentrations of 7.8–152 µg/L.[91] Aluminum is bound to low and high protein fractions (transferrin, albumin) along with small-molecule plasma binders (bicarbonate, citrate, fluoride, phosphate). Under normal conditions, ~80–90% of plasma aluminum is bound to transferrin and, to a lesser extent, albumin with the remainder forming soluble, small-molecular complexes (e.g., citrate, phosphate) including hydrolyzed forms.[92,93] Aluminum closely follows the iron pathway in the extracellular environment of humans.[94]

The average healthy individual contains ~30–50 mg Al with the highest concentration (i.e., ~1/2 the body burden) in the skeleton (5–10 mg/kg wet weight).[95] Ingested aluminum distributes primarily to bone (i.e., ~50–60%) and, to a lesser extent, to lung (i.e., ~25%), muscle (10%), liver, spleen, and kidney.[96,97] The retention half-times for aluminum in bone are long depending on bone turnover. The estimated retention half-times in trabecular bone (20% turnover/year) are ~500 days compared with 29 years for cortical bone (3% turnover/year).[98] Under normal circumstances, Al does not accumulate in the body. The brain contains ~1% of the aluminum body burden (0.25–0.75 mg Al/kg wet weight).[23] In animal studies, the steady-state V_d is dose dependent, ranging from 38–1.175 L/kg.[91] Most of the inhaled aluminum dust remains in the lungs.

Elimination

In healthy patients with normal renal function, elimination of aluminum occurs almost exclusively (>95%) by renal excretion with biliary excretion accounting for ~2% of the absorbed dose;[99,100] however, biliary excretion is the major route of elimination in patients with renal failure.[101] Normal renal excretion of aluminum in humans is <20 µg/day, but daily urinary Al excretion can increase up to 3,800 µg in patients receiving aluminum-contaminated total parenteral nutrition solutions.[102]

Blood

Animal studies suggest the plasma half-life of aluminum is relatively short (<40 hours) when renal function is normal.[103] The plasma elimination half-life increases to ~85 days in dialysis patients given aluminum-containing antacids.[91]

Urine

Studies of urinary Al elimination in aluminum-exposed workers indicate the existence of at least a two compartment elimination phase: 1) a relative rapid elimination phase, and 2) a much slower compartment probably dependent on redistribution of Al from body stores (e.g., bone, lungs), duration of exposure, and solubility of the aluminum compound. Examination of welders exposed to aluminum indicates two functional compartments exist: 1) an easily exchangeable compartment for recently exposed welders (<1 year) with an estimated $t_{½}$ of 9 days, and 2) a deep compartment in welders exposed >10 years with an estimated $t_{½}$ > 6 months.[104] A field study of seven workers exposed to alumina (Al_2O_3), aluminum fluoride (AlF_3), and cryolite (Na_3AlF_6) in potrooms from an aluminum fluoride

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

production plant demonstrated a mean initial urinary Al elimination half-life of 7.5 hours (range, 5–9 hours) based on urine samples collected over the weekend.[105] These workers were exposed to variable amounts of soluble and insoluble aluminum with a ratio typically <1.

The terminal urinary Al elimination half-life based on urine Al concentrations in retired aluminum workers is much longer than the general population depending on differences in particulate size, solubility, and subsequent absorption.[104,106] The calculated elimination half-life of urinary aluminum in 10 retired aluminum workers exposed to poorly soluble aluminum flake powders ranged from 0.7–8 years depending on the length of retirement (0.5–14 years).[84] In this study, the urinary elimination half-life of Al was nearly constant (5–6 weeks) after cessation of Al exposure for 4–5 weeks, despite a large variation in the duration of Al exposure (1–20 years). In contrast to the relatively small particulates released during welding (i.e., <0.4 μm), the much larger aluminum flakes form a long-term pulmonary aluminum pool with a slow, fixed elimination rate.

Maternal–Fetal Kinetics

In a study of the four stages of breast milk production (colostrums, transitional milk, early mature milk, mature milk), the concentrations of microelements decreased with advancing lactation stages.[107] The mean aluminum concentration in samples from 45 lactating women in each lactation stage ranged from 56.45 ± 22.77 ng/mL in colostrum samples to 13.44 ± 6.28 ng/mL in mature breast milk samples.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Aluminum has no known physiological role in mammals; under normal circumstances, the amount of aluminum in the body is small. The mechanism of aluminum toxicity is not well defined. Al competes in biological systems with cations (e.g., magnesium) despite differences in the oxidation states.[23]

Central Nervous System

Aluminum-containing phosphate binding agents increase gastrointestinal aluminum absorption and predispose patients with renal dysfunction to aluminum toxicity including ataxia, dysmetria, tremors, hyperreflexia that progresses to cognitive and motor dysfunction.[108] Aluminum toxicity occurs almost exclusively in patients unable to excrete dietary aluminum. The pathogenesis of aluminum encephalopathy remains unclear. Animal studies indicate that aluminum inhibits many enzymes in the brain including acetylcholinesterase, ADP-ribosylation, acetyltransferase, cytosolic and mitochondrial glycolysis, monoamine oxidase, and dihydropteridine reductase.[109] Existing data suggest that aluminum may inhibit neurological processes that determine the uptake of γ-aminobutyric acid, choline, glutamate, and serotonin by replacing magnesium on DNA-protein binding sites. The comparatively slow release of aluminum from neurological sites would cause dysregulation of protein synthesis in the central nervous system (CNS).[110] Neuropathological changes include nerve cell atrophy and death, stromal spongiosis, and proliferation of astrocytes and microglia in the cerebral cortex, basal ganglia, and thalamus.

Alzheimer's Disease

Pathology

The characteristics of Alzheimer's disease are senile plaques with β-amyloid and aluminosilicate deposits at the core, neurotransmitter deficits (decreased cholinergic activity), and neurofibrillary tangles identified as helical filaments in damaged neurons. Alzheimer's disease results from both genetic and environmental factors with neurofibrillary tangles and amyloid-β oligomers accounting for <50% of the cognitive impairment. The neurofibrillary tangle is the characteristic pathological feature of Alzheimer's disease; this lesion contains primarily aluminum. Higher concentrations of both aluminum and silicon in the form of aluminosilicates are found in the central region of senile plaque cores compared with the distribution of other inorganic constituents. This finding suggests that aluminosilicates may be involved in the early initiation of senile plaques;[111] however, increased brain aluminum concentrations occur in other diseases that do not produce dementia (e.g., hepatic and renal failure, metastatic carcinoma, amyotrophic lateral sclerosis).

Etiology

Animal models of aluminum toxicity demonstrate pathological changes similar to those found in Alzheimer's disease; however, significant differences also exist between aluminum encephalopathy and Alzheimer's disease.[103] In 1973, Crapper et al. suggested aluminum was a potential neurotoxic factor in Alzheimer's disease because of elevated aluminum concentrations in the postmortem examination of the brains

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of these patients;[112] however, there was no elevation of aluminum concentrations in postmortem samples of hair, serum, or cerebrospinal fluid.[113] Banks et al. suggested that aluminum alters the blood–brain barrier,[114] but the potential role of aluminum and its neurotoxic mechanism await further clarification. Other potential mechanisms for the effect of aluminum on the development of Alzheimer's disease include the effect of aluminum on the phosphatidylinositol-derived second messenger system[115] and the elevated basal levels of inflammatory markers present in Alzheimer's disease.[116]

Pathological studies in humans do not support a strong causal link between Alzheimer's disease or dialysis-associated encephalopathy and aluminum exposure.[117] Case-control studies of patients using antacids for peptic ulcer disease have not demonstrated an excess incidence of Alzheimer's disease.[118] Other factors that may contribute to the formation of Alzheimer's disease include slow viruses or virions (most favored etiology, although unproved) and autoimmune processes. Aluminum toxicity is one of several theories on the etiology of this disease; however, there is no direct evidence to support a primary role for aluminum in the etiology of Alzheimer's disease.[19,119] Consequently, the association between dementia and aluminum exposure remains unproven.[120]

Pulmonary

Although long-term exposure to stamped aluminum powder used in pyrotechnics potentially produces pulmonary fibrosis, most other types of aluminum particles do not appear fibrogenic. Potential toxic exposures in aluminum-producing facilities include dusts (alumina, carbon, cryolite, fluorides), fumes, gases (hydrogen fluoride, sulfur dioxide), trace elements (chromium, nickel, vanadium), and strong electromagnetic fields. The cause of potroom asthma is not well established. A cross-sectional study of potroom workers did not reveal a difference in immune function between workers who did or did not develop asthma.[121] The similarity of serum IgE concentrations in potroom asthma with and without asthma and evidence of airway inflammation suggests an irritant, nonimmunological mechanism.[122] In a study of 7 aluminum smelters in Australia and New Zealand, the incidence of occupation asthma was correlated with the geometric mean total fluoride concentration as measured by personal samples of employees undertaking anode changing.[123]

Bones

Chronic renal failure patients on long-term hemodialysis develop high serum and tissue aluminum concentrations, especially in bone. Children with azotemia,[124] infants receiving aluminum-contaminated intravenous solutions,[66] and uremic neonates drinking powdered milk with high aluminum content[125] are particularly susceptible to this complication. Aluminum reduces bone resorption by multiple mechanisms including the following: 1) production of a relative phosphorus deficiency by binding to phosphorus; 2) enhancement of calcium excretion by prevention of calcium uptake into bone; 3) inhibition of the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D (active form); and 4) reduction of parathyroid hormone secretion.[126] Quantitative bone histology in uremic children with excessive aluminum loads in their bone demonstrates osteomalacia and/or a lack of mineralization that resolves with the removal of the aluminum.[31] The histological characteristics of this vitamin D-resistant osteomalacia include deranged membranous bone formation characterized by the accumulation of osteoid matrix along with decreased lamellar and osteoid bands, reduction of osteoclasts and osteoblasts, and poor mineralization. The effect of aluminum on bone occurs mainly in trabecular bone rather than the less metabolically active cortical bone. Aluminum localizes in patients with aluminum-induced osteomalacia at the interface between osteoid and calcified matrix in trabecular bone based on the azurine stain.[1] Consequently, the presence of aluminum in bone inhibits the incorporation of calcium into the matrix.

The cause of osteomalacia in renal failure is probably multifactorial, but the exact mechanism of the effect of aluminum on bone remains unclear. Proposed mechanisms include direct effects on crystal seeding and growth as well as disturbances of collagen formation and impaired mineral entrance. Indirect effects include altered vitamin D metabolism, increased vitamin D resistance,[127] and osteoblast inhibition. The effect of aluminum on parathyroid hormone secretion is controversial. One theory assumes that the deposition of aluminum in bone blocks the incorporation of calcium into osteoid, leading to osteomalacia. The prevention of calcium deposition in bone results in elevated serum calcium concentrations as the calcium returns to the circulation; subsequently, the elevated serum calcium concentration inhibits the release of parathyroid hormone by the parathyroid glands.[128]

Blood

Aluminum may be a contributing factor to the development of uremic toxins, a functional deficiency in erythropoietin, and microcytic anemia during chronic renal insufficiency.[129] Animal experimentation as early

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

as 1929 demonstrated that aluminum toxicity produced anemia similar to lead poisoning.[130] Even in the absence of severe anemia or microcytosis, aluminum contributes to the microcytic, hypochromic anemia of chronic renal disease, probably by impairing iron utilization or enhancing fecal iron/zinc elimination.[78,131] Modest accumulation of aluminum (<100 μg/L) probably inhibits hemoglobin synthesis based on a study using a 3-month course of deferoxamine treatment.[132] Iron binding of transferrin-binding sites is probably an important mechanism in the production of aluminum-induced microcytic anemia.

Postmortem Examination

Although the postmortem examination of the brain from a hemodialysis patient dying from aluminum encephalopathy revealed some immunohistochemical staining by phosphorylated neurofilaments, there were no neurofibrillary tangles, neuropil threads, or senile plaques associated with Alzheimer's disease.[133] The autopsy demonstrated nerve cell atrophy in the cerebral cortex along with mild loss of spongiosis of the stroma and proliferation of astrocytes. Five months before her death, her serum aluminum concentration was 195 μg/L.

CLINICAL RESPONSE

Medical Therapy

Children and adults with kidney disease have an elevated risk of aluminum toxicity along with preterm infants. Elevated aluminum concentrations (serum Al 150–350 μg/L) are associated with dialysis-associated encephalopathy and dialysis-associated osteomalacia[129] that require 3–7 years of dialysis for clinical expression.[134,135] Symptoms usually develop insidiously over months to years in chronic renal failure patients unless dietary aluminum loads are excessive. In dialysis patients with high Al body burdens, microcytic anemia is a common finding. The erythrocyte Al concentration correlates with decreases in the MCV and hematocrit. In a study of dialysis patients with Al overload comparing the highest and lowest quartiles of erythrocyte Al concentrations, these reductions were dose-dependent.[136]

Neurological

Aluminum-induced dialysis encephalopathy is pathologically distinct from Alzheimer's disease with epidemiological evidence insufficient to link aluminum to Alzheimer's disease. The most common neurological features of dialysis encephalopathy beginning with the most frequent include the following: multifocal seizures, disturbance of speech, mood change, dyspraxia other than of speech, myoclonus, gait disorder, episodic confusion, intellectual deterioration with poor concentration and short-term memory loss, and changes in personality and behavior.[137] Typically, these symptoms are episodic; however, the disease may be fatal in the absence of measures to reduce the Al load.[138] Nonspecific symptoms often precede major symptoms including malaise, anxiety, depression, and loss of memory and concentration. Premature infants with reduced renal function may develop excessive aluminum concentrations and an encephalopathy when dialyzed with aluminum-containing fluid or receiving TPN with excessive Al loads.[139]

Bone

Bone fragility (dialysis-associated osteomalacia) occurs in renal dialysis patients with high body burdens of aluminum (plasma Al concentrations >63 μg/L).[135] Typical features of vitamin D-resistant osteomalacia include progressive bone pain, fractures, bone deformities, and proximal myopathy.[1] Bone pain is an early sign of dialysis-associated osteomalacia, particularly in the back and feet. Dialysis-associated osteomalacia and encephalopathy are clinically distinct manifestations of aluminum toxicity that may present as separate clinical illnesses. The presence of osteomalacia does not necessarily indicate the presence of an encephalopathy as many patients with dialysis-associated osteomalacia do not have clinical evidence of cognitive impairment.[98] The oral administration of aluminum hydroxide to infants with renal disease has been associated with the development of bone disease.[140]

Acute Oral Toxicity

Aluminum compounds have relatively low acute toxicity as a result of poor gastrointestinal and pulmonary absorption, particularly the water-insoluble hydrated aluminum silicates. Attapulgite (palygorskite) is an aluminum-containing absorbent used in large doses for Traveler's and HIV/AIDS-related diarrhea without acute systemic effects.[141] The systemic toxicity associated with the ingestion of aluminum phosphide results from the formation of phosphine gas rather than the absorption of aluminum.

Environmental Exposure

The acute toxicity of aluminum is low with little evidence of acute toxicity following dietary exposure in the general population.[142] Epidemiology studies do not clearly demonstrate a causal link between the aluminum concentrations in drinking water and the incidence of Alzheimer's disease. Some,[143,144] but not all[119] epidemiological studies demonstrate a statistically significant positive association between chronic aluminum intake from drinking water and cognitive decline or dementias (e.g., Alzheimer's disease). Some of these studies also report inverse associations between other factors (low pH, silicon, fluoride) and dementias. An 8-year follow-up study of 3,777 subjects from southwestern France detected a relative risk of Alzheimer's disease after adjustment for age, gender, educational level, place of residence, and wine consumption of 2.14 (95% CI, 1.21–3.80) for subjects exposed to Al concentrations exceeding 0.1 mg/L.[145] However, there was no dose-response relationship between aluminum concentrations in drinking water and Alzheimer's disease. The bioavailability of Al is low (<1%), and drinking water represents a small fraction (1–2%) of the daily Al intake. Consequently, unidentified confounders probably contribute to the positive results in these epidemiology studies. There is no epidemiological evidence to suggest that environmental (e.g., drinking water, ambient air) Al exposure causes bone fragility.[146]

Occupational Exposure

Lungs

Pulmonary Fibrosis

Pulmonary fibrosis (i.e., aluminosis in Sweden) has been reported in some,[147] but not all, studies of workers heavily exposed to fine aluminum dust in the aluminum industry. Frequently, co-exposure to silica occurs with the handling of aluminum ores (e.g., bauxite, corundum). The combined exposure to dust from these ores has been associated with pulmonary fibrosis (Shaver's disease),[148] but studies of workers exposed only to aluminum dust are contradictory. Severe pulmonary fibrosis developed in workers exposed to some aluminum metal dyes in Germany, Sweden, and England.[149] Pulmonary aluminosis was associated with the use of submicron-sized aluminum pyrotechnic flakes that were lubricated with a nonpolar aliphatic oil. The contribution of the oil to the development of pulmonary pathology was limited because other processes that used polar lubricants did not produce pulmonary abnormalities.[150] Exposure to low-temperature transitional aluminas in aluminum chemical refineries, high-temperature transitional aluminas in smelters (i.e., after 1960), and high-fired alpha-aluminum oxide found in potteries indicated that these aluminas demonstrate minimal, if any, fibrogenic potential.[151]

As a result of improved working conditions in recent decades, the occurrence of aluminum pneumoconiosis is rare. Several studies of aluminum workers and Chinese workers exposed to fine aluminum dust did not demonstrate excess cases of pulmonary fibrosis, although exposure to aluminum oxide during abrasive production was a *suspected* cause in nine workers with abnormal chest X-rays.[152] A case report associated chronic interstitial pneumonia of a predominantly desquamative pattern with work as an electric arc welder based on the presence of aluminum in alveolar macrophages;[153] however, a cross-sectional study of 64 aluminum welders did not reveal an excess of pulmonary disease.[154] The use of high-resolution CT scans demonstrated ill-defined, small, rounded opacities predominately in the upper lung regions in 24% ($n = 15$, mean exposure = 15 years) of 62 men working in 2 Al powder producing plants.[155] The CT findings suggested an alveolitis that had not progressed to fibrosis. Several of the affected workers had low plasma and urine Al concentrations; hence, other factors may have contributed to the development of mild alveolitis.

Asthma

A persistent, asthma-like syndrome ("potroom asthma") develops in workers exposed to fumes from the electrolytic extraction of aluminum (Hall–Heroult process) that often improves following removal from work.[156] The pot (Søderberg or prebake type) is the electrolytic cell where the reduction of alumina occurs; the surrounding building is the potroom. Some,[157] but not all, studies of potroom workers have demonstrated an increased incidence of asthma and chronic bronchitis. Although the occurrence of asthma is associated with the duration of employment in potrooms (OR = ~3 for 10 years of employment), studies have not demonstrated a statistically significant increase in asthma in potroom workers compared with the general population.[158] Risk factors for the development of potroom asthma include smoking, family history of asthma, and exposure to fluoride particulates and perhaps sulfur dioxide,[159,160] The incidence of potroom asthma has dramatically decreased with improvements in fume extraction systems at these plants, and there is no direct evidence that exposure to aluminum alone produces asthma in these workers.[123] Occupational asthma has not been

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. associated with the separation of alumina (Al_2O_3) from bauxite ores (Bayer process).[158]

Central Nervous System

Reports on the cognitive effects of exposure to aluminum are conflicting with most studies using small populations, questionable methodology, inadequate exposure assessment, and poor control of confounding variables.[19] Case reports suggest that workers with aluminosis may develop central nervous system (CNS) dysfunction and dementia.[161] The first case report associating CNS abnormalities with occupational aluminum was published in 1962.[4] A 49-year-old ball-mill operator in an aluminum flake powder factory developed seizures, memory loss, dysarthria, and increased left hemiparesis after working for over 13 years in this factory. He died of bronchopneumonia within 1 year; however, no imaging studies were reported to clarify the etiology of his CNS abnormalities. Three aluminum smelter workers developed spinocerebellar degeneration without peripheral nerve involvement.[162] These three workers received long-term, low-dose exposures to aluminum in the same environment; all three displayed a lack of coordination, intention tremor, and cognitive deficits consistent with potroom palsy. The direct effect of aluminum is unclear in these cases because bone aluminum concentrations were normal.

Welders

Some case series and epidemiological studies report an increased prevalence of neurological symptoms in workers exposed to airborne aluminum concentrations exceeding current workplace standards. However, these symptoms are often not associated with objective evidence of neurological abnormalities or correlated to aluminum exposure or biomarkers. In a study of metal inert-gas welders separated into high, medium, and low exposure groups based on the sum of Monday-morning urine Al and concurrent serum Al concentrations, there were statistically significant differences in some symptoms (fatigue, mild depression, memory, concentration) between the high and low exposure groups.[163]

In a cross-sectional study of 38 aluminum welders and 44 railway track welders without lead, manganese, or aluminum exposure (controls), acute CNS symptoms were statistically more common in aluminum welders than controls, particularly fatigue.[164] These complaints increased with increasing urine aluminum concentrations. Complaints of pain and aches over the preceding 6 months were statistically less common in aluminum welders than controls. There were no significant differences between the two groups for symptoms related to tremor, peripheral nervous system symptoms, chronic fatigue, sleep disturbances, or chronic neurological symptoms related to mood, memory, or sensory systems. Additionally, there was no significant difference in the responses of the two groups to the Q16 questionnaire. A cross-sectional study of 98 aluminum welders with a median of 6 years exposure to aluminum welding fumes and 50 nonexposed car-production workers from the same plant did not reveal any statistically significant differences between welders and controls on a variety of tests including Q16 questionnaire, physical examination, or neuropsychological testing.[165] The annual measurement of the mean pre-shift and post-shift urinary Al was ~52 µg/g and 58 µg/g creatinine, respectively, whereas the median respirable air dust was 0.47 mg/m^3 and 0.67 mg/m^3. Welders typically do not develop an encephalopathy manifested by impaired memory, disorientation, or dementia.

Potroom Workers

There were frequent complaints of poor coordination, poor memory, impairment in abstract reasoning, and depression in a case series of 25 potroom workers examined at an occupational clinic for work-related illness.[166] However, there were no direct measures of aluminum available to confirm the extent of their aluminum exposure. In a cross-sectional study of 63 current and former aluminum potroom workers employed for at least 10 years, there was a statistically significant increase in responses to questions regarding depression, difficulty buttoning, and incoordination when compared with 37 cast house and carbon plant workers at the same facility.[167] However, tests of arm, hand, and leg tremor as well as measures of postural stability demonstrated no significant differences between the two groups. A cross-sectional study of aluminum potroom and foundry workers, aluminum welders, and workers exposed to aluminum during the production of flake powder did not demonstrate any consistent neurological effects in the exposed workers when compared with mild steel workers (controls).[168] Outcome measures included responses to mood and symptoms questionnaires and results from neuropsychological testing. The median duration of exposure and blood aluminum concentrations for the smelter workers, flake powder workers, aluminum welders, and mild steel workers (controls) were 15 years and 1.0 µg/L, 8 years and 9.0 µg/L, 15 years and 3.0 µg/L, and 12 years and 1.0 µg/L, respectively.

Skin

A unique dermatological condition developed in Canadian and Soviet workers at an aluminum plant.[169] These

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

workers acquired skin telangiectases chiefly on the upper parts of their bodies (chest, back, shoulders, forearms, neck, face) characterized by 1–30 mm round, sharply demarcated, nonpruritic red macules that blanched on applied pressure. These lesions occurred primarily in aluminum workers in the Søderberg electrolysis process, which releases more aromatic hydrocarbons than the newer pre-bake process. Most workers develop these lesions within 20 years of working in these facilities. These lesions were dermatological abnormalities that were not associated with other diseases (e.g., ischemic heart disease).[170] There is no direct evidence that aluminum caused these lesions. Aluminum can produce a delayed-hypersensitivity granuloma in the skin when injected under the skin for tattooing.[171] Contact allergy to aluminum is extremely rare considering the ubiquity of aluminum in the environment.[172]

Bone

There is no epidemiological evidence to suggest occupational Al exposure causes bone fragility.[146]

Reproductive Abnormalities

Few human data are available on the teratogenicity of aluminum. There is no direct evidence that the ingestion of aluminum produces clinically significant alterations in the reproduction of animals or humans at concentrations present in the environment or workplace. Aluminum does cross the placenta and is excreted in breast milk.[173] Rodent models indicate that parenteral Al doses of 50 and 100 mmol as $AlCl_3$ cause growth retardation, delayed ossification, and malformations when administered during early organogenesis; however, these high aluminum concentrations produce maternal toxicity.[174] Furthermore, the severity of the effect is highly dependent on the form of Al administered; the use of nitrates confounds the interpretation of the studies because of the ability of nitrates to cause fetal damage.

Carcinogenesis

There is no direct evidence that aluminum is a carcinogen in humans or animals. Rats did not develop an excess of tumors following the ingestion of drinking water containing 5 ppm Al during a study that lasted the whole lifetime of the rats. Epidemiological studies have not demonstrated a consistent association between aluminum exposure and breast cancer risk. Case-control studies did not detect a causal link between antiperspirant use and breast cancer risks;[175,176] consequently, current epidemiological data are inadequate to confirm an association linking antiperspirant use and breast cancer.[177]

The International Agency of Research on Cancer (IARC) lists aluminum production as a group 1 carcinogen.[178] Statistically significant excesses of lung cancer[179,180,181] and bladder cancer[169] were reported in some, but not all, epidemiological studies of aluminum workers. Most of these studies involve the older Søderberg aluminum reduction plants where relatively high concentrations of polycyclic aromatic hydrocarbons occurred, particularly in the anode production areas and to a lesser extent in the potrooms. A historical cohort study of 4,213 men who worked >5 years at a Søderberg aluminum reduction plant demonstrated a statistically significant excess incidence (SIR = 1.69, 90% Cl 1.06–2.57) of bladder cancer but not of lung cancer.[182] In an updated cohort study of Canadian Søderberg smelter workers, Poisson regression analysis correlated the standardized mortality and incidence ratios for stomach and bladder cancer to cumulative exposure to coal tar pitch volatiles measured as benzene-soluble materials and benzo(a)pyrene.[183] Although the overall rate of lung cancer was similar to the general population, the risk of lung cancer in these workers also increased in a dose-dependent relationship (P_{trend} <0.001). As prebake technology gradually replaced the older Søderberg pots, cancer mortality and incidence decreased.

A Canadian study of 4,396 men working in a newer prebake smelter for at least 3 months detected no overall excess of standardized cancer mortality or incidence ratios with the exception of mesothelioma and kidney cancer.[184] There was no significant trend for cancer incidence and duration of exposure, and the incidence of lung and bladder cancers was similar to the general population. Consequently, confounders (e.g., coal tar oils, smoking) probably account for the excess rates of cancer in the earlier studies on Søderberg workers rather than direct exposure to aluminum. Cancer mortality and incidence studies of bauxite mine and alumina refinery workers have not detected an increased risk of cancer including lung and bladder cancers.[185]

DIAGNOSTIC TESTING

SI Conversion Units

1 μmol/L = 27.03 μg/L
1 μg/L = 0.037 μmol/L
1 μmol/mol creatinine ~3.05 mg/g creatinine
1 mg/g creatinine ~0.30 μmol/mol creatinine

Analytical Methods

Flameless atomic absorption spectrometry is a simple, quick method of determining aluminum levels.[186] The earlier use of neutron activation and flame atomic absorption spectrophotometry has been replaced by flameless atomic absorption spectrometry because of the greater sensitivity and the smaller sample size necessary for the latter process.[187] The detection limit of Zeeman (flameless) absorption spectrometry is ~1 μg/L, and the precision is about 3–6%.[188] Speciation of aluminum is a complex process because of the influence of pH on Al species, contamination, and instability of some Al species.[189]

Sample contamination is a major problem with the analysis of aluminum concentrations in biological fluid because of the low Al concentrations in mammals and the high Al concentrations in the environment. Improper storage conditions result in the loss of aluminum and contamination of the storage vials. Leaching of aluminum occurs on the surface of glass vessels stored at 4°C.[190] The best storage conditions are polypropylene or polystyrene containers stored at −20°C with acidification of urine and dialysis fluid.

Biomarkers

Intravenous challenge doses of deferoxamine (DFO)[127] are a controversial method of assessing the total body burden of aluminum that is not currently recommended. One study suggested baseline plasma aluminum concentrations of 200 μg/L are highly specific (93%) but not sensitive (43%) for aluminum-induced bone disease, whereas the same plasma aluminum concentrations after deferoxamine infusion (40 mg/kg over 2 hours) are highly sensitive (94%), but not very specific (50%) for aluminum-induced bone disease.[191] The DFO infusion test is negative when the plasma aluminum concentration is <150 μg/L. The aluminum content of hair is too variable to reliably predict aluminum intoxication.[192] Hair aluminum concentrations in the scalp do not correlate well with daily or cumulative aluminum intake, plasma aluminum concentrations, or stainable bone aluminum concentrations.[193]

Blood

The distribution of Al between serum and plasma is similar; however, data on the distribution of Al between plasma/serum and red blood cells are conflicting. Some authors report the approximately equal distribution of Al between plasma and erythrocytes, resulting in similar Al concentrations between whole blood, plasma, and serum.[80] The mean whole blood/serum Al ratio in a series of healthy Italians was 1.67 as measured by flame atomic absorption spectrometry.[194] In a study of plasma and erythrocytes from rats and patients on dialysis, the distribution between the two was near unity.[195] The mean Al concentration in blood samples from four renal dialysis patients with Al concentrations of >100 μg/L was ~8% higher in whole blood than plasma.[196] However, the aluminum erythrocyte/plasma ratio was ~0.1 in subjects followed 3 months after the ingestion of ^{26}Al in a citrate-containing drink.[98] The difference is partially explained by variations in the solubility of different Al compounds. Serum is the preferred blood sample because some anticoagulants (e.g., heparin, citrate) may contain aluminum.

General Population

The serum aluminum concentrations in individuals from the general population without excessive exposure are usually <5–10 μg/L.[197] The estimated 95% upper limit of serum Al based on data from 21 Finnish laboratory workers without exposure to antacids was 2.7 μg/L as measured by graphite furnace/atomic absorption spectrometry.[198] The distribution of plasma aluminum in the general population follows a log-normal pattern; a study of subjects with normal renal function and no excessive intake of aluminum demonstrated plasma aluminum concentrations with an upper 95% CI <0.175 μmol/L (4.73 μg/L).[199] Substantial interindividual variation in plasma aluminum concentrations occurs. Whole blood Al concentrations may exceed serum and plasma Al concentrations. In a cross-sectional study of 85 healthy infants (median age, ~10 months) with normal renal function and no history of parenteral nutrition or aluminum-containing pharmaceutical use, the median whole blood aluminum concentration was 15.4 μg/L with a range of 0.9–952 μg/L.[200] There was no statistically significant correlation between blood Al and the estimated Al dose from vaccines. The authors did not explain the reason for the 7 outliners ranging from 98–952 μg/L. Without those 7 outliers, the median whole blood Al concentration was 14.3 μg/L (95% CI: 11.6–18.2 μg/L).

The administration of high doses of aluminum-containing antacids to infants[201] and adults in critical care units[202] increased plasma Al concentrations up to 40 μg/L; the patients did not develop symptoms of aluminum intoxication. These patients had normal renal function. Blood aluminum concentrations should be interpreted cautiously because some differences exist between chronic toxicity in patients with similar serum aluminum concentrations.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Dialysis Patients

Typical serum aluminum concentrations are <50 μg/L in asymptomatic patients on chronic hemodialysis compared with <5–10 μg/L in the general population.[197] Clinical studies of renal dialysis patients indicate serum Al is a biomarker for total body burden and clinical effects (dialysis-associated bone disease and encephalopathy).[135] Serum aluminum concentrations may exceed 50 μg/L in patients with chronic renal failure following ingestion of 60 mL of aluminum hydroxide daily for 2 weeks.[203]

Serum aluminum levels of >60–100 μg/L indicate increased absorption and the potential for aluminum-related bone disease.[204] Typically, symptoms of encephalopathy (e.g., confusion and delirium) do not develop in patients with chronic aluminum intoxication until the serum aluminum concentration exceeds 100 μg/mL. Clinical symptoms of encephalopathy are frequent when serum aluminum concentrations are >200–300 μg/L.[205,206,207] In a renal dialysis center, 27 patients developed nausea, vomiting, and hypercalcemia after the replacement of a water conduit pipe containing Al- and Ca-rich cement mortar that provided tap water.[208] In antemortem blood samples from 7 patients dying after developing seizures, sepsis, and coma, the mean serum aluminum concentration was 808 μg/L (range, 359–1,189 μg/L) compared with 255 μg/L (range, 113–490 μg/L) in 17 survivors.

Occupational Exposure

Al concentrations in blood and urine do not correlate well to Al concentrations in brain or bones of aluminum-exposed workers;[98] only about 0.1% of the total body burden of aluminum exists in the blood. Serum aluminum concentrations are indirect measures of the total body burden of aluminum because aluminum is highly protein bound. Aluminum concentrations in the blood should be interpreted in relation to cumulative aluminum exposure because chronic, low-dose exposure may produce excess aluminum concentrations in the tissues without high (>100 μg/L) plasma aluminum concentrations.[209] In a nonrandomized study involving 28 potroom workers followed for 3 years after the construction of a modern aluminum smelter, the mean serum aluminum concentration was 6.41 ± 1.61 μg/L with air samples never exceeding the ACGIH-TLV of 10 mg/m^3.[210] The mean serum Al concentration doubled during the first year before becoming relatively stable during the next 2 years as the urine Al concentration continued to increase.

Urine

General Population

In the general population without exposure to typical amounts of Al, the urinary Al concentration is usually <10–15 μg/L. The mean Al concentration in 766 spot urine samples excluding the first voided specimen from healthy Italians was 10.9 μg/L (range, 2.3–19.5 μg/L) compared with 6.4 μg/L (range, 1.5–29.6 μg/L) for 178 British citizens as measured by electrothermal/atomic absorption spectrophotometry.[211] In urine samples from 44 healthy Finnish population without antacid use, the Al concentration was 8.9 ± 4.9 μg/L with a range of 1.9–22.2 g/L as measured by graphite furnace atomic absorption spectrometry (GFAAS) method with Zeeman background correction and corrected to a relative density of 1.024.[198] The estimated 95% upper limit for Al in urine was 16 μg/L.

Occupational Exposure

Workweek urine Al concentrations reflect both recent exposure and the body burden of aluminum, particularly in workers exposed to insoluble aluminum in ambient air; there are limited data on the use of pre-shift and first morning of the workweek urine samples as a means to measure the total body burden of aluminum by reducing the influence of recent aluminum absorption. In general, post-shift and end-of-week urine samples reflect primarily recent exposure; pre-shift and first-day-of-week urine samples reflect primarily body burden. For recently exposed workers, urine sampling during the workweek reflects recent exposure more than the body burden. The timing of urine samples depends on recent exposure history and the solubility of the Al compound. Urine and blood Al concentrations during a work shift (i.e., pre- and post-shift) are relatively constant for aluminum welders given a constant Al dust exposure; therefore, the timing of these samples during the shift is not critical for recent Al exposure.[212] In welders chronically exposed to aluminum, the Monday morning pre-shift Al urine probably reflects the total body burden; sample timing during the workday (i.e., pre-shift or post-shift) is probably not important in determining the Al body burden.[213] Occupational studies suggest that urine Al concentrations are more sensitive to recent fluctuations in airborne aluminum concentrations than serum or plasma Al.[214] The occurrence of unexpectedly high urine Al concentrations should prompt a search for Al-containing food and drugs, sample contamination, or highly concentrated urine, particularly if present in first-day-of-the-week samples. Normalization of urine aluminum concentrations to creatinine clearance is usually not necessary

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

because aluminum clearance correlates to urine output and indirectly specific gravity rather than creatinine clearance.

Bone

Histological examination of bone biopsy material is a measure of the total body burden of aluminum because the bone is the main storage organ of aluminum in the body;[215] however, there are few data on noninvasive techniques (e.g., X-ray fluorescence) to determine the usefulness of these techniques for biomonitoring. Histochemical stains typically demonstrate no aluminum in bone specimens at aluminum concentrations below 50 mg/kg bone. The mean aluminum concentration in bone biopsies from three cases without renal disease was 6.4 mg/kg dry weight (range, 3.6–8.1 mg/kg dry weight) compared with 124.6 mg/kg dry weight (range, 71.2–194.0 mg/kg dry weight) for biopsies from three autopsies of individuals requiring dialysis during their lifetime.[100] In this study, a bone biopsy from a patient with normal renal function and a 25-year history of ingesting large doses of aluminum contained 24.1 mg Al/kg dry weight. Following an incident involving contamination of drinking water with aluminum sulfate,[96] serial bone biopsies demonstrated the presence of stainable aluminum for up to 18 months.[216]

Abnormalities

Blood

Manifestations of aluminum toxicity include hypercalcemia and a microcytic, hypochromic anemia that may or may not respond to iron therapy.

Neurophysiological

EEG abnormalities characteristic of aluminum encephalopathy in dialysis patients exposed to elevated aluminum concentrations include episodic bursts of spiking, high-voltage activity on a background of slow-wave activity.[217] Consistent abnormalities on the EEG have not been detected in epidemiological studies of aluminum-exposed workers. In a study of 17 Swedish aluminum welders, the amount of delta and theta activity in the quantitative EEG correlated positively and the amount of alpha activity negatively with serum Al concentrations.[218] In an expanded Swedish study of 65 aluminum welders and 25 mild steel welders (referents), the slowing of alpha activity did not reach statistical significance; there were no characteristic pathological EEG changes in the aluminum welders.[163] However, there were more diffuse ($P = 0.005$) and epileptiform ($P = 0.02$) abnormalities in the aluminum welders compared with the mild steel welders.

Neuropsychological

Clinical and occupational (smelting, welding, grinding) studies over the last several decades evaluating neuropsychological tests on aluminum-exposed subjects suggest the possibility of mild adverse effects, primarily in welders (e.g., complex attention tasks, information processing in working memory, visuospatial recall, and analysis); however, the neuropsychological data on dose-response are conflicting. These cognitive abnormalities are more easily detected when performance normally declines with age. A meta-analysis of 9 occupational studies of aluminum workers (5 aluminum welders, 3 aluminum production workers, 1 aluminum smelter) based on estimates of effect sizes included 449 exposed workers (welding, smelting, electrolysis) and 315 controls. The mean urine Al concentrations in the studies of exposed workers ranged from 13–133 μg/L.[219] The study evaluated overall effect sizes for 6 neuropsychological/psychomotor tests with 10 variables. The variables included seven attention tests (simple reaction time, digit span forward/backward, digit symbol computerized/noncomputerized, trail making A), two motor performance tests (Santa Ana dexterity preferred/nonpreferred hand), and one construction test (block design). Although nine of the overall effect sizes suggested inferior performance in the exposed groups, only the overall effect size on the paper version of the digit symbol test was statistically significant.

Miners and Salvage Workers

A study of workers exposed to McIntyre powder (15% finely ground elemental aluminum, 85% aluminum oxide) demonstrated decreased performance on examinations of cognitive function compared with a control group, but there were no significant differences in the prevalence of neurological diseases.[220] The standard dose prior to each underground shift was 35.6 mg/m^3 for 10 minutes. A cross-sectional study of 30 aluminum salvage workers and 60 controls without aluminum exposure did not detect statistically significant differences in the Mini-Mental State Examination, verbal short-term memory (Digit span), or clock drawing test.[221] None of the exposed workers exceeded the Biological Tolerance Value of 200 μg/L in urine; the mean Al concentration in end-of-shift urine samples from these workers was 11.59 ± 10.09 μg/L ($\text{mean}_{\text{controls}} = 4.37 \pm 3.67$ μg/L). The urine Al concentrations in the exposed workers were

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

lower than those of railway workers in the Sjögren study of aluminum welders (median = ~22 μg/L).

Welders

Cross-sectional and longitudinal studies of aluminum welders generally demonstrate no statistically significant differences in neuropsychological tests between aluminum-exposed workers and controls. Although these studies do demonstrate some correlation between a few neuropsychological parameters and urine or blood Al concentrations, there are no consistent decrements in specific domains (e.g., motor, memory, verbal, visuospatial). A 4-year longitudinal study compared 41 Al welders in the train and truck construction industry with 37 controls (unexposed assembly workers) on neuropsychological scores in verbal intelligence, attention, logical thinking, memory, and psychomotor skills. Aluminum exposure ranged from 5–8 mg/m^3; biomonitoring data demonstrated pre-shift plasma and urine Al concentrations of 13–16 μg/L and 88–140 μg/g creatinine, respectively, in samples from the welders. Twenty welders and 12 controls completed the study. Explorative regression and covariance analyses demonstrated a correlation between premorbid intelligence and neuropsychological scores but no correlation between performance and Al exposure; additionally, there was no difference between performance scores in the two groups (i.e., 20 welders, 12 controls) over the 4-year study.

A study of 17 aluminum welders with a history of ~4 years of aluminum exposure and a mean urine aluminum concentration of 2.8 μmol/L (75.7 μg/L) with a range of 0.9–6.1 μmol/L (24.3–164.9 μg/L) demonstrated no abnormalities on neuropsychological testing, when compared with established reference levels.[218] However, the authors suggest that aluminum may affect short-term memory, learning, and attention based on decreased scores on these tests with increasing urine aluminum concentrations. In a cross-sectional study of 38 aluminum welders, there were statistically significant differences in 4 tests of motor function between the aluminum welders and a control group of 44 railway track welders.[164] These differences included the following tests: tapping speed, nondominant hand only, pegboard, dominant hand only, and two motor tasks on the Luria–Nebraska motor scale. These changes did not correlate to urine aluminum concentrations. There were no differences between the 2 groups in the scores on tracking tasks, simple reaction time, symbol digit coding, digit span, or vocabulary. This study did not control for age. In a study of 92 male Al welders in the automobile industry and 50 nonexposed construction workers in the same industry and of similar age (35–39 years), symptoms and neuropsychological scores (i.e., verbal intelligence, logical thinking, psychomotor behavior, memory, attention) did not differ between the two groups over the 4-year study period.[222]

A cross-section study of 20 aluminum welders with a mean aluminum exposure of about 8 years and mean urine aluminum concentrations of ~50 μg/L at the time of examination demonstrated significantly better performance on measures of reaction times and hand steadiness than 20 construction workers.[223] However, the welders reported a statistically significant increase in the mean number of neuropsychological symptoms (2.5 vs. 1.6) compared with the control group of construction workers. A cross-sectional study of 98 aluminum welders with a median of 6 years of exposure to aluminum welding fumes demonstrated a small, but significant decrease in simple reaction time, when compared with education and age-matched controls (i.e., car-production workers).[165] The study detected no other neuropsychological abnormalities (i.e., block design, trail-making, standard progressive matrices, recall of digits, psychomotor performance, verbal intelligence). In a study of metal inert-gas, welders separated into high, medium, and low exposure groups based on the sum of Monday-morning urine Al and concurrent serum Al concentrations, there were mild differences in scores on some, but not all, neuropsychological tests of attention (Bourdon–Wiersma cancelation test, counting backward, dual task), memory (memory for designs), and verbal abilities (synonyms).[163] There were no significant differences in the scores for the low- and medium-exposure groups. The scores were adjusted for age and lead exposure but not for any hold tests.

Pulmonary Function Tests

Most cross-sectional studies of aluminum workers have not detected changes in the FEV_1 and FVC,[224] whereas one study demonstrated a mean reduction in FEV_1 of 0.29–0.39 L in workers exposed >20 years to Al-containing dust when compared with predicted values.[225] A review of respiratory disorders in aluminum smelter workers reported increased mortality from chronic obstructive pulmonary disease and longitudinal decline in FEV_1 in aluminum potroom workers consistent with potroom asthma; however, the causative agent or agents of potroom asthma remain unknown.[226] Detecting pulmonary function abnormalities in workers exposed to aluminum dust is complicated by the difficulty in separating smoking effects and other pulmonary toxins from the effect, if any, of aluminum exposure. In a study of potroom workers, impairment of lung function secondary to occupational exposure

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

occurred only in nonsmokers with statistically significant reductions ($P < 0.001$) in FVC, FEV_1, and PEF compared with controls.[227] At the present time, no current immunological test establishes the diagnosis of potroom asthma.

HEALTH SURVEILLANCE

Risk Assessment

The development of tissue damage as a result of aluminum exposure depends on the length of the exposure and the amount of aluminum deposited in the tissue.[228] In a study of hemodialysis patients receiving $Al(OH)_3$ for up to 7 years as a phosphate binder, the no-observable-adverse-effect-level (NOAEL) was 13 mg/kg/day as total Al. The calculated oral reference dose (RfD) was 1.3 mg/kg/day using an intraspecies uncertainty factor of 10; this value corresponds to a maximum concentration of 9 mg total Al/L in drinking water assuming a 70-kg person consumes 2 L of drinking water/day and adjusting for a default 20% relative source contribution.[78] This drinking water concentration exceeds the US EPA secondary maximum contaminant level (MCL) for total Al of 0.05–0.2 mg/L. However, the domestic use of water with high Al concentrations is unlikely because of the turbidity associated with these concentrations.

Environmental Monitoring

US Occupational Health and Safety Administration (OSHA) set the PEL–TWA for metal dust as Al at 15 mg/m^3 as total particulate and 5 mg/m^3 as the respirable fraction in order to prevent physical irritation from the dust. The American Conference of Governmental and Industrial Hygienists Threshold Limit Value Time–Weighted Average (ACGIH TLV–TWA) for metallic Al dust is 10 mg/m^3. These two organizations have set the same standard for the following Al exposures as TWA: pyro powders, 5 mg/m^3; welding fumes, 5 mg/m^3; soluble salts, 2 mg/m^3; and alkyls, 2 mg/m^3. The California Primary Drinking Water Action Level is 1 mg Al/L based on the lack of adverse effects of 125 mg Al/day and a 10-fold safety factor for sensitive individuals (e.g., hemodialysis patients). In California, the secondary action level of 200 µg/L is designed to prevent any cloudiness that results from aluminum in drinking water; however, in the European Economic Community, the 200 µg/L level is the maximum admissible Al concentration in raw water supplies for small water treatment facilities (100 µg/L for large water treatment facilities). Table 1.3 lists current regulations and guidelines for exposure to aluminum.

TABLE 1.3. Regulations and guidelines for aluminum exposure.

Type	Values
	ACGIH
TLV–TWA (8-hour)	1 mg/m^3 (insoluble Al respirable particulate matter)[a]
BEI (urine)	None
	NIOSH
REL–TWA (10-hour)	
Metallic Al	10 mg/m^3 (total dust)
	5 mg/m^3 (respirable fraction)
Aluminum oxide	15 mg/m^3 (total dust)
	5 mg/m^3 (respirable fraction)
IDLH	None
	OSHA
PEL–TWA (8-hour)	
Metallic Al (General industry)	5 mg/m^3 (total dust)
(Shipyard industry)	15 mg/m^3 (total dust)
Aluminum oxide	5 mg/m^3 (respirable fraction)
	DFG
BAT	60 µg/g creatinine (welding fumes, end-of-shift)
MAK	1.5 mg/m^3
	FIOH
BAL	162 µg/L (pre-shift, first-day-of week)[b]
	ATSDR
MRL	1 mg/kg/day (oral intermediate/chronic)
	WHO
Drinking water	≤200 µg/L (small water treatment facilities)
	≤100 µg/L (large water treatment facilities)
	EFSA
Daily food intake	1 mg Al/kg body weight

Biological Monitoring

The objective of aluminum biomonitoring is the prevention of harmful aluminum concentrations in the lungs and other target organs (brain, kidneys, lungs). The ubiquity of Al complicates the biomonitoring of exposed workers from potential sample contamination, the presence of Al in food and drinking water, the ingestion of Al-containing drugs (antacids), and the use of Al-containing products (antiperspirants). The concentration of Al in urine and blood depends on the intensity of recent exposure, the solubility of the form of Al, and the body burden. The inhalation of fine particles of poorly soluble aluminum salts causes the retention of Al in the lungs, whereas soluble Al compounds do not accumulate in the respiratory tract.

Blood

Monitoring aluminum is substantially different in dialysis patients than in workers with occupational Al exposure. In patients with severe renal insufficiency, serum/plasma Al concentrations reflect total body burden of aluminum and potential Al toxicity.[213] Plasma Al concentrations exceeding 190 µg/L are associated with an increased risk of bone disease and encephalopathy in hemodialysis patients.[229] Increased monitoring of serum/plasma Al concentrations and enhanced health surveillance are recommended for dialysis patients with serum Al concentrations of >60–100 µg/L because of the potential increased adverse effects suggested in clinical studies.[230,231]

In subjects with normal renal function, urinary excretion of aluminum is a more sensitive indicator of the absorption of aluminum than the plasma/serum Al concentration. A study of 31 workers exposed to aluminum in a bauxite mining process did not demonstrate a statistically significant difference between the serum aluminum concentration of the workers and the control group (wood processors).[232] Although the mean plasma aluminum concentration of workers currently exposed to aluminum flake powders was only slightly above (12.5 µg/L) the upper range of normal urinary concentration of aluminum was 80–90 times higher (200 µg/L) than nonexposed workers.[233]

Urine

On a group basis, airborne aluminum concentrations (i.e., primarily the respirable fraction of finely-divided, poorly soluble Al compounds) correlate to urine Al concentrations. Biomonitoring of urinary Al is useful for Al exposures in the grinding, cutting, polishing, and thermal spraying of aluminum, aluminum welding (e.g., MIG/MAG-welding), production, and use of Al powders, and aluminum smelting. In a study of 12 workers exposed for 6 hours to 2.5 mg/m^3 aluminum-containing welding fumes from a metal inert gas welding process, the mean urine Al concentration increased from 13.5 ± 4.1 µg/L (baseline) to 23.5 ± 7.3 µg/L (immediately postexposure).[234] The urine Al concentrations returned to baseline within ~1 week. The pre-exposure and postexposure plasma concentrations were not statistically different.

In contrast to occupational exposure to poorly soluble Al salts (e.g., welders), long-term occupational Al exposure (e.g., Al sulfate production workers) typically exhibits urinary Al concentrations only slightly higher than local controls.[86] Urinary Al roughly quantitates the Al exposure during the production/use of soluble Al salts (sulfates, chlorides, nitrates), but the results are difficult to interpret following mixed exposure to soluble and insoluble Al compounds (e.g., potroom exposures).[197] In a study of potroom and Al fluoride production workers exposed to Al_2O_3 and AlF_3, post-shift urinary Al concentrations of 200 µg/g creatinine corresponded to an airborne Al exposure of 1.36 mg/m^3 during the shift.[24] Biomonitoring of aluminum in electrolytic reduction processes has limited value because the main chemical hazards are fluorides and polycyclic aromatic hydrocarbons.

Available data suggest that 150 µg Al/g creatinine in urine at the end of the shift is a safe biological limit value,[213] although some authors suggest limiting occupational exposure to sparingly soluble Al compounds to <62 µg Al/g creatinine (3 µmol/L).[197] A post-shift Al concentration of 200 µg/g creatinine and 400 µg/g creatinine correlated to Al concentrations in ambient air of 1.04 mg/m^3 and 2.25 mg/m^3 as soluble Al.[105] However, some studies suggest that subtle adverse neurological effects may occur in welders with urine Al concentrations in the range of 110–160 µg/L.[163] A longitudinal study of 32 workers from an Al powder-producing plant did not detect any statistically significant differences in scores on a battery of neuropsychological tests or the event-related P300 potentials when compared with age- and education-matched, unexposed controls from the same plant.[235] Follow-up 5 years later with 21 of the 32 workers did not demonstrate any significant differences in scores between the workers (15 still exposed, 6 formerly exposed) and the control group. Urine samples from the 21 workers and 30 controls at the initial examination contained median aluminum concentrations of about 77 µg/g creatinine (98.8 µg/L) with a range of 4.6–321.4 µg/g creatinine (5.0–336.6 µg/L) compared

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. with a median of 9 μg/g creatinine (7.6 μg/L) and a range of 1.9–51.8 μg/g creatinine (1.9–51.8 μg/L) for the 30 controls.

TREATMENT

Mechanism of Action

Deferoxamine (DFO) is a recognized, specific aluminum chelator that effectively removes aluminum from patients with dialysis-associated encephalopathy,[236] microcytic anemia, and osteomalacia.[237] Chelation is also associated with improvement of symptoms in these patients.[238] Theoretically, 1,000 mg DFO binds 41 mg Al, but the removal of the Al-deferoxamine complex by dialysis is relatively inefficient because DFO does not remove significant amounts of aluminum bound to transferrin. The affinity of DFO for ferric iron as measured by the stability constant is ~9 orders of magnitude greater than aluminum, whereas the stability constants are much lower for essential elements (calcium, copper, magnesium, zinc) than aluminum. Consequently, iron deficiency may occur during DFO therapy, but clinically significant reductions in other essential elements are unlikely.

Pharmacokinetics

In the presence of substantial aluminum stores in bone, the plasma aluminum concentration increases two to four times above the baseline aluminum concentration with the maximum concentration occurring 24–48 hours after administration of DFO.[191]

Indications

The most common presentation of aluminum toxicity is the exposure of renal dialysis patients to excessive phosphate binders or aluminum-contaminated dialysis fluids, resulting in osteomalacia and/or encephalopathy;[61,239] however, aluminum poisoning in renal dialysis patients is now rare in developed countries with modern renal replacement therapies. The administration of aluminum-containing TPN solution may cause aluminum toxicity (osteopenia, pathological fractures) in premature neonates with immature renal function.[77] Case reports also suggest an acute encephalopathy may develop in patients with renal dysfunction treated with alum (aluminum potassium sulfate) for a hemorrhagic bladder.[240]

Although no randomized controlled clinical trials are currently available, the National Kidney Foundation (K/DOQI clinical practice guidelines for bone metabolism and disease in chronic kidney disease) and Kidney Disease Improving Global Outcomes (KDIGO) Work Group provide recommendations for treating these patients based on case reports and expert opinion. Indications for the use of deferoxamine include symptomatic dialysis patients with serum Al concentrations between 60 and 200 μg/mL;[135,241] however, aluminum-associated bone disease may correlate better to Al concentration in bone than serum. The Kidney Disease Improving Global Outcomes guidelines for evaluation and treatment of dialysis-induced bone disease recommend using bone biopsy rather than serum.[242]

Dosage

The DFO dose depends on renal function, chronic vs. acute aluminum exposure, and concern about minimizing the risk of encephalopathy from DFO-induced redistribution of mobilized aluminum to brain in patients with high serum Al concentrations (>200 μg/mL). In dialysis patients, DFO is infused weekly in doses of 5 mg/kg[243] to 15 mg/kg[51] during the last hour of dialysis in order to reduce the loss of DFO in the dialysate.[244] The occurrence of adverse effects to deferoxamine may require DFO treatment 1 and 5 hours before dialysis. For the treatment of acute aluminum intoxication from bladder irrigation with alum, the administration of DFO 6–8 hours prior to daily dialysis was associated with clinical improvement within 3 days and normalization of mental status within 3 weeks.[245] After clinical improvement, hemodialysis decreased to three times per week. The duration of DFO/hemodialysis therapy for chronic aluminum intoxication is long-term ranging from 1–9 months. For dialysis patients with chronic aluminum overload, the use of lower thrice-weekly DFO doses of 0.5 mg/kg[246] or 2.5 mg/kg weekly[247] may be sufficient based on case series; however, there are limited pharmacokinetic data to determine the most efficacious dose.

Adverse Effects

Dialysis-associated encephalopathy has complicated DFO use in chronic renal failure patients with very high serum aluminum concentrations (>200 μg/mL) from prior parathyroidectomy or redistribution of the mobilized aluminum.[248] The weekly DFO dose should be reduced to 5 mg DFO/kg body weight in these patients. Other potential complications of DFO therapy include systemic hypersensitivity reactions, hyperparathyroidism, hypocalcemia, low serum ferritin,

iron deficiency, adult respiratory distress syndrome, and systemic infections (*Yersinia*, *Mucor*).[249]

Adjunctive Treatment

In vitro and *in vivo* studies suggest that coated charcoal hemoperfusion and hemodialysis almost double the removal of aluminum from dialysate compared with hemodialysis alone;[250] however, few human data are available to determine the efficacy of combined hemoperfusion/hemodialysis and charcoal cartridges are difficult to obtain in the United States. Calcium disodium ethylenediaminetetraacetic acid does not appear as effective as deferoxamine in chelating aluminum.[251] The efficacy of deferiprone and deferasirox for aluminum toxicity is not well studied; both of these iron chelators also chelate essential elements (e.g., copper, zinc).[252] Sources of aluminum should be identified including aluminum in the dialysis water and the use of aluminum-containing medications. The current practice involves the use of calcium carbonate together with minimum amounts of aluminum-containing phosphate binding antacids when necessary.

Chapter 2

ANTIMONY

ANTIMONY AND ANTIMONY SALTS

HISTORY

The use of antimony for cosmetic and medicinal purposes dates back to antiquity.[1] Chaldeans manufactured vessels and vases from the black sulfide salt of this metal as early as 4,000 BC. Antimony sulfide was a cosmetic for the embellishment of eyes and eyelashes in Roman times; in Arab countries, women also used antimony (*al-kohl*) to paint their eyes. Although Paracelsus documented the toxicity of tartar emetic (antimony potassium tartrate) in his book *Opera omnia* in 1556, the medicinal use of antimony was reintroduced in 1657 when King Louis XIV recovered from typhoid fever allegedly after the administration of an antimony compound by an unknown physician.[2] For the next several hundred years, trivalent antimony compounds (e.g., tartar emetic) were popular remedies for a variety of purposes including cathartic, diaphoretic, emetic, expectorant, irritant, antidiarrheal agent, antipyretic, skin preparations, and sedative.[3] During the 17th and 18th centuries, drinking wine stored in antimony cups was a popular method for inducing vomiting, purging, and sweating. Dr. James' Fever Powder contained ~33% antimony oxide in addition to potassium tartrate. This product was a popular constituent of the domestic medicine chests of people during the 18th and 19th centuries, including Queen Victoria.[4] Oliver Smith, one of the great English authors of the 18th century, died after developing a severe gastroenteritis following the ingestion of James' Powder for a febrile illness.[5]

The industrial use of antimony on a large scale began in the 19th century. A purification process for gold involved the use of antimony sulfide to form an alloy. Importation of antimony ore (stibnite, Sb_2S_3) in northeastern England occurred from 1870–2003. Processing of this ore involved roasting with charcoal or coke and the collection of the volatile oxide fumes to refine pure antimony. Toxicity associated with dusty conditions in these processing plants included rash (antimony spots), rhinitis, sore throat, bronchitis, conjunctivitis, perforations of the nasal septum, discolored teeth, and gastrointestinal irritation.[6] Excess pneumoconioses and lung cancers occurred in the antimony ore processors during the middle 20th century, but the etiology of these illnesses probably resulted from co-exposure to silica and arsenic.[7] Tartar emetic has been a poisoning agent since the Middle Ages; the infamous modern poisoner, Graham Frederic Young, used a mixture of antimony and thallium to poison his victims.[8]

The use of tartar emetic for dysentery decreased during the American Civil War as a result of the association of tartar emetic with the development of serious intestinal lesions.[9] In 1918, Christopherson demonstrated the efficacy of antimony potassium tartrate in the treatment of schistosomiasis in humans.[10] Later, antimony injections were used successfully to treat cutaneous and visceral leishmaniasis. By the late 1920s, the use of trivalent antimony compounds (anthiomaline, antimony sodium tartrate, stibophen) was replaced by less toxic pentavalent antimony drugs including the sodium

stibogluconate salt of antimony (Pentostam, meglumine antimoniate).

PHYSIOCHEMICAL PROPERTIES

Antimony, bismuth, and arsenic belong to Group 15 (Group Va) in the periodic table that shares similar chemical and biological properties. Antimony is a metalloid with physiochemical properties between metals and nonmetals similar to arsenic. The two stable isotopes of antimony are ^{121}Sb and ^{123}Sb with natural abundances of 57.25% and 42.75%, respectively. ^{125}Sb is a fission product of nuclear fuel preprocessing plants and nuclear explosions with a half-life of 2.7 years. Pure elemental antimony is a brittle, silvery-gray metalloid that crystalizes in a feathery pattern. This metal is stable under normal conditions. Antimony tarnishes little in dry air; this metal oxidizes slowly to blackish-gray mixtures of antimony and antimony oxide.[2] The expansion of antimony during solidification is a useful property for lead–antimony alloys in printing type.

Of the four oxidation states (3−, 0, 3+, 5+), the most common and stable form in the environment is Sb^{3+}. Trivalent forms of antimony occur as thioantimonites *in vivo* after reacting with sulfhydryl groups. Pentavalent antimony is an oxidizer that converts to Sb^{3+} in acidic media. In contrast to most inorganic antimony compounds, antimony potassium tartrate has relatively high water solubility as demonstrated in Table 2.1 on the physical properties and identifying information on antimony and antimony forms complex ions with organic and inorganic acids (e.g., tartrate).

EXPOSURE

Processes

In nature, antimony occurs primarily as the sulfur ore (stibnite, Sb_2S_3) and, to a lesser extent, as an oxide

TABLE 2.1. Physical properties and identifying information of antimony and antimony compounds.

Physical Characteristic	Antimony	Antimony Pentasulfide	Antimony Pentoxide
CAS RN	7440-36-0	1315-04-4	1314-60-9

(valentinite and senarmontite, Sb_2O_3); arsenic is a common constituent of the former ore. The antimony content in these ores ranges from 5–60%. Antimony is a common constituent of lead and copper ores; consequently, Sb is a byproduct of the smelting of lead ores.

Oxidation of the sulfide ore in gas-fired roller furnaces produces oxide fumes (Sb_4O_6), which are collected in a baghouse. Bagging operations are one of the major antimony sources of contamination in the production process.[11] Reduction of the oxide fumes allows the escape of sulfur dioxide. Chemical analysis of airborne dust at these smelting facilities indicates the dust consists primarily of antimony oxides and antimony trioxides (39–89%) and lesser amounts of antimony pentoxide (2–8%), ferric trioxide (1–4%), and arsenic oxide (0.2–6.5%).[12] Until 1972, arsenical slags were byproducts of the removal of arsenic during the production of metallic antimony for antimony–arsenic alloys in the battery industry.[13]

Uses

Industry

Antimony is a brittle compound that is not easily fabricated; therefore, antimony is a common constituent of metal alloys (e.g., lead, tin, copper). The use of antimony up to 2.5% in grid metal of lead storage batteries to increase the mechanical firmness of lead is now uncommon. Potential byproducts of using antimony in lead starter batteries include antimony trioxide (Sb_2O_3) and stibine (SbH_3). Intermetallic compounds (e.g., AlSb) are constituents of thermoelectric devices (e.g., infrared detectors). Semiconductor production uses high-purity antimony. Other uses of antimony compounds include the production of white paint pigment (trioxide), the manufacture of munitions, fireworks, and lubricants for brake pads (antimony trisulfide), ceramics, electrolytic generation of hydrogen (filling of hydrogen balloons), ruby glass (antimony trisulfide), and the creation of fire-proofing chemicals and textiles (antimony trioxide). Antimony oxychloride ($Sb_6O_6C_{14}$) is an effective flame retardant when added to materials as a result of reaction of hydrogen and hydroxy radicals to reduce the rate of flame propagation; heating these materials causes smoldering rather than bursts of flame. The use of flame-retardant clothing by firefighters is not associated with increased exposure to antimony as monitored by urine antimony concentrations.[14] Antimony trioxide is used in the manufacture of ceramics and glass as an agent to remove bubbles and stabilize colors; in plastic, antimony is a bromine receptor for the flame retardants in these objects. Additionally, SbO_3 is an esterification agent in the stabilization of polyester resins and a polycondensation catalyst for plastic polyethylene terephthalate bottles.

Medical Therapy

Anthroposophical medicines (i.e., alternative medicine prescribed based on the spiritual philosophy of Rudolf Steiner) sold in the United Kingdom may contain up to 5% elemental antimony. Trivalent antimony compounds are no longer used for medicinal purposes because of unacceptable side effects and difficulty with drug administration. The pentavalent salt, sodium stibogluconate, remains the drug of choice for visceral leishmaniasis secondary to African *Leishmania donovani* in combination with paromomycin.[15] The trivalent antimony compound, tartar emetic (antimony potassium tartrate, tártaro emético), is a treatment for alcoholism and *Schistosomiasis japonicum* in several countries.[16]

Sources

Antimony is a nonessential element for humans; the daily intake of antimony ranges from 2–29 μg with an average intake of ~5 μg.[17] Antimony is a constituent of tobacco averaging 0.1 mg/kg dry weight; the bioavailability of antimony in smoke is ~20% as measured by neutron activation analysis.[18] The bioavailability of antimony is dependent both on the speciation and physiochemical properties (e.g., antimony present in mineral lattices is almost inert).

Air

Release of Sb into the environment results from both natural and anthropogenic sources (e.g., antimony mines, heavy-duty brake pads), with the former source accounting for about 40% of the emissions of Sb into the air.[19] Coal-fired power plants, metal smelting, and refining and refuse incineration are the major anthropogenic sources of antimony. Because antimony is a relatively volatile metal, combustion processes cause the formation of fine (<1 μm) particles that are not efficiently trapped by air pollution control devices. Workplace ambient air may contain Sb concentrations ranging up to 1–10 mg/m^3.[20]

Soil

Most of the antimony released to the environment partitions into soil; however, antimony is present in soil in very low concentrations (1–8.8 mg/kg, mean =

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

0.48 mg/kg). Little data are available on the adsorption of Sb to soil, but limited data suggest that antimony is relatively mobile under diverse environmental conditions.[21]

Water

Most of the antimony in water is associated with particulate matter. Antimony appears in water as a result of the weathering of soil and of the discharge from anthropogenic sources; however, antimony concentrations in surface waters are usually low (0.02–0.1 μg/L).[21] Concentrations of antimony in groundwater and surface water are similar.

Diet

The mean daily Sb intake is relatively small compared with other common trace metals. In 1,319 samples from the French National Total Diet Study, the mean value for Sb was 0.03 μg/kg bw with a 95% upper limit of 0.07 μg/kg bw.[22] For the general population, drinking water is the most important dietary source of antimony.[2] Cereals, fruit, vegetables, meat, poultry, and freshwater fish contain relatively small amounts of Sb (i.e., 1–10 ng/g wet weight). Radiochemical neutron activation analysis of homogenized composites from 12 table-ready foods obtained during the US FDA Total Diet Study Program demonstrated Sb concentrations ranging from 0.22–2.81 ng/g wet weight.[23] The highest Sb concentrations occurred in shrimp, baked potatoes, clams, and oysters. Antimony trioxide is a polycondensation catalyst in the production of polyethylene terephthalate (PET); leaching of antimony from containers may cause migration of the antimony into drinks (e.g., orange juice) or food.[24] The amount of antimony migrating into bottled water varies with varying storage conditions and containers from different countries. Antimony concentrations in containers may increase near to regulatory limits (e.g., 6 μg/L) with prolonged storage time (e.g., 6–12 months), high temperatures (e.g., 60–80°C), and use of new, recently manufactured bottles.[25] The mean antimony concentration in pristine groundwater increased from 1.7 ± 0.4 ng/L ($n = 6$) to 26.6 ± 2.3 ng/L ($n = 3$) following 6 months of storage in Canadian PET bottles and 281 ± 38 ng/L ($n = 3$) in German PET bottles.[26] In a study of six samples of ready-to-eat foods (pasta, fish fillets, cannelloni), the amount of antimony migrating from the PET container to the food after cooking ranged from 1.8–4.7 μg.[27] Although Sb may leach from plastic polyethylene terephthalate bottles,[28] typical use of plastic beverage bottles does not significantly increase urinary Sb concentrations.[29]

ENVIRONMENTAL FATE

Once released into the atmosphere, antimony particles settle slowly to the ground. Both wet and dry deposition contribute to the transfer of antimony from the air to the surface of the earth. The estimated atmospheric half-lives for antimony and antimony trioxide are 2.8 days and 4.6 days, respectively; the atmospheric half-lives of sub-micron particles of Sb may range up to 30 days.[30] Consequently, antimony may be deposited far from anthropogenic or natural sources. Once released into the atmosphere, the reactions of atmospheric oxidants transform antimony into antimony trioxide. Transportation of antimony into surface water results from the weathering of rocks as well as anthropogenic sources. Antimony occurs in seawater and aerobic freshwater primarily in the 5+ oxidation state (i.e., antimoniate), whereas trivalent antimony predominates in anaerobic environments (e.g., bed sediment). Sediment is a significant sink for antimony. Methylation of antimony by microorganisms (e.g., *Scopulariopsis brevicaulis*, *Clostridium* spp.) in anaerobic water and rotting wood (*Phaeolus schweinitzii*) reduces antimony to dimethylstibonic acid and methylstibonic acid.[31,32]

DOSE EFFECT

Gastrointestinal symptoms begin following the ingestion of >30–60 mg Sb. The ingestion of 2–6 g of trivalent antimony may produce serious toxicity, whereas 10–15 g is a potentially fatal dose. Pentavalent antimony compounds are less toxic than trivalent antimony compounds. A 4-hour infusion of 8.5 g pentavalent antimony (sodium stibogluconate) produced mild elevation of liver enzymes and a 43% reduction of the baseline white cell count, but the patient did not develop serious cardiac or liver toxicity.[33] Vomiting developed in a worker following the ingestion of antimony tartrate (tartar emetic)-contaminated lemonade that contained an estimated 0.53 mg Sb/kg body weight.[34] Oral dosing in pharmacological aversion therapy for the induction of vomiting ranged from ~25–140 mg.[16] The ingestion of ~500 mg tartar emetic by a 19-year-old man produced severe gastroenteritis and dehydration that resolved over 48 hours with supportive care.[35] He was lost to follow-up.

TOXICOKINETICS

Absorption

Most antimony compounds are poorly absorbed (i.e., <1%) from the gastrointestinal tract, and the strong

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

emetic properties of these compounds further limit the absorption of large Sb doses. The absorption of trivalent compounds (trichloride, tartrate) is probably <10% based on an estimated range of absorption of 2–7% in animal studies.[36] Once absorbed, relatively small amounts (<5–10%) of the pentavalent form are reduced to the trivalent form.[37,38] In a pharmacokinetic study of 29 men receiving 600 mg intramuscular pentavalent antimony daily for 10 days, the mean time to peak Sb concentration was 1.34 ± 0.09 hours with a range of 0.5–2 hours.[39] Data on the absorption of antimony from the lung are limited, but animal experiments suggest that the lung rapidly absorbs and distributes antimony following inhalation.[40]

Distribution

The estimated total body burden of antimony in the general population is very low (i.e., ~7.9 mg).[30] Trivalent compounds bind avidly to cells and remain bound to erythrocytes disrupting hemoglobin function. The volume of distribution of pentavalent antimony compounds approximates total body water. In a study of 29 men with cutaneous leishmaniasis receiving 600 mg Sb daily for 10 days, the mean V_d was 45.7 ± 2.6 L with a range of 30.5–86.8 L.[39] The patients weighed 60–70 kg; however, individual weights were not reported. Highly vascular organs (e.g., spleen, liver, kidney, thyroid, bone) contain the highest Sb concentrations.[41] A study of smelter works exposed to ambient antimony indicates inhaled lung deposition of antimony may persist for several years. In a pathological study of 40 deceased, former smelter workers and 11 age-matched, nonexposed men from a nearby rural area, the median antimony concentration in the exposed workers was 315 μg/kg compared with 26 μg/kg in controls.[42]

Elimination

The rate and route of Sb elimination depend on the valence of the compound. The kidney slowly excretes trivalent compounds with 10% recovered in the urine after 24 hours and 30% recovered after 1 week.[43] In contrast to inorganic arsenic, antimony is not methylated *in vivo*; most absorbed trivalent antimony is eliminated in the feces after conjugation with glutathione. Some enterohepatic recirculation probably occurs.[44] The estimated urinary elimination half-life of trivalent antimony in workers at a starter battery production plant was ~95 hours.[45] Excretion of pentavalent antimony compounds occurs primarily in the urine. The kidney excretes pentavalent compounds more rapidly than trivalent compounds with 90% of a parenteral dose eliminated by 24 hours.[46] The elimination of pentavalent follows a multicompartment model with a rapid initial distribution phase followed by slower elimination phase. Primate studies suggest the intracellular conversion of pentavalent Sb to the trivalent form occurs during the resultant slow terminal elimination phase (i.e., 30–140 days) of trivalent Sb.[47] In a study of 12 young adults receiving 600 mg pentavalent antimony IM daily for 3 weeks, the mean terminal Sb elimination half-life from the blood was ~9.5 hours as measured by flameless atomic absorption spectrophotometry.[48] At the end of treatment, the kidneys excreted ~40% of the intramuscular dose of Sb during the first 24 hours after injection. Following the intramuscular injection of pentavalent compounds (stibogluconate, meglumine antimoniate) in 10 subjects, the mean half-life during the initial phase was ~2 hours compared with 76 hours for the terminal elimination phase based on a three-compartment model.[49] The slow terminal elimination phase may represent the *in vivo* conversion of pentavalent antimony to the trivalent form; small amounts of Sb may persist for many days (e.g., >50 days) after prolonged courses of pentavalent Sb.[50] The daily applications of trivalent antimony (antimony potassium tartrate) over 10 days did not result in Sb accumulation in the experimental animals.[51]

Maternal–Fetal Kinetics

Pentavalent antimony is excreted in breast milk. In a case report of a lactating mother receiving 20 mg pentavalent antimony/kg IV for leishmaniasis, the serum/breast milk ratios 4 hours and 23 hours after the last IV dose were 2.8 and 0.2, respectively.[52] The mean peak antimony concentration occurred 4 hours after the IV dosing.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Like arsenic, antimony has a strong affinity for sulfhydryl groups on many enzymes; however, antimony is less toxic than arsenic on a dose-response basis. Antimony potassium tartrate is a potent emetic with both local irritating and central emetic effects. Trivalent antimony compounds inhibit phosphofructokinase, which is an energy source for intracellular parasites. The exact mechanism of toxicity in humans remains unclear; *in vitro* studies suggest that antimony may inhibit pyruvate dehydrogenase complex and ATP production similar to arsenic by limiting acetyl coenzyme A from entering the Krebs cycle.[53]

CLINICAL RESPONSE

Medical Therapy

Cardiotoxicity is the most serious side effect in patients treated with antimony compounds for parasitic infections. Conduction delays, prolongation of the QT interval, and ST-T wave abnormalities occur commonly in patients administered trivalent antimony compounds; rarely, ventricular dysrhythmias may develop. Minor electrocardiographic changes usually occur after therapeutic doses of pentavalent antimony compounds, but high doses of these compounds may cause life-threatening dysrhythmias.[54] Prolongation of the corrected QT interval (i.e., $QT_c > 500$ msec) and concave ST segments are the most significant prognostic signs of the development of serious cardiotoxicity. In a UK case series of 65 British travelers returning with New World cutaneous or mucosal leishmaniasis, each patient received a 21-day course of 20 mg/kg intravenous sodium stibogluconate daily.[55] Six asymptomatic patients developed a QT_c interval ≥450 msec or ≥50 msec increase above baseline in the third week of therapy. An 81-year-old man in this case series developed episodes of ventricular tachycardia without cardiovascular compromise. He had hypokalemia and a QT_c of 567 msec that resolved after normalization of the serum potassium concentration and resolution of the dysrhythmia.

Acute Oral Toxicity

The clinical presentation of acute antimony poisoning is similar to arsenic poisoning with the exception that neurotoxicity does not usually occur following Sb poisoning. Gastrointestinal symptoms (nausea, vomiting, diarrhea, abdominal pain) begin within 4–6 hours after ingestion of toxic doses (i.e., >30–60 mg Sb); gastroenteritis can cause severe dehydration as a result of intractable vomiting and diarrhea. Hepatic necrosis, coagulopathy, hepatic encephalopathy, and acute tubular necrosis may occur in severe cases of acute Sb poisoning.[56] High antimony doses can cause corrosion of the upper gastrointestinal tract and massive gastrointestinal bleeding, particularly in elderly patients.[41]

Occupational Exposure

Lungs

Although antimony in high concentrations is a respiratory irritant, co-exposure to arsenic complicates the interpretation of reports on Sb toxicity. Acute exposure to high ambient concentrations of antimony oxide and other ores can produce severe pulmonary edema along with cutaneous burns and pruritic papules that progress to pustules (*antimony spots*). Transient exposure to fumes of hydrochloric acid and antimony trichloride was associated with upper respiratory tract irritation from the HCl as well as gastrointestinal distress (abdominal pain, nausea, vomiting, anorexia), and headache; symptoms resolved within 1 week without sequelae.[57]

A simple pneumoconiosis was associated with the inhalation of antimony trioxide/pentoxide by workers with at least a decade of antimony exposure at antimony sulfide smelters. The clinical presentation was similar to other mild pneumoconioses (e.g., siderosis, stannosis, baritosis).[12] The etiology of pneumoconiosis may be mixed; consequently, the role of antimony in this disease remains unclear because of the presence of several confounders (e.g., silica, arsenic oxide, sodium hydroxide, ferric oxide). Animal studies indicate that exposure to dust from antimony ore produces mild, transitory pneumonitis, but neither the ore nor trivalent antimony induces progressive chronic inflammation of the lung.[58] A case series of workers at a smelter processing antimony sulfide ore associated work at the smelter with laryngitis, pharyngitis, rhinitis, and conjunctivitis; however, co-exposure to arsenic in the ores complicates interpretation of the study.[20] A case report associated exposure to high concentrations of antimony pentachloride with the development of pulmonary edema (presumably noncardiogenic); however, there was no ambient air monitoring to determine the actual exposure.[59] Two of the three workers died.

Skin

A pustular dermatitis is a recognized effect of exposure to antimony compounds (e.g., tartrates, trioxides) in antimony smelters,[60] welding,[61] production of grinding wheels,[62] and the use of metallic antimony for the manufacture of brazing rods.[63] These antimony spots are characterized by gray-white papules and pustules that surround sweat and sebaceous glands. Eczema may develop in areas of irritation that eventually form lichenification. Typically, these lesions appear on the legs, arms, back of neck, and scrotum during summer months as a result of heat and sweating. The face, hands, and feet rarely have lesions.[13] These lesions disappear following cessation of antimony exposure. Antimony chloride is a strong caustic.[64]

Heart

Although cardiotoxicity is a complication of the medicinal use of pentavalent antimony, there is no direct

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

evidence that Sb exposure at concentrations typically present in the work environment causes or exacerbates cardiac disease. Exposure to antimony in the workplace primarily involves trivalent Sb. Older literature suggest inhalation of high Sb concentrations in the workplace may cause cardiomyopathy with prominent T-wave depression and dysrhythmias;[62] however, the documentation of exposure levels and confounding variables limit regarding the causation of these cardiovascular effects.

Carcinogenicity

Neither the IARC nor the US National Toxicology Program lists metallic antimony as a potential animal or human carcinogen. The IARC lists antimony trioxide as possibly carcinogenic to humans (Group 2B) based on animal data, whereas antimony trisulfide is listed as unclassifiable (Group 3). Both trivalent and pentavalent antimony compounds are usually negative in non-mammalian genotoxicity testing, whereas the former is positive and the latter negative in mammalian test systems.[65] A statistically significant excess of lung cancer occurred in workers exposed to fumes from the antimony smelting process before 1960 when compared with standardized national cancer rates.[13] Workers in antimony smelters before 1960 were exposed to antimony and antimony oxides at ambient air concentrations exceeding current standards by 20 times in addition to arsenic and arsenic oxides, sulfur dioxide, and polycyclic aromatic hydrocarbons. The excess risk of lung cancer disappeared after the 1960s when arsenic concentrations decreased in these processes.[66] The minimum latency period between first exposure and death from lung cancer for the pre-1960 cohort was 20 years. Exposure of rats to Sb concentrations ~100 times above the current TLV (50 mg Sb_2O_3/m^3) for 1 year at 7 hours/day and 5 days/week produced a statistically significant excess of lung neoplasms in female but not in male rats.[67] In this study, the appearance of interstitial pulmonary fibrosis usually preceded the development of lung tumors.

DIAGNOSTIC TESTING

Analytical Methods

Analytical methods for the quantitation of antimony (Sb^{3+}, Sb^{5+}) in biological samples include flow injection-hydride generation atomic absorption spectrophotometry (limit of detection, 0.5–1 μg/L),[68] anodic stripping voltammetry and graphite furnace atomic absorption spectrometry (LOD, 20–25 μg/L),[69] inductively coupled plasma/mass spectrometry (ICP/MS; LOD, 0.03 μg/L; coefficient of variance, 4%),[70] and neutron activation (NAA; LOD, 5 μg/L). Currently, ICP/MS is the most common method for detection of antimony; this method is more sensitive than older techniques (e.g., NAA). Consequently, the use of older methods may overestimate the antimony concentration in biological samples from the general population when a significant number of samples are below the LOD.

Only NAA does not require digestion of the sample. Losses of antimony as the chloride salt during the volatilization step of sample preparation for atomic absorption spectrophotometry may occur. The use of online ion chromatography/inductively coupled plasma/mass spectrometry allows the speciation of antimony compounds with LOD_s of trivalent and pentavalent in the range of 0.16 μg/L.[50]

Biomarkers

Blood

Pentavalent compounds bind poorly to erythrocytes; therefore, these pentavalent compounds typically produce much higher plasma antimony concentrations than similar doses of trivalent compounds. As a result of the very small fraction of pentavalent antimony bound to erythrocytes, plasma and whole blood antimony concentrations are similar following the administration of these compounds.[50] Trivalent Sb concentrates in erythrocytes; therefore, whole blood Sb concentrations are higher than serum or plasma Sb concentrations following absorption of trivalent Sb compounds.

General Population

Antimony is a trace element that occurs in small quantities in the blood. Several European studies indicate that Sb concentrations range from 0.03–3.5 μg/L (mean = 2.16 μg/L) in whole blood and from 0.01–1.7 μg/L (mean = 0.3–0.5 μg/L) in serum.[71,72] In a study of schoolchildren from rural areas of Kwazulu/Natal, South Africa, whole blood antimony concentrations ranged from <0.03–3.82 μg/L (median = 0.39 μg/L) compared with 1.40–4.35 μg/L (median = 2.08 μg/L) in whole blood samples from adults living in Dearborn, Michigan, as measured by inductively coupled plasma/mass spectrometry (LOD, 0.03 μg/L).[70] The mean whole blood antimony concentrations were 0.85 ± 0.90 μg/L and 2.51 ± 1.11 μg/L, respectively. In a French study of 100 healthy adults, the median antimony concentration in plasma samples was 0.11 μg/L (95% reference range, 0.03–0.15 μg/L) compared with 0.08 μg/L (95% reference range, 0.05–0.13 μg/L) in whole blood samples as measured by ICP/MS.[73] The LOQ was 0.02 μg/L and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

0.03 μg/L, respectively, with inter-assay imprecision of ~4–5%.

Medical Therapy

In a study of 12 Brazilian patients with cutaneous leishmaniasis receiving intravenous injections of 20 mg Sb^{5+}/kg/day for 20 days, the mean plasma Sb concentration prior to the last dose was 210 ± 19 μg/L with a range of 61–452 μg/L.[74] The blood samples were collected from 5 minutes to 48 hours prior to the last injection. Half of the patients reported arthralgias and myalgias during the course of treatment. The baseline plasma Sb concentrations for 18 Brazilian patients in this study were 3.39 ± 3.12 μg/L. In a study of 29 patients receiving a 10-day course of intramuscular 600 mg pentavalent antimony daily, the peak Sb concentration ~1.5 hours after injection was 8,770 ± 390 μg/L.[39] Ten patients received 5 mg Sb^{5+}/kg bodyweight intramuscularly for 30 days or 60 days; whole blood samples were collected 24 hours after the last dose. The mean steady-state Sb concentration in whole blood samples was 220 ± 7 μg/L.[50] Prior to initiation of therapy, the baseline mean whole blood Sb concentration was 0.69 μg/L.

Environment

Cross-sectional studies of subjects living in areas contaminated with antimony from mining activities indicate that antimony does not easily transfer from soil to humans. In a German study of 89 residents exposed to heavily Sb-contaminated soil (i.e., up to 776 mg/kg), the mean whole blood Sb was 0.89 μg/L compared with 0.69 μg/L in 49 referents as measured by graphite furnace/atomic absorption spectrometry after microwave digestion.[75] The mean amount of Sb excreted in 24-hour urine samples from the exposed group was 1.03 μg compared with 1.61 μg for the referents.

Overdose

Following an IV dose of 1,400 mg sodium stibogluconate (20 mg/kg), the serum antimony concentration in a 27-year-old woman 15 minutes after the infusion stopped was 85,000 μg/L.[52] The inadvertent infusion of 8,500 mg of sodium stibogluconate (143 mg/kg) over 4 hours produced a serum antimony concentration of 210,000 μg/L 30 minutes after the infusion stopped.[33] The serum antimony concentration 3½ and 8 hours later was 27,500 μg/L and 4,600 μg/L, respectively. No serious effects developed.

Urine

Typical urine Sb concentrations in the general population without occupational exposure are <0.1 μg/L as measured by more sensitive analytical methods (e.g., inductively coupled plasma/mass spectrometry).[76] In a French study of 100 healthy adults, the median antimony concentration in urine samples was 0.04 μg/L (95% reference range, 0.02–0.08 μg/L) as measured by ICP/MS.[73] The LOQ was 0.009 μg/L with inter-assay imprecision of ~5%. Pentavalent antimony is the predominant Sb species in human urine with traces of trivalent antimony and pentavalent organic Sb (e.g., trimethyl Sb) as measured by liquid chromatography coupled with ICP/MS.[77] Ten patients received 5 mg Sb^{5+}/kg bodyweight intramuscularly for 30 days or 60 days; spot urine samples were collected 24 hours after the last dose. The mean steady-state Sb concentrations in urine samples were 38,000 ± 800 μg Sb/g creatinine.[50] Prior to initiation of therapy, the baseline mean urine Sb concentration was 2 μg/g creatinine.

Abnormalities

The chest x-ray in workers with antimony pneumoconiosis generally demonstrates small, rounded and irregular opacities (p, s type).[78] Although chest x-rays may demonstrate numerous small opacities in the middle and lower lung fields, large opacities and massive fibrosis are not characteristic of antimony-associated pneumoconiosis. No specific clinical finding or laboratory abnormality distinguishes this pneumoconiosis from other types of simple pneumoconioses.

Biochemical abnormalities typically associated with antimony toxicity include mild leucocytosis, evidence of dehydration (e.g., elevated BUN/creatinine ratio), and rhabdomyolysis; measures of hepatic and renal function usually remain normal when fluid imbalance is corrected.[35,41,56] In a case series of 65 returning travelers treated with a 21-day course of pentavalent sodium stibogluconate, a majority developed asymptomatic elevations of serum amylase and hepatic aminotransaminases.[54] Mild to moderate hyperkalemia, anemia, and hepatorenal dysfunction may occur in severe cases along with rhabdomyolysis.[79] Electrocardiographic abnormalities associated with the therapeutic use of trivalent antimony (tartar emetic) include reduced T wave amplitude, T wave inversions, and QT prolongation.[80]

HEALTH SURVEILLANCE

The ACGIH currently recommends TLV–TWA for antimony of 500 μg/m^3. This recommendation corresponds to the NIOSH REL–TWA and the OSHA PEL–TWA. The US EPA maximum contaminant level

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

for antimony in drinking water is 6 μg/L. Preplacement physical examinations should include comprehensive medical and work histories with emphasis on the skin, respiratory tract, and cardiac systems. Laboratory tests should include a chest x-ray, an electrocardiogram, and screening pulmonary function tests.

Blood

In a Taiwanese study of 103 optoelectronic workers with some exposure to antimony, the mean whole blood Sb concentration obtained during physical examinations prior to work was 0.72 ± 0.72 μg/L; these workers had co-exposure to arsenic (mean = 8.58 ± 6.36 ppb).[81] These values were similar to the mean whole blood Sb concentration (0.64 ± 0.64 μg/L) in 67 office workers without occupational exposure to antimony. The mean whole blood antimony concentration in a convenience sample of 15 Brazilian port workers exposed to Sb from heavy-weight brake pads was 27 ± 9 ng/kg as measured by hydride generation/atomic fluorescence spectrometry.[82] The end-of-work week venous samples from 14 formation workers exposed to median ambient air trivalent Sb concentration of 12.4 μg/m^3 (range, 0.6–41.5 μg/m^3) contained a median of 10.1 μg/L (range, 0.5–17.9 μg/L).[45]

Urine

In a Taiwanese study of 103 optoelectronic workers with some exposure to antimony, the mean urine Sb concentration obtained during physical examinations prior to work was 0.46 ± 0.22 μg/L.[81] These values were similar to the mean urine Sb concentration (0.30 ± 0.43 μg/L) in 67 office workers without occupational exposure to antimony. In a German study of 45 batch mixers exposed to trivalent antimony trioxide during glass manufacturing, the median urinary Sb concentration was ~5 μg/L with a range of 1.5–15.7 μg/L as measured by hydride generation and electrothermal atomic absorption spectrometry.[83] The concentrations of trivalent antimony trioxide in three personal air samples from the batch mixing area were <50 μg/m^3, 720 μg/m^3, and 840 μg/m^3. In a study of 32 workers from 6 art glass manufacturing plants exposed to trivalent Sb, the biological monitoring concentrations of Sb were higher than in the previous study. An exposure of 500 μg Sb/m^3 corresponded to an estimated total urinary Sb concentration of 49 μg/L as measured by electrothermal atomic absorption spectrometry.[84] The median Sb concentrations in ambient air samples from two plants were 14.0 μg/m^3 (n = 10; range, 3.9–31.0 μg/m^3) and 23.0 μg/m^3 (n = 14; range, 4.7–412.0 μg/m^3). Ambient air concentrations of antimony may not correlate to urinary antimony concentrations when airborne exposure to antimony is relatively low (e.g., 1–2 μg/m^3).[85] There are no biological exposure limits for antimony as a result of the limited occupational data on antimony exposure and the difference in urinary excretion between trivalent and pentavalent Sb compounds. Preliminary data suggest that an 8-hour exposure to 500 μg/m^3 increases the urinary Sb concentration to 35 μg Sb/g creatinine.[44] The end-of-work week urine samples from 14 formation workers exposed to median ambient air Sb concentration of 12.4 μg/m^3 (range, 0.6–41.5 μg/m^3) contained a median of 15.2 μg/g creatinine (range, 3.5–23.4/g creatinine).[45]

TREATMENT

There are little data to guide treatment and treatment primarily is supportive. Chelation with British Anti-Lewisite (BAL) is a potentially useful treatment for serious antimony exposures based on structural similarity to arsenic; however, there are inadequate clinical data to evaluate the efficacy of BAL for antimony toxicity. 2,3-Dimercapto-1-propanesulfonic acid (DMPS) and meso-2,3-dimercaptosuccinic acid (DMSA) are oral analogs of BAL that may provide an alternative to BAL therapy, but there are few data on the use of DMPS (50 mg every 8 hours) or DMSA (100 mg PO tid) for antimony poisoning. Several literature reviews suggest the use of DMSA based on the chemical similarity (e.g., high electronegativity, high affinity to sulfur-containing chelating agents) with arsenic.[86,87] All cases of serious antimony poisoning should be monitored closely for the development of dysrhythmias, fluid depletion, hepatorenal dysfunction, hepatic encephalopathy, and electrolyte imbalance.

STIBINE GAS (ANTIMONY HYDRIDE)

STIBINE GAS

The reaction of elemental antimony with hydrogen produces the highly toxic gas (stibine, antimony hydride, SbH_3) in the 3− oxidation state. This reaction occurs during the reduction of antimony compounds, the electrolysis of basic or acidic solution and Sb-containing cathodes, or following the reaction of acids with metal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TABLE 2.2. Physical properties and identifying information of stibine gas.

Physical Characteristic	Stibine Gas
CAS RN	7803-52-3
Molecular formula	SbH_3
Molecular weight (g/mol)	124.77
Valence	−3
Color	Colorless
Physical state	Gas
Odor	Disagreeable (similar to H_2S)
Melting/boiling points (°C)	−88/−17
Density (g/mL)	2.204 (at boiling point)
Water solubility	4.1 g/L (0°C)
Vapor pressure	>760 torr (20°C)
Conversion factor (25°C, 760 torr)	1 ppm = 5.1 mg/m^3 1 mg/m^3 = 0.196 ppm

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number

antimonides or antimony alloys. Stibine is a colorless gas with a disagreeable odor. Table 2.2 lists some physical properties and identifying information of stibine gas. Stibine gas evolves from the exposure of Sb alloys to acids and electrolysis or from the action of hydrogen on metallic Sb. This substance decomposes slowly in to elemental antimony and hydrogen. Oxidation of stibine gas in air forms antimony trioxide and water. In a study of workers exposed to trivalent antimony and stibine gas, the initial elimination half-life of antimony was similar (i.e., ~95 hours) following exposure to either substance.[45]

Few clinical data are available on the effects of stibine gas exposure. Interpretation of existing data is complicated by coexposure to arsenic in sources of stibine gas; however, existing data suggest stibine and arsine (AsH_3) gases produce similar effects. Clinical features of stibine gas exposure include hemolytic anemia, myoglobinuria, renal failure, weakness, profuse vomiting, nausea, headache, abdominal and low back pain, and hematuria.[88] Vomiting is usually prominent. The off-gassing of hydride gases including stibine gas generated from the effect of fungal degradation on fire retardants in PVC cot mattress covers was suggested as a possible cause of sudden infant death syndrome (SIDS);[89] however, there are insufficient data to establish a causal link.[90] *In vitro* studies indicate that antimony volatilization from PVC in cot mattresses does not occur under normal environmental conditions; off-gassing of antimony requires heating 80–100°C.[91] For stibine gas, the ACGIH TLV–TWA, US OSHA PEL, and the NIOSH REL are 0.1 ppm (0.5 mg/m^3). Treatment for stibine gas poisoning is supportive. There is no human evidence that BAL improves clinical outcomes after stibine gas exposure.[92] Few human data are available on the efficacy of exchange transfusion following stibine gas exposure; however, exchange transfusion is a potential option in the clinical setting of acute renal failure, hemolysis, or rhabdomyolysis.

Chapter 3

ARSENIC

ELEMENTAL AND INORGANIC ARSENIC

HISTORY

Arsenic has a long history of abuse as a common, inexpensive homicidal agent and use as a medicinal agent in Greco-Roman and traditional Chinese medicine. Commercial applications of arsenicals in modern ages include a wood preservative, pesticide, veterinary anthelminthic, and ant paste; however, many of these arsenical products have been replaced by less toxic substances. Arsenic poisoning also occurs from the accidental addition of arsenic to commercial products. In 1955, the Morinaga Dry Milk Company produced arsenic-contaminated milk when a disodium phosphate stabilizer contained 5–8% of a soluble inorganic arsenic compound expressed as arsenous acid. The estimated arsenic concentration in the reconstituted milk was ~4–7 mg/L with a maximum of 4 months of exposure. Over 12,000 infants developed arsenic poisoning (fever, hyperpigmentation, hepatomegaly, anemia) with at least 130 infant deaths.[1] Follow-up studies suggest significantly increased mortality occurred in the survivors.[2]

Poisoning

The nonspecific, widespread effect of this odorless, tasteless compound enhanced the popularity of arsenic as a homicidal agent causing slow, painful deaths.[3] In one of the first recorded cases of arsenic poisoning, Nero poisoned Britannicus in 55 AD to solidify his position as Emperor of Rome. During the early Middle Ages, poisoning was a prevalent part of social and political life. Arsenic gained a reputation as "inheritance powder;" legendary arsenic poisoners included Cesare Borgia, Teofania di Adamo, Marie Madeleine, and later in the 19th century, Goeie Mie ("Good Mary") of Leiden, The Netherlands. The latter poisoner distributed arsenic trioxide-laced hot milk to over 100 victims. Other famous arsenic poisoners include Herbert Armstrong, Marie Besnard, and Marie Lafarge. Acute diarrhea associated with arsenic poisoning was easily confused with cholera. The German–Swedish apothecary and pharmacist, Carl Wilhelm Scheele, developed the Scheele test for detecting arsenic.[4] Heating a mixture of arsenic with metallic zinc and nitric acid produced arsine gas (AsH_3) that was detectable as a garlic odor; however, the test was unreliable and inadmissible in court. The British chemist, James Marsh, improved the Scheele test by heating the trapped arsine gas in a funneled tube to form a gray metallic film ("arsenic mirror") and hydrogen gas. The development of the Marsh test in 1836 allowed the detection of 20 μg of arsenic by conversion of arsenic to arsine gas with nitric acid and the modified Scheele test.[5] Sufficient arsenic was collected as a silver-black deposit on a cold ceramic bowl to provide visual proof of the presence of arsenic. The popularity of arsenic as a homicidal agent declined significantly after the development of this test and the subsequent conviction of the celebrated poisoner,

Marie Lafarge, in September 1840.[6] Her controversial trial was the first legal case using forensic evidence to convict, when the Dean of the Paris Faculty of Medicine, Mathieu Orfila, confirmed the presence of arsenic in her husband's body using the Marsh test.[7]

Activation analyses of authenticated hairs of Napoleon correlated arsenic concentrations to clinical symptoms of chronic arsenic poisoning as recorded in the written diaries of his exiled companions.[8] In the month before his death, Napoleon complained of coffee-ground vomiting, yellow skin, scleral icterus, weight loss, and anorexia. Other complaints in the preceding year included right scapular pain, nausea, headaches, weakness, coughing, and abdominal distension. Although elevated arsenic concentrations occurred in hair samples reportedly from his scalp before and during his incarceration at St. Alba,[9] the contribution of arsenic to the death of Napoleon remains speculative. Another author attributed the final phase of Napoleon's chronic illness to the ingestion of calomel (mercurous chloride) flavored with oil of bitter almonds that formed mercuric cyanide. Besides arsenic exposure, Napoleon received several compounds that would potentially predispose him to hypokalemia, QT prolongation, and sudden death from ventricular fibrillation including quinine from Jesuit's bark, antimony in tartar emetic, and mercurous chloride in calomel.[10] An interdisciplinary analysis of the medical data recorded during Napoleon's internment indicated that his clinical course was not consistent with chronic arsenic toxicity.[11] An official autopsy performed by Francesco Antommarchi soon after Napoleon's death documented an upper gastrointestinal bleed and a perforated 10-cm-cancerous tumor in the lesser curvature of his stomach with cancer as the listed cause of death. His father also died of stomach cancer. The autopsy included no histological confirmation of the stomach cancer, as was the custom in the early 1800s; his autopsy contained no confirmation of any stigmata of chronic arsenic poisoning (Mees' lines, alopecia, hyperkeratosis, hyperpigmentation). Potential sources for the arsenic in hair samples from Napoleon include the volatilization of trimethylarsine from arsenic compounds in wallpaper, hair products, clothing, food wrappers, medicines, and well water.[12] Green copper arsenite (Paris green, Scheele's green) pigments were common constituents of wallpapers in the early 1800s; molds are capable of releasing trimethylarsine from damp wallpaper.[13] X-ray fluorescence spectroscopy of a wallpaper sample from the room where Napoleon died suggested the wallpaper was capable of off-gassing sufficient trimethylarsine to produce illness, but probably not death.

Medical Therapy

Hippocrates, Aristotle, and Pliny the Elder wrote about the medicinal properties of arsenicals. Hippocrates used arsenic sulfides (realgar, orpiment) for the treatment of ulcers; the Greek physician, Dioscorides, used orpiment as a depilatory.[14] In China, the Nei Jing Treaty recommended arsenic for the treatment of periodic fever. Si-Miao Sun (581–682) used an arsenic-containing medicine (orpiment, realgar, arsenic trioxide) for the treatment of malaria. In 1786, Thomas Fowler published a study on the treatment of malaria with a solution of potassium arsenite (Fowler's solution, Liquor Mineralis). This solution was widely administered for a variety of diseases (e.g., malaria, syphilis) until the mid-20th century. Beginning in the middle of the 19th century, a variety of arsenic-containing compounds including Fowler's solution (1% potassium arsenite), Asiatic pills (arsenic trioxide), Donovan's solution (AsI_3), and De Valagin's elixir (arsenous acid/hydrochloric acid) were remedies for a variety of ailments (e.g., rheumatism, asthma, chorea, tuberculosis, diabetes, fever, skin and blood abnormalities, nutritional disturbances, syphilis, trypanosomiasis).[3] Erasmus Wilson first described arsenical keratoses of the palms and soles in 1868.[15] By the early 1900s, physicians began substituting less toxic organic arsenicals for inorganic arsenic compounds. Although traditional Chinese and Western medicine used inorganic arsenic compounds to treat cancer for several hundred years, the popularity of inorganic arsenic as a treatment for chronic myelogenous leukemia did not increase significantly until the 1930s; however, adverse effects from the high arsenic doses limited the use of inorganic arsenic compounds. Beginning in the 1970s and 1980s, successful Chinese and Indian studies resulted in a resurgence of the use of arsenic trioxide for the treatment of acute promyelocytic leukemia in combination with all-*trans*-retinoic acid.[16] The key driver for this disease results from the fusion of the retinoic acid receptor α gene (*RAR*α) on chromosome 17 to the promyelocytic leukemia gene (*PML*) on the long arm of chromosome 15 (15q) that creates the PML-RARα fusion protein, producing the fusion protein responsible for acute promyelocytic leukemia. Arsenic binds to thiol groups on this protein.[17]

Environment

Arsenic is a constituent of arsenopyrite (FeAsS); this sulfide mineral commonly occurs in association with copper and iron ores. Consequently, arsenic trioxide

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. is a byproduct of the smelting of these ores. Agricola and Paracelsus described arsenic poisoning in miners in the 15th and 16th centuries.[18] Arsenic is an occasional contaminant of well water and food. At the beginning of the 20th century in Salford, England, the ingestion of arsenic-contaminated beer was associated with the development of gait disturbances and sensorimotor neuropathy.[19] The cause of the Staffordshire beer epidemic was the use of arsenic-containing Spanish pyrite as a source of sulfuric acid to produce inverted sugar during the brewing process. In 1955, the contamination of sodium phosphate stabilizer in infant formula caused over 12,000 cases of arsenic poisoning in Japanese infants including 130 deaths.[20] Clare Booth Luce developed arsenic intoxication while she was the American Ambassador to Italy in the 1950s; the source of her poisoning remains unknown.[21] A review of 17 cases of arsenic toxicity during the 1980s in Minnesota demonstrated the following distribution of etiologies: accidental (41%), suicidal (41%), homicidal (12%), and malingering (6%).[22] The source of the vast majority of these poisonings was Terro Ant Killer®. A retrospective review of arsenic exposures reported to a poison control center during the 1980s indicated that exposure of children to arsenic primarily involved sodium arsenate in ant poison.[23,24] In 1989, the US EPA instituted the phase out of certain arsenic-containing ant poisons to reduce arsenic exposure in US children.

Chronic arsenic poisoning results from the natural contamination of drinking water with arsenic in several areas of the world including Argentina, Bangladesh, Chile, China, Finland, Hungary, India, and Mexico. Additionally, sporadic contamination of drinking water wells may result from the mining of ores (gold, silver, copper, lead, tin) that contain arsenic sulfides. The largest epidemic of arsenic poisoning occurred in Southeast Asia with an estimated 1.5 million inhabitants in West Bengal, India, and 21 million inhabitants in Bangladesh exposed to drinking water containing >50 μg arsenic/L.[25] In these inhabitants, consumption of high arsenic concentrations in drinking water up to 3.4 mg/L from tube wells was associated with the development of skin lesions (hyperpigmentation, hyperkeratosis, gangrene).[26,27] These tube wells have been installed in Bangladesh since the 1940s as a means to avoid microbial contamination. During the 1960s and 1970s, the United Nations Children's Fund (UNICEF) worked with the Department of Public Health Engineering to provide approximately one million wells, consisting of 5-cm-tubes inserted up to 200 m into the ground and capped with hand pumps; the arsenic concentration in the drinking water was not analyzed prior to the installation of these wells. Additional tube wells were installed privately in the 1970s and 1980s; by the end of the 1980s, 97% of the population drank water from tube wells. KC Saha at the Department of Dermatology at the School of Tropical Medicine in Calcutta, India, identified the first cases of arsenic-induced skin lesions in the early 1990s.[28] In Bangladesh, confirmation of arsenic contamination in tube-wells occurred in 1993 in the Nawabganj district. Ecological studies in Taiwan and Argentina during the 1990s suggest an elevated prevalence of skin and bladder cancers following chronic exposure to arsenic in drinking water.[29] Blackfoot disease is a unique peripheral vascular disease resulting from continuous exposure to arsenic-contaminated well water. Retrospective case-control studies of liver, lung, and bladder cancer in areas of Taiwan where Blackfoot disease is endemic suggest an elevated incidence of these cancers.[30]

PHYSIOCHEMICAL PROPERTIES

Elemental arsenic is a reactive transitional, nonessential element that belongs to Group 15 (Group VA) of the periodic table along with antimony, bismuth, nitrogen, and phosphorus. Arsenic is a naturally occurring metalloid capable of combining with metals or nonmetals to form inorganic (arsenites, arsenates), organic compounds (methyl and phenyl arsenates), and nonmetal/metal combinations (arsenopyrite, FeAsS). Arsenic occurs in the following four valence states: −3 (arsine), 0 (elemental), +3 (arsenite, AsO_2^-, including monomethylarsonite and dimethylarsenite), and +5 (arsenate, AsO_4^{-3}, including monomethylarsonate and dimethylasinate). Metallic arsenic is a brittle, crystalline, brilliant steel-gray metalloid that turns black upon exposure to air. Elemental arsenic is water-insoluble. Arsenite is the dominant form under reducing conditions, whereas arsenate is the stable form in well-oxygenated environments.[31] Heating arsenic-containing ores to 193°C releases arsenic fumes that combine with precipitation to form "white arsenic" (arsenic trioxide) in water. From a toxicological perspective, the major classifications of arsenic compounds include inorganic arsenic, metalloid arsenides, organic arsenic, and arsine gas. Figure 3.1 illustrates the chemical structure of some toxicologically relevant trivalent and pentavalent arsenic compounds.

Inorganic trivalent arsenic compounds include arsenic trioxide, arsenic trichloride, and sodium arsenite. Arsenic salts exhibit a wide range of solubilities depending on the redox potential and the pH. Arsenic trioxide is slightly soluble in water and forms arsenite in highly alkaline solutions. The aqueous solubility

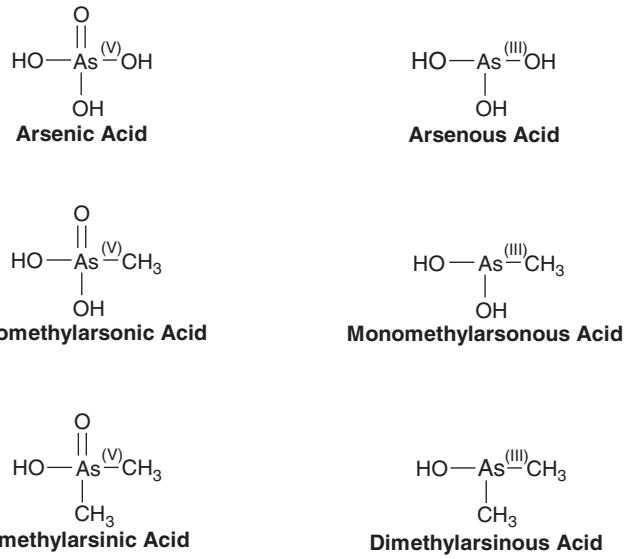

FIGURE 3.1. Chemical structures of toxicologically relevant trivalent arsenic (III) and pentavalent arsenic (V) compounds. (Adapted from Ren et al.).[32]

of arsenic trisulfide (0.0005 g/L at 18°C) is relatively low compared with arsenic trioxide (17 g/L at 16°C). The interaction of concentrated hydrochloric acid with arsenic trioxide produces arsenic trichloride. Pentavalent inorganic compounds include sodium pentoxide, lead arsenate, calcium arsenate, and arsenic acid. Arsenate is a phosphate analog; organisms living in elevated arsenate environments require high concentrations of phosphate to avoid arsenic toxicity. Both sodium arsenite and sodium arsenate are highly soluble in water. Inorganic arsenic compounds can change valence in water depending on the pH and the presence of other substances.[33] The oxidation of trivalent arsenic is more rapid in alkaline solutions than acidic solutions, whereas pentavalent inorganic arsenic is relatively stable in neutral and alkaline solutions.[34] The reduction of pentavalent inorganic arsenic increases as the pH decreases. Tables 3.1 and 3.2 list the identifying data and physical properties of some common inorganic arsenic compounds.

EXPOSURE

Production Processes

Arsenic compounds (e.g., arsenic trioxide) are byproducts of lead, copper, and gold extraction. Smelting of arsenic-containing ores (e.g., arsenopyrite (FeAsS)) during these processes releases gaseous arsenic that electrostatic precipitators collect as crude flue dust. Roasting this dust oxidizes the gaseous arsenic to arsenic trioxide (white arsenic). Aluminum oxide is the main impurity in this process. The primary process for the production of elemental As is the reduction of arsenic trioxide with charcoal; however, low demand limits the production of elemental As. Currently, there is no domestic production of elemental or arsenic trioxide in the United States.[35]

Uses

Processes that produce arsenic include high-temperature combustion, waste incineration, household waste disposal, glassware production, semiconductor and bronze production, nonferrous smelting, lead and copper alloys, galvanizing, ammunition production, and the production of certain chemicals (dyes, wood preservatives, pesticides, pyrotechnics, drying agents for cotton and oil). Elemental arsenic is an alloying element in ammunition and solders, an antifriction additive for bearings, and a strengthening agent in lead-acid storage battery grids. Arsenic trioxide and arsenic acid are decolorizers and fining agents in the production of bottle glass and other glassware. Previously, the manufacture of pesticides (arsenic acid, arsenic pentoxide, arsenic trioxide, sodium arsenate), rodenticides, herbicides (calcium arsenate, lead arsenate, sodium arsenite), and other agricultural products accounted for a majority of inorganic arsenic uses.[36] Less toxic products are currently replacing these products. Commercial applications of arsenical compounds include pesticides, herbicides, glassware, marine paints, alloy makers, and pigment production. Although most medicinal uses of inorganic arsenic have been replaced by more effective and less toxic drugs, arsenic trioxide is now an approved treatment for acute promyelocytic leukemia and melarsoprol (aromatic arsenical) for trypanosomiasis in the United States.[37] Rarely, arsenic toxicity develops following the consumption of homeopathic medicines, manifested by melanotic skin lesions and polyneuropathy.[38]

Sources

Arsenic is a natural constituent of sulfide minerals (e.g., arsenopyrite, FeAsS). The arsenic concentrations in various types of igneous rocks range from <1–15 mg/kg with an average value of ~2 mg/kg.[31] The major anthropogenic sources of arsenic in the environment are the smelting of nonferrous metals and the production of energy from fossil fuels.[31] Food and, to a much lesser extent, water represent the major sources of arsenic exposure for the general population. The mean daily intake of total arsenic in a reference group from the Midwestern US was 0.13 μg/kg body weight.[39] These arsenic concentrations are usually below the arsenic concentrations that produce toxicity. The typical concentrations of arsenic in the air are relatively low (<80 ng/L). Case reports of arsenic toxicity secondary to environmental exposure (e.g., 9–11 mg/L well water) are rare in developed countries.[40] Most human health problems associated with environmental arsenic exposure result from the chronic ingestion of As-contaminated groundwater in Asia including Bangladesh, West Bengal,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. China (Inner Mongolia), Taiwan, Cambodia (Upper Mekong River Basin), and northern Vietnam (Red River Delta).[41] Arsenic concentrations in groundwater in the Mekong Delta of Cambodia ranged from 1–1,610 μg/L in Cambodia (mean = 217 μg/L) and from 1–3,050 μg/L (mean = 159 μg/L) in the Red River Delta of northern Vietnam.[42]

Air

With the exception of workers exposed to arsenic fumes, inhalation is not a major source of exposure for the general population. Even in situations where arsenic-contaminated coal is used to fire open indoor cooking and drying pits, arsenic-contaminated food accounts for most of the daily exposure to arsenic.[43] High-temperature processes (e.g., coal-fired power generators, burning vegetation, volcanic activity) release arsenic to the atmosphere, primarily in the oxidized, pentavalent (As^{5+}) state.[44] Arsenic in ambient air occurs primarily as a mixture of arsenate and arsenite oxides with few organic arsenic compounds.[35] Typical background concentrations of As in ambient air are 0.2–1.5 ng/m^3 for rural areas, 0.5–3 ng/m^3 for cities, and <50 ng/m^3 for industrial sites.[31] Mean arsenic concentrations in remote areas of the United States range from <1–3 ng As/m^3 compared with 20–30 ng As/m^3 in the ambient urban air.[45] The higher concentrations present in urban air usually result from the emissions from coal-fired power plants. Arsenic concentrations in ambient air near nonferrous metal smelters may reach 2,500 ng/m^3.[46]

Soil

Concentration

In soil, arsenic exists as a complex mixture of mineral phases (e.g., co-precipitated, sorbed, dissolved species), primarily as sulfide complexes (e.g., iron pyrites (FeAsS), orpiment (As_2S_3), realgar (As_2S_2)). The heating of ores containing these sulfide complexes produces a white powder (arsenic trioxide). Arsenic is the 20th most abundant element in the crust of the earth, although the concentration of arsenic varies substantially between different locations.[47] Generally, the natural As concentrations in soil range from 1–40 ppm with a mean of 5–7 ppm.[48] Arsenic occurs in natural soil near active geothermal areas in concentrations up to 20 ppm.[49] Soils near arsenic-containing sulfide ores may contain As concentrations of several orders of magnitude higher than typical mean As concentrations. In a study of 15 samples from 2 English counties with a long history of mining and smelting, the mean total arsenic concentration in soil was 4.45 ppm with a range of 0.345–52.6 ppm.[50] About 80% of the arsenic released to the environment from anthropogenic sources partitions into the soil. Fossil fuel combustion, application of pesticides, and disposal of solid wastes are the main sources of these releases. US coals contain relatively small amounts of arsenic compared with other coals in the world (e.g., Slovakia). In a study of US coals, bituminous coal contained the highest concentration of arsenic (mean = 23.5 ppm) compared with a mean of 2.7 ppm for sub-bituminous coal and a mean of 5.0 ppm for lignite coal.[51]

Soil samples from an area of high natural arsenic concentrations near a closed arsenical pesticide-producing plant contained As concentrations ranging from 32–1,597 mg/kg soil.[52] Speciation of the arsenic demonstrated that trivalent arsenite species averaged 44.8% of total arsenic in rock and ranging from 0.32–56% in soil. The median As concentration in 15 surface soil samples from South Australia was 3.9 ± 2.0 mg/kg compared with 0.6 ± 0.55 mg/kg for 6 Tasmanian soil samples.[53] Chromated copper arsenate is a wood preservative used in pressure-treated wood. Studies of decks built with arsenate-treated wood indicate that arsenic concentrations in soil samples below the deck may exceed US EPA standards for arsenic.[54] The contamination does not usually migrate beyond the immediate area below the deck; however, indoor sanding of the treated wood may release airborne arsenic concentrations exceeding current indoor workplace standards.[55]

Bioavailability

The bioavailability of arsenic species is not well defined, but current evidence indicates that the bioavailability of arsenic in soil is relatively low. Using a rat model, the estimated bioavailability of trivalent and pentavalent arsenic ranged from 1.02–9.87% and 0.26–2.98%, respectively. In a study of female monkeys, the oral bioavailability of arsenic in soil and dust was 19% and 14%, respectively, after normalization of the intravenous recovery data.[56] Animal models indicate that bioavailability does not correlate to leachates using water with a pH of 1.0 (acidic) or 7.0 (neutral). The degree of arsenic solubility in soil depends on several factors including mineral phase, particulate size, soil oxidation–reduction potential, and type of inorganic compound. In a study of soil near the Anaconda, Montana smelter, arsenic existed primarily as the sparingly soluble arsenic oxides and phosphates.[57]

A Danish study compared a group of adults and children from an area of high arsenic soil concentrations (mean ~20 ppm) with a control group from an unpolluted area.[58] There was no statistically significant difference in the mean urine concentrations of inorganic arsenic or methylated metabolites between subjects from the area of high and low arsenic soil concentrations. The urine arsenic concentrations in the children of both groups were higher than in adults. A study of children (<6 years old) residing in the area of an old smelter demonstrated a correlation between soil arsenic concentrations and total speciated arsenic in urine samples, but the low arsenic concentrations suggested that the bioavailability of arsenic in contaminated soil was low.[59]

Water

Arsenic is widely distributed both in surface and groundwater, primarily as inorganic arsenic. The presence of As in groundwater results from a variety of factors including the intrusion of geothermal water, dissolution of sulfide minerals or oxyhydroxide ions, drainage from thermal springs and geysers, atmospheric depositions, and natural weather and leaching.[60] Most arsenic in well-oxygenated natural waters exists in the soluble pentavalent form (arsenate) rather than the less soluble trivalent form (arsenite).[61] The background concentration of As in open ocean seawater is ~1–2 μg/L with dissolved forms consisting of arsenate, arsenite, monomethylarsonic acid (MMA), and dimethylarsinic acid (DMA).[31]

Arsenic concentrations in groundwater typically average ~1–2 μg/L, except in some western and north-central US states with volcanic rock and arsenic-containing sulfide mineral deposits high in arsenic (i.e., As concentrations up to 3,400 μg/L).[35] In wells contaminated by arsenic from local tin mines, arsenite represented <5% of the total arsenic species in shallow wells compared with ~39% of the total arsenic in deep wells.[62] Sediments in aquatic systems often contain higher concentrations (e.g., 0.1–4,000 ppm As) compared with surrounding rivers and lakes.[63]

The average daily intake of total arsenic from water is about 5 μg. Substantially higher arsenic intake occurs in some developing countries (e.g., Bangladesh, lowland Nepal), where arsenic contaminates tube wells used for drinking water.[64] In drinking water systems in developed countries, arsenic concentrations typically range from 0.2–10 μg/L with 99% of all systems containing <50 μg/L.[65] Most epidemiological studies indicate that arsenic concentrations in drinking water above 400 μg/L may produce toxicity, whereas As concentrations of <100 μg/L are not usually associated with toxicity. The US EPA maximum contaminant level (MCL) for As is 50 μg/L water (50 ppb). The US EPA ambient water quality standard for fish consumption is 17 ppt arsenic (0.017 μg/L) and 2.2 ppt arsenic (0.0022 μg/L) for fish and water consumption.

Diet

For the general US population, food is the primary source of arsenic. Other significant factors that modify total arsenic exposure include tap water, gender (males typically consume more water than females), smoking, and habitual seafood consumption (organic As).[66] Estimates of the average daily intake of *total* arsenic ranged from 38 μg in Canadian subjects (range 15 μg in young children to 59 μg in young adults)[67] to 110–348 μg in Japanese subjects.[68] Of the total As in the diet, inorganic arsenic averages about 35–40%. The estimated daily US intake of arsenic averages ~50 μg elemental As depending on age and seafood consumption.[69] Substantial differences in the estimated daily intake of arsenic probably result from differences in the temporal consumption of seafood[70] with estimates ranging from ~40–60 μg in the adults from 6 Canadian cities to 160–280 μg in Japanese adults from Shiga Prefecture.[71] Analysis of seafood products from Spain indicated that the highest arsenic concentration occurred in white fish, followed by blue fish, mollusks, crustaceans, and preserved fish.[72] Although seafood mostly contains the less toxic, methylated forms of arsenic, small amounts of inorganic arsenic may occur in seafood.[73] Typically, the As concentration in freshwater fish is <1 ppm (fresh weight). In a market basket survey, the total arsenic concentration in fish fillets ranged from 160 ppb wet weight in freshwater fish to 2,360 ppb wet weight in saltwater fish.[74] The average inorganic arsenic concentrations in these samples were ≤2 ppb wet weight. The inorganic arsenic content in saltwater fin fish was somewhat higher (5–38 ppb) in other studies.[68,75] Meat, poultry, grains, cereal products, and oils contain lesser amounts of arsenic (average 19–24 ppb) than seafood.[67,76] In a study of the US diet, the highest As concentrations occurred in seafood followed by rice, mushrooms, and poultry.[77] Terrestrial mushrooms contain relatively high concentrations of nontoxic arsenobetaine; store-bought mushrooms may contain low total arsenic concentrations with the predominant species being inorganic arsenic.[78] In 14 samples of store-bought mushrooms, the average total arsenic concentration was 0.20 mg/kg (ppm) dry mass with a range of 0.02–1.3 mg/kg. Rice may contain substantial amounts of arsenic depending on the surrounding soil. Boiling the fruiting bodies

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in rice water containing high As concentrations (i.e., 47–450 μg/L) may substantially increase the release (i.e., bioavailability) of As from parboiled and non-parboiled rice.[79] Although most vegetables adsorb As on their surface, the As content in most leafy vegetables is relatively low, even though local water may contain relatively high As concentrations.[80] The amount of arsenic in foods obtained through foraging or hunting (country foods) is highly variable. In a Canadian study, the total arsenic concentrations were as follows (wet weight): berries, 0.6–21 mg/kg; Labrador tea, 1.9 mg/kg; mushrooms, ≤46 mg/kg; and hare muscle tissue, 0.007–0.6 mg/kg.[81] The latter two foods contained substantial amounts of organic arsenic species including arsenobetaine.

In arsenic-contaminated regions of Bangladesh and India, drinking water is the main source of arsenic exposure when drinking water As concentrations exceed 50 μg/L. For residents exposed to drinking water below this standard, diet becomes an important source of arsenic. In a study of 47 women from Pabna, Bangladesh, the median daily total arsenic intake was 48 μg from food and 4 μg from drinking water.[82] Inorganic arsenic accounted for 82% of total arsenic, and about one-third of these residents exceed the World Health Organization's provisional tolerable daily intake of 2.1 μg total As/kg. Irrigation of rice and vegetables with arsenic-enriched groundwater is an important pathway of arsenic exposure in the Ganga–Meghna–Brahmaputra basin in West Bengal. In general, the arsenic content in fleshy vegetables (beans, tomatoes, peas, lentils) grown in this region is less than that of leafy (cabbage, spinach) and tuberous (potatoes, radish) vegetables.[80] The estimated daily *total* arsenic intake for adults and children in this region was 560 μg and 393 μg, respectively, as measured by flow injection hydride generation atomic absorption spectrometry.[83] Inhalation of arsenic from well water during bathing is probably not a significant route of exposure for acute or chronic toxicity.[84] Ayurvedic medicine is a potential source of chronic arsenic toxicity, particularly dermatological drugs. A case series of three Indians associated the ingestion of arsenic-contaminated Ayurvedic medicine (As > 0.1 mg/kg) with clinical features of chronic As toxicity (hyperpigmentation, hyperkeratosis, peripheral sensory neuropathy, pedal edema, gastrointestinal disturbances).[85]

In terrestrial foods, the percentage of inorganic arsenic ranges from 25–100% compared with elemental and organic arsenic species. In a market survey of 40 foods, the highest inorganic arsenic concentrations occurred in raw rice (74 ppb wet weight), flour (11 ppb), grape juice (9 ppb), and cooked spinach (6 ppb).[74] Consequently, diets high in rice (e.g., gluten-free) are potential sources of relatively elevated inorganic As concentrations compared with standard diets.[86,87] A study of 112 composite foods in the Canadian diet revealed that the highest mean total arsenic concentration occurred in fish (1,662 ppb) followed by cereals (24.5 ppb), meat and poultry (24.3 ppb), and fats and oils (19 ppb).[67] Arsenic may contaminate wine produced from grapes sprayed with arsenic-containing insecticides in concentrations up to 530 ppb, primarily as trivalent arsenite.[88] This study did not detect organic arsenic compounds in the wine (LOD, 1 ppb As). Arsenic accumulates primarily in the exoskeleton of invertebrates and fish livers.

Lifestyle

Homeopathic medications may contain arsenic concentrations ranging from 0.005–323 μg/g remedy.[89,90] Rare case reports associate the use of Chinese herbs with the cutaneous manifestations of arsenic poisoning including hyperpigmentation, palmar and plantar hyperkeratosis, and transverse lines of the fingernails.[91] The burning of arsenic-treated wood in home stoves can produce toxicity.[92] Arsenic compounds may contaminate moonshine whiskey.[93]

Arsenic occurs in processed tobacco products including cured tobacco leaves and some smokeless tobacco products. The US EPA estimates that As concentrations in tobacco leaves average ~1.5 ppm (1.5 μg/cigarette).[94] In a study of 17 commercial tobacco snuffs, the mean As concentration was 0.23 ± 0.06 μg/g dry weight.[95] Exposure to arsenic from tobacco products depends on the type of product, growing conditions (arsenic content), and parameters of product use (e.g., frequency, smoking techniques, duration of use). Arsenic yields in mainstream cigarette smoke range from 0–1.4 μg/cigarette depending on growing conditions and smoking techniques.[96] The IARC estimates the arsenic content in mainstream smoke from a standard cigarette averages 40–120 ng.[97] The mean As concentration in machine-generated mainstream smoke from 34 different products from the US cigarette market evaluated by the Reynolds Tobacco Company was 12.7 ng/cigarette with a range of 4.8–18.4 ng/cigarette.[98] In this study, analysis of NHANES data (2003–2008) did not detect a statistically significant difference in total urinary arsenic concentrations between tobacco smokers and nonsmokers. The study defined smokers as individuals who used cigarettes in the last 5 days.

ENVIRONMENTAL FATE

Most arsenic in the environment exists in rock or soil. Speciation determines the interaction of arsenic with the environment.[31] Because most arsenic compounds adhere to soil or sediment, these compounds migrate only a short distance as a result of leaching. Soluble forms of arsenic may move much farther in rivers than insoluble forms. In the atmosphere, arsenic appears as particulates, primarily <2 μm in diameter.[99]

Air

Arsenic is released to the atmosphere primarily as arsenic trioxide and, to a lesser extent, as arsine gases. Arsenic in the atmosphere is a mixture of trivalent and pentavalent arsenic compounds because arsenic trioxide and methyl arsines oxidize to pentavalent As. Photolysis does not contribute significantly to the fate of arsenic in the atmosphere. The residence time of these particles in air depends on the size and meteorological conditions, but the average time is ~7–10 days.[100,101]

Soil

The mobility of As in soil is highly dependent on speciation, soil type, and pH.[31] In general, As released to the soil is relatively nonmobile as a result of the binding of As to soil particles, particularly iron and manganese oxides, aluminum and manganese hydroxides, manganese compounds, clay minerals, and organic material in the form of arsenate.[101] Acidic environments and strongly absorbant soils limit the mobility of arsenite and arsenate species. *In vitro* studies indicate that arsenate transport is strongly inhibited at pH 4.5 and 6.5, whereas transport increases rapidly at pH 8.5.[102] The enhanced transport of arsenate at pH 8 is consistent with the pH dependence of surface complexation reactions (e.g., ligand exchange mechanism) describing arsenate sorption by metal oxide minerals.

Arsenite is moderately unstable in the presence of oxygen, whereas arsenate is strongly absorbed by soils under aerobic conditions and rapidly desorbed under anaerobic conditions. Rainwater may leach soluble forms of arsenic into groundwater or surface water; soil microorganisms may release small amounts of arsines into the atmosphere. Microorganisms may convert sparingly soluble forms of arsenic into more soluble forms that are capable of migrating into groundwater. The top 1.37 m of contaminated soil near a copper acetoarsenite-manufacturing plant adjacent to Calcutta contained arsenous acid, arsenic acid, and methylated forms (methylarsonic acid, dimethylarsinic acid), but only inorganic arsenical compounds appeared in the borehole at levels below 1.37 m.[103] The transformation of arsenic in soil is complex similar to the transformation that occurs in water. Arsenate predominates in aerobic soils, whereas arsenite predominates in slightly reduced soils (e.g., during flooding). Reduction of desorbed arsenate to arsenite increases the mobility of arsenic in soils. Certain terrestrial plants may accumulate substantial amounts of As via absorption through the roots.[100] However, a study of a grassland ecosystem contaminated by arsenic (arsenopyrite) indicated that the potential for bioaccumulation of arsenic is small.[104]

Water

In water, arsenic undergoes a variety of complex transformations including biotransformation, ligand exchange, and oxidation–reduction reactions.[63] The predominant form of arsenic in surface water is pentavalent arsenate because of the positive redox potential and relatively low pH values that result from the interaction of atmospheric oxygen and carbon dioxide.[105] Oxidation of arsenite to arsenate occurs via chemical reactions and microbial activity (chemolithoautotrophic arsenite oxidizers). Microbial species (e.g., α-*Proteobacteria*) use oxygen as the terminal electron acceptor, arsenite as the electron donor, and carbon dioxide as the carbon source.[106,107] Aquatic microorganisms may also reduce pentavalent arsenate to methylated, trivalent arsenite, or other trivalent arsenic compounds via dissimilatory arsenate-reducing prokaryotes.[108] The predominant form of arsenic in groundwater is arsenate, but significant amounts of arsenite may occur depending on local geology and the characteristics (pH, sulfide content, oxidation–reduction potential, salinity, temperature) of the water, particularly in anaerobic environments.[109] Although there are limited data, the accumulation of As in biota is usually not clinically significant. Limited bioconcentration of As may occur in aquatic organisms, particularly in algae and invertebrates with bioconcentration factors ranging from 1–17.[35] Bioconcentration factors for As in fish are usually <5.[31] Biomagnification of As in the aquatic food chain is probably not clinically significant as most arsenic appears as the relatively nontoxic organic form.[110,111] Additionally, the accumulation of As in the edible portion of plants is usually low with As accumulation generally occurring in the roots rather than the leaves or fruits.[60]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. DOSE EFFECT

The toxicity of an arsenic compound depends on the physical state (gas, solution, powder), the particle size, solubility, the rate of absorption and elimination, and the presence of other constituents. Additional factors include the inherent toxicity of the specific arsenic compound and less quantifiable parameters (hand–mouth transfer, particle retention in lungs, mucociliary clearance to gastrointestinal tract). Pentavalent As (arsenate or organic form) is less toxic than trivalent As (arsenite or inorganic form) based on its lower solubility. In general, the insoluble salts of arsenic (arsenic trioxide, lead arsenate) and organic alkane arsonate possess substantially less toxicity than the more soluble inorganic arsenic compounds (sodium arsenite, arsenic acid, arsenous acid).[112,113] The least toxic form is elemental arsenic. The WHO maximum recommended daily intake of arsenic is 2 μg ingested inorganic arsenic/kg body weight.[114]

Trivalent Arsenic

Acute Toxicity

The toxicity of inorganic arsenic depends on both solubility and particle size (e.g., the rate of dissolution is inversely proportional to particle diameter). The estimated dose of trivalent that produces serious toxicity and death in children is ~1 mg/kg and 2 mg/kg, respectively.[115] The ingestion of about 9–14 mg of arsenic trioxide by a 16-month-old infant produced serious toxicity that required chelation therapy.[116] The acute, adult toxic dose of arsenic trioxide ranges from 5–50 mg. The estimated lethal range for adults is 200–300 mg arsenic trioxide, although survival occurs at higher levels (1.4 g arsenic trioxide, 2.15 g arsenous oxide, 10 g arsenic trioxide) in adults following aggressive treatment.[117,118,119] A 77-year-old dentist arrived at the hospital 5 hours after the suicidal ingestion of 4 g arsenic trioxide.[120] He received chelation with BAL, and he survived following the development of nonhemolytic anemia and gastritis with superficial ulcerations. The experimental use of arsenic trioxide for refractory acute promyelocytic leukemia involves daily doses of 20–30 mg for up to 60 days.[121] In a series of acute promyelocytic leukemia patients treated with 0.1 mg arsenic trioxide/kg, 3 of 10 patients died suddenly 9–15 days after initiating treatment.[122] Case series document the occurrence of QTc prolongation and torsade de pointes during the use of arsenic trioxide (10–20 mg/days) in patients with hematological malignancies.[123]

A 57-year-old amateur geologist presented to an urban emergency department 13 hours after the intentional ingestion of estimated 84 g arsenic that he obtained from crushing a chicken egg-sized rock of orpiment (arsenic trisulfide).[124] He was asymptomatic in the emergency department with sinus tachycardia (129 bpm) and a normal QTc interval (387 msec). He was treated with whole bowel irrigation and hydration, but no chelation. He remained asymptomatic, and he was transferred to an inpatient psychiatric unit.

Chronic

Chronic inhalation of air containing >0.8 mg trivalent As/m^3 causes irritation of the mucous membranes and hoarseness.[125] Analysis of exposure-risk relationships in several occupational cohorts suggests that cumulative pulmonary exposure to arsenic concentrations exceeding 0.75 mg/m^3 year is associated with an increased risk of lung cancer.[31,126] Arsenic in drinking water occurs primarily in the form of inorganic arsenate or arsenite depending on the pH and the presence of reducing or oxidizing agents.[127] The evidence of subclinical neuropathy when total arsenic concentrations in drinking water are <300–1,000 μg/L is conflicting; potential causes for the inconsistent results include genetic polymorphisms altering arsenic metabolism, nutritional status (e.g., selenium, folate), and lifestyle factors (e.g., body mass index, cigarette smoking).[128] In a review of data up to the late 1990s, the National Research Council concluded that there was no consistent evidence of peripheral neuropathy in residents following chronic exposure to total arsenic in well water below 1,000 μg/L.[129] A review of relevant epidemiological studies with individual-level data indicated an estimated threshold level near 100 μg/L (range, 50–150 μg/L) for inorganic arsenic in drinking water and urinary bladder, lung, and skin cancers consistent with the value (~65 μg/L) calculated based on mechanistic *in vitro* and *in vivo* investigations.[130] In a cross-sectional study of 147 Alaskan residents exposed to total arsenic in well water ranging from 1–4,781 μg/L, there was no dose-response relationship between the arsenic concentration in the well water and either neurological signs or nerve conduction velocities.[131] Similarly, a cross-sectional study from Inner Mongolia compared nerve conduction velocities in 32 residents ingesting well water with low arsenic concentrations (mean = 5.3 μg/L) with 109 residents with higher arsenic exposure (mean = 158.3 μg/L).[132] There were no statistically significant differences in motor or sensory nerve conduction velocities between the two groups. Other studies suggest the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

possibility of subclinical neuropathy in residents chronically exposed to arsenic concentrations in well water below 1,000 μg/L. A cross-sectional study of 320 Mongolian farmers with exposure to a mean total arsenic concentration of 270 μg/L in well water suggested a correlation between vibration thresholds of fingers and arsenic concentration.[133] A similar cross-sectional study of 137 residents in Bangladesh found deficits in vibration thresholds (Vibraton II Sensitivity Tester) of toes, but not fingers.[134] The mean total arsenic in well water for residents in the latter study was 115 μg/L. A retrospective case-control study of arsenic-associated skin lesions in West Bengal, India, suggested that the development of skin keratoses and hyperpigmentation requires at least 10-year exposure to arsenic concentrations in drinking water exceeding 100 μg/L.[135] However, the average latency period for documented arsenic-induced skin lesions on 42 individuals was 19–23 years with peak arsenic concentrations in the drinking water of controls averaging about 180 μg/L.

Pentavalent Arsenic

Widely used arsenic-containing ant killers usually consist of the pentavalent form of arsenic. For example, Terro Ant Killer (Senoret Chemical Co., Kirkwood, MO) contains 2.28% sodium arsenate (0.91% inorganic arsenic) and 1 mL of this product contains 27.7 mg of sodium arsenate (11.2 mg elemental arsenic). Poison center specialists may manage accidental ingestion of small amounts (<5 mL) of this substance in the home.[136] Most of these products are no longer available in the United States.

TOXICOKINETICS

Absorption

Ingestion

Both animal and human studies indicate that the gastrointestinal tract absorbs soluble forms of trivalent arsenic and pentavalent arsenic almost completely based on studies of arsenic elimination in the feces and urine; however, little absorption of insoluble arsenic (e.g., arsenic selenide) occurs following ingestion.[137,138] The bioavailability of As in soil is probably less than that of in food. In a pilot study of the bioavailability of As in soil, the estimated relative bioavailability of soil As was 54.3% (95% CI: 40.3–68.4%) compared with As in food.[139] The uptake of As^{5+} and As^{3+} occurs via phosphate transporters and aquaglyceroporins, respectively.[140] The absorption of arsenic trioxide following ingestion would be less than the more soluble forms of inorganic arsenic. Factors that affect the amount of arsenic absorption include particle size and the pH of the stomach content.

Inhalation

The absorption of arsenic following inhalation depends on the particle size and the chemical form. Little human data exist to estimate the amount of arsenic absorbed after inhalation. A study of eight terminal lung cancer patients inhaling smoke from radioactive arsenic-containing cigarettes demonstrated retention of ~20–40% of the inhaled dose with ~75–80% of the arsenic absorbed within 4 days.[141] The estimated pulmonary absorption of arsenic from the air in an arsenic smelter was ~42% based on measurements of ambient air samples and urine inorganic arsenic (inorganic species plus methylated metabolites).[142]

Dermal

Little quantitative data are available on the cutaneous absorption of arsenic compounds. Case reports of arsenic toxicity following cutaneous exposure to arsenic acid and arsenic trichloride indicate that some arsenic compounds are absorbed through the skin;[143] however, cutaneous absorption of arsenic is probably low, except in cases of damaged skin.[144]

Distribution

Both trivalent and pentavalent forms of arsenic diffuse out of the blood within hours, initially accumulating in the kidney, liver, and lungs. The clearance of arsenic from these tissues is relatively rapid with long-term storage of arsenic occurring in hair, skin, thyroid gland, lens, skeleton, and the squamous epithelium of the gastrointestinal tract following chronic ingestion.[33] Autopsy data in humans indicate that relatively high arsenic concentrations occur in the following tissues: bone, hair, nails, skin, and teeth.[145] Within 30 hours after ingestion, arsenic deposits in the hair. The hair of an individual dying within 6–8 hours of an arsenic overdose does not usually contain arsenic.

Trivalent arsenic tends to accumulate to a greater extent than pentavalent arsenic compounds. Following the fatal ingestion of trivalent arsenic trioxide, the highest concentrations of total arsenic occurred in the liver and kidneys with the blood arsenic concentrations ranging from 0.2–14% of the As concentrations

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

present in tissues as measured by electrothermal atomic absorption spectrometry.[146] Trivalent arsenic was the predominant species in these tissues. Methylated species were more common in tissues with high lipid content. The sulfhydryl groups on keratin in the skin and hair preferentially bind trivalent arsenic compounds, whereas pentavalent compounds (e.g., arsenate) have an affinity for the bone because of their chemical similarity to phosphate. Only small amounts of arsenic penetrate the blood–brain barrier. The normal body burden in adults is ~20 mg of arsenic.[3]

Biotransformation

Humans metabolize arsenic primarily in the liver via the two following basic processes: 1) oxidation/reduction reactions that interconvert As^{3+} and As^{5+}, and 2) oxidative methylation with arsenite methyl transferase enzymes. DMA (dimethylarsinic acid) is the major metabolite with the urine containing lower concentrations of As^{3+} (inorganic arsenite), As^{5+} (inorganic arsenate), and MMA (monomethylarsonic acid) depending on multiple factors (e.g., chemical form, dose, species, route of exposure, time since exposure, genetic polymorphisms).[35] Epidemiological studies suggest the presence of some functional genetic polymorphisms in arsenic methylation among different ethnic groups.[147] In a study of healthy volunteers in the United Kingdom, the mean proportion of total urinary arsenic as dimethylarsenate was higher for the Somali Black-African group (50%) than the Asian (16%) or Caucasian (22%) groups.[148] The concentration of total arsenic was also significantly lower in the Somali Black-African group compared with the other two groups.

In the cytosol, rate-limited methylation occurs via: 1) oxidative methylation via *S*-adenosylmethionine and arsenic–sulfur intermediates, and 2) reductive methylation via conjugation of arsenite with glutathione. Arsenic triglutathione acts as a substrate for *S*-adenosylmethionine-dependent arsenite methyltransferase in the latter reaction.[149] Although vitamin B_{12}, coenzyme B_{12}, and methyl B_{12} can be methyl donors, the major methyl donor is adenosylmethionine.[150] The enzyme, methyltransferase, is a 42-kDa protein that is encoded by *cyt19* genes.[151] Arsenite methyltransferase was previously known as *cyt19* (*as3mt*) gene.

Biotransformation of inorganic arsenic involves methylation to pentavalent dimethylarsinic acid (DMA) and, to a lesser extent, to pentavalent methylarsonic acid (MMA, monomethylarsonic acid) and reduction of pentavalent arsenic (As^{5+}) to trivalent arsenic (As^{3+}). The reduction of pentavalent arsenic can occur non-enzymatically in the presence of a thiol (e.g., glutathione) or via reductases (e.g., glutathione-*S*-transferase).[152] The liver is the primary site for arsenic methylation. Methylation occurs enzymatically via the oxidative addition of methyl groups to trivalent arsenic with glutathione as a reducing agent and *S*-adenosylmethionine as the methyl donor.

Figure 3.2 demonstrates the classic metabolic pathway for the biotransformation of arsenate to dimethylarsinic acid. Methylation of pentavalent arsenic requires a two-electron reduction of arsenate (As^{5+}) to arsenite (As^{3+}) prior to the oxidative addition of a methyl group. Several studies of urine samples from residents exposed to high concentrations of inorganic arsenic in well water suggest that trivalent monomethylarsonous acid (MMA) and, to a lesser extent, dimethylarsinous acid (DMA), are metabolic intermediates of the biomethylation pathway in these subjects.[153,154] An alternative biotransformation pathway displayed in Figure 3.3 exists that involves the nonenzymatic formation of glutathione complexes with arsenite, resulting in the formation of arsenic triglutathione. The subsequent methylation of arsenic triglutathione forms monomethyl arsenic glutathione and ultimately MMA or DMA depending on glutathione concentrations.[150] Methylation of monomethyl arsenic glutathione to dimethylarsinic glutathione (DMAG) occurs in high-glutathione environments, whereas hydrolysis of MADG to trivalent MMA occurs in low-glutathione environments.[150,155] Consequently, the classical inorganic arsenic pathway converts MMA^{5+} to the more toxic trivalent MMA, while the alternative pathway converts trivalent MMA to the less toxic pentavalent MMA.

A substantial difference in the biotransformation of arsenic compounds exists between species. Squirrel monkeys, chimpanzees, marmosets, tamarins, and guinea pigs methylate little or no As species, whereas humans and the most common laboratory animals (hamster, rat, mouse, rabbit, rhesus monkey) extensively methylate As species via arsenite methyltransferases.[156] Furthermore, the ratio of MMA/DMA is substantially higher in humans than in common laboratory animals.[31] Additionally, there are relatively large interindividual variations in the methylation of inorganic arsenic; reduced methylation capacity (i.e., decreased dimethylarsinic acid to monomethylarsonic acid ratio) may increase susceptibility to the health effects associated with chronically high arsenic exposure.[151] Little conversion of cacodylic acid (DMA) and arsanilic acid to inorganic arsenic occurs in humans.

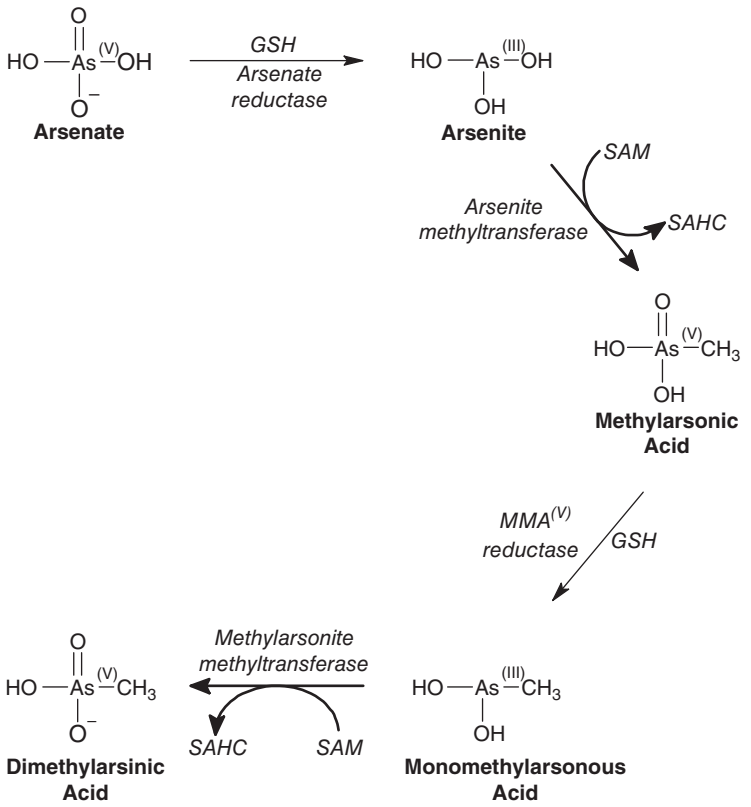

FIGURE 3.2. The classic pathway for biotransformation of inorganic arsenic. The pathway includes: 1) reduction/oxidation reactions that interconvert As^{5+} and As^{3+}, and 2) methylation reactions that convert As^{3+} to MMA^{5+} and DMA^{5+}. *Abbreviations:* GSH = reduced glutathione; SAM = *S*-adenosylmethionine; SAHC = *S*-adenosylhomocysteine. (Aposhian et al.).[153]

Elimination

Humans eliminate inorganic arsenic metabolites rapidly in the urine, primarily as dimethyl arsenic.[157] The kidney excretes almost all the absorbed dose of inorganic arsenic within 4 days, but small amounts of arsenic appear in the urine even after 10 days as a result of a triphasic renal excretion pattern that develops within 4–8 hours after absorption. The biological half-lives of trivalent arsenite and pentavalent arsenate are roughly similar depending on the amount of methylation that occurs.

Human retention studies with the pentavalent arsenic acid (^{74}As) demonstrated a three-compartment model with mean half-lives of ~2, 9.5, and 38 days.[158] These compartments account for 65.9%, 30.4%, and 3.7% of the total excretion of pentavalent arsenic, respectively, over 103 days. After 2–4 weeks, the skin, hair, and nails contain most of the arsenic as a result of the high sulfhydryl content of keratin in these tissues. Feces and sweat are minor excretory pathways.

In the general population and workers exposed to arsenic, the urinary excretion of an absorbed dose of inorganic arsenic varies as follows: DMA (60–70%), MMA (10–20%), and unchanged inorganic arsenic (10–30%).[159,160] In a study of 93 pregnant women exposed to inorganic arsenic in drinking water in Chile, the urine contained the following arsenic species: DMA, 79–85%; inorganic arsenic, 8–16%; and MMA, 5–6%.[161] This variability may result in variable sensitivity to disease with individuals having a higher proportion of inorganic arsenic and MMA along with reduced concentrations of DMA being more susceptible to the development of skin or bladder cancer.[162] Experimental and observational studies indicate a variety of factors that influence the methylation of inorganic As including dose, route of administration, species of arsenic, population group, and nutritional status.[163,164] The efficiency of methylation decreases with increasing doses of inorganic arsenic. Based on a Taiwanese study of residents chronically exposed to high arsenic concentrations in well water, women methylate inorganic arsenic more efficiently than men and the efficiency of methylation decreases with age.[165] Saturation of the metabolic pathways for arsenic probably occurs following severe intoxication (e.g., suicide

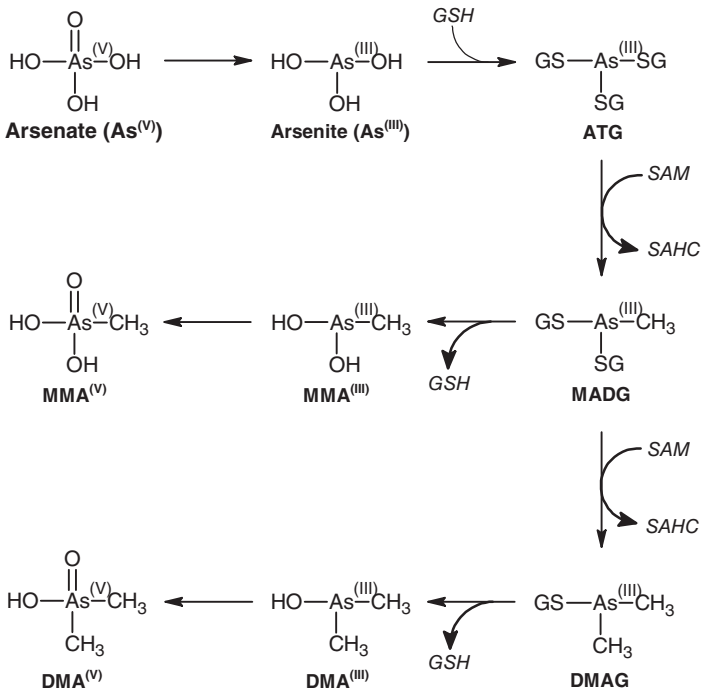

FIGURE 3.3. Alternate biotransformation pathways for inorganic arsenic. The methylation of arsenic triglutathione forms monomethyl arsenic glutathione and ultimately MMA^{3+} or DMA^{3+} depending on glutathione concentrations. In high-glutathione environments, methylation of monomethyl arsenic glutathione to dimethylarsinic glutathione (DMAG) occurs, whereas hydrolysis of MADG to trivalent MMA occurs in low-glutathione environments. Compared with the classical inorganic arsenic pathway, the alternative pathway converts MMA^{3+} to the less toxic MMA^{5+}. *Abbreviations:* ATG = arsenic triglutathione; DMA^{3+} = dimethylarsinous acid; DMA^{5+} = dimethylarsinic acid; DMAG = dimethylarsinic glutathione; GSH = reduced glutathione; MADG = monomethyl arsenic glutathione; MMA^{3+} = monomethylarsonous acid; MMA^{5+} = monomethylarsonic acid; SAHC = *S*-adenosylhomocysteine; SAM = *S*-adenosylmethionine.

attempt, acute arsine toxicity) rather than occupational exposure to trivalent arsenic.[166] Although the methylation of inorganic arsenic varies between individuals in different populations, the daily variation in inorganic arsenic methylation within a specific individual is small.[167]

Maternal–Fetal Kinetics

There are little human data on the transfer of arsenic across the placenta. The low molecular weight and poor protein binding of inorganic arsenicals favor the passage of arsenic from the placenta to fetal blood. In a study of 125 urban women delivering healthy singlets, the arsenic concentration was lower in umbilical cord blood than maternal blood.[168] The mean whole blood total arsenic concentration in maternal blood was 6.91 ± 5.32 μg/L (upper quartile, 8.55 μg/L) compared with 5.41 ± 4.81 μg/L (upper quartile, 6.41 μg/L) in cord blood. The percentage of samples below the LOD (0.1 μg/L) was 1.6% and 2.4%, respectively, as measured by ICP/MS. The arsenic was not speciated. Animal studies suggest that both As^{3+} and As^{5+} distribute into the embryo, but there are little data on the sites of uptake.[169]

Breast milk does not usually contain significant amounts of arsenic despite relatively high maternal arsenic exposure; consequently, arsenic exposure may be lower in breastfed infants than bottle-fed infants depending on the arsenic concentration in tap water. A study of infants in New Hampshire indicated tap water contributed ~70% of the arsenic exposure in bottle-fed infants.[170] In the study of 10 lactating Andean women with exposure to high arsenic concentrations (~200 μg/L) in well water, the mean total arsenic concentrations in their blood and urine were 10 μg/L and 320 μg/L, respectively.[171] The mean concentration of arsenic detected in human milk was 2.3 μg/kg fresh weight (range 0.83–7.6 μg/kg). In a study of the four stages of breast milk production (colostrums, transitional milk, early mature milk, mature milk),

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the concentrations of microelements decreased with advancing lactation stages.[172] The mean arsenic concentration in samples from 45 lactating women in each lactation stage ranged from 1.50 ± 1.50 ng/mL in colostrums samples to 0.16 ± 0.24 ng/mL in mature breast milk samples. In a study of 226 breast milk samples from lactating women in Bangladesh, 39 samples contained detectable arsenic concentrations.[173] The median detectable As concentration in breast milk samples from lactating women with arsenical skin lesions was 30 ng/mL (range, 15–44 ng/mL; $n = 11$) compared with 12 ng/mL (range, 2–49 ng/mL; $n = 28$) in lactating women without skin lesions. Although the infants' arsenic burden was relatively high, maternal urine arsenic concentrations did not correlate to arsenic concentrations in breast milk. In a prospective study of 120 mother–baby pairs in a Bangladesh study published in an open access journal, maternal urinary and breast milk arsenic concentrations were weakly correlated to infant arsenic concentrations at 1 month and 6 months of life.[174]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanisms of Action

Although there are no data from human studies that As is an essential metal, animal studies suggest that low arsenic concentrations may be essential to some animals.[175] Abnormalities detected following the administration of arsenic-deficient (10 ng As/g diet) diets included decreased concentrations of *S*-adenosylmethionine in the liver and pathological alterations of the heart muscle.[176]

Mechanism of Toxicity

Trivalent

Acute Toxicity

The mode of trivalent arsenic toxicity is not well understood. In animal experiments on arsenic intoxication, the main form of arsenic bound to tissues is trivalent arsenic rather than pentavalent arsenic or methylated metabolites.[177] Arsenite is electrophilic. Trivalent arsenic does not form complexes with nitrogen or phosphorus, but As^{3+} can replace nitrogen by binding to carbon. This compound interacts with thiol groups in the body by binding to electron-rich sulfhydryl groups on proteins and causing oxidative stress (activation of c-Jun *N*-terminal kinase/stress-associated protein kinase and formation of reactive oxygen species).[178] However, most arsenite toxicity probably results from the susceptibility of many critical enzymes (e.g., pyruvate dehydrogenase, other dehydrogenases) to deactivation by binding thiol-containing active sites.[179] Arsenite compounds bind to the sulfhydryl cofactor (dihydrolipoate), thereby causing inhibition of pyruvate and succinate oxidative pathways as a result of limiting the conversion of dihydrolipoate to lipoate.[119] Thus, inhibition of pyruvate dehydrogenase produces depletion of cellular citrate and blockade of the citric acid cycle. Carbohydrate depletion and depletion of the reductive energy supply that result from the inhibition of gluconeogenesis are major consequences of the inhibition of pyruvate dehydrogenase and α-ketoglutarate dehydrogenase enzymes.[180]

QT prolongation, *torsade de pointes*, and sudden death are adverse effects following the treatment of acute promyelocytic leukemia with arsenic trioxide. Predisposing factors for the development of these complications include prior treatment with cardiotoxic chemotherapeutic agents (e.g., all-trans retinoic acid, anthracycline-based drugs) and electrolyte imbalance (e.g., hypokalemia, hypomagnesemia). Studies of HERG- and KCNQ1+KCNE1-transfected CHO cells indicate arsenic trioxide blocks I_{Kr} and I_{Ks} tail currents at therapeutically relevant concentrations; additionally, As_2O_3 activates a time-independent potassium current ($I_{K\text{-}ATP}$) that maintains normal repolarization.[181] The competing effects of these three potassium currents result in variable QT prolongation and ventricular dysrhythmias.

Cancer

Like most carcinogenic metals, arsenic is not genotoxic and does not form DNA adducts; however, *in vitro* studies indicate inorganic As causes oxidative DNA damage through alterations of aneuploidy (i.e., abnormal diploid number) and DNA repair via epigenetic mechanisms (DNA methylation, histone modifications, miRNA alterations) depending on the dose.[182,183] The former mechanism results from disruption of spindle tubulin,[184] whereas the latter results from inhibition of P53 signaling.[185] Potential mechanisms for the development of cancer following arsenic exposure include cocarcinogenesis, epigenetic dysregulation (i.e., heritable changes in gene expression with no dependence on DNA sequencing), chromosomal instability, tumor promotion, altered cell proliferation or DNA methylation, and the formation of reactive oxygen species.[32,186] A cross-sectional, dose-response study of generally healthy individuals in Bangladesh did not find evidence of an association between arsenic concentration

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(water, blood, urine) and measures of oxidative damage (plasma protein carbonyl, 8-oxo-deoxyguanosine).[187] Arsenite inhibits glutathione reductase, lowers intracellular concentrations of reduced glutathione, increases oxidative stress, and activates caspase 3 and the apoptosis pathways.[188] Trivalent arsenic is an indirect animal carcinogen in doses of >400 μg/day through promotion rather than a direct genotoxic effect.[189] Arsenic probably acts through epigenetic mechanisms (e.g., DNA methylation, microRNA expression, posttranslational histone modifications) by modulating the signaling pathways responsible for cell growth.[190,191] Arsenic does not react directly with DNA or cause gene mutations, except at very high doses; however, arsenic does cause gene amplification and chromosomal damage at lower doses as well as enhancing the mutagenesis of other agents. Arsenic produces carcinogenic effects in some *in vitro* tests (sister-chromatid exchange, gene amplification).[192,193] These tests indicate that arsenite is the primary carcinogenic agent; the carcinogenic activity of arsenate probably results from its conversion to arsenite and the subsequent formation of reactive metabolites that interact with critical cellular sulfhydryl groups and cause cytotoxicity along with regenerative cell proliferation.[194] This mechanism of toxicity suggests a nonlinear, threshold dose-response relation for noncancer and cancer end points.[195] Arsenite inhibits DNA repair and methylation as well as increasing the formation of radicals and the activation of the proto-oncogene *C-Myc*.[196] However, none of these potential mechanisms are well-accepted etiological events for arsenic carcinogenesis. The data on the carcinogenicity of arsenic in animals are limited; the extrapolation of animal data to humans is also limited by the lack of adequate animal models of cancer following exposure to arsenic.

Pentavalent

Arsenate is structurally similar to inorganic phosphate. Pentavalent arsenicals are less reactive and cause fewer biological effects than trivalent arsenicals. Potential mechanisms for the acute toxicity of arsenic include the reduction of pentavalent arsenic to trivalent arsenic and the replacement of phosphate in biological reactions.[32] Arsenate uncouples oxidative phosphorylation by the formation of unstable arsenate esters. Although pentavalent arsenic does not directly affect enzymes, this form of arsenic inhibits high-energy bonds by competitive substitution of arsenate for phosphate (arsenolysis).[3] Although glycolysis continues, the substitution of arsenate for phosphate reduces the amount of ATP formed; therefore, the cell produces less ATP. Consequently, both the pentavalent and trivalent forms of arsenic limit energy-linked functions of the mitochondria; however, arsenolysis appears less important in the production of arsenic toxicity than the arsenite (As^{3+})-induced inhibition of sulfhydryl groups. Additionally, arsenate can mimic the phosphate moiety of pyridoxal phosphate, resulting in the inhibition of several reactions including conversion of DOPA to dopamine and 5-hydroxytryphtophan to 5-HT.[197]

At relatively high doses, the weight-of-evidence indicates that dimethylarsinic acid (DMA) is a multi-organ tumor promoter in rodents and a complete carcinogen in the bladder of rats.[198] The incidence of bladder tumors increased in male F344 rats administered 50 ppm pentavalent DMA in drinking water for 2 years, but not in rats given 12.5 ppm DMA in drinking water for 2 years.[199] The relevance of these effects to human arsenic exposure remains unclear because large doses were required and because of the presence of species differences in the toxicokinetics of DMA.

Pathological Changes

Cardiovascular System

Vasodilation occurs initially in response to small doses of arsenic, but transudation of the fluid reduces preload, leading to reflex arteriolar constriction. Decreased contractility causes direct myocardial depression. QT prolongation and T-wave inversion may persist months after clinical recovery. The chronic ingestion of high arsenic doses produces the Blackfoot disease characterized by vasospasm, peripheral vascular insufficiency, and gangrene. The contamination of artesian well water primarily with pentavalent arsenic[200] and another substance (fluorescent humic substance) is an area of study into the etiology of this endemic peripheral vascular disease along the southwestern coast of Taiwan.[201] Statistically significant reductions in the amount of selenium and iron along with marked elevations of arsenic were detected in the hair of patients with the Blackfoot disease, particularly in the patients with severe disease.[202] As a result of the implementation of a tap water supply system, drinking water and cooking no longer involved the use of highly arsenic-contaminated water after the mid-1970s. Mortality related to peripheral vascular disease declined gradually for ~25–27 years following cessation of consumption of this arsenic artesian well water, suggesting a causal relationship between high arsenic exposure and peripheral vascular disease.[203]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Gastrointestinal Tract

Dilation of splanchnic vessels causes submucosal vesicle formation. Rupture of these vesicles leads to rice water stools and bleeding. Subsequently, a protein-losing enteropathy may develop.

Kidney

Pathological changes associated with acute arsenic toxicity include acute tubular necrosis and renal cortical necrosis based on a case report of a 39-year-old man presenting with anuria and azotemia after consuming moonshine whiskey; he required peritoneal dialysis temporarily.[204] His admission serum arsenic concentration was 331 μg/L. Samples of the moonshine whiskey were not available for analytical confirmation. He also had an elevated serum lactic dehydrogenase concentration (10-fold over reference value); there were no measurements of urine myoglobin.

Skin

Arsenic-induced skin lesions include palmar erythema, local edema, hyperkeratosis, hyperpigmentation, atrophy, pyoderma, palmoplantar ulcerations, and skin cancer (intraepithelial squamous cell carcinoma *in situ* or Bowen's disease, multiple basal cell carcinomas). Hyperpigmentation is usually the earliest cutaneous manifestation of arsenic toxicity, particularly in heavily pigmented areas (e.g., groin, areola).[205,206] Within these hyperpigmented areas, scattered areas of hypopigmentation may occur that resemble raindrops. Hyperkeratotic papules on the palms and soles are common, but diffuse keratosis on the palms and soles is rare. There are no histological features that reliably distinguish arsenical keratoses or Bowen's disease from similar lesions produced by exposure to sunlight. Arsenic-induced Bowen's disease has the same histological features as other forms of Bowen's disease.

Neuromuscular System

Axonal degeneration is the predominant change associated with inorganic arsenic-induced peripheral neuropathy. Single, acute doses of arsenic produce Wallerian degeneration and various stages of nerve fiber degeneration in myelinated and unmyelinated axons.[207] Resorption of myelin and destruction of axon cylinders lead to stocking-glove distal sensory neuropathy followed by muscle atrophy. Theories on the pathophysiological effect of arsenic on peripheral nerves involve the disruption of axon function that initially produces segmental demyelination and then eventually distal axonal degeneration.[208] Key features of muscle biopsies following severe rhabdomyolysis include myofibrillar disruption, mitochondrial abnormalities, abundant cytoplasmic vacuoles containing lipids, and peri-fascicular, hyper-contracted fibers.[209]

Metabolic/Hepatic

Negative nitrogen balance, hepatic fatty degeneration, central necrosis and cirrhosis, and hypothyroidism may occur during arsenic toxicity. Although chemical hepatitis is uncommon following an acute arsenic ingestion, chronic arsenic poisoning may produce hepatic veno-occlusive disease, sinusoidal dilation, and perisinusoidal fibrosis, perhaps by direct injury to the vascular endothelium.[210] In a rat model of promotion, arsenic was one of seven chemicals fed to rats in drinking water at environmentally relevant concentrations (3.1 ppm As, 31 ppm As, 310 ppm As).[211] The mixture did not act as a promoter of preneoplastic foci in the rat liver.

Postmortem Examination

Anatomic changes noted on autopsy after fatal acute exposure to arsenic include hepatocellular and renal tubular necrosis, intense visceral congestion, pulmonary edema, hemorrhages and ulceration of the gastrointestinal tract, and subendocardial hemorrhages with interstitial myocarditis. Death usually results from circulatory failure, and the myocardium often demonstrates widespread foci of necrosis, but leucocyte diapedesis may not be present.[212]

The major types of lung cancer include small cell carcinomas and non-small cell carcinomas (squamous cell carcinoma, adenocarcinoma). In a postmortem study of biopsies from 1,786 East German uranium miners dying of lung cancer between 1957–1990, polytomous logistic-regression analysis suggested that arsenic exposure was associated with non-small cell carcinomas (squamous cell carcinoma, adenocarcinoma).[213] The highest fraction of squamous cell carcinoma occurred in miners with the highest exposure to arsenic, radon, and quartz (silicon); in miners with silicosis, the proportion of adenocarcinomas increased with elevated arsenic exposure. However, this study was retrospective, and control of confounding factors (e.g., smoking, quartz, radon) required retrospective estimates of exposure. Only about 7% of the German uranium miners were nonsmokers based on a sample size of 539; there was no smoking data on 1,247 of the 1,786 miners in the study. Smoking is associated with a higher risk of squamous

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cell carcinoma and small cell lung cancer than adenocarcinoma, whereas the cell type associated with arsenic and skin cancer is squamous cell cancer.

CLINICAL RESPONSE

Medical Therapy

Rare case reports associate the use of arsenic trioxide for the treatment of acute promyelocytic leukemia with QT prolongation and ventricular tachycardia.[214] Several patients on arsenic trioxide therapy developed QT prolongation and *torsade de pointes* during the terminal phase of their illness; these patients also had additional risk factors (sepsis, hypokalemia, hypomagnesemia, hypoxia).[123] In a case series of 10 patients with acute promyelocytic leukemia on daily arsenic trioxide therapy, 2 patients died suddenly without identifying the cause of death on autopsy.[122] These patients were not monitored; however, a third patient on continuous cardiac monitoring developed QT prolongation along with respiratory distress prior to the development of asystole. Other case reports associate the development of high-grade AV block with an incomplete right bundle-branch block with arsenic trioxide therapy that resolved after chelation.[215]

Acute Oral Toxicity

Prominent gastrointestinal symptoms (e.g., vomiting, bloody diarrhea, severe abdominal pain, burning esophageal pain) develop within 30 minutes to 2 hours after ingestion of toxic doses of inorganic arsenic. Garlic odor on the breath and salivation may occur. Severely poisoned patients develop multiorgan failure and cardiac decompensation characterized by shock secondary to vasodilation and myocardial depression (e.g., cold clammy skin, cyanosis, weakness, lightheadedness). The development of cerebral edema leads to headaches, lethargy, delirium, coma, and convulsions. Death usually results from circulatory failure within 1–4 days.[119] Prolongation of the QT interval may occur during episodes of serious arsenic toxicity in the absence of hypokalemia, hypomagnesemia, or hypocalcemia.[216] Typically, these patients demonstrate gastrointestinal disturbances, leukopenia, and paresthesias. Rarely, polymorphic ventricular tachycardia (*torsade de pointes*)[217] or ventricular fibrillation occurs during severe As intoxication.[218] *Torsade de pointes* also occurs during the use of arsenic trioxide as a chemotherapeutic agent for acute promyelocytic leukemia.[123] Late sequelae of acute inorganic arsenic toxicity include jaundice, renal failure, and peripheral neuropathy. Intracerebral hemorrhage has occurred after the parenteral use of arsenical compounds for syphilis. Intense abdominal pain, bloody diarrhea, albuminuria, and a garlic odor suggest acute arsenic toxicity. Other clinical features of severe arsenic poisoning include hepatorenal dysfunction, adult respiratory distress syndrome, and serious cardiac dysrhythmias. The differential diagnosis for inorganic arsenic toxicity includes Addison's disease, other heavy metals (thallium), Guillain–Barré syndrome and other peripheral neuropathies, Korsakoff's syndrome, porphyria, and septic shock.

Skin

Biopsies of large keratotic papules from patients with arsenic toxicity reveal an extremely thickened stratum corneum and multiple layers of compacted parakeratotic cells around an epidermal crater.[61] Granular layers below these cells are reduced or absent. The differential diagnosis of an absence of the granular layer includes ichthyosis vulgaris, pityriasis rotunda, Bowen's disease, and psoriasis. Rete pegs may extend into the upper dermis. Aggregation of tonofilaments and the absence of the granular layer are highly suggestive of arsenic-induced keratosis.[61,219] Pathological features of arsenic toxicity include alopecia (late), brittle fingernails, and Mees' lines of striated leukonychia (horizontal white lines that appear after the exposed nail bed area grows to the exterior). The latter finding is not specific to arsenic poisoning, as these discolorations represent dysfunctional growth of the nail matrix rather than deposition of arsenic. Mees' lines also occur in other diseases (e.g., thallium poisoning, congestive heart failure, chronic renal disease, chemotherapeutic drugs).[220] Rarely, direct dermal contact with arsenic compounds produces local inflammation that leads to the formation of blisters.[221] Rare case reports associate the application of extremely high dermal doses of arsenic (30% arsenic solution in isopropyl alcohol to the entire body) with severe burns and bullae, vomiting, respiratory distress, hypotension, oliguria, and death.[222] The arsenic species was not reported.

Neurological

A subacute, commonly ascending peripheral neuropathy frequently develops within 10 days–3 weeks of a massive overdose of inorganic arsenic. Numbness and paraesthesias appear first, followed by weakness in the distal lower extremities. The neuropathy evolves over 2–5 weeks; the severity of the clinical course is variable with a majority of the patients developing a

TABLE 3.3. Clinical features of acute and chronic arsenic toxicity. (Adapted from Gorby).[3]

System	Acute Symptoms	Chronic Symptoms
Skin	Hair loss, Mees' lines 2–3 weeks after ingestion	Hyperpigmentation, facial edema, hyperkeratosis, Bowen's disease, cancer
Neurological	Hyperpyrexia, tremor, convulsions, coma	Polyneuropathy, tremor, encephalopathy
Gastrointestinal tract	Vomiting, bloody or rice-water diarrhea, dysphagia, abdominal pain, mucosal erosions	Nausea, vomiting, diarrhea, anorexia, weight loss
Liver	Fatty infiltration	Hepatomegaly, jaundice, cirrhosis
Kidney	Renal tubule and glomerular damage, uremia	Nephritis
Hematological		Bone marrow hypoplasia with pancytopenia, basophilic stippling
Cardiac	ST-T wave abnormalities, prolonged QTc interval, atypical ventricular tachycardia, ventricular fibrillation	

severe distal sensorimotor polyneuropathy.[207] Recovery from peripheral neuropathy is usually slow and often incomplete. Facial nerve palsies[221] and phrenic nerve involvement[223] are rarely associated with exposure to arsenic. Encephalopathy is a common complication of acute inorganic arsenic poisoning manifested by seizures, delirium, and progressive obtundation. Persistent, chronic encephalopathy (Korsakoff-like psychosis) occurs rarely following acute exposure to massive doses of arsenic.[224,225] Table 3.3 outlines the clinical and pathological findings of acute and chronic arsenic poisoning.

Environmental Exposure

The diagnosis of chronic arsenic toxicity may be difficult because the presentation is insidious and nonspecific, particularly premeditated poisoning.[226] Early features involve the gastrointestinal tract (diarrhea, abdominal pain) and the skin (hyperpigmentation and hyperkeratosis, especially on the palms and the soles in half of the cases). A large case series of chronic inorganic arsenic toxicity secondary to contaminated drinking water suggested that melanosis is the earliest cutaneous sign of chronic arsenic toxicity with keratosis (dry, irregular, papular skin lesions) appearing later.[227] Papular keratosis and ulcerative lesions appear less frequently.[228] A symmetrical sensory neuropathy with paresthesias and loss of vibratory or position sense is a potential complication of chronic As exposure. Other signs and symptoms of chronic intoxication include localized edema (face, ankles), sore throat, stomatitis, pruritus, coryza, lacrimation, salivation, perspiration, garlic odor, vitiligo, and alopecia. Late sequelae of chronic arsenic poisoning include a Wernicke-like encephalopathy, gangrene of the extremities (endarteritis obliterans), esophageal varices secondary to portal hypertension,[229] lung cancer and nasal septal perforations,[230,231] and possibly multiple visceral tumors including hepatic angiosarcoma.[232]

Skin

Skin lesions are the first visible symptoms of chronic arsenic exposure.[233] The chronic ingestion of drinking water from arsenic-contaminated well water (up to 2 mg As/L) produced the following lesions: keratosis of the palms and soles, hyperpigmentation, Bowen's disease (squamous cell carcinoma *in situ*), hypopigmentation, and superficial basal cell carcinomas.[228,234,235] Melanosis, keratosis, and leukomelanosis (small hypopigmented macules) may also occur on the tongue, gums, and lips.[236] The duration of the latency period of these skin lesions is dose-dependent. Typically, the estimated latency period for these skin lesions is ~10–20 years,[135] although some studies suggest that children under 10 years of age may develop arsenic-induced skin lesions (i.e., melanosis) within a few years of exposure to highly arsenic-contaminated drinking water.[237] Reducing the inorganic arsenic exposure from drinking water decreases the incidence and severity of arsenic-induced dermatological disorders.[238] In a study of 550 Bangladesh residents with skin lesions from arsenic exposure, resolution of the skin lesions occurred in 65 patients over 10 years.[239] Lower baseline arsenic concentrations were significantly associated with increased odds of resolution.

Noncancerous areas of hyperpigmentation primarily occur on the trunk, pressure points, and intertriginous areas. This brown-gray pigmentation has oval-shaped areas of normal pigmentation that produce the appearance of raindrops. New lesions appear as multiple brownish patches and plaques covered with thick scales and crusts arising from areas of normal skin. Keratosis

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

begins on the palms and soles as small (0.4–1 cm), hard, yellowish papules without central depressions that progress to verrucous lesions.[240] After an ~10–20-year latency period, these keratotic lesions may develop into squamous cell carcinomas, but they have a low incidence of metastasis.[241] Some[242] but not all studies[243] of patients with hyperkeratosis and Bowen's disease suggest an association between the occurrence of these adverse effects and internal malignancies (lung, urothelial renal cancer). However, the positive studies did not demonstrate a consistent biological gradient.

Nervous System

Chronic exposure to inorganic arsenic produces an insidious sensorimotor peripheral neuropathy over a few weeks to a few months depending on dose, characterized initially by numbness and paresthesias of the soles of the feet and hands followed by mild weakness in the extensors of the feet and hands. Pain and paresthesias are typically more severe in the feet than in the upper extremities.[233] The earliest symptoms of arsenic neuropathy are symmetrical sensory changes. Continued exposure results in severe distal stocking-glove-type sensorimotor neuropathy that persists despite the cessation of exposure. Neurological signs include reduced pinprick sensation, reduced or absent vibratory perception, and decreased perception of joint position.[237] Motor features are much less common than sensory symptoms, ranging from mild extensor weakness of distal muscles to diffuse weakness and muscle atrophy in severe cases.[244] The differential diagnosis of neuropathy associated with arsenic includes alcoholism, amyloidosis, cancer, diabetes mellitus, diphtheria, dysproteinemias, Guillain–Barré syndrome, intermittent porphyria, nutritional deficiencies, paralytic shellfish poisoning, tick paralysis, uremia, and lead toxicity.

A meta-analysis suggested a negative effect of environmental arsenic exposure exceeding current guidelines on neurodevelopment in children aged 5–15 years as measured by Full Scale IQ, particularly verbal and performance domains with less effect on memory tests.[245] Most of the included studies (n = 18) were cross-sectional designs in populations (e.g., Bangladesh, Mexico, China, Taiwan) with high arsenic exposure by current standards and substantial heterogeneity in the results. The estimated negative effect was 0.5 Full Scale IQ point for children with As exposure of 118–194 μg/L in drinking water or 51–117 μg/L in urine. Two cross-sectional studies on the relationship between urine arsenic concentrations and behavioral disorders did not demonstrate a significant effect. The median urinary total arsenic concentration in the first-grade Mexican children (6–7 years) was 52.5 μg/L,[246] whereas the mean urinary total As concentration in the Bangladesh children (8–11 years) was 81.2 μg/L ± 75.2 μg/L.[247]

Cardiovascular

Retrospective cohort studies in southwestern Taiwan, India, and Chile associate high arsenic concentrations (>500 ng/mL) in drinking water with carotid atherosclerosis,[248] ischemic heart disease,[249] and hypertension,[250,251] when compared after multivariate adjustment with cohorts lacking excessive arsenic exposure in drinking water. Blackfoot disease (vasospasm, peripheral vascular insufficiency, gangrene) occurred primarily in Taiwan.[252] The causal association between hypertension and exposure to inorganic arsenic in drinking water is unclear because there are few data and significant methodological limitations (e.g., lack of prospective studies). An Argentinean study of 225 Andean women with a median urine arsenic concentration of 200 μg/L (range, 22–545 μg/L) suggested the cardiovascular effects of arsenic may vary between different populations.[253] In this study, urinary arsenic concentrations were inversely related to diastolic (P = 0.002) and systolic (P = 0.081) blood pressures without evidence of increased inflammation as measured by cytokine concentrations.

In a review of eight studies (mostly cross-sectional design) that compared the highest and lowest categories of arsenic exposure, the pooled odds ratio was 1.27 (95% CI: 1.09–1.47, P-value for heterogeneity = 0.001, I^2 = 70.2%).[254] However, the pooled OR for the five studies with moderate to high arsenic exposure was not statistically significant (OR = 1.15, 95% CI: 0.96–1.37, P-value for heterogeneity = 0.002, I^2 = 76.6%). The substantial heterogeneity suggests the estimated risks may not accurately reflect the true value. Examination of data from the 2003–2008 US National Health and Nutrition Examination Survey did not detect an association between systolic or diastolic hypertension and low to moderate arsenic exposure (<50 μg/L) common in the United States.[255] The median total urine arsenic concentrations were 8.3 μg/L (interquartile range, 4.2–17.1) compared with 3.6 μg/L (interquartile range, 2.0–6.0) for DMA and 1.4 μg/L (interquartile range, 0.3–6.3) for arsenobetaine. After multivariable adjustment, the odds ratio of hypertension for a 2-fold increase in total arsenic was 0.98 (95% CI = 0.86–1.11); similarly, there was no statistically significant increase in the odds ratio for hypertension after a 2-fold increase in urine DMA.

Studies on the mortality from cardiovascular disease in areas of long-term, low to moderate arsenic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

concentrations (<50–100 ng/mL) in drinking water are inconsistent.[256] Some studies suggest an increased risk for cardiovascular and cerebrovascular disease from inorganic arsenic exposure below these concentrations. In the prospective cohort Strong Heart Study of 3,575 American Indians followed for 18 years, hazard ratios comparing the highest and lowest quartiles of arsenic concentrations (>15.7 vs. <5.8 μg/g creatinine) were statistically significant for *incident* cardiovascular (HR = 1.32, 95% CI: 1.09–1.59, P_{trend} = 0.002) and coronary heart disease (HR = 1.30, 95% CI: 1.04–1.62, P_{trend} = 0.006), but not incident stroke (HR = 1.47, 95% CI: 0.97–2.21, P_{trend} = 0.032).[257] The hazard ratios were also elevated for coronary heart disease (HR = 1.71, 95% CI: 1.19–2.44) and stroke *mortality* (HR = 3.03, 95% CI: 1.08–8.50) after adjustment for sociodemographic factors, body mass index, lipids, and smoking. These results were based on a single urinary inorganic plus methylated arsenic concentration without measurement of arsenic drinking water concentrations; the definition of arsenic exposure was total urinary inorganic arsenic species (inorganic arsenic plus DMA and MMA species) at baseline examination. Hence, the arsenic exposure over the course of the study was unknown. The highest and lowest quartiles were >15.7 μg/g creatinine and <5.7 μg/g creatinine, respectively. Additionally, the population had a relatively high prevalence of diabetes and cardiovascular disease.

Mortality from hypertensive heart disease was increased in Mormon women (but not men) in Millard County, Utah, exposed to <200 ng As/mL in drinking water based on historical records of arsenic exposure in the community. A cohort study in Bangladesh reported a dose-response increase in mortality from cardiovascular disease in relation to arsenic concentrations in wells with a hazard ratio of 1.16 (95% CI: 0.96–1.40) for households exposed to 50–149 μg/L in drinking water.[258] In a prospective cohort study in Bangladesh with a 6-year follow-up, 28.9% (range, 1.4–60.0%) of deaths from heart disease were attributable to arsenic concentrations of >12 μg/L in well water. A prospective study of 208 cases of fatal and nonfatal heart disease in Bangladesh demonstrated a statistically significant increase in the adjusted hazard ratio for heart disease (aHR = 1.20, 95% CI: 1.04–1.38), but not for stroke (aHR = 1.08, 95% CI: 0.90–1.30), for each 112 μg/L increase in well water inorganic arsenic.[259] Classification of disease was based on interviews with 5% of death certificates available for review. Examination of urinary dimethylarsinic acid/monomethylarsonic acid ratios suggested an increased risk of heart disease in subjects with incomplete methylation capacity (i.e., lower DMA/MMA ratio). The lack of clear mechanisms of toxicity, potential unmeasured confounding, and the difficulty extrapolating beyond the study population limit definite conclusions regarding the role of arsenic in cardiac mortality and the development of cardiac disease. Retrospective cohort and ecological studies have not demonstrated an association between arsenic exposure and mortality from cerebrovascular disease.[260,261]

Occupational Exposure

Systemic inorganic arsenic toxicity (excluding cancer) occurs rarely following occupational exposure. In a study of copper smelter workers funded by the former Smelter Environmental Research Association, mortality from all cases of death combined and all cancers combined was not elevated including the most specific cause of death categories, when compared with national and local mortality rates.[262] The exception was a significant association between arsenic exposure and lung cancer in a southwestern US smelter that processed ores with relatively high As content. Similarly, an updated mortality study of 2,422 copper smelter workers in southeastern Tennessee did not demonstrate elevated mortality in most categories of nonmalignant deaths. There was limited evidence of a trend for increasing cumulative As exposure and cerebrovascular disease, but not heart disease when compared with national and local mortality rates. The most common effect of occupational exposure to arsenic is local irritation of the upper respiratory tract (e.g., hoarseness, nasal irritation, perforated septum), particularly in industries with relatively high arsenic ambient air concentrations (smelting As-containing ores, pesticide application). Clinical peripheral neuropathies, primarily sensory, are potential complications of excessive occupational exposure to arsenic (e.g., total urinary As, 250 μg/L).[263] In a study of 21 copper smelter workers exposed to arsenic ($mean_{urine}$ = 11.91 ± 9.5 μg/L; duration, 18.1 ± 7.8 years), complaints of paresthesias were correlated to duration of exposure (P = 0.05), but not to urinary or airborne arsenic concentrations.[264] The difference in sural nerve conduction velocity between exposed and 16 nonexposed workers matched for smoking and age was statistically significant, but the reduction in sural nerve conduction velocity did not correlate to urinary or airborne As concentrations.

Carcinogenesis

Arsenic and inorganic arsenic compounds are recognized as human carcinogens based on studies of workers

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

exposed to arsenic during mining and copper smelting. Both the International Agency for Research on Cancer (IARC Group 1) and the US National Toxicology Program list arsenic and certain arsenic compounds as known human carcinogens. Occupational exposure to inorganic arsenic in the mining and copper smelting industries is associated with an increased risk of cancer, particularly lung cancer. Epidemiological studies of cancer following medical treatment with inorganic arsenic indicate an excess incidence of skin cancers;[265] associations between medical or occupational exposure to arsenic and other non-cutaneous, non-pulmonary cancers (e.g., hepatic angiosarcoma, renal cell cancer, transitional cell bladder carcinoma[266]) are less consistent. Similarly, consumption of high arsenic concentrations in well water has been associated with an increased incidence of skin cancers (i.e., squamous cell and basal carcinomas, but not melanomas);[267] the association of other types of cancer (e.g., bladder) with environmental exposure to arsenic is less clear. Variation in cumulative arsenite dose, genetic polymorphism (*NAT2* slow acetylator and *GSTM1* null genotypes), and differences in arsenic methylation capacity (i.e., high MMA/low DMA) may account for some of the heterogeneity in these studies.

In a mortality study of a Southwestern Taiwanese cohort with a high incidence of Blackfoot disease and exposure to high arsenite concentrations in well water, age-adjusted standardized mortality rates were elevated for liver, lung, and bladder cancer.[268] However, after adjustment for risk factors (age, gender, education, smoking habits), only bladder cancer mortality was elevated in a dose-response relationship based on questionnaires about the duration of well water exposure from 1910 to the early 1970s. Average arsenic concentrations and cumulative arsenic exposure did not demonstrate a similar dose-response relationships, and the 95% confidence limits were very high for all categories. An ecological study of residents of Antofagasta, Chile, exposed to a mean arsenic concentration in drinking water of 870 μg/L for ~12 years demonstrated increased SMRs for bladder cancer (SMR = 18.1, 95% CI: 11.3–27.4), laryngeal cancer (SMR = 8.1, 95% CI: 3.5–16.0), and liver cancer (SMR = 2.5, 95% CI: 1.6–3.7).[269] These rates were based on death certificates and national mortality rates.

Childhood cancers are not typically associated with exposure to environmental sources of inorganic arsenic.[270] A long-term prospective Japanese study of 6,104 survivors of arsenic poisoning during infancy did not detect a statistically significant excess cancer mortality (SMR = 1.2, 95% CI: 1.0–1.5) when compared with Osaka residents.[271] Individual exposure data were not available; however, 130 infants died of arsenic poisoning during this epidemic. The average follow-up for this 1955 epidemic was about 24 years.

Lung

Environmental Exposure

There are limited data on the risk of lung cancer from exposure to inorganic arsenic in drinking water; most of the existing studies have methodological limitations (e.g., poor exposure data, lack of adjustment for potential confounders). However, the results of these studies consistently reveal a statistically significant association between exposure to high arsenic concentrations (>100 mg/L) and lung cancer.[272] A case-control study of 152 lung cancer cases and 419 controls from different hospitals demonstrated a trend of increasing cancer risk with increasing arsenic concentrations in drinking water based on historical estimates of arsenic exposure.[273] There was no speciation of arsenic in the drinking water. For residents in Northern Chile with a 65-year exposure to 200–400 μg As/L water, the odds ratio for lung cancer was 8.9 with 95% CI = 4.0–19.6. There was some evidence of synergy between cigarette smoking and the ingestion of arsenic-contaminated drinking water.[274] In a case-control study of multiple chemical exposures in 304 lung cancer cases, the odds ratio for lung cancer in smokers (>10 cigarettes/day) with arsenic exposure to >335 μg/L in drinking water was 16 (95% CI: 6.5–40) compared with controls (<11 μg As/L drinking water, never-smokers).[275] Secondhand smoke exposure did not significantly alter the odds ratio. The International Agency for Research on Cancer (IARC) concluded that high concentrations of arsenic in drinking water are probably causally related to primary lung cancer.[276] Previously, only inhaled carcinogens were causally related to lung cancer.

Occupational Exposure

A study of copper smelter workers exposed to arsenic trioxide revealed a progressive, dose-related increase in the respiratory cancer mortality rate (two to nine times normal) that was correlated with the cumulative arsenic dose.[277] Exposure to arsenic trioxide was the primary cause of lung cancer in a cohort of smelter workers after adjustment for cigarette smoking and exposure to SO_2.[262] Most,[278] but not all[279] epidemiological studies of cohorts exposed to arsenic demonstrate synergic effects of cigarette smoking on the development of lung cancer with the effect being somewhere between additive and multiplicative. A study of copper smelter workers demonstrated a relative excess of adenocarcinomas and a slight excess of oat-cell cancer compared with other

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

types of lung cancer (e.g., squamous cell).[280] A mortality study of workers formulating arsenic for pesticides (lead arsenate, calcium arsenate, copper acetoarsenite, magnesium arsenate) demonstrated an approximate 3-fold elevation (SMR = 333, 95% CI: 218–433) of the standardized mortality rate for respiratory cancers in workers first exposed to arsenic compounds before 1940 and followed until 1974.[281] In a follow-up study, the risk ratio for respiratory cancer in the time interval 1974–1982 was smaller (SMR = 116, 95% CI: 53–220); the results were not statistically significant.[282]

Skin

Medical Therapy

The medicinal use of inorganic arsenic compounds (Fowler's solution, potassium arsenite) has been associated with an increased incidence of skin cancer, but not with other types of internal cancer.[283] Follow-up studies of cancer following medical treatment with arsenic demonstrate an increased incidence of skin cancers, but the association between other types of cancer and arsenic is also less clear. A cohort study of 478 patients treated with Fowler's solution (potassium arsenite) demonstrated a significant excess of bladder cancer (5 cases observed/1.6 expected, $P = 0.05$).[243] There were no other causes of excessive deaths.

Environmental Exposure

Skin cancers (squamous cell, basal cell) are the most prevalent malignancy associated with arsenic ingestion in highly exposed populations drinking arsenic-contaminated drinking water. The three types of cutaneous tumors associated with chronic arsenic toxicity are arsenical keratosis, multiple basal cell carcinomas, and Bowen's disease.[284] The presence of these markers of chronic As exposure suggests an increased risk of internal cancers, particularly lung and urothelial cancers.[242] In contrast to skin cancers produced by UV light or X-rays, arsenic-induced skin cancers develop in areas not exposed to sunlight or X-rays. Preferential formation of arsenical keratoses occurs in areas of friction and trauma (e.g., palms, heels, toes). The most common form of skin cancer associated with arsenic exposure arises from areas of hyperkeratosis (squamous cell carcinomas). Multiple basal cell carcinomas may occur in non-hyperkeratinized areas of the skin. Some hyperkeratotic lesions and squamous cell carcinomas *in situ* may progress to invasive carcinoma.[240] Although metastasis of some cutaneous squamous cell cancers may occur, the incidence and mortality from metastatic skin lesions are low. Malignant melanomas are not usually associated with arsenic ingestion.[267]

Bowen's disease is a form of *in situ* squamous cell carcinoma that usually appears *de novo* as solitary plaques on glabrous skin. Consequently, there are no preexisting skin lesions (e.g., arsenical keratosis). About 15–20% of a group of patients with arsenic-associated Bowen's disease developed invasive squamous cell carcinomas.[285] Tseng et al. demonstrated a dose-response relationship between inorganic arsenic in contaminated well water and the development of skin cancer among residents of Taiwan where the Blackfoot disease was prevalent.[286] The mean latency period following arsenic exposure for Bowen's disease is ~10 years and ~18–20 years for invasive squamous cell carcinoma.[287] A case report associated the development of skin cancer with latency periods of 20 years and 23 years following the chronic ingestion of ~1 mg arsenic/day (cumulative total of ~8 mg As) from contaminated well water.[288] Although epidemiological studies link the development of skin cancer with exposure to arsenic-contaminated well water, the cumulative dose required to produce these skin cancers remains controversial. An ecological study of the mortality rates of skin cancer in US counties with open-pit copper mines did not demonstrate elevated skin cancer rates in the counties with the mines.[289]

Occupational Exposure

The interpretation of studies of occupational exposure to arsenic and skin cancer is complicated by multiple confounding variables; the results of these studies are inconsistent.

In a case-control study of 618 incident cases of nonmelanoma skin cancer (515 basal cell carcinomas, 70 squamous cell carcinomas) and 527 hospital-based controls aged 30–79 years, the lifetime prevalence of occupational arsenic exposure in cases and controls was 23.9% and 15.5% (statistically nonsignificant).[290] The odds ratio for nonmelanoma skin cancer was elevated in the high vs. low arsenic exposure groups (OR = 1.94, 95% CI: 0.76–4.95) based on expert evaluation of lifetime arsenic exposure, but the difference was not statistically significant. Adjustment of the odds ratio suggested that co-exposure to sunlight and arsenic may increase the prevalence of nonmelanoma skin cancer, but the ratio was based on four cases. Overall, the support for an association between arsenic exposure in the workplace and skin cancer was weak.

Genitourinary

Studies of environmental, but not occupational arsenic exposure suggest an association with genitourinary cancer. Several mortality studies of Taiwanese and Japanese populations exposed to high arsenic concentrations in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

well water suggest an increased bladder cancer risk;[30,291] however, other case-control studies have not detected a dose-related increase in the incidence of bladder cancer following exposure to lower mean arsenic concentrations (i.e., <100 μg/L) in well water.[292] A review of studies of bladder cancer mortality data in endemic areas of southwest Taiwan with the Blackfoot Disease secondary to high arsenic concentrations in well water determined that arsenic exposure concentrations alone did not explain the increased bladder cancer mortality rates in these areas.[293] In an ecological study of a region of Northern Chile where average arsenic concentrations reached 570 μg/L before 1970, the standardized mortality ratio between 1989 and 1993 for bladder cancer was elevated in men (SMR = 6.0, 95% CI: 4.8–7.4) and women (SMR = 8.2, 95% CI: 6.3–10.5).[294] A case-control study of residents in Utah with exposure to much lower concentrations of arsenic in drinking water (mean = 5 μg/L, range 0.5–160 μg/L) did not detect an elevated risk of bladder cancer.[295]

Another case-control study in Northern Chile of 122 kidney cancer cases and 640 population-based controls detected a dose-related response (P_{trend} = 0.008) between cumulative As exposure based on standardized questionnaires and renal pelvis and ureter cancers. The adjusted odds ratio of renal and ureter cancers for >25 mg As was 10.35 (n = 5, 95% CI: 2.57–41.64) compared with 5.49 (n = 12, 95% CI: 2.02–14.88) for cumulative As exposure 10–25 mg As. The trends in cumulative As exposure for renal cell cancer and all kidney cancers were not statistically significant.

Reproductive Abnormalities

Data on humans are limited to a few case reports of adverse reproductive outcomes and acute maternal arsenic toxicity[296,297] along with several ecological studies of drinking water and airborne exposure near point sources of arsenic.[298,299] Although the ecological studies suggest an association between inorganic As exposure and adverse pregnancy outcomes (low birth weight, spontaneous abortion, neural tube defects, cardiac anomalies), the marginal adjusted odds ratios, poor exposure data, and lack of control of confounding variables limit conclusions regarding the causal effect between environmental arsenic exposure on adverse pregnancy outcomes.[300] In a prospective, nested, community-based study of 1,578 pregnant women in Bangladesh, linear regression analyses suggested a statistically significant negative effect between low maternal urine total As concentrations (<100 μg/L at 8 weeks and 30 weeks of gestation) and the following birth outcomes: birth weight (−1.68 ± 0.62 g/μg As/L); head circumference (−0.05 ± 0.03 mm/μg As/L); and chest circumference (0.14 ± 0.03 mm/μg As/L).[301] Adjustment for asset scores, body mass index, and other covariates decreased the effect size for birth weight, but the effect remained statistically significant. However, there was no dose-effect association between maternal As concentration and birth weight when evaluated over the full range of arsenic exposure (median, 95 μg/L; range, 6–978 μg/L). Additionally, there were no further negative effects (i.e., no biological gradient) for maternal As exposure above 100 μg/L. About 1/3 of the women were malnourished, and ~2/3 engaged in betel nut chewing during pregnancy. A clinical pilot study of 27 Japanese survivors of the arsenic contamination from the Morinaga Dry Milk incident and 23 age-matched, unexposed local controls suggested abnormalities in bone metabolism.[302] The average height of the exposed group was 6.5 cm less than the unexposed group (P = 0.02). The mean serum alkaline phosphatase was also higher in the exposed group (233 ± 63 U/L, P = 0.01) than the unexposed group (191 ± 44 U/L). A 35-year-old woman received arsenic trioxide for acute promyelocytic leukemia; 9 months later, she conceived and delivered a healthy infant at 39 weeks, gestation.[303] In a study of CD-1 mice and New Zealand White rabbits, there were no dose-related developmental effects in either species at doses that did not produce maternal toxicity.[304] The developmental NOAEL for mice and rabbits in this study was 7.5 mg As/kg/day and 0.75 mg/kg/day, respectively.

1 μg/L = 0.013 μmol/L
1 nmol/mol creatinine ≈ 0.75 μg/g creatinine

Analytical Methods

Total Arsenic

Flame and graphite furnace atomic absorption spectrometry are the most common analytical procedures for the detection of *total* arsenic in biological samples.[31,305] Heat atomizes arsenic and a source transmits radiation through the atomic vapor of arsenic as a photoelectric detector measures the intensity of radiation that

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. passes unabsorbed. Sample preparation techniques (e.g., gaseous hydride procedure) are necessary prior to atomic absorption spectrometry (AAS). In order to measure total arsenic, special steps (e.g., acid digestion with nitric or sulfuric acid) are necessary to degrade all organic arsenic species to inorganic arsenic.[306] Other analytical techniques for quantitating total arsenic include neutron activation analysis and X-ray fluorescence. The latter procedure does not require sample preparation. For analysis of a wide range of trace elements including total arsenic, inductively coupled plasma mass spectrometry is a well-recognized technique that has greater sensitivity and a larger elemental range than inductively coupled plasma atomic emission spectrometry or electrothermal atomic absorption spectrometry.[307] Confirmation of arsenic in contaminated water requires a 250-mL sample collected in Nalgene bottles that may need acidification with concentrated nitric acid.

Arsenic Species

Speciation of arsenic in biological specimens is important because traditional measurements determine total arsenic concentrations; this value may overestimate arsenic toxicity because of the contribution of organic arsenic species with relatively low toxicity (methylarsonic acid, dimethylarsinic acid, arsenobetaine, arsenocholine) to the total arsenic concentration.[308] The three steps of speciation are sample preparation, species separation, and detection. Generally, the separation of inorganic arsenic species from organic arsenic species involves the use of chromatographic separation procedures (e.g., liquid chromatography) prior to the introduction of the sample into the detection system (e.g., spectrometry). The combination of chromatographic separation (HPLC) with element-specific detection (e.g., AAS, inductively coupled plasma/mass spectrometry (ICP/MS), inductively coupled plasma/atomic emission spectrometry (ICP/AES), inductively coupled plasma/dynamic reaction cell/mass spectrometry (ICP/DRC/MS)) provides a sensitive method for the speciation of arsenic at the low concentrations present in the environment.[309,310] ICP/MS is the most specific method, and sensitivities can range up to 1,000 times greater than other methods.[311] Organic solvents in the mobile phase may interfere with the detection of arsenic species as measured by ICP/AES. The use of water extraction with high-performance liquid chromatography coupled with hydride generation and inductively coupled plasma mass spectrometry (HPLC/HG/ICP/MS) allows the speciation of arsenic in hair.[312]

Solvent extraction with toluene followed by graphite furnace-AAS separates inorganic arsenic from mono- and di-methylated arsenic species.[313] However, this method does not determine the concentration of individual organic arsenic species (e.g., arsenobetaine). A hydride generation technique also separates inorganic arsenic (trivalent and pentavalent) from organic arsenic of marine origin, but the technique does not detect individual organic arsenic species. After acid digestion of the sample, the hydride generation technique measures total arsenic. Organic arsenic species (arsenobetaine, arsenocholine, arsenosugars) do not form arsine with sodium borohydride; therefore, these relatively nontoxic arsenic species are not measured by this method. The cold trapping speciation technique measures inorganic arsenic and its major methylated metabolites (MMA and DMA). The estimated detection limits for these three compounds by hydride cold-trapping technique were 1.0 ng, 1.3 ng, and 3 ng, respectively.[314] The difference between total arsenic and value from the cold trapping speciation technique is the arsenic attributed to marine origin. An intercomparison study of analytical methods for the speciation of arsenic in human urine indicated that current techniques are not precise or accurate at arsenic concentrations of <5 µg/L.[315] Arsenic species are relatively stable in urine samples stored at low temperatures (4°C, −20°C). Arsenic speciation profiles are similar in most urine samples before and after storage at –20°C for 8 months even without preservative.[316] Although dilute acids (pH 4.5) are added to urine samples in order to reduce the adsorption of trace elements from sample containers, the use of strong acidification alters the concentrations of arsenic species in the urine sample. Speciation analysis of arsenic primarily has been applied to environmental samples,[317] although detection limits of 0.3–0.4 µg As/L urine were achieved with the use of LC and ICP/MS.[318]

The Gutzeit test provides immediate qualitative confirmation of arsenic exposure, but this test is not specific for arsenic exposure. The procedure includes the following:

1. Add 5 mL of urine to a test tube.
2. Add several drops of sulfuric acid and several granules of zinc.
3. Cover the tube with filter paper wetted with two drops of silver nitrate.
4. Black or brown discoloration indicates the presence of arsenic but does not distinguish between As^{5+} and As^{3+}.

Biomarkers

Blood

Clearance of As from the blood is initially rapid with a first-phase elimination half-life of inorganic arsenic of ~2 hours; therefore, blood arsenic concentrations reflect very recent (i.e., 4–6 hours) exposure. Consequently, the serum arsenic concentration is relatively low soon after the ingestion of potentially dangerous amounts of arsenic compared with urine As concentrations. Although the biological half-life of inorganic arsenic in the blood is relatively short, the half-life of the methylated metabolites of inorganic arsenic in the blood is longer (range 5–20 hours).[319] As a result of the short half-life of inorganic arsenic in the blood, blood arsenic concentrations are less useful measures of recent arsenic exposure (1–2 days) than urine arsenic concentrations unless exposure occurred on the same day as the collection of the blood sample.

Whole blood levels of arsenic exceed the plasma arsenic concentration by several fold because arsenic concentrations are higher in erythrocytes compared with the serum and plasma. In a study of 25 patients with chronic arsenic toxicity (melanosis, keratosis) and no arsenic exposure for 2 years, the erythrocytes contained 72% of the total arsenic compared with 28% in plasma; the whole blood/plasma ratio was ~3.57:1.[320] Speciation of the total arsenic indicated that arsenic species are not evenly divided between erythrocytes and plasma, as demonstrated in Table 3.4.

General Population

Typical values of arsenic in whole blood from subjects without occupational exposure to arsenic range from 1–5 μg arsenic/L, whereas the whole blood arsenic concentration ranged from 6–123 μg/L in samples from residents living in communities with well water containing up to 393 μg As/L.[321] In an Italian study of 148 residents without occupational exposure to arsenic and no recent ingestion of seafood, the total blood arsenic concentration averaged ~5.1 ± 6.9 μg/L (range, 0.5–32 μg/L).[322]

TABLE 3.4. Distribution of arsenic species between plasma and erythrocytes in a study of 25 patients with chronic arsenic toxicity. (Based on Mandal et al.).[320]

Species	Plasma[a]	Erythrocytes[a]
Arsenobetaine	16.7	22.5
Arsenite	21.1	77.5
Monomethylarsonic acid	27.1	ND
Dimethylarsinic acid	35.1	ND
Total arsenic	28	72

Abbreviation: ND = not detected.
[a] Percentage of total arsenic (sum of trivalent and pentavalent arsenic).

Overdose

On admission 20 hours after the ingestion of 13 mg As_2O_3, the blood of a 23-year-old pharmacist contained 410 μg As/L.[117] His prior weakness, profound diarrhea, and vomiting resolved, and he complained only of constricted visual fields. He was treated with 5 days of BAL until he developed mildly elevated serum aminotransferases. His paresthesia and muscle weakness with bilateral footdrop resolved within 3 weeks; he was discharged without residual symptoms. A 25-year-old man presented to the hospital several hours after ingesting 8 g of As_2O_3 with abdominal pain and vomiting; the admission total serum arsenic concentration was 0.15 μg/mL.[323] He developed multiorgan failure and died 8 days later, despite intensive supportive care and BAL chelation.

Postmortem

The reported range of postmortem blood As concentrations is large. The arsenic concentration in postmortem samples of heart blood (left cardiac chamber) and the aorta from a termite control company employee found dead at his home was 6.3 μg/mL and 5.1 μg/mL, respectively.[324] The stomach contained 196 mg of arsenic (i.e., equivalent to 255 mg of arsenic trioxide) indicating a suicide. Postmortem blood (site not specified) from a 38-year-old man dying in the hospital 14 hours after ingesting a massive dose of A_2O_3 contained 20.1 μg/mL as measured by spectrophotometry compared with 16.2 μg/mL in postmortem blood from a 63-year-old man dying in the hospital 8 hours after ingesting ~15 g A_2O_3.[325] A 32-year-old man died in the hospital after developing an idioventricular rhythm and cardiac arrest 6 hours after admission for hypotension, dehydration, and gastrointestinal symptoms.[326] His wife admitted adding arsenic to his food including a large dose on the day of admission. His postmortem blood arsenic concentration (site not reported) was 7.2 μg/mL. A 28-year-old chemist developed profuse vomiting, diarrhea, hypotension, and renal failure after intentionally ingesting an estimated 75 g of arsenic trioxide.[327] He died 16 hours after ingestion despite intensive care; his postmortem blood (site not specified) contained 2,300 μg As/L.

Urine

Total (Inorganic and Organic) Arsenic

Urinary total arsenic concentrations measure both inorganic and organic arsenic; the corresponding value reflects recent exposure (1–3 days) to arsenic.[328] In contrast to total arsenic concentrations, total speciated (inorganic) arsenic measures inorganic species plus the methylated metabolites of inorganic arsenic with the exclusion of organic arsenic species. The 95th percentiles for total urinary arsenic and total speciated arsenic (arsenic acid, arsenous acid, dimethylarsinic acid, monomethylarsonic acid) in the 2003–2004 US National Health and Nutrition Examination Survey (NHANES) were 65.4% and 18.9%, respectively.[310] The latter value represents inorganic-related arsenic species. Inorganic arsenic species were detected (LOD, 0.6–1.2 μg/L) in the following percentages (age ≥6 years): arsenic acid, 7.6%; arsenous acid, 4.6%; trimethylarsine oxide, 0.3%; and monomethylarsonic acid, 35%. The geometric mean of the total urinary arsenic concentration in this population was 8.30 μg/L (95% CI: 7.19–9.57 μg/L). The main species contributing to the total urinary arsenic concentration were dimethylarsinic acid (geometric mean = 3.71 μg/L) and arsenobetaine (geometric mean = 1.55 μg/L); however, the contribution of arsenobetaine to the overall total urinary arsenic concentration increased as the overall total urinary arsenic concentration increased.

Baseline total urinary arsenic concentrations are stable over the course of the day and from day-to-day in the same individual unless there is a recent, large ingestion of arsenic.[329] Total urinary arsenic concentrations may remain elevated for 1–2 months after severe acute arsenic intoxication. The relative proportion of trivalent (As^{3+}) and pentavalent (As^{5+}) species in the urine is pH dependent. Three to four days after ingestion, the methylated forms of inorganic arsenic (monomethylarsonic acid, MMA; cacodylic acid or dimethylarsinic acid, DMA) predominate in the urine as a result of biotransformation.[330] Approximately 24 hours after the intentional ingestion of As_2S_3 (orpiment), the total As in a spot urine sample was 1,490 μg/L; the patient complained of nausea, but otherwise, he remained asymptomatic during his hospitalization.[124]

Concentration Concentrations of total urinary arsenic are usually <30–50 μg/L with concentrations between 100–200 μg/L suggesting excessive arsenic exposure in the absence of heavy seafood consumption or occupational arsenic exposure within the last 7 days.[331] Interpretation of total urinary arsenic concentrations in the general population and workers requires a dietary history within the last 48 hours because methods that analyze total arsenic concentrations include the relatively nontoxic, trimethylarsenic (organic) compounds (e.g., arsenobetaine, arsenocholine) that are common constituents of marine foods (e.g., fish, shellfish, octopus, shrimp, mussel, seaweed, kelp, health food).[332,333]

In a cross-sectional study of 788 adults from the 2003–2004 National Health and Nutrition Examination Survey (NHANES), the median total urinary arsenic concentration was 7.1 μg/L.[334] The subset of this cohort without a history of recent seafood intake had a median total urinary arsenic concentration of 3.4 μg/L. In a study of spot urine samples from 4,276 participants in the 2003–2006 NHANES, the median total urine arsenic concentrations in participants without seafood consumption within 24 hours of sampling were 7.3 μg/L compared with 24.5 μg/L in participants reporting seafood consumption.[335] Dietary recall interviews conducted during the examination phase of NHANES using an automated multiple-pass method provided information on seafood intake during the past 24 hours prior to sampling. The median urinary arsenobetaine was 0.9 μg/L in participants without a history of recent seafood consumption compared with 10.2 μg/L in participants with a history of recent seafood consumption. There is substantial interindividual variation in the total urinary arsenic concentrations even in the absence of significant seafood consumption. In a study of American Indian communities, the median total urinary arsenic concentration ranged from 6.4 μg/g creatinine (90% CI: 3.9–15.2 μg/g creatinine) in Oklahoma to 16.9 μg/g creatinine (90% CI: 8.1–29.2 μg/g creatinine) in Arizona.[336]

Time Course Following the ingestion of single doses of inorganic sodium arsenite, methylarsonic acid (MMA), or cacodylic acid (dimethylarsinic acid, DMA), the kidneys excrete ~½ of the As^{3+} dose and ¾ of As dose in MMA and DMA within 4 days.[337] In this study, ~13% of the MMA dose was methylated to DMA, whereas the kidneys excreted the DMA unchanged (i.e., without metabolism). In a study of copper smelter workers exposed to arsenic trioxide, the approximate mean urinary half-lives were as follows: As^{3+}, 12 hours; As^{5+}, 8 hours; MMA, 20 hours; and DMA, 40 hours.[338] Consequently, DMA becomes the primary methylated arsenic species in the urine 1 week after arsenic ingestion with DMA accounting for 60–80% and MMA for 10–20% of urinary arsenic excretion.[50] The remainder of urinary arsenic excretion is unchanged in inorganic arsenic species. The time course of arsenic species in urine varies with time as a result of the methylation

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. of inorganic arsenic. Initial excretion of arsenic during the first 48–96 hours involves unchanged inorganic arsenic; subsequently, progressively increasing amounts of MMA and DMA appear in the urine.

Seafood Ingestion of seafood increases the total urinary arsenic species, depending on the amount ingested and the type of seafood. The heavy consumption of seafood within 1–2 days of testing can increase the total urine arsenic concentration up to 1,500–2,000 μg/L;[339] the history of heavy consumption of seafood with 2 days of urine collection indicates the need to repeat the urine collection 2–3 days after ingestion. In a study of volunteers, the ingestion of seafood increased the total urinary arsenic species over baseline values as follows: tuna, 180%; crab, 280%; herring, 640%; and mackerel, 690%.[340] The ingestion of seafood also increased the urinary concentration of the methylated metabolites of inorganic arsenic, but relatively small increases in the urinary concentrations of inorganic arsenic occurred. Changes in the distribution of urinary arsenic species (e.g., trivalent, pentavalent, methylated metabolites) are not sensitive indicators of recent seafood consumption.[341]

Environment The mean total arsenic concentrations in the urine samples from a European reference population were 17.2 ± 11.1 μg/L as measured by AAS with organic arsenic species accounting for about 70% of the total arsenic concentration.[322] Inorganic arsenic and the methylated metabolites accounted for about 30% of total urinary arsenic.

Most excretion of organic arsenic from seafood occurs within 48 hours of ingestion. The mean total urinary arsenic concentration of 75 Vietnamese residents without occupational exposure to arsenic or seafood consumption within the previous 48 hours was 62.4 ± 11.6 μg/L as measured by AAS.[342]

Total Speciated (Inorganic) Arsenic

Current analytical methods allow the differentiation of inorganic arsenic and methylated metabolites of inorganic arsenic from the organic arsenic species (arsenobetaine, arsenocholine, arsenosugars) present in seafood.[343,344] Unlike the urinary excretion of complex organic arsenic compounds (arsenobetaine, arsenocholine) unchanged, most inorganic arsenic compounds are methylated to DMA (pentavalent dimethylarsinic acid, cacodylic acid) with smaller amounts of MMA (pentavalent monomethylarsonic acid) and MMA (trivalent monomethylarsonous acid). As determined by these techniques, total speciated arsenic (As_{itm}) measures inorganic arsenic (arsenite, arsenate) and the methylated metabolites (MMA^{5+}, MMA^{3+}, DMA^{5+}, DMA^{3+}) with organic arsenic species excluded. Although these methods exclude most organic arsenic species present in seafood, the presence of substantial amounts of di-methylated forms of inorganic arsenic (DMA) in some seafood (e.g., bivalves) and seaweed complicates interpretation of urine assays using methods (e.g., hydride generation technique) that report the total speciated arsenic concentration as the sum of inorganic arsenic and methylated metabolites. In a study of the arsenic species in seafood, inorganic arsenic species accounted for about 3% of the total arsenic in the flesh of mussels, but the flesh of other fish (ray, cod, sole, plaice, seabream) contained little inorganic arsenic.[75] Additionally, some arsenosugars in seafood are metabolized into DMA. Therefore, the consumption of seafood within several days of sampling can complicate the interpretation of results from analytical methods using speciation.

Individual Variation There is substantial interindividual variability in the ratio of unchanged inorganic arsenic, total MMA, and total DMA as a result of differences in methylating capacity and the subsequent pattern of the urinary excretion of arsenic metabolites. Factors that potentially alter the arsenic methylation capacity include individual genetic differences, age, arsenic dose, sex, pregnancy (estrogen), dietary and lifestyle (smoking, ethanol), and cooking.[345] The presence of relatively high concentrations of monomethylarsonic acid suggests inefficient methylation and the potential for increased susceptibility to chronic arsenic toxicity as a result of the intracellular accumulation of the toxic metabolite, MMA (trivalent monomethylarsonous acid). In contrast to substantial interindividual variation in methylation capacity, there are relatively minor intraindividual differences in the urinary arsenic metabolites. Several epidemiology studies suggest that individuals with relatively high urinary inorganic arsenic and MMA concentrations along with relatively low urinary DMA concentrations are more susceptible to the development of skin and bladder cancer.[346,347]

Environment Typically, the average total urinary speciated arsenic concentration (i.e., arsenate, arsenite, MMA species, DMA species) in the general population is <10 μg/L.[348] In a study of 37 German adults without occupational exposure to arsenic, speciation of the urine demonstrated the following arsenic species: pentavalent dimethylarsenate (DMA), 81%; pentalvalent methylarsonate (MMA), 10%; and inorganic As, 9%.[349] Trivalent MMA is an intermediate in the formation of trivalent

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

DMA that varies substantially in urine samples. In a study of Romanian residents, trivalent MMA was not detectable in residents exposed to 2.8 μg As/L in their drinking water, whereas trivalent MMA represented an average of 7% of the speciated As in residents exposed to 161 μg/L in their drinking water.[153] The total urinary speciated arsenic (As_{itm}) from residents near point sources (e.g., As smelting or mining) may be higher than that from unexposed reference populations. In a pilot study of 24 residents near As mining and smelting sources, the mean As_{itm} (inorganic arsenic plus metabolites) concentration for the exposed and unexposed control group was 13.4 μg/g creatinine (range 2.7–58.9 μg/g creatinine) and 4.2 μg/g creatinine (range 2.5–5.3 μg/g creatinine), respectively, as measured by LC/ICP/MS.[50] In a study of 49 Stockholm residents, the mean As_{itm} and total organic As (As_{org}) concentrations were 12 μg/g creatinine (range 2.2–52 μg/g creatinine) and 49 μg/g creatinine (range 2.1–434 μg/g creatinine), respectively.[350]

Hair

As a result of the high affinity of arsenic for keratin, arsenic accumulates in hair, reflecting an integrated exposure depending on the growth rate of the hair (e.g., ~2–3 months for scalp hair). Although As in hair is an indicator of past As exposure, hair analysis is not a specific method for confirming chronic toxicity because this method does not discriminate between externally deposited arsenic and arsenic found within the hair shaft. Washing procedures may not remove all As from external contamination as arsenic in water and dust binds to the sulfhydryl groups in keratin and other proteins in hair based on studies of residents switching from As-contaminated well water to bottled water.[84] Sampling hair on the nape of the neck near the skin minimizes the chance of external contamination. Establishing reference ranges for As is complicated by the issue of external As contamination as well as the limited data available on the influence of age, hair sampling location and growth rate, gender, hair color, and ethnicity on As hair concentrations. The As hair concentrations in a convenience sample of 271 non-occupationally exposed US adults were below the LOD (1.10 μg/g) as measured by inductively coupled/argon plasma emission spectrometry.[351] In populations chronically exposed to arsenic in drinking water, the total arsenic concentration in hair ranges from 1–>9 μg/g.[12] As a result of external contamination and analytical issues, the total arsenic concentration in hair does not correlate well to total arsenic in drinking water.[352] Postmortem hair samples from 24 Chinese cases of accidental death demonstrated a mean concentration of 0.4 ± 0.22 μg As/g.[353]

The diagnosis of arsenic toxicity requires a correlation of the hair analysis to other samples (blood, urine) and the clinical presentation. In general, the presence of endogenous arsenic in the hair at concentrations exceeding 10 μg/g suggests chronic exposure, whereas arsenic hair concentrations exceeding 45 μg/g suggest high arsenic exposures.[12] External contamination of hair shafts may produce arsenic concentrations in the range of several thousand ppm (μg/g). The presence of high arsenic concentrations in hair and low urine arsenic levels after chelation indicates external contamination of the hair sample. The use of HPLC/HG/ICP/MS to analyze hair samples from two Chilean populations exposed to arsenic-contaminated drinking water demonstrated four arsenic species (As^{3+}, As^{5+}, pentavalent DMA, pentavalent MMA^{5+}).[312] Following chronic exposure to drinking water containing an average total arsenic concentration of 1.25 mg/L consisting almost exclusively (>99%) As^{5+}, the average As^{3+} and As^{5+} concentrations in 21 hair samples were 3.75 μg/g (range 0.23–13.72 μg/g) and 0.45 μg/g (range 0.1–1.52 μg/g), respectively. Thus, arsenite was the main arsenic species in hair, despite the consumption of water containing almost exclusively arsenate species. Methylated arsenic species accounted for <2% of the total arsenic extracted from the hair samples. Similar results were reported in a study of residents of As-affected areas in West Bengal, India. In that study, using the same analytical technique, Table 3.5 lists the approximate percentage of As species in scalp hair clipped at various locations on the head.[354]

Segmented hair analysis of full-length hairs using graphite furnace atomic absorption spectrophotometry is expensive, but this method provides an approximate estimate of the time since exposure and the amount

TABLE 3.5. Speciation of arsenic in hair and nails from residents of West Bengal, India, exposed to arsenic-contaminated drinking water without exposure to seafood. (Based on Mandal et al.).[354]

	Hair[a]	Nails[a]
Arsenite	60.9	58.6
Arsenate	33.2	21.5
Monomethylarsonic acid	2.2	7.7
Dimethylarsinic acid	3.6	3.0
Dimethylarsinous acid	ND	9.2

Abbreviation: ND = not detected.
[a] Percentage of total arsenic. These residents were not exposed to organic arsenic (e.g., arsenobetaine, arsenocholine) because of a lack of exposure to seafood.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of exposure based on the rate of hair growth (i.e., ~1–1.3 cm/month).[355] Because of the difference in the growth rate of hairs from different parts of the body, the use of sequential analysis of individual hairs is more accurate than analysis of bulk or aligned hair samples. Full-length hairs should be marked with a clear indication of which end is the root. The distribution of arsenic in the length or cross-section of hair shafts does not distinguish between external contamination and endogenous arsenic.[12] Results from hair analysis of arsenic must be interpreted cautiously because of the propensity of As from external contamination (e.g., washing with As-containing water) to irreversibly bind to sulfhydryl groups and other proteins in the hair; hence, measurements of hair arsenic should be confirmed by urine and blood arsenic analysis.

Nails

Analysis of As in fingernails and toenails has the same advantages and limitations as measuring As concentrations in hair including the binding of arsenic from external sources to sulfhydryl groups in keratin proteins in the nail matrix; concentrations of As species in these two matrices are similar, but not identical, as demonstrated in Table 3.5. Nails grow more slowly than hair with average daily growth rates of about 0.1 mm for fingernails and 0.03–0.05 mm for toenails; however, the nail growth rate varies with age and individual nails. In general, As concentrations in toenail clippings reflect an integrated exposure over 12–18 months, depending on the growth rate, sample length, and the presence of external contamination.[356] Consequently, As concentration in toenail clipping varies substantially in the general population. In a study of 440 Michigan residents, the median As concentration in toenail clippings was 0.06 μg/g with a range of 0.003–1.26 μg/g.[357] Arsenic concentrations in nails from healthy subjects without excessive exposure to arsenic ranged from 0.02–2.9 ppm with a mean of 0.36 ppm.[358] Significantly higher arsenic concentrations (4.55 ± 2.25 ppm) were detected in subjects exposed to arsenic-contaminated well water.[359] Equations to correlate arsenic levels with arsenic concentration in nails have been formulated,[360] but the validity of these equations requires confirmation. Toenail arsenic concentrations have been proposed as a long-term biomarker of total arsenic exposure to drinking water exceeding 50 μg As/L and an alternative to the variability of urine arsenic concentrations,[361] but further validation of the exposure-response curve is necessary to validate this biomarker.

Abnormalities

Unabsorbed arsenic trioxide may appear as radiopaque flecks in the stomach.[362] Arsenic is radiopaque;[363] however, abdominal radiographs do not often demonstrate the radiopacity of arsenic in the gut because of rapid As absorption. The cerebrospinal fluid from patients with arsenic intoxication does not usually contain cells or increased amounts of protein.

Electrophysiology

Characteristic changes of inorganic arsenic-induced peripheral neuropathy begin with reduced sensory nerve conduction followed by decreased motor nerve conduction amplitude initially with only minor changes in motor nerve conduction velocity.[364] Reduction in motor nerve velocity is a later finding in chronic arsenic intoxication. Electromyography usually demonstrates denervation in the distal lower extremities.[365] Recovery from the electrophysiological effects of acute arsenic poisoning begins within a few weeks, but the residual slowing of nerve conduction velocity and decreased sensory nerve potentials may persist for several years.[207] Early electrodiagnostic testing may not distinguish arsenic toxicity from an acute inflammatory demyelinating polyradiculopathy (Guillain-Barré syndrome).

Electrocardiography

Occasional case reports associate electrocardiographic abnormalities with acute arsenic poisoning including heart block, nonspecific ST-T wave abnormalities, QTc prolongation, ventricular tachycardia (*torsade de pointes*),[217,218] and ventricular fibrillation.[366] A 34-year-old man developed syncope with polymorphic ventricular tachycardia along with clinical features of arsenic poisoning and a markedly elevated serum arsenic concentration.[367] The serum electrolytes were normal, and the electrocardiogram demonstrated dramatic QTc prolongation (660 msec) and T-U wave alternans.

In a Phase II trial of arsenic trioxide in the treatment of acute promyelocytic leukemia, QT prolongation occurred in all eight patients studied during the induction phase.[368] Four of these patients developed nonsustained ventricular tachycardia requiring antiarrhythmic drugs. Several studies suggest an association between chronic exposure to high arsenic concentrations in well water and QT prolongation. In a cross-sectional study of 280 men and 355 women from southwestern Taiwan exposed to arsenic in well water, the prevalence of QTc prolongation increased with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

arsenic concentrations exceeding 700 μg/L.[369] In a Bangladesh study of 1,715 participants in the Health Effects of Arsenic Longitudinal Study, QTc prolongation, as defined by a QTc of ≥460 msec in women and ≥450 msec in men, was associated with the highest quartile of arsenic exposure only in women (OR = 1.61, 95% CI: 1.00–2.58). The adjusted odds ratio of QTc prolongation in women for each standard deviation in well water arsenic concentration (108.7 μg/L) was 1.24 (95% CI: 1.05–1.47). The mean QTc interval for the 237 participants with QTc prolongation was 484 ± 45.0 msec.

Blood

Rare case reports associate acute arsenic poisoning with severe rhabdomyolysis.[209] Hematological abnormalities following arsenic poisoning include basophilic stippling of karyorrhexis of erythrocytes, normochromic, normocytic anemia, aplastic anemia, eosinophilia, leukopenia, thrombocytopenia, erythroid hyperplasia, megaloblastic anemia,[370] bone marrow hyperplasia, and myelodysplastic syndrome.[371] The most common hematological abnormalities resulting from chronic arsenic toxicity in the order of frequency are leukopenia, anemia, and thrombocytopenia.[372] A study of 40 workers exposed to arsenic detected a significant correlation between the concentration of glycosylated hemoglobin and the arsenic concentration in the urine of these workers. However, the clinical significance of these concentrations remains unclear.[373]

Urine

A study of 36 individuals exposed chronically to elevated As concentrations in drinking water demonstrated increased excretion of urinary porphyrins.[374] The threshold concentration was 1 mg As/g creatinine. Patients above this concentration had significant reductions in coproporphyrin III excretion, decreased coproporphyrin III/coproporphyrin I ratio, and increased excretion of urinary porphyrins compared with controls. The contaminated well water contained 92% pentavalent arsenate and 8% trivalent arsenite.

HEALTH SURVEILLANCE

Preplacement and annual physical examinations should include a chest X-ray and a careful examination of the skin for hyperpigmentation and keratosis.

Risk Assessment

Ingestion

The US EPA calculated a chronic oral reference dose (RfD) of 0.3 μg As/kg/day for inorganic arsenic based on an NOAEL of 0.8 μg As/kg/day for dermal effects and possible vascular complications in a Taiwanese farming population exposed to arsenic in well water[286] and an uncertainty factor of 3. The lack of arsenite-induced direct genotoxicity suggests the possibility of a nonlinear dose-response curve for arsenic-induced cancer with the potential for a threshold.[375]

Drinking Water

The WHO provisional guideline for drinking water is 10 μg As/L, but many areas in the world (Bangladesh, West Bengal, India, China, Taiwan, Mongolia, Finland, Hungary, Chile, Argentina, Thailand) substantially exceed this standard.[376] Epidemiological data from these regions with high arsenic concentrations (>150 μg/L) demonstrate a strong association between arsenic exposure and the risk of cancer (skin, lung, bladder). However, the risk of exposure to lower arsenic concentrations (<100 μg/L) is less well-defined because of the small sample size (i.e., power to detect OR <1.5–2), difficulty estimating past arsenic exposure (i.e., exposure misclassification), and potential confounding (e.g., smoking, radon).[377] Some studies suggest a threshold level near 100 μg/L based on analysis of cancer mortality data from Taiwanese villages with the endemic Blackfoot disease.[378] Comparison of dose-response data from different studies is complicated by potential variations in arsenic species (As^{3+}, As^{5+}, organic As), toxicity, interaction of trace elements (selenium, antimony, zinc),[379] population behavioral patterns, reliability of exposure measures, misclassification, and alternate exposure pathways for arsenic.[62,380] The magnitude of the estimated carcinogenic potency of arsenic ranges from cancer unit risk of 1×10^{-3} to $\sim 15 \times 10^{-3}$ depending on the linearity of the dose-response data.[381] Other potential factors that may modulate the effect of low doses of arsenic include genetic polymorphism, nutrition and other dietary factors, and the presence of a threshold for the saturation of the inorganic arsenic detoxification pathways at high doses.[382] However, a study of residents exposed to arsenic concentrations ranging from 17–980 μg/L in well water did not detect a threshold for the methylation of inorganic arsenic at the concentrations present in the well water.[383] The geometric mean of total speciated arsenic in the urine of current users of the well water was 58 μg/L with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a range of 3–500 μg/L. Inorganic arsenic, MMA, and DMA represented about 19%, 9%, and 68%, of the mean speciated arsenic concentrations, respectively.

Skin

The current public drinking water standard for arsenic in the United States is 10 μg/L based on a low-dose linearity model and extrapolation of skin cancer risks from exposure to 170–800 ppb in the study of Taiwanese residents by Tseng et al.[286] Using US EPA methods, the estimated lifetime risk of developing skin cancer for an American male ingesting 1 μg As/kg/day is $\sim 15 \times 10^{-3}$. This risk estimate is highly dependent on the type of model used to extrapolate the risk of cancer to the doses of arsenic near the regulatory standard of 10 μg As/L. Using maximum likelihood estimation and a multistage Weibull model with nonzero linear and quadratic coefficients of dose, the lifetime risk of developing skin cancer for the same scenario was 1.3×10^{-3}.[384] Major limitations of the use of the Tseng data for low-dose extrapolation of cancer risk include the lack of exposure data for individuals and the absence of prevalence data for skin cancer in individual villages.[385] A single value represented the arsenic exposure at each village, and there were only three data points for skin cancer rates because these rates were grouped into three exposure categories.

In a longitudinal study of 11,746 participants in Bangladesh, the estimated risk of developing nonmalignant skin lesions was increased at drinking water concentrations of <50 μg total arsenic/L.[386] Based on linear dose-response analyses, the estimated excess relative risk of nonmalignant skin lesions for a 10 μg/L increase in total arsenic concentration in tube well water was 0.122 (95% CI: 0.087–0.171) as measured by graphite furnace atomic absorption spectrometry (limit of detection = 5 μg/L). When the result was near or below the detection limit, the sample was reanalyzed by inductively coupled plasma/mass spectrometry (detection limit of 0.1 μg/L).

Bladder

Species-specific arsenic toxicity, limited data on arsenic effects at low concentrations, and interindividual variables (e.g., smoking, arsenic methylation) complicate risk assessment of developing bladder cancer following environmental arsenic exposure.[387,388] Most evidence for an association between arsenic in drinking water and bladder cancer derives from studies of populations exposed to high arsenic concentrations (>150 μg/L) in drinking water.[29] In contrast to data from exposure to high arsenic concentrations, increased mortality from bladder or lung cancer is not clearly associated with exposure to well water containing arsenic concentrations below 150 μg/L.[389] A population-based bladder cancer case-control study of Michigan residents did not detect an increased risk of bladder cancer (OR = 1.10, 95% CI: 0.65–1.86) in residents exposed in their lifetime to >10 μg As/L drinking water, when compared with controls (<1 μg As/L).[390] A meta-analysis of eight studies of bladder cancer and low-level arsenic exposures (<100 μg/L) did not indicate that low-level arsenic exposure is an independent risk factor for bladder cancer.[391] The summary relative risk estimates (SRRE) for never-smokers were <1.0, whereas the SRRE for ever-smokers was slightly, but not statistically significantly elevated (SRRE = 1.24, 95% CI: 0.99–1.56). An update of this meta-analysis with data from two new publications yielded a slightly elevated, but non-statistically significant, summary relative risk estimate for the nine studies of 1.07 (95% CI: 0.95–1.21; $P_{\text{heterogeneity}} = 0.543$).[392] The predicted risk of bladder cancer from these studies was lower than the extrapolated risk from the high-exposure Taiwanese studies, particularly for never-smokers.

Chen et al. stratified Taiwan residents into four groups (<0.1 ppm, 0.1–0.29 ppm, 0.3–0.59 ppm, and ≥0.6 ppm) based on the median arsenic concentration in village well water.[393] The excess risk of developing bladder cancer as well as liver, lung, and kidney cancers following daily As exposure to 10 μg/kg was similar for men and women, assuming men consumed 3.5 L/day of well water and women consumed 2.0 L/day of well water. The calculated lifetime excess risk of males developing bladder cancer following this dose (i.e., corresponding to 0.2 ppm As in well water) was 1.2×10^{-2} compared with the following other cancers: liver, 4.3×10^{-3}; lung, 1.2×10^{-2}; and kidney, 4.2×10^{-3}.

Lung

Most,[291,394] but not all,[279] studies of workers exposed to inorganic arsenic indicated that smoking and arsenic act synergistically to increase the risk of lung cancer with the effects being intermediate between additive and multiplicative.[395] In the former study, no cases of lung cancer were detected among cases exposed to well water containing inorganic concentrations of arsenic of <50 μg/L.[291] A cohort study of residents from arseniasis-endemic areas in Taiwan did not detect a statistically significant increase in the relative risk of lung cancer in residents exposed to well water concentrations of <100 μg As/L.[394] After adjusting for age, an ecological study of lung cancer in Taiwan detected increased lung cancer mortality in populations exposed to well water containing inorganic arsenic concentrations of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

>640 μg/L, but statistically significant increases in lung cancer mortality were not detected in populations exposed to drinking water containing inorganic arsenic concentration below this concentration.[396]

Inhalation

The USEPA inhalation unit risk factor for As is 4.3×10^{-3} based on excess lung cancer mortality in the Asarco and Anaconda smelters in the Western United States. The Texas Commission on Environmental Quality reevaluated the As inhalation unit risk factor based on updates of the Asarco[397] and Anaconda[398] smelters along with data from a Swedish copper smelter cohort study.[399] Based on these data, the group recommended a value of 1.5×10^{-4}. This value correlates to 1/100,000 excess lung cancer deaths at 0.067 μg/m^3. Radon progenies frequently contaminate arsenic-containing materials, complicating the interpretation of cancer data from workers exposed to arsenic.[400] To date, the USEPA has not accepted a reference concentration (RfC) for chronic As inhalation.

Environmental Monitoring

Because arsenic is a recognized carcinogen, US OSHA regulations require the use of protective equipment (respirators, clothing), clean facilities (change areas, designated dining areas), engineering controls whenever employees are exposed to arsenic concentrations exceeding OSHA PEL; the goal is to control As ambient air concentrations to the lowest possible concentration below the PEL. Ambient air concentrations exceeding the action level (5 μg As/m^3) require the use of medical surveillance, protective equipment, notification, engineering controls, and training to reduce arsenic exposure. Regulated areas above the PEL require respiratory protection for the workers and prohibition on oral substances (food, beverages, gum, tobacco). The ACGIH established an 8-hour TLV–TWA of 10 μg/m^3 for inorganic arsenic based on the presence of an elevated risk of lung cancer (SMR 213, n = 47) in copper smelter workers exposed to mean airborne total arsenic concentration of 200 μg/m^3.[401] Table 3.6 lists the standards and recommendations for inorganic arsenic.

TABLE 3.6. Regulations and guidelines for inorganic arsenic exposure including the metal.

Exposure Limit	Values
ACGIH	
TLV-TWA (8-hour)[a]	
Elemental and inorganic arsenic	10 μg total As/m^3
BEI (urine)	35 μg inorganic As plus methylated metabolites/g creatinine[b]
NIOSH	
REL (15-minute ceiling)	2 μg As/m^3
IDLH	5 mg As/m^3
OSHA	
PEL-TWA (8-hour)	10 μg As/m^3
Action level	5 μg As/m^3
US EPA	
Carcinogenicity classification	A (known carcinogen)
Oral slope factor	1.5 per mg/kg/day
Inhalation unit risk	4.3×10^{-3} per μg/m^3
MCL	10 ppb (10 μg/L) As
RfD	0.3 μg/kg/day
Tolerance for residues–citrus, fruits	0.35 ppm As
US FDA	
Bottled drinking water	10 μg As/L
ATSDR	
MRL	
Oral acute	5 μg/kg/day
Oral chronic	0.3 μg/kg/day

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; BEI = biological exposure indices; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfD = reference dose; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency; US FDA = US Food and Drug Administration.

Biological Monitoring

Blood

The mean total blood concentration of arsenic from four glass workers exposed to airborne arsenic concentrations of 4.5–619 μg/m^3 was 30.7 μg/L (range, 8–48 μg/L) compared with a mean of 13.4 μg/L (range, 0.5–37 μg/L) for relatively unexposed store clerks.[322] Arsenic elimination from the blood is rapid; therefore, urine is the preferred sampling site for assessing occupational As exposure.

Urine

After the ingestion of inorganic arsenic, part of the dose is methylated and smaller amounts are

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

excreted unchanged in the urine. In general, the kidney excretes ~10–25% of the absorbed inorganic As dose unmethylated.

Method

Although organic arsenic compounds (e.g., arsenobetaine, arsenocholine) are not relevant to the determination of arsenic toxicity, the critical dose metric for biological monitoring of arsenic exposure (i.e., total inorganic arsenic, oxidation state, DMA, MMA) remains unclear. Using the sum of speciated inorganic arsenic (trivalent, pentavalent) and major metabolites (DMA species, MMA species), the estimated biological equivalents (BE) based on the US FDA reference dose and the Agency for Toxic Substances and Disease Registry minimal risk level is 6.4 µg/L urine.[402] The BE is a screening tool to evaluate the margin of safety for current exposure guidelines; this level does not predict the likelihood of adverse health effects in individuals or populations.

The measurement of total speciated (inorganic) arsenic as a biomarker of occupational exposure to arsenic is a method to reduce the effect of diet on total urinary arsenic concentrations.[403] However, the consumption of certain types of seafood can increase the urinary DMA excretion, particularly when ingested within 24 hours of exposure, resulting in an elevation in the total urinary speciated arsenic.[340] The most complete assessment of occupational exposure includes total inorganic arsenic and arsenic speciation. Alternatively, evaluation may begin with total urinary arsenic with speciation of samples outside normal ranges.

Concentration

Total Speciated Arsenic Typical ranges of the components of As_{itm} in the urine of arsenic-exposed workers are as follows: pentavalent arsenate, 1–6%; trivalent arsenite, 11–14%; monomethylarsonic acid (pentavalent MMA), 14–18%; and dimethylarsinic acid (pentavalent DMA), 63–70%.[404] Using the speciation method during a study of workers exposed to arsenic, the average concentrations (µg As/g creatinine) of urinary speciated arsenic (As_{itm}) were as follows: unexposed controls, 4.4; workers in the electronics industry, <10; timber treatment workers applying arsenical wood preservative, 47.9; glassworkers using arsenic trioxide, 79.4; and chemical workers engaged in manufacturing inorganic arsenicals, 245.[404] About 70–75% of the urinary elimination of As_{itm} (inorganic As + metabolites) occurs within 3–4 days after exposure.

For workers exposed to arsenic trioxide at a geometric mean of 17 ± 3.1 µg As/m^3, the geometric mean of As_{itm} (inorganic arsenic plus metabolites) was 79 ± 2.4 µg As/g creatinine with a maximum of 328 µg As/g creatinine.[142] In a study of a copper smelter, the time-weighted average (TWA) ranged from 1–746 µg As/m^3 and the urinary As_{itm} ranged from 2–850 µg/L.[405] The calculated mean concentrations of urinary As_{itm} for workers exposed daily to ambient air concentrations of 10 µg As/m^3 and 50 µg As/m^3 were ~30 µg/L and 70 µg/L, respectively, corrected to a specific gravity of 1.024. The mean urinary As_{itm} concentration in a group of 40 workers using arsenic-containing products was 22.3 nmol As/mmol creatinine (maximum, 294.5 nmol As/mmol creatinine); the mean in urine samples from 26 referents without occupational exposure to arsenic was 12 nmol As/mmol creatinine.[373] The best correlation between ambient arsenic air concentrations and urine arsenic species occurred when the sum of As^{3+} and As^{5+} was measured in urine samples collected within 8 hours of the cessation of exposure. Urine DMA concentrations did not correlate well to ambient air As concentrations because of the confounding dietary exposure.

Based on a study of workers exposed to arsenic trioxide at a sulfuric acid chemical factory, the official permissible exposure limit of OSHA (10 µg/m^3) correlated to total inorganic arsenic plus methylated metabolites of ~28 µg/g creatinine.[406] A study of boiler cleaning operations in a Slovak coal-fired power plant examined the relationship between airborne exposure to pentavalent arsenic and urinary concentrations of inorganic arsenic and methylated metabolites.[407] The 8-hour time-weighted mean arsenic air concentration was 48.3 µg/m^3 (range, 0.17–375 µg/m^3; 90% particles ≤3.5 µm). The predicted mean concentration of urinary inorganic arsenic plus methylated metabolites was 13.2 µg/g creatinine (95% CI, 10.1–16.3 µg/g creatinine). This concentration is substantially below (i.e., 1/3) the urinary concentrations of inorganic arsenic and methylated metabolites predicted from studies of workers exposed to trivalent arsenic in copper smelters. This study suggests that As bioavailability may vary between industries, depending on particle size distribution, composition of matrix, and the type of arsenic compound.

Total Arsenic Most occupational studies of arsenic exposure involve exposure to arsenic trioxide vapors and arsenic-containing dust in copper smelters and refineries. Some of these studies measured total urinary arsenic concentrations rather than inorganic arsenic plus methylated metabolites. The total arsenic concentrations were measured in the urine of workers from two copper smelters[401,408] with airborne arsenic concentrations ranging up to 3,400 µg As/m^3 and a lead–acid

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

storage battery factory with maximum airborne particulate arsenic concentrations of 5.1 μg/m^3 and a maximum arsine concentration in breathing-zone air samples of 49 μg/m^3.[409] The overall average predicted total urinary arsenic concentrations following exposure to airborne concentrations of 10 μg As/m^3 was 33.4 ± 8.7 μg/g creatinine based on these three studies. In a study of 14 copper smelter workers exposed to airborne arsenic concentrations up to 194 μg/m^3 (geometric mean = 17 μg/m^3), the mean urinary concentration of inorganic arsenic and methylated metabolites was ~49 μg/g creatinine. Another study of copper smelter workers measured airborne arsenic concentrations up to 1,000 μg/m^3 and corresponding urinary concentrations of inorganic arsenic plus methylated metabolites. Exposure to airborne arsenic concentrations of 10 μg/m^3 correlated to speciated urinary arsenic concentrations of ~25 μg/L.[410] Assuming a urinary creatinine concentration of 1.13 g/L, this value correlates to ~22.1 μg/g creatinine.

The physiochemical properties of the arsenic species, matrix composition, and particle distribution may alter the relationship between airborne As exposure and the urinary excretion of inorganic arsenic and methylated metabolites at a specific plant.

In a study of 24 copper smelter and arsenic trioxide refinery workers exposed primarily to trivalent arsenic, the concentrations of inorganic arsenic (As^{3+}, As^{5+}) and metabolites MMA (monomethylarsonic acid) and DMA (dimethylarsinic acid) were analyzed in urine from 0–20 hours after exposure.[338] The best correlation between the time-weighted average of arsenic in the air (range, 0.8–45 μg/m^3) and urine arsenic species was the sum of As^{3+} and As^{5+} in urine samples collected 0–8 hours postexposure. An inorganic As concentration of 5 μg/L urine correlated to an 8-hour TWA of 10 μg As/m^3. The predicted end-of-shift urinary concentration of inorganic arsenic plus methylated metabolites following exposure to airborne arsenic concentrations of 10 μg/m^3 was ~35 μg/g creatinine.

Sample Collection

Although previous studies of arsenic-exposed workers used total urine As at the end of shift as a biomarker, the currently recommended method for monitoring workers exposed to inorganic As is the determination of inorganic As and methylated metabolites. Use of this method reduces the influence of organic arsenic compounds that do not contribute significantly to toxicity.

The urine should be collected during the mid-to late week.[405] Analysis of the urine from workers with elevated arsenic concentrations should be repeated, particularly if the consumption of seafood occurred within 48 hours. Speciation helps determine the contribution of arsenic related to seafood consumption when the total urinary As is elevated. Over 99% of the arsenic in most, but not all, seafood occurs in the organic form. However, microorganisms may release inorganic arsenic from arsenobetaine present in some marine animals (e.g., mussels), and some marine organic compounds release dimethylarsinic acid in the body.[75] Consequently, the consumption of seafood within 48 hours of the collection of urine samples should be avoided in order to accurately interpret the sum of inorganic and methylated metabolites.

TREATMENT

Decontamination

In the absence of contraindications, gastric lavage is an option for decontamination when the patient presents within the first 1–2 hours postexposure and activated charcoal is not indicated. However, there are inadequate data to determine if these measures improve clinical outcomes. Case reports suggest exposure to arsine fumes from the interaction of stomach acids with large quantities of arsenic trioxide can cause local skin and mucous membrane irritation in health care workers administering these decontamination measures.[411] The presence of radiopaque material in the stomach after lavage is an indication that decontamination measures were inadequate. Whole bowel lavage is an alternative decontamination measure if the radiopaque material is past the pylorus, but data are inadequate to evaluate the efficacy of this measure. Decontaminate any exposed skin. The efficacy of activated charcoal is unclear because of the limited data on the adsorption of various inorganic arsenic compounds to activated charcoal. Case reports suggest the use of alkaline irrigation of the stomach (i.e., 60 mEq $NaHCO_3$/L at 1 L/hour in the proximal fundus with drainage via a pyloric tube) improves the decontamination of radiopaque arsenic;[412] however, there are inadequate data to confirm the efficacy of this procedure, particularly in the setting of multiple therapies. If repeat KUB demonstrates residual radiopaque material in the colon, colonic irrigation via a colonoscope is an option to remove arsenic concretions.[413]

Elimination Enhancement

Arsenic is not readily dialyzable; early dialysis removes relatively small amounts of arsenic compared with the total body burden of arsenic.[414] In a case of massive arsenic ingestion (10 g sodium arsenate), hemodialysis accounted for about 20% of the elimination of pentavalent arsenic in combination with BAL.[415] Continuous venovenous hemofiltration combined with hemodialysis and peritoneal dialysis removed negligible amounts (i.e., about 0.5% of the estimated dose) of arsenic over an 11-day period in a patient surreptitiously administered ~10 g of arsenic trioxide.[416] Hemodialysis is useful primarily as an adjunct for the removal of the BAL-arsenic complex when renal failure occurs.[417] Experimental evidence suggests that other chelating agents (e.g., DMPS or 2,3-dimercapto-1-propane sulfonic acid, DMSA or meso-dimercaptosuccinic acid) do not cross hemodialysis membranes.[418]

Chelating Agents

Chelation therapy should be administered early (within several hours if possible) to prevent serious toxicity in acute As exposures when the patient is symptomatic. A spot total urine arsenic concentration (2–4 hours after an acute arsenite exposure) exceeding 200–300 μg/L is an empiric indication for early chelation.[23] Arsenic is rapidly cleared from the blood following chelation; urine arsenic concentrations typically return to normal within 7–14 days after the ingestion of inorganic arsenic. Although chelation may increase urinary arsenic excretion after chronic arsenic exposure, the efficacy of chelation for chronic arsenic poisoning is unclear. Neurological symptoms frequently persist in patients with peripheral neuropathy despite the prompt use of BAL or DSMA for acute arsenic trioxide poisoning.[412,419]

British Anti-Lewisite Compound (BAL)

The use of this traditional heavy metal chelator is indicated in all serious acute arsenic exposures except arsine gas. The actual dosage range depends on the severity of exposure. The usual regimen of BAL for the treatment of arsenic toxicity is as follows: 3–5 mg/kg intramuscularly every 4 hours for 2 days; 3 mg/kg intramuscularly every 6 hours for 1 day; and then 3 mg/kg intramuscularly every 12 hours for 7 days until symptoms clear or the urine concentration decreases to <50 μg As/24 hour. Little data exist to guide the duration of treatment. Typically, the duration of BAL treatment is 5–10 days, followed by 14–19 days of oral succimer (DMSA) 10 mg/kg twice daily. A 50-mg dose of BAL combines with a maximum of 30 mg of arsenic.[420]

BAL therapy is effective for hematological manifestations of chronic arsenic poisoning, but this type of chelation probably does not improve chronic neurological symptoms. Side effects include nausea/vomiting, abdominal pain, myalgias, urticaria, burning sensation in the oropharynx (lips, mouth, throat), fever, conjunctivitis, rhinitis, lacrimation, salivation, diaphoresis, headache, anxiety, irritability, transient leukopenia, mild hepatic aminotransferase elevation, hypertension, and allergic reactions to peanut oil in BAL. Some relief of adverse effects results from administration of 1–1.5 mg diphenhydramine (Benadryl)/kg intramuscularly or by mouth every 6 hours.

2,3-Dimercaptosuccinic Acid (DMSA)

Animal experiments suggest oral BAL analogs may improve symptoms of acute arsenic trioxide poisoning,[421] primarily when administered within 1–2 hours of intoxication.[422] Efficacy decreases rapidly with an increasing interval between poisoning and chelation. Compared with BAL, DMSA has lower toxicity, oral administration, and a higher therapeutic index, particularly for the treatment of chronic arsenic toxicity.[423] Although DMSA enhances arsenic excretion from the soft tissue body stores several fold following acute organic arsenic poisoning, there are inadequate data to determine which chelating agents improve clinical outcomes following acute or chronic arsenic intoxication. The lipophilic properties of DMSA limit the ability of this compound to remove metals from the brain and bone.

Administration

The typical oral DMSA dose is 10 mg/kg t.i.d. for 5 days, followed by twice-daily administration for an additional 2 weeks. Maculopapular and vesicular rashes may develop during therapy; however, cessation of DMSA chelation rarely is necessary. A recommended chelation end-point is a 24-hour urinary arsenic concentration of <50 μg/L.[424] Arsenic inhibits T cell activation and IgG/IgM formation, resulting in reactivation of varicella-zoster and herpes simplex viruses;[425] suspicious rashes should be cultured and acyclovir administered as indicated.

Acute Toxicity Several case reports of acute trivalent (As_2O_3)[426] and pentavalent arsenic (sodium methanearsonate herbicide)[427] poisoning temporally associate the administration of DMSA with increased arsenic

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

excretion and good clinical outcome. The intentional ingestion of 4–8 g DMSA during chelation therapy for an arsenic trioxide overdose was not associated with adverse effects other than a minimal elevation of serum ALT.[428] Incomplete recovery from arsenic-induced peripheral neuropathy may occur despite chelation therapy, with permanent impairment of nerve conduction.

Chronic Toxicity Although rodent studies suggest some improvement with DMSA use in chronic arsenic intoxication,[429] the efficacy of DMSA in chronic arsenic poisoning is unproven.[430] A 3-week course of DMSA did not improve the symptoms of a group of patients who ingested excessive amounts of arsenic from well water when compared with the control group (no treatment).[431] The use of DMSA in a 39-year-old woman with tetraplegia secondary to chronic arsenic poisoning reduced serum arsenic concentration; however, the neuropathy did not improve despite chelation.[432] The arsenic source was never identified; chelation therapy began about 2 months after she was hospitalized with a peripheral neuropathy.

2,3-Dimercapto-1-propanesulfonic Acid (DMPS)

A few studies and case reports from Europe and Australia suggest DMPS may be more effective than DMSA for arsenic intoxication; however, DMPS is not a USFDA-approved chelator for arsenic toxicity. Although some US compounding pharmacies carry DMPS, its availability is limited and fatal anaphylactic reactions have occurred following the use of non-pharmaceutic DMPS preparations. Analysis of urine samples from volunteers suggests DMPS chelates trivalent MMA; the latter is the substrate necessary for the biomethylation of arsenic from pentavalent MMA to pentavalent DMA.[433] Consequently, the urine from these subjects contained relatively more pentavalent MMA and less pentavalent DMA compared with pre-chelation concentrations.

Some case reports describe improvement in neurological outcome that began after intravenous DMPS therapy was initiated because for the continuing deterioration of the patient despite oral DMSA[434] and intramuscular BAL therapy.[435] The suicidal ingestion of an estimated 600 mg-dose of arsenic trioxide was treated promptly with 12 days of DMPS (patient left after 12 days); trivalent and pentavalent inorganic arsenic accounted for ~40% of the urinary output of arsenic during treatment.[436] DMPS administration in these patients involved oral DMPS (4–8 mg DMPS/kg q6h) or intravenous DMPS (3–5 mg q4h by slow IV infusion over 20 minutes) when the patient could not tolerate oral fluids (hypotension, severe diarrhea, vomiting, or intestinal ileus).

A randomized, placebo-controlled, single-blind trial of 11 patients hospitalized for chronic arsenic intoxication treated with DMPS (100 mg 4 times/day on weeks 1, 3, 5, and 7) demonstrated a statistically significant improvement in observed clinical scores during the first 3 months after therapy when compared with 10 controls (placebo).[437] Significant improvements in clinical scores of the treatment group occurred for weakness, lung disease, and pigmentation, whereas no significant difference occurred in hematological or biochemical parameters. Arsenic exposure ceased in both groups during the study; both groups had statistically significant improvements in clinical scores when compared with pre-study values. A similar randomized, placebo-control study of DMSA did not demonstrate statistically significant differences in clinical scores between treatment and placebo groups.[438] Potential observer bias and short-term follow-up limit conclusions regarding the efficacy of DMPS for chronic arsenic intoxication based on this study.

Penicillamine

This compound provides adjunctive therapy in serious ingestions[439,440] producing fewer adverse reactions than BAL. The efficacy of D-penicillamine is controversial; animal studies have not supported the effectiveness of this drug in the treatment of arsenic toxicity.[441] Serious side effects from D-penicillamine usually occur from long-term use (optic neuritis, nephrotoxicity). Sensitivity reactions to penicillamine include fever, rashes, leukopenia, eosinophilia, and thrombocytopenia. The dose for adjunctive chelation in children is 100 mg penicillamine/kg/day for 5 days in 4 oral doses up to 1 g/day and up to 500 mg 4 times a day in adults. The administration of penicillamine should be reconsidered following a 5-day rest period when symptoms reappear or when the urine arsenic concentrations remain elevated. The use of penicillamine is contraindicated in penicillin-sensitive patients.

Supplemental Care

1) Follow fluid/electrolyte balance carefully because arsenic causes vasodilation. Treat hypotension with fluids before using vasopressors.
2) Obtain an electrocardiogram and monitor the cardiac rhythm. The treatment for *torsade de*

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

pointes includes magnesium, restoration of potassium balance, and overdrive pacing along with the avoidance of Class IA antiarrhythmic drugs (procainamide, quinidine, disopyramide).

3) Follow renal and hepatic function with serum creatinine and hepatic enzymes.
4) Obtain a baseline chest X-ray. Pulmonary edema is a rare complication, and respiratory failure secondary to neuromuscular weakness may develop several weeks after severe poisoning.[442]
5) Review any underlying disease and observe for complications of anemia, particularly in patients with cardiopulmonary disease.
6) Treatment options for arsenical keratoses includes topical chemotherapy, electrodessication and curettage, cryosurgery, and excisional surgery.

TABLE 3.7. Some physical properties and identifying information of gallium arsenide.

	Gallium Arsenide
Formula	GaAs
Synonym	Gallium monoarsenite
CAS RN	1303-00-0
Valence	−3
Molecular weight (g/mol)	144.64
Color	Dark gray
Physical state	Solid
Melting point (°C)	1,238
Density (g/mL)	5.31
Odor	Odorless[a]
Water solubility (20°C)	Very low

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.
[a] May emit garlic-like odor is in contact with water.

GALLIUM ARSENIDE

PHYSIOCHEMICAL PROPERTIES

The oxidation state of arsenide compounds ranges from 0 (elemental state) to 3− (nonmetallic), whereas only the oxidation state of gallium arsenide (GaAs) is 3−.

Gallium arsenide is a poorly soluble, synthetic metalloid that does not exist naturally. This crystalline solid is resistant to reactions with air and water in the wafer form; however, chemical properties of GaAs change (e.g., water solubility substantially increases) following the grinding of this metalloid into low micron-sized particles. Strong acids (e.g., nitric acid) decompose gallium arsenide into gallium and arsenic oxides. Table 3.7 lists some physical properties and identifying information of gallium arsenide. Hydrolysis of gallium arsenide in high-concentration hydrochloric acid produces arsine; however, these conditions are not usually present in animals or the environment. Gallium arsenide has greater electron mobility and substantially less electrical capacitance than silicon.

EXPOSURE

The use of gallium arsenide, indium arsenide, and aluminum arsenide occurs mainly in the semiconductor industry (telecommunications, solar cells, space research) with gallium arsenide being the most common arsenide in this industry. High electron mobility and saturation velocity along with desirable electromagnetic and photovoltaic properties favor the use of gallium arsenide in high-speed semiconductor and optoelectronic devices. Gallium arsenide is an important component of photoelectric chemical cells, light-emitting diodes, laser diodes, photodetectors, microwave devices, and semiconductors. The semiconductor industry uses arsine for the epitaxial growth of gallium arsenide in the manufacture of light-emitting diodes and as a doping agent in silicon-based, solid-state electronic devices.[443] Potential exposure to GaAs occurs during the formation of GaAs-silicon wafers, sandblasting GaAs ingots, and maintenance of these work areas. Although workers in the electronics industry using gallium arsenide are exposed to arsenic and arsine, the typical occupational exposure to arsenic during the production of optoelectronic devices and integrated circuits is below current work standards.[444,445]

ENVIRONMENTAL FATE

Gallium arsenide is a synthetic compound without natural sources in the environment. After anthropogenic release to the environment, gallium arsenide undergoes slow dissolution and oxidation to gallium trioxide and arsenite based on *in vitro* studies.[446] The low solubility of GaAs and its binding to other materials in solution limit the toxicity of this metalloid following environmental release.[447]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

TOXICOKINETICS

The bioavailability of GaAs is relatively low. In rodent studies, the intratracheal administration of single doses of 10, 30, and 100 mg/kg of GaAs particles to rats produced dose-dependent increases in arsenic concentrations, but the gallium concentration in blood was not detectable.[446] Similarly, the oral administration of 10, 100, and 1,000 mg/kg did not produce detectable gallium concentrations. Rodent studies suggest that arsenic bioavailability is substantially greater following intratracheal administration than ingestion based on analyses of urinary porphyrins and blood arsenic. Regardless of the route, excretion of arsenic and gallium occurred almost primarily in the feces. Arsine gas is not a byproduct of GaAs biotransformation in animals.

HISTOLOGY AND PATHOPHYSIOLOGY

The toxicity of GaAs is limited by poor solubility and the composition of materials that bind or solubilize gallium.[447] In animal studies, the target organs are the lungs and testes, but some inorganic arsenic oxides may be released from absorbed GaAs. Although there are limited data, animal studies suggest that indium arsenide produces more pulmonary toxicity than GaAs based on intratracheal administration of equimolar doses of GaAs, indium arsenide, and aluminum gallium arsenide to hamsters.[448] The latter metalloid was the least toxic.

CLINICAL RESPONSE

There are few data on the toxicity of GaAs in humans. In animal models, the lungs and testes are target organs following inhalation. The poor solubility and bioavailability of GaAs limit the toxicity following ingestion. Gallium arsenide is not listed as a substance reasonably anticipated to be a carcinogen by the US National Toxicology Program. Although the IARC determined that there is inadequate evidence of carcinogenicity of gallium arsenide in humans and limited evidence in experimental animals, the IARC lists gallium arsenide as carcinogenic to humans (Group 1) based on the biotransformation of GaAs to inorganic arsenic species in the body and concern that gallium may contribute to the formation of lung tumors in female rats.[449] Although data are limited, existing studies are not suggestive of an overall or site-specific excesses of mortality or cancer incidence in semiconductor manufacturing plants including semiconductor wafer fabrication in cleanrooms using GaAs.[450,451] Conclusions are limited by the small number of selected cancers and the relatively young age of exposed workers.

The issue of whether lung tumors occurring in these studies result from particulate-induced inflammation and increased proliferation rather than the primary carcinogenic effect of GaAs remains controversial.[452] Long-term animal studies indicate that GaAs exposure increases the incidence of lung tumors in female rats, but not in male rats, male mice, or female mice. In a 2-year study of 50 male and 50 female Fischer 344/N rats exposed by inhalation to gallium arsenide concentrations of 0, 0.001, 0.1, or 1 mg/m^3 6 hours/day, 5 days/week, there was a clear neoplastic response in the lungs and adrenal medulla of female rats.[453] The predominant non-neoplastic pulmonary effect was alveolar proteinosis followed by chronic active inflammation. Although inflammatory and proliferative lesions developed in the respiratory tract of the male rats, there was no evidence of carcinogenic activity in male rats. These studies used small particles of GaAs formed by mechanical treatment that destroyed the crystalline structure normally present in the workplace.[452]

DIAGNOSTIC TESTING

Methods for the determination of gallium in ambient air include hydride generation/atomic fluorescence spectroscopy and instrumental neutron activation analysis.[454] Monitoring of occupational exposure to gallium arsenide typically involves analysis of arsenic concentrations rather than gallium because of the limited analytical techniques for the determination of gallium.

HEALTH SURVEILLANCE

Biological monitoring of GaAs usually involves monitoring speciated arsenic in urine using arsenic recommendations and standards. The NIOSH recommended ceiling value is 0.002 mg/m^3 for GaAs, but there are no regulations specifically for GaAs exposure.

TREATMENT

Treatment is based on the amount of inorganic arsenic exposure.

ORGANIC ARSENIC

HISTORY

Erasmus Wilson first described arsenical keratoses of the palms and soles in 1868.[15] By the early 1900s, physicians began substituting less toxic organic arsenicals (sodium cacodylate, sodium arsanilate) for the use of inorganic arsenic compounds as a treatment for pellagra, malaria, and sleeping sickness. In 1910, Nobel laureate Paul Ehrlich (1854–1915) developed the organic arsenical, arsphenamine (Salvarsan) for the treatment of syphilis and trypanosomiasis.[455] Between 1910 and the introduction of penicillin in the 1940s, arsphenamine was the primary drug available to treat syphilis; however, the treatment of syphilis with intravenous arsenicals was prolonged (>18 months), alternating with previously used mercury or bismuth treatments. Nausea, vomiting, and rapid oxidation of arsphenamine complicated the treatment of syphilis with arsenicals. The use of arsenic compounds for the treatment of diseases associated with protozoa, helminths, amoeba, and spirochetes was superseded by more effective antimicrobial therapy. Melarsoprol [2-(*p*-(4,6-diamino-*s*-triazin-2-ylamino)phenyl)-1,3,2-dithiarsolane-4-methanol] is still used to treat trypanosomiasis.

Organic arsenic-based chemical warfare agents include Adamsite (phenarsazine chloride, CAS RN: 578-94-9), Clark 1 (diphenylchloroarsine, CAS RN: 712-48-1), Clark 2 (diphenylcyanoarsine, CAS RN: 23525-22-6), and Lewisite (dichloro(2-chlorovinyl)arsine, CAS RN: 541-25-3). Nazi Germany produced arsine oil (50% phenyldichloroarsine, 35% diphenylchloroarsine, 5% arsenic trichloride, 5% triphenylarsine) as chemical weapons during World War II.[456] The Japanese Imperial Army synthesized diphenylchlorarsine and diphenylcyanoarsine as emetic-type chemical weapons during World War II under the code name Agent Red No. 1. Case reports associate the development of neurological abnormalities (speech difficulty, diplopia, gait disturbance, myoclonus, ataxia, hyperreflexia) with the consumption of well water contaminated with diphenylarsinic acid, a degradation product of these chemical weapons.[457,458]

PHYSIOCHEMICAL PROPERTIES

Common organic arsenic compounds include arsanilic acid (4-aminophenyl arsonic acid), dimethylarsinic acid (cacodylic acid, DMA), monomethylarsonic acid (pentavalent MMA), and the trivalent intermediate metabolite of inorganic arsenic, monomethylarsonous acid (trivalent MMA). Most organic arsenic compounds are pentavalent compounds that are positively charged quaternary "arsenonium" salts without a covalent bond to an oxygen atom. Arsenobetaine $[(CH_3)_3As^+CH_2COO^-]$ and arsenocholine $[(CH_3)_3As^+CH_2CH_2OH]$ are common constituents of seafood; arsenosugars frequently occur in seaweed. Cooking alters the concentration of arsenic species in seafood; this process transforms arsenobetaine to trimethylarsine oxide and tetramethylarsonium ion.[459] Table 3.8 lists identifying information and physical properties of common organic arsenic compounds.

EXPOSURE

Uses

Traditional uses of organic arsenic compounds since the 1940s include weed control (herbicide) and wood preservation; these compounds were introduced as substitutes for the more toxic inorganic arsenic compounds. Several organic arsenic compounds are herbicides including sodium methanearsonate (weed control on cotton and turf), disodium methanearsonate (weed control), calcium acid methanearsonate (post-emergent weed control on lawns), and cacodylic acid (defoliant, herbicide). The latter herbicide is a highly soluble organic arsenic compound that in the powder form is called Agent Blue. This herbicide contained 4.7% cacodylic acid and 26.4% sodium cacodylate.[460] Most organic arsenical pesticides are banned by the USEPA with the exception of sodium methanearsonate (methanearsonate, MSMA) used as a broadleaf weed herbicide on cotton. The use of chromated copper arsenic as a wood preservative has been phased out in US residential construction and most industrial applications. Other organic arsenicals are agricultural antimicrobials in animal and poultry feeds including arsanilic acid, sodium arsanilate, and 3-nitro-4-hydroxyphenylarsonic acid (roxarsone).[35]

Sources

Environment

Inorganic forms of arsenic are the predominated species in ambient air with minor amounts of organic arsenic.[35] In soil, organic arsenic may be mineralized to inorganic arsenic compounds or arsine depending on moisture

content and aerobic conditions (e.g., anaerobic conditions favor the formation of arsine, whereas aerobic conditions favor the formation of inorganic arsenates). Severe contamination of underground aquifers occurred as a result of the gross contamination of soil with copper acetoarsenite (Paris-Green) ranging up to 51,000 mg As/kg soil.[103] The concentration of organic arsenic in open waters is low (0.01–7.4 ppb) with most samples <0.3 ppb.[461] The main organic species in freshwater are DMA and its degradation product, MMA; these species are usually present at lower concentrations than inorganic arsenic species.

Food

Marine organisms normally contain arsenic, predominately as organic arsenic including arsenobetaine (invertebrates, fish) and arsenosugars (macroalgae). In the environment, microorganisms convert inorganic arsenic to the organic, dimethyl, and trimethyl forms that accumulate in fish. The arsenic content in edible marine fish and shellfish typically contain ~85–>90% organic arsenic (e.g., arsenobetaine, arsenocholine, dimethylarsinic acid) with ~10% inorganic arsenic.[35] However, the inorganic arsenic content in seafood may be highly variable. In a dietary study of Japanese adults, trimethyl arsenic compounds, dimethylarsinic acid, monomethylarsonic acid, and inorganic arsenic accounted for ~48%, 27%, 4%, and 6% of the total arsenic intake, respectively.[68] Arsenobetaine, a trimethyl arsenic compound, is the primary organic arsenic species in seafood (e.g., fin fish) with arsenocholine, tetramethylarsonium ion, and monomethylarsonic acid generally accounting for small portions (i.e., <4–5%) of the total arsenic present in seafood.[462,463] Trimethyl arsenic compounds originate primarily in fish, shellfish, octopus, and shrimp, whereas dimethyl arsenic compounds occur in seaweed and humans following the biomethylation of inorganic arsenic. Dimethylarsinic acid appears in most seafood items with DMA representing ~20–25% of the total arsenic content.[464] Arsenosugars (arsenoribosides) are the predominant organic arsenic species in seaweed,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

algae, and some marine animals (e.g., scallops) that feed on algae.[465,466] The Asian seaweed product nori contained 17–28 μg As/g dry weight; this product is processed from red algae.[467] Almost all of the arsenic was present as arsenosugars. In a study of 18 algae food products from Spain, the concentration of total arsenic ranged from 2.3–141 mg/kg dry weight with *inorganic* arsenic accounting for 0.15–88 mg/kg dry weight.[468] Other, less common organic arsenic species in seafood include trimethylarsine, trimethylarsine oxide, and tetramethylarsonium salts.[462]

Bioconcentration factors for As are lower in freshwater invertebrates and fish than in marine organisms.[31] Mean As concentrations in whole samples from fish and seafood usually average ~4–5 ppm As with a range up to 170 ppm As, depending on the source.[67,469] Although traditional seafood is the primary source of arsenosugars, other foods contain arsenobetaine and other arsenosugars including edible seaweeds, mushrooms, rice, spices, and meat products using fish meal as feed.[348]

ENVIRONMENTAL FATE

Arsenic in the atmosphere is a mixture of trivalent and pentavalent arsenic compounds as a result of the oxidation of arsenic trioxide and methyl arsines to the pentavalent state. Biotransformation of As in the environment involves redox changes between arsenite and arsenate, reduction and methylation, and biosynthesis of organic arsenic compounds. The biomethylation of arsenic maximizes near-neutral pH, whereas acidic pH limits biomethylation. Organic arsenical pesticides do not degrade by hydrolysis or soil photolysis. The reduced conditions of swamps and bogs favor the formation of arsine, methylated arsenical compounds, and elemental arsenic.

DOSE EFFECT

Pentavalent arsenic (As^{5+}, arsenate or organic form) is less toxic than the trivalent form (arsenite or inorganic form) based on its lower solubility. Although dimethylthioarsinic acid is pentavalent, this organic compound is highly reactive with thiol substances, and its toxicity in rodent studies is similar to that of trivalent monomethylarsonous acid (MMA).[470] The toxicity of organic arsenic depends on the specific organic compound. Sodium methanearsonate (monosodium methylarsonate, MSMA) is a selective pre-emergent herbicide that contains concentrated organic (pentavalent) arsenic. The ingestion of an estimated 500 mL of 16% MSMA by a 20-year-old cocaine-dependent man was associated with nausea, vomiting, transient hypotension, elevated hepatic aminotransferases, and renal insufficiency.[471] He was lost to follow-up after receiving DMSA chelation. The ingestion of up to 240 mL of 47% MSMA by a 16-year-old adolescent was associated with vomiting, generalized abdominal pain, weakness, and paresthesias.[472] She received 192 mg of British anti-Lewisite 12 hours after ingestion, followed by a 14-day course of dimercaptosuccinic acid. At follow-up 6 weeks after discharge, she had a normal physical examination without alopecia, Mees' lines, or objective evidence of neuropathy.

TOXICOKINETICS

Absorption

The organic arsenical compounds found in seafood are well absorbed by the gastrointestinal tract.[75] In a study of mice and hamsters receiving 40 mg As/kg body weight as dimethylarsinic acid, ~75–85% of the dose was detected in the urine and feces.[473]

Biotransformation

With the exception of arsenosugars, most organic arsenic compounds do not usually undergo biotransformation. Oxidation of arsenocholine to arsenobetaine occurs rapidly following the absorption of this compound from fish, but essentially no biotransformation of arsenobetaine or arsenocholine occurs *in vivo*. The metabolism of arsenosugars is more complicated than arsenobetaine metabolism. Dimethylarsenate is the main metabolite of biotransformation of arsenosugars with minor metabolites including dimethylarsinoylethanol.[474] In a study of a volunteer ingesting ~70 g of arsenosugars, analysis of urine samples indicated the presence of 12 metabolites including the major metabolite, dimethylarsenate, along with smaller amounts of dimethylarsinoylethanol and trimethylarsine oxide.[475] The remaining metabolites were not identified. Consequently, organic arsenic compounds contribute little to the total body burden of arsenic.

Elimination

The renal elimination of most organic arsenic is more rapid (i.e., ~1 day) than the elimination of inorganic arsenic species with ~75–85% excreted as DMA and MMA. The kidneys excrete arsenobetaine within

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

48 hours, primarily as the unchanged compound.[476,477] During experimental studies, the elimination half-life of sodium arsenite was approximately twice as long as the elimination half-life of arsenobetaine (30 hours vs. 18 hours, respectively) as measured by arsine generation/atomic absorption spectrometry (AG/AAS).[478] In a study of 6 volunteers ingesting a fish meal containing 13.6 ppm As (wet weight), the kidney excreted a majority of the organic arsenic dose within 2 days, but ~23% of the arsenic dose remained in the body 9 days after ingestion.[479]

Maternal–Fetal Kinetics

Laboratory analysis of the placentas of mothers treated with organic arsenic compounds (arsphenamine, neoarsphenamine) in the 1920s indicated that arsenic accumulated in the fetus.[480,481] However, none of these studies linked arsenic concentrations in cord blood with adverse pregnancy outcomes.

CLINICAL RESPONSE

The most prominent symptoms during organic arsenic intoxication (methyl arsine sulfide, methyl arsine bislaurylsulfide, ammonium salts of ferric methyl arsonic acid) were abdominal pain and vomiting.[482] Acute arsenical dermatitis previously was a common manifestation of the use of arsenic (arsphenamine) as a treatment for syphilis. Signs of this dermatitis included a generalized erythematous papular, pustular, and/or bullous eruption that sometimes evolved into erythema multiforme bullosum or an exfoliative dermatitis.[483]

As reported by the Mississippi Poison Control Center in 2011, seven teenagers inadvertently ate an estimated 2–4 oz of fish fried in sodium methanearsonate herbicide. All developed early gastrointestinal symptoms (nausea, vomiting, loose stool) that resolved in 12 hours. The admission whole blood arsenic concentrations ranged from 348–613 μg/L. They were treated with dimercaprol for 24 hours and succimer for 19 days. None of these teenagers developed any long-term toxicity.

DIAGNOSTIC TESTING

Speciation of arsenic usually requires separation procedures prior to quantitation by a detection system (e.g., atomic absorption spectrometry, inductively coupled plasma/atomic emission spectrometry, inductively coupled plasma/mass spectrometry). Most analytical techniques for measuring arsenic in biological samples do not accurately quantitate arsenobetaine because of the inability of arsenobetaine to form a hydride and the quantitatively different response to electrothermal AAS than inorganic arsenic. The detection of arsenobetaine and arsenocholine requires liquid chromatography to separate these arsenic species because these organic arsenic species are not volatile. Detection limits below 1 μg As/L can be achieved with liquid chromatographic separation combined with inductively coupled plasma instrumentation with mass spectrometry or atomic emission spectrometry (ICP/MS, ICP/AES). The use of high-performance liquid chromatography (HPLC) with ICP/MS allows the speciation of arsenic in plasma and the quantitation of arsenobetaine.[484]

The biological half-life of organic arsenic in the blood is relatively short (4–6 hours). Volunteer studies also indicate that the kidney excretes ~70% of a dose of organic arsenic in fish within 3 days via the urine;[479,485] however, case reports suggest that occasionally organic arsenic concentrations in 24-hour urine samples may exceed 2,000 μg/L soon after a seafood meal.[486] A 54-year-old diabetic with distal extremity paresthesias ate two lobster tails 5 days prior to the collection of a 24-hour urine sample.[487] The urine contained a total arsenic concentration of 4,749 μg/L (3,769 μg/g creatinine). Speciation of the urinary arsenic demonstrated no inorganic or methylated arsenic; a subsequent 24-hour, seafood-free urine sample contained 30 μg/L (21 μg/g creatinine). The concentrations of these arsenic species in urine stabilize after the second day of the workweek. Following a meal containing arsenobetaine, this arsenic species is usually rapidly absorbed and eliminated mostly unchanged with a biological half-life of ~18 hours compared to 30 hours for arsenite.[337]

HEALTH SURVEILLANCE

The US OSHA 8-hour TWA PEL for organic arsenic in the air is 500 μg/m^3. Arsenic standards and guidelines for food, water, and biomonitoring are based on total or inorganic/metabolite concentrations.

TREATMENT

Most organic arsenic species lack clinically significant toxicity. Treatment is primarily supportive. A 20-year-old cocaine-dependent man drank ~500 mL of a 16% pentavalent sodium methanearsonate herbicide solution; he received four 5-day courses of 30 mg DMSA/kg/day.[471] The initial serum and urine arsenic concentrations were 2.871 mg/L and 78.92 mg/L, respectively. He recovered without sequelae; there were no adverse effects attributed to the DMSA therapy.

ARSINE

PHYSIOCHEMICAL PROPERTIES

Arsine (CAS No. 7784-42-1) is a colorless, nonirritating gas that volatilizes from arsenic compounds upon addition of an acid; this gas has relatively poor odor warning properties (i.e., substantially below currently recommended ambient air concentrations).[488] The odor threshold of the mild, garlic-like smell is ~1.5–3 mg/m^3.[443] Although arsine gas is a strong reducing agent that deposits arsenic following exposure to light and moisture, *in vitro* studies indicate that arsine cannot reduce organic disulfides to thiols at physiological pH (7.4).[489] Arsine is heavier than air (i.e., ~2.5); thus, this gas accumulates in relatively low areas. The production of arsine gas occurs following the contact of nascent hydrogen with arsenic or following the exposure of metallic arsenide to water. Volatile arsine (AsH_3) gas also forms following the exposure of labile hydrogen to elemental arsenic or arsenic oxides. Arsine gas is slightly soluble in water and boils at 62.5°C. The presence of acidic water or borohydride promotes the formation of arsine gas. Decomposition of arsine gas into arsenic occurs following exposure to light and elevated temperatures.[490]

EXPOSURE

The primary use of arsine gas (AsH_3) is a dopant in the semiconductor industry during the production of microchips and the epitaxial growth of gallium arsenide. Arsine exposure may occur while recycling various grades of gallium arsenide chips during degassing processes[491] or during the burnishing of metal with dilute acidic arsenic trioxide solutions.[492] Oil combustion may release arsine into the atmosphere.[35] Marine environments typically do not release arsine into the atmosphere. In seawater, marine algae transform arsenate into nonvolatile methylated arsenic compounds (methylarsonic and dimethylarsinic acids) rather than arsine.[493] Potentially, arsine may be released from metal refining, acidified metal, or acid cleaning of metal castings, particularly castings with galvanized metal.

ENVIRONMENTAL FATE

Methyl arsine compounds undergo oxidation in the atmosphere to form pentavalent compounds. After releasing to the atmosphere, oxidation of volatile arsine compounds to nonvolatile species occurs followed by distribution of these As species back to the surface.[35] Biomethylation and reduction of nonvolatile arsenic compounds (arsenite, arsenate) by terrestrial microorganisms produce volatile arsine compounds (e.g., methyl arsine, dimethyl arsine, alkyl arsine) depending on soil conditions (oxygenation, moisture). High-moisture conditions favor alkyl arsine, whereas aerobic conditions favor methyl arsine compounds.[494] The chemical instability of arsine limits the conversion of arsine to inorganic arsenic oxides as arsine decomposes in water within a few hours to elemental arsenic and hydrogen.[447]

DOSE EFFECT

Arsine gas (AsH_3) is the most toxic form of arsenic. Immediate death occurs at arsine gas concentration of 150 ppm. Estimated fatal exposures include 30 minutes of exposure to 25–50 ppm and <30 minutes at 100 ppm.

TOXICOKINETICS

Although there are few data on the absorption of arsine in humans, arsine absorption probably crosses the alveolar membranes rapidly based on the appearance of symptoms within a few hours after exposure to arsine gas. *In vitro* studies indicate that arsine rapidly distributes to erythrocytes after absorption, particularly in rat red blood cells.[495] Rats are much more susceptible to arsine-induced hemolysis than humans. Case reports suggest that arsine is rapidly metabolized to As^{3+}, to a lesser extent, As^{5+}, then to MMA and DMA. In a worker exposed to arsine gas at a recycling factory, the approximate biological half-lives of arsenic species in the blood were as follows: As^{5+}, 43 hours; As^{3+}, 30 hours; and MMA^{5+}, 96 hours.[491] The biological half-life of DMA was not calculated because the urinary DMA concentration was increasing near the end of the 5-day study.

Renal elimination accounts for most of the arsenic excretion from arsine metabolism. The biological half-life of arsenic species in the urine was ~15–20 days in a worker exposed to arsine at a recycling plant.[491] In a urine sample collected 6 days after his exposure, speciation of the urine detected the following values: As^{5+}, <1%; As^{3+}, 14%; MMA, 20%; and DMA, 65%. The excretion of arsenobetaine following arsine exposure is small compared with these four species. In a worker exposed to arsine gas during metal burnishing, the arsenic elimination in the urine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. was triphasic with biological half-lives of 28 hours, 59 hours, and 9 days.[492] Urinary arsenobetaine concentrations were slightly higher than expected from seafood consumption.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Arsine binds directly to erythrocytes and produces dose-dependent hemolysis as a result of irreversible damage to the cell membrane. Although the presence of hemoglobin is a necessary component of arsine toxicity, the exact mechanism is not well delineated. *In vitro* studies indicate that arsine gas releases heme in the presence of oxyhemoglobin, but not in the presence of carboxyhemoglobin.[496] How arsine interacts with hemoglobin molecules (e.g., sixth ligand position of the Fe^{2+} of heme) is unclear. Oxidative stress and interaction with sulfhydryl groups on the Na^+/K^+ ATPase pump are probably not important mechanisms of arsine-induced hemolysis. Although arsine causes a diffuse, direct cytotoxicity at high doses, *in vitro* studies indicate that unchanged arsine gas produces oxidative stress, but not direct cell toxicity at arsine concentrations up to 1 mmol.[489] At this concentration, trivalent arsenic causes both oxidative stress and cell death. *In vitro* experiments indicate that arsine concentrations in the range of 0.2–0.3 mmol are models of hemolytic, near-lethal arsine doses.[447]

Pathological Changes

Renal biopsies of patients with kidney damage secondary to arsine gas exposure typically demonstrate an acute interstitial nephritis with preservation of glomeruli.[497] Abnormalities in tubular cells include mitochondrial degeneration (dense matrix, small size, variable shapes), rupture of outer mitochondrial membranes, and disruption of cristae.[498] Additionally, electron microscopy demonstrates vacuolated structures (lysosomes) containing dense granular material.

CLINICAL RESPONSE

The classic presentation of arsine exposure involves a latent period of 2–24 hours, followed by the onset of abdominal pain, hemolysis, jaundice, and subsequently, oliguric renal failure.[499,500] Constitutional (headache, lightheadedness, malaise, weakness) and gastrointestinal (nausea, vomiting, abdominal pain) complaints predominate initially. Susceptible patients may develop congestive heart failure or neurological deficits, in part from lowered oxygen-carrying capacity secondary to hemolysis. Hyperkalemia and anemia with dark red urine (hemoglobinuria) indicate severe hemolysis; the latter may persist for 3–4 days. Bronze-colored skin may also appear, but jaundice and hepatotoxicity occur rarely. Renal failure is usually associated with hemolysis, probably as a result of myoglobinuria. An arsenic-hemoglobin complex may concentrate in the kidney, contributing to renal damage. Sudden death resulting from overwhelming arsenic exposure may occur in the absence of pulmonary edema and hemolysis. Rarely, permanent renal dysfunction may result from severe exposure to arsine gas.[501]

Signs of chronic arsenic poisoning may follow acute arsine gas exposure including coryza, paresthesias, garlic perspiration, hyperpigmentation, keratosis, hair loss, Mees' lines, and anemia. Chronic arsenic toxicity from prolonged low-dose arsine exposure may occur in the industrial setting; clinical features include a hoarse voice, perforated nasal septum, anemia, and gastrointestinal distress. Renal damage is rare with this type of arsenic exposure. There are few data on the mutagenicity or carcinogenicity of arsine gas in experimental animals or humans.

DIAGNOSTIC TESTING

Conversion Factors

1 mg arsine gas/m^3 = 0.309 ppm
1 ppm arsine gas = 3.24 mg/m^3

Analytical Methods

Techniques to speciate arsenic in biological samples after arsine exposure include liquid chromatography/inductively coupled plasma/mass spectrometry.[502] The analysis of air samples by graphic furnace atomic absorption spectrometry after nitric acid desorption and a nickel matrix modifier allows the detection of arsine concentration in the range of 1–200 µg/m^3.[31]

Biomarkers

At admission 34 hours after arsine gas exposure, a worker had vomiting, hematuria, and hemolysis; during the 5-day hospitalization, he required four blood

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

transfusions.[491] The total serum arsenic concentrations at admission and discharge were 245 μg/L and 97 μg/L, respectively. A 46-year-old man was accidentally exposed to arsine gas at work.[503] Within 6 hours, he developed nausea, vomiting, paresthesias, fatigue, and dark urine. His blood arsenic concentration at admission was 1,250 μg/L. His renal function deteriorated, and he received supportive care, plasma/erythrocyte exchanges, and hemodialysis. His kidney function returned to baseline within 1 month. Total urinary arsenic concentrations do not correlate well to clinical arsine gas toxicity.

Abnormalities

Acute arsine gas exposure may cause free plasma hemoglobin and decreased serum haptoglobin within 3–24 hours after exposure. In addition to hemolytic anemia, substantial leukocytosis may occur with bandemia and toxic granulations. Other laboratory changes include abnormal urinalysis (proteinuria, hematuria, white cell clumps), elevated serum creatinine phosphokinase, and increasing serum creatinine.[504]

HEALTH SURVEILLANCE

The ACGIH TLV-TWA for arsine gas is 0.005 ppm (0.016 mg/m^3). In a study of 21 ion implanter maintenance engineers at 3 semiconductor plants, 22 of 45 area air samples contained detectable arsine concentrations with mean arsine concentrations ranging up to 2.9 ppb (9.4 μg/m^3); 15 of the 35 personal air samples contained detectable arsine concentrations with a geometric mean arsine concentration in positive samples of 0.07 (range, 0.01–1.66 ppb).[505] The presence of arsenic on wipe samples, the relatively low airborne arsine concentrations, and the increase in the total urinary arsenic concentration of 1.0–7.8 μg/g creatinine during ion implant maintenance suggested ingestion as a predominant pathway of exposure. In a study of 48 workers at a lead-acid battery plant exposed to arsine concentrations ranging up to 49 μg/m^3, exposure to 15.6 μg/m^3 in personal air samples correlated to total urinary arsenic concentrations of 50 μg/L.[409] The airborne As exposure of these workers was mixed as ambient air samples detected particulate As concentrations up to 5.1 μg/m^3; the history of individual As exposure was not well defined including a lack of dietary history.

TREATMENT

Stabilization

In the presence of dangerous ambient arsine concentrations, self-contained breathing apparatus, a full-face mask, protective clothing, and boots should be worn. Wash the skin of the victim copiously. Insert an intravenous line, administer fluids, and provide oxygen and cardiac monitoring during transport.

Elimination Enhancement

Anecdotal case reports suggest that patients with severe arsine poisoning may benefit from exchange transfusion as a method to improve oxygenation and reduce renal tubular necrosis. When free hemoglobin concentrations exceed 1.5 g/dL, exchange transfusion should be considered because this procedure may remove significant amounts of arsenic trapped in erythrocytes during the early phase of toxicity.[492] However, existing clinical data are not sufficient to decide if exchange transfusion is superior to blood transfusion alone. In a study of 12 patients treated with plasma exchange for severe acute arsine poisoning, the total fresh frozen plasma used for replacement fluid ranged from 1,400–4,000 mL.[506] The total arsenic removed by the plasma exchange ranged from 55.4–177.4 mg. The authors observed that the arsine-induced hemolysis associated with arsine poisoning in these cases terminated rapidly during plasma exchange. Hemodialysis is limited to the support of renal function rather than the removal of arsine or other arsenic compounds. Chelation therapy with BAL is not useful acutely because chelation does not prevent hemolysis. Current data are inadequate to determine if BAL therapy prevents renal failure or reduces the incidence of chronic arsenic poisoning after acute arsine exposure.

Supplemental Care

Blood samples should be monitored for hyperkalemia, hemolysis, liver damage, and rhabdomyolysis for at least several days. Maintain a urine flow of 2 mL/h/kg in patients who demonstrate hemolysis. Alkalinization of the urine is a therapeutic option if rhabdomyolysis develops; however, the clinical efficacy of alkalinization in addition to fluid replacement in this setting is unproven.

Chapter 4

BARIUM

ELEMENTAL BARIUM AND POORLY ABSORBABLE BARIUM SALTS

HISTORY

Barium (Ba) is the heaviest divalent alkaline metal existing in nature primarily as barite ($BaSO_4$) and witherite ($BaCO_3$). Scheele discovered barium in 1774; the name originates from the Greek word *barys*, meaning heavy. Medicinal uses for barium salts (e.g., terra ponderosa, $BaCO_3$; muriata, $BaCl_2$) from the 17th–19th centuries included administration as a diuretic, depilatory, and emetic;[1] soon thereafter, muscle paralysis was a recognized complication of barium treatment primarily involving barium chloride and barium carbonate.[2] The use of insoluble barium sulfate as a radiopaque gastrointestinal contrast media began in 1910.[3] Few adverse effects were associated with the use of barium sulfate, despite its widespread use. In Brazil, the use of barium contrast media highly contaminated with soluble barium compounds (carbonate, sulfite) resulted in 44 illnesses and 9 deaths, primarily from ingestion.[4] Six of the 44 cases resulted from the rectal administration of the barium contrast. The industrial poisoning of workers by barium is rare unless exposed to soluble barium compounds.

PHYSIOCHEMICAL PROPERTIES

Barium is a dense alkaline earth metal belonging to Group 2 (Group IIA) of the periodic table.[5] This highly reactive metal readily combines with halogens, oxygen, and sulfur to form halides, oxides, and sulfides. Elemental barium is a silver-white, soft metal that is relatively volatile. Powdered barium easily ignites in the presence of air or other oxidizing agents. Consequently, barium exists in the divalent state in nature rather than the elemental form; the only oxidation state of barium in nature is the divalent form. Elemental barium combines readily with most metals to form alloys; barium reduces the halides, oxides, and sulfides of less reactive metals to form the corresponding metal. In moist environments, barium sulfide may decompose in to barium carbonate with the evolution of hydrogen sulfide gas. Barium sulfate is poorly water-insoluble; barium oxide and sulfate are odorless compounds. Barium oxide reacts rapidly with carbon dioxide in water to form barium hydroxide and barium carbonate.

Table 4.1 lists the physical properties and identifying information of common poorly water-soluble barium compounds. These properties are similar to those of other alkaline earth metals (calcium, strontium). The acetate, chlorate, and nitrate salts of barium are very soluble in water, whereas the arsenate, carbonate, chromate, fluoride, oxalate, phosphate, and sulfate salts of barium are poorly water-soluble. Acid-soluble barium salts include acetate, carbonate, chloride, hydroxide, nitrate, and sulfide. The solubility of all these salts increases with decreasing pH with the exception of barium sulfate.

TABLE 4.1. Physical properties and identifying information of elemental barium and poorly absorbable barium compounds. (Based on WHO).[5]

Property	Barium	Barium Oxide	Barium Sulfate
CAS RN	7440-39-3	1304-28-5	7727-43-7
Synonym	–	Barium monoxide or protoxide, baryta	Artificial heavy spar; barytes, barium sulfate
Chemical formula	Ba	BaO	$BaSO_4$
Physical description	Silvery-yellow metal	White-yellow powder/cubic or hexagonal crystals	White crystals
Molecular weight (g/mol)	137.327	153.326	233.391
Melting point (°C)	727	1,972	1,580
Boiling point (°C)	1,897	NA	NA
Density (g/mL)	3.62	5.72	4.49
Water solubility	Reacts with water	1.5 g/100 g (20°C)	0.00031 g/100 g (20°C)
Vapor pressure (mmHg)	0.000665 (630°C) 0.998 (1,050°C)	Essentially zero	NA

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number; NA = not available.

EXPOSURE

Commercial Processes

The primary source of barium is the mineral barite ($BaSO_4$) and less commonly witherite ($BaCO_3$). During the production of barium compounds, high-temperature sintering with charcoal reduces barite and witherite to their more reactive forms (i.e., barium sulfide and barium oxide, respectively).

Uses

Barium is a valuable nonmagnetic metal because of its high specific gravity, low abrasiveness, and chemical stability. Commercial uses for barium include oil and gas drilling muds, automotive paints, dyes, fireworks, stabilizers for plastics, case hardening steels, bricks, tiles, lubricating oils, jet fuel, vulcanization of rubber, and pesticides.[6] Table 4.2 lists products that may contain barium salts. Oil and gas industries use most (i.e., 85–95%) industrially produced barium as weighting agents for drilling mud in oil and gas wells.[5] Barium sulfate is used as a contrast medium for the gastrointestinal tract because the extreme insolubility substantially limits barium absorption from the GI tract. Barium chlorate and nitrate are used to produce yellow-green flames during the ignition of fireworks; in contrast to barium sulfate, these barium salts are very water-soluble and highly toxic.

Sources

Barium is a highly reactive metal that exists naturally in the stable divalent state primarily as inorganic complexes, primarily as carbonates and sulfates. This metal is ubiquitous as almost all living organisms contain barium.[8] For the general population, exposure to barium occurs via the ingestion of water and food, usually at low concentrations.

TABLE 4.2. Commercial uses of barium salts. (Modified from Johnson and Van Tassell).[7]

Salt	Uses
Acetate	Lubricants, fabrics, mordant (printing)
Carbonate	Ceramic glazes, enamels, chrome cleaner, marble substitutes, paper manufacturing, pesticides, rat poison, rubber manufacturing
Chloride	Acid dyes, equine purgatives, isotope (bone scan), glass manufacturing, pesticides, rat poison
Chlorate	Dyeing, explosives, matches, pyrotechnics (green)
Fluoride	Embalming, enamels, glass manufacturing
Hexafluorosilicate	Insecticides
Hydroxide	Pesticides, rat poison
Sulfide	Depilatory, luminous paints, rubber

Air

Barium is ubiquitous in air, primarily in the form of barium sulfate and carbonate from industrial emissions; however, limited data exist on the levels of barium in air. Higher barium concentrations occur near smelters;[9] however, surveys have not detected significantly higher ambient barium concentrations with industrialization. Consequently, the correlation between industrial sources of barium and barium concentrations in surrounding ambient air is relatively poor.[6] Coal ash contains widely variable amounts of barium that enter

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the ambient air as barium particulates.[6] The barium concentration in ambient air is typically <0.05 μg/m.[3,5] A US survey revealed ambient barium concentrations ranging from 0.0015–0.95 μg/m^3.[10]

Soil

Barium is a relatively abundant element that combines with other elements in soil and rocks. Concentrations of barium in soil range from 100–3,000 μg/g.[5] Nuclear explosions produce radioactive barium (^{140}Ba, ^{143}Ba), but the short half-life and small concentrations of radioactive barium in the fallout limit the significance of barium in the environment after atmospheric testing. Barium probably is not very mobile in soil because of the formation of insoluble salts except under some acidic conditions. Barium apparently does not undergo biotransformation other than the formation of divalent cations.

Water

Barium concentrations in seawater range from 2–63 μg/L with a mean concentration of ~13 μg/L.[6] Almost all surface waters contain barium as a result of the leaching of barium from sedimentary rocks into groundwater, and the barium concentration depends on local geological and chemical conditions. Rivers transport soluble barium compounds over long distances, and most barium in surface water reaches the ocean unless removed by precipitation with sulfate ions.

Diet

The average daily intake of barium ranges from ~4–25 μg/kg bodyweight depending on age and food consumption. In a study of 156 inhabitants of the Midwestern United States, the mean daily dietary intake of barium was 14 μg/kg bodyweight with an upper 90% of 16 μg/kg (95% CI: 13–23 μg/kg). Barium intake is substantially higher in infants and toddlers than in adults.[11] Typically, barium concentrations in food and herbs are below amounts considered potentially toxic as well as below recommended limits for daily intake.[12] The barium content of most foods is <4 ppm with bread accounting for the largest portion (i.e., ~20%).[6] Although barium is present in many plants, it does not generally accumulate in most plants in significant enough quantities to produce toxicity. Of all edible portions of plants, Brazil nuts contain the highest barium concentrations ranging from 1,500–3,000 mg/kg.[13,14] Barium is not an essential element in humans.

Drinking water is an important source of exposure to barium for the general population. Studies of drinking water in the United States indicate that the barium concentration ranges up to 10 mg/L with average barium concentrations of 1–30 μg/L.[15,16,17] In a survey of flushed drinking water samples from representative residences in the Midwestern United States, the average barium concentration was 30 μg/L with an upper 90% of 77 μg/L (95% CI: 51–120 μg/L), as measured by inductively coupled plasma/mass spectrometry.[18] There was little difference in the barium concentration between flushed and standing water. The US EPA limit for barium in drinking water under the Safe Drinking Water Act is 1 mg/L.

ENVIRONMENTAL FATE

Barium is a highly reactive and abundant metal being the 14th most abundant element in the earth's crust averaging about 425 ppm. In natural conditions, barium occurs almost exclusively in the divalent (+2) state combined with inorganic complexes. The most important features of the partitioning of barium in the environment are wet and dry deposition on the earth's surface, adsorption to the soil, leaching from geological formations to groundwater, and biomagnification in the food chain.

Air

The main mechanism of barium removal from the atmosphere is wet and dry deposition. Barium rapidly oxidizes in moist air. The residence time of barium in the air is usually several days, depending on rainfall, particulate size, and the chemical composition of the particulate matter.[6] Consequently, barium released into the air is not widely dispersed.

Soil

Barium is poorly mobile in the soil as a result of the adsorption of barium to soil particulates, particularly clay minerals; barium forms relatively water-insoluble metal oxides and hydroxides, but not soluble complexes with fulvic or humic acids. The presence of organic matter and the precipitation of barium by high concentrations of anions (carbonate, sulfate) limit the migration of barium in soil.[6] In general, barium mobility in soil increases with the formation of water-soluble salts (e.g., acetate, chloride, hydroxide, nitrate), particularly with decreasing soil pH.

Water

In aqueous media, barium precipitates as water-insoluble salts (e.g., carbonate, sulfate); barium does not

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

hydrolyze appreciably except in highly alkaline environments (i.e., pH ≥10). Appreciable concentrations of barium sulfate occur in natural water as a result of high sulfate concentrations, particularly in ocean water. Sedimentation removes a large portion of the barium from surface water, primarily in the form of barium sulfate (barite). The high content of sulfate in ocean waters enhances the formation of barite, particularly at locations where rivers enter the ocean. Other poorly soluble barium compounds include arsenate, chromate, fluoride, oxalate, and phosphate. In the marine environment, the bioconcentration factor for barium in marine plants is ~1,000; however, the bioconcentration factor for terrestrial plants appears much smaller.[6] Some plants (e.g., legumes, forage plants, Brazil nuts, corn, mushrooms) accumulate barium with bioconcentration factors ranging from 2–20 in tomatoes and soybeans.[19] The residence time of barium in aquatic systems is several hundred years.[5]

DOSE EFFECT

Poorly absorbed barium salts (e.g., barium sulfate) are relatively nontoxic compared with water-soluble Ba salts, particularly the acid-soluble barium salts (acetate, carbonate, chloride, hydroxide, nitrate, sulfide). Deaths associated with barium enemas typically involve the contamination of the barium solution with toxic substances, rupture of internal organs, or perforation of the intestines.[20]

TOXICOKINETICS

Absorption

The oral absorption of barium compounds depends on water solubility, the presence of food in the intestines, sulfate content of food, and stomach acidity. Tracer studies in dogs suggest some absorption of poorly soluble $^{131}BaSO_4$ occurs in the lung following dust exposure with a biological half-life of 8–9 days.[21] Recent studies also indicate some absorption of barium sulfate occurs during radiographic procedures as measured by the appearance of barium in the urine.[22]

Distribution

Barium preferentially deposits in active sites of bone growth (i.e., ~90%), teeth, and to a lesser extent in muscle and lung;[8] rodent studies suggest that barium storage in kidneys, liver, spleen, heart, brain, and hair is small based on tracer studies with $^{140}BaCl_2$.[23] The average body burden of barium in an adult is ~22 mg with ~90% present in the skeleton and the remainder in soft tissue.[8,24] In soft tissue, the highest barium concentrations are found in the eye, particularly in the pigmented parts of the eye (e.g., choroid).[25] Studies in rodents suggest that skeletal uptake of barium decreases with age.[26]

Elimination

Elimination of barium occurs primarily in the feces with only small amounts (<2–10%) of an ingested or injected dose of barium appearing in the urine.[27] The body clears a majority (i.e., ~75%) of the absorbed barium dose within 3 days with prolonged terminal excretion (1–6 weeks) based on a limited tracer ^{133}Ba study in a human volunteer.[28] Analysis of barium kinetics in this subject suggests a three-compartment model with biological half-lives of ~3½ days, 34 days, and 1,033 days.[29]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Barium is a trace mineral with no proven physiological role in the human body. Like other divalent ions (e.g., calcium, magnesium), barium may affect muscle function when absorbed into the body. Barium is a physiological antagonist of potassium that is associated with hypokalemia from impairment of passive K^+ efflux rather than increased urinary/fecal potassium losses or alteration of the sodium–potassium pump.[30] The poor solubility of these barium salts limits alteration of potassium concentrations and muscle function.

CLINICAL RESPONSE

Medical Therapy

Contrast media contains extremely insoluble and relatively nontoxic barium sulfate. In a case report, hypotension and disseminated intravascular coagulation occurred after the rupture of a barium enema balloon. *In vitro* experiments suggest that the barium sulfate may have contributed to endotoxemia by generating bradykinin.[31] Commercially available barium preparations contain a number of additives including acacia, bentonite, benzoate, carboxymethylcellulose, methylparaben, polyethylene glycol, saccharin, silica, and simethicone. Systemic allergic reactions that develop

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

following the administration of barium-containing contrast media most likely result from a hypersensitivity reaction to the additives rather than barium toxicity.[32] Acute aspiration of low-density barium sulfate (100% weight/volume) during radiographic procedures may cause hypoxemia secondary to alveolar shunting and ventilation–perfusion mismatches.[33] The aspiration of high-density barium sulfate (250% weight/volume) may cause an intense acute inflammatory reaction in the alveoli along with life-threatening disruption of gas exchange.[34] The aspiration of gastric fluid enhances the effects of barium aspiration.[35] Although barium aspiration produces dramatic opacities on chest X-ray, emphysema and pulmonary fibrosis do not usually occur.

Acute Oral Toxicity

Barium and *insoluble* barium compounds (e.g., barium sulfate) have low oral toxicity.

Environmental Exposure

There is no clear, consistent association between barium exposure in the general population and mortality. An epidemiology study suggested that communities with relatively high barium concentrations (≥2.0–10 mg/L) in drinking water had statistically significantly higher mortality rates for all causes, heart disease, arteriosclerosis, and all cardiovascular disease than communities with little or no barium (nondetectable to 0.2 mg/L) in drinking water.[36] The death rate ratios were 1.107, 1.143, 1.152, and 1.136, respectively. However, this study had a number of methodological limitations including poor control of confounding variables (calcium, magnesium, sodium) and wide variation in the study population (population size, duration, and amount of exposure). Other studies with similar limitations have not detected increased mortality in populations with relatively barium concentrations in drinking water when compared with the general population.[37]

Occupational Exposure

Case series suggest that chronic occupational exposure to fine dust composed of barium oxide or sulfate produces a relatively benign pneumoconiosis (baritosis). Workers exposed to finely ground barium including barium salts for many years may develop fine punctate and annular lesions on their chest X-rays; these lesions rarely progress to larger nodular lesions.[38] Typically, the lesions resolve after exposure ceases with no significant symptoms or decline in pulmonary function.[39] Cases of pneumoconiosis associated with barium miners usually involve chronic exposure to silica; barium is not typically found in the lungs of these workers.[40]

Carcinogenesis

Barium is not a recognized human or animal carcinogen.

DIAGNOSTIC TESTING

Inductively coupled plasma/atomic emission spectrometry (ICP/AES) is a fairly rapid and sensitive analytical method for the quantitation of barium in biological samples with a limit of detection (LOD) in the range of 0.25 µg Ba/L urine and 0.4–0.6 µg Ba/L blood.[41] Accuracy (% relative error) as measured by inductively coupled plasma/optical emission spectrometry (ICP/OES) after microwave digestion of blood and urine samples spiked with 15 µg Ba/L was 4% and 7%, respectively.[42] The atomic-line emission spectra for barium is 455.50 nm; this value overlaps with boron, resulting in spectral interference when the boron concentration exceeds 100 mg/L. ICP/AES is also a method for the determination of barium in food and several other metals (Al, Sr, Ti) with a lower limit of quantitation of ~10 ppm.[43,44] Neutron activation analysis is an alternative to ICP/AES that requires minimal sample preparation, but the costs are more expensive and the sensitivity is much lower (LOD, 66 µg/L plasma) than ICP/AES; consequently, the current use of NAA is limited.[45] Flame/atomic absorption spectroscopy lacks adequate sensitivity for the detection of barium concentrations in biological solutions below 10 µg/L. Electrothermal atomic absorption spectroscopy (EC AAS) is a common analytical technique for measuring barium in air, water, and soil; this technique is complex and time-consuming, particularly for the analysis of multiple elements.[46] Acid digestion with nitric acid is the most common method of preparation. Methods recommended by the USEPA for the determination of barium in water include flame atomic absorption spectroscopy (Methods 208.1 and 7080) and graphite furnace atomic absorption spectroscopy (Methods 208.2 and 7081); the limit of detection for these techniques is 100 µg/L and 2 µg/L, respectively.[6]

HEALTH SURVEILLANCE

Table 4.3 lists international and US regulations and guidelines related to barium and barium compounds.

TABLE 4.3. Guidelines and regulations for exposure to metallic barium and insoluble barium sulfate.

Substance	Value
	OSHA
PEL–TWA	
Barium sulfate	15 mg/m^3 (total dust)
	5 mg/m^3 (respirable fraction)
	ACGIH
TLV–TWA	
Barium	0.5 mg/m^3[a]
Barium sulfate	5 mg/m^3[b,c]
	NIOSH
REL–TWA	10 mg/m^3 (total dust)
Barium	0.5 mg/m^3
Barium sulfate	
(total dust)	10 mg/m^3
(respirable fraction)	5 mg/m^3
	WHO
Drinking water quality guideline	1.3 mg/L
	US EPA
MCL	2 mg/L (drinking water)
10-day health advisory 10-kg child	0.7 mg/kg (drinking water)
Carcinogenicity classification	Not classifiable as to human carcinogenicity
	US FDA
Bottled drinking water	2 mg/L

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; MCL = maximum contaminate level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time-weighted average; US EPA = United States Environmental Protection Agency; US FDA = United States Food and Drug Administration; WHO = World Health Organization.
[a]Eye, skin and gastrointestinal irritant; [b]Inhalable particulate matter; [c]The value is for particulate matter containing no asbestos and <1% crystalline silica.

TREATMENT

Elemental barium and nonabsorbable barium salts (oxide, sulfate) are relatively nontoxic. Decontamination measures are usually unnecessary. Patients with symptoms of barium toxicity should be treated similarly to poisoning from absorbable barium salts (see Treatment section below); other etiologies for their illnesses should be considered.

ABSORBABLE BARIUM SALTS

HISTORY

Medicinal use of barium included the administration of barium salts as emetics, diuretics, and depilatories, as well as treatment for a variety of diseases (scrofula, scabies, rickets, asthma, tumors, congestive heart failure). By the end of the 19th century, the medical literature documented ~30 cases of barium poisoning, primarily as a result of the substitution of soluble barium salts in medicine and the contamination of flour by barium carbonate. During the early 20th century, barium chloride was administered for the treatment of heart block.[47] In 1930, a Canadian medical missionary, A. Stewart Allen observed an illness (*Pa Ping*) in what is now Leshan, China; the illness began with periodic episodes of paresthesias and gastrointestinal symptoms (nausea, vomiting, diarrhea) that progressed to respiratory paralysis, areflexia, ascending paralysis, and occasionally death.[48] Subsequent investigations of Chinese food poisoning cases with clinical presentations similar to familial periodic paralysis documented the presence of high barium chloride in contaminated salt consistent with barium-induced hypokalemia.[49] The substitution of soluble barium carbonate for barium sulfate in cream administered during gastrointestinal radiographic procedures produced stiffness of the mouth, blurred vision, severe hyporeflexia, and weakness in seven patients.[50] Several episodes of severe barium poisoning resulted from the contamination of food by toxic barium salts. An epidemic of food poisoning occurred in Israel when barium carbonate contaminated potato flour was used in making sausage.[51] Approximately 100 people developed extreme gastrointestinal irritation, weakness of the limbs, dry mouth, headache, testicular pain, and paresthesias as well as bulbar and respiratory weakness in severe cases. Contamination of food with barium carbonate caused illness in 13 Taiwanese family members and one death.[52]

PHYSIOCHEMICAL PROPERTIES

Table 4.4 lists the physical properties and identifying information of absorbable barium compounds. The following barium salts are very water-soluble: acetate, chloride, and nitrate. Although barium carbonate

is poorly water-soluble, both barium carbonate and barium chloride are soluble in the acidic pH of the stomach. Barium carbonate and chloride are odorless compounds, whereas barium sulfide is a sulfurous compound. Barium sulfide slowly decomposes in water, forming barium hydroxide and barium hydrosulfide. Additionally, barium sulfide undergoes slow oxidation in solution to form elemental sulfur and various oxidized sulfur species (sulfate, sulfite, thiosulfate, polythionates).[6]

EXPOSURE

Uses of barium compounds include processes in the brick, ceramic, photographic, and chemical manufacturing industries, as displayed in Table 4.2.[6] The chemical manufacture of most barium compounds begins with barium sulfide. Barium styphnate is a 2,4,6-trinitroresorcinol salt derived from styphnic acid used as a propellant in the production of explosives, whereas barium chlorate is a constituent of fireworks that produces green smoke on incineration. Barium carbonate, hydroxide, and chloride are pesticides. Barium compounds generally are not available to the public except for certain pesticides, fireworks, and depilatories. Rarely, epidemics of barium poisoning result from contamination of food sources (e.g., table salt, flour). Suicidal ingestions of soluble barium compounds often involve persons with access to chemistry laboratories.[53]

DOSE EFFECT

Serious toxicity occurs following the absorption of 200–500 mg of Ba in a soluble salt with potentially fatal Ba amounts near 1,000 mg depending on access to medical care. A 52-year-old man survived the ingestion of an estimated Ba chloride dose of 13 g after developing severe weakness, hypokalemia, respiratory failure, and renal dysfunction; at 3 months, the only sequelae was a serum creatinine of 1.4 mg/dL (baseline, 0.9 mg/dL).[54] A 39-year-old woman developed severe hypokalemia, paralysis, and respiratory failure after the intentional ingestion of 40 g of barium carbonate; all symptoms resolved within 7 days after intensive supportive care including intubation.[55] Recovery also occurred after the development of severe hypokalemia, metabolic acidosis, and respiratory failure following the ingestion of 12 g Ba as barium chloride[56] and 12.8 g Ba as barium sulfide.[57] The latter patient recovered completely within 30 hours of treatment. Studies of epidemics of barium carbonate

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. poisoning suggest that children are less susceptible to muscle weakness and paralysis, perhaps as a result of reduced stomach acidity and decreased conversion of the carbonate salt to the more absorbable chloride salt. However, the number of children in epidemics of barium poisoning is too small to reach definitive conclusions regarding pediatric susceptibility.[58]

TOXICOKINETICS

Absorption

The acid in the stomach converts barium salts (e.g., barium carbonate) into the absorbable form, barium chloride; then, absorption of barium occurs beyond the pylorus. The gastrointestinal tract absorbs both acid-soluble and water-soluble barium compounds; however, the amount absorbed is compound-dependent and highly variable ranging from 3–60%.[59] The International Commission for Radiation Protection (ICRP) estimates that the gastrointestinal absorption of barium is as follows: adults, 20%; children aged 1–15 years, 30%; and infants, 60%.[60] All segments of the respiratory tract absorb soluble salts of barium relatively well.[61] Studies of aerosolized barium compounds in animals suggest that the respiratory tract of dogs absorbs ~50–75% of inhaled barium chloride or barium sulfate,[62] whereas the nasal epithelium of hamsters absorbs ~65% of an insufflated barium chloride dose similar to gastrointestinal absorption.[63] Dermal absorption of barium compounds from intact skin is minimal, but toxicity may occur when wounds are contaminated by soluble barium compounds. Animal studies suggest that peak barium concentrations occur rapidly (i.e., within ~1 hour) following ingestion.[64]

Distribution

Barium is primarily distributed to bone (i.e., ~90%) with ~1–2% of the total body burden in muscle, adipose, skin, and connective tissue.[8]

Elimination

Following the injection of 72–80 kBq of carrier-free ^{133}Ba in 6 volunteers, excretion of the barium was primarily fecal with the fecal/urinary clearance ratio ranging from 6–15 during the first 2 weeks after administration.[65] Fecal and urinary excretion during the first 2 weeks accounted for ~90% of the intravenous barium dose. Following the intravenous administration of soluble Ba^{2+}, the barium excretion followed a three-compartment model with biological half-lives of 3.6, 34.2, and 1,033 days, respectively.[29] Barium does not undergo biotransformation in humans.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Barium is a competitive potassium channel antagonist that blocks the passive efflux of intracellular potassium, resulting in a shift of potassium from extracellular to intracellular compartments.[66] Seventeen *KCNJx* genes grouped into seven subfamilies ($K_{IR}1.x$–$K_{IR}7.x$) code channel proteins that modulate the potassium inward rectifier current and the inward rectifier channels. These channels affect the resting membrane potential in excitable cells, and repolarization in cardiac myocytes is important in the regulation of the heart rhythm, cardioprotection during ischemia, insulin secretion, and water homeostasis.[67] The inward rectifier channels are very sensitive to barium ion-dependent blockade. During acute intoxication, barium directly stimulates striated, cardiac, and smooth muscle, resulting in gastrointestinal hypermotility, hypertension, and muscle cramps. Muscle paralysis develops after initial stimulation as the intracellular translocation of potassium reduces the resting membrane potential and decreases muscle excitability.[54] Barium is the only alkaline earth metal capable of producing hypokalemia as a result of the intracellular shift of potassium rather than the blockade of the sodium–potassium pump.[68] Total body stores of potassium remain normal, and the hypokalemia reflects an intracellular shift of potassium stores. Changes in muscle biopsy consistent with hypokalemic periodic paralysis are not seen following barium-induced paralysis.[55]

Pathological Changes

Pathological findings in patients dying from barium chloride poisoning are nonspecific (e.g., severe pulmonary edema, hypokalemia, petechial hemorrhages of the gastric, and small bowel mucosa).[50,69] In a case series of four accidental deaths from barium chloride poisoning, postmortem examination demonstrated subendocardial hemorrhage in the ventricles, fatty changes in the liver, vacuolar changes in the proximal tubular epithelium, mild hyaline droplet degeneration of the proximal convoluted tubules, and aggregates of amorphous, flocculent foamy material in the renal tubules.[70] Internal organs were edematous with visceral petechiae.

CLINICAL RESPONSE

Acute Oral Toxicity

Marked hypokalemia, hypertension, and progressive skeletal muscle weakness characterize toxicity from the absorption of some barium salts (e.g., carbonate, chloride, sulfide); the clinical pattern of toxicity from absorbed barium salts is similar. Characteristically, barium toxicity follows three stages: 1) acute gastroenteritis with mild paresthesias; 2) loss of deep tendon reflexes with the onset of muscle weakness; and 3) progressive muscle paralysis.[71] Following large ingestions of toxic amounts of acid- or water-soluble barium salts (acetate, carbonate, chloride, hydroxide, nitrate, sulfide), severe gastrointestinal irritation develops within 30–60 minutes, followed within 2 hours of ingestion by hypertension tachycardia, severe hypokalemia,[72,73] and neuromuscular effects (muscle twitching, myoclonus, paresthesia, hyporeflexia, profound weakness). The clinical course may progress to hypotension, progressive flaccid paralysis, intractable hypokalemia,[74] metabolic acidosis, respiratory failure, and death.[4,75] The vomiting and diarrhea typically resolve within 24 hours for survivors. Table 4.5 lists the symptoms associated with acute barium poisoning in 226 patients reported in the medical literature.

The cervical and intercostal muscles are particularly susceptible to barium toxicity; extensor muscle groups are usually affected before the flexor groups begin in the upper extremities.[57] Paresthesias typically begin around the mouth and neck followed by the hands and feet within several hours. The dose-dependent paralysis begins peripherally and progresses centrally with respiratory failure being a common complication of barium poisoning. Rhabdomyolysis,[7] renal failure,[54] respiratory arrest,[76] and occasionally cardiac dysrhythmias (ventricular tachycardia, *torsade de pointes*, transient asystole, decreased ventricular conduction, atrial fibrillation) may result from an acute barium ingestion.

Occupational Exposure

Occupational poisoning from barium compounds is unusual. A chrome-plating worker developed gastrointestinal distress, progressive muscle weakness, rapid paralysis, and renal dysfunction after a large quantity of barium carbonate powder blew into his face while cleaning chrome tanks.[77] Barium poisoning may occur when penetrating wounds or burns are contaminated by soluble barium compounds. Hypertension, ventricular bigeminy, hypokalemia, and vomiting without paralysis developed in a jackhammer operator when he broke into a furnace area containing molten barium chloride.[78] Muscle paralysis and weakness may persist for 1 week; however, there are no documented musculoskeletal sequelae of acute barium poisoning. Workers exposed to finely ground barium salts for many years develop fine punctate and annular lesions on their chest X-rays (baritosis) that rarely progress to larger nodular lesions or pulmonary dysfunction.[38]

Reproductive Abnormalities

Barium probably crosses the placenta because studies of stillborn rodents demonstrate the presence of barium.[79] During a food poisoning epidemic resulting from the use of barium carbonate-contaminated flour, the ingestion of toxic amounts of barium in the first and third trimesters of pregnancy was not associated with adverse effects on the fetus.[7] These women had gastrointestinal symptoms without serious hypokalemia or muscle weakness.

Carcinogenesis

Neither the IARC nor the US National Toxicology Program lists barium or barium salts as suspected carcinogens with the exception of barium chromate. The latter salt is a member of the group of hexavalent chromium compounds for which there is sufficient evidence of carcinogenicity (IARC Group I: carcinogenic to humans). A 2-year study of male and female rats and mice receiving barium chloride hydrate in drinking water did not detect evidence of carcinogenicity in either species.[80] Nephropathy occurred in both female and male mice.

DIAGNOSTIC TESTING

Conversion Factors

1 μmol/L = ~56 μg/L
1 μg/L = ~0.018 μmol/L

Analytical Methods

Analytical techniques for measuring barium and barium compounds in biological and environmental samples include flame atomic absorption spectroscopy (FAAS), graphite furnace atomic absorption spectroscopy (GFAAS), X-ray fluorescence spectroscopy (XFS), neutron activation analysis (NAA), direct

current argon plasma-atomic emission spectroscopy (DCAP/AES), inductively coupled plasma/mass spectrometry (ICP/MS), inductively coupled plasma/atomic emission spectrometry (ICP/AES; LOD, 0.6 µg/L),[81] scintillation spectroscopy, and spectrography.[6] ICP/AES (Method 7300) is a technique recommended by NIOSH for analyzing soluble barium compounds in air with a limit of detection of 0.005 µg per sample (~0.005 µg/m^3); this method is 400 times more sensitive than FAAS (NIOSH Method 7056). The use of ICP/MS allows the isotopic analysis of barium and the determination of the source of environmental emissions. Limits of detection for ICP/MS for environmental (e.g., water)[82] and biological (e.g., urine)[83] samples using ICP/MS are 0.001 µg/L and 1 µg/L, respectively. This method is much more sensitive than X-ray fluorescence spectroscopy, neutron activation analysis, or spectrography. All of these techniques measure total barium concentrations in the sample without speciation.

Biomarkers

Blood

Case reports suggest barium is not equally distributed between serum and whole blood. In a patient intentionally ingesting barium chloride, the serum barium concentration 3 hours after admission was 20.45 µg/L compared with 150 µg/L in whole blood.[53]

General Population

Most of the barium in the blood resides in the plasma/serum with the erythrocytes containing little barium. In a study of 141 healthy adult Norwegians (age 21–87 years), the median Ba concentration in serum samples was ~60 µg/L with a range of ~30–98 µg/L as measured by ICP/AES after microwave digestion.[84] In a French study of 100 healthy adults, the median barium concentration in plasma samples was 111 µg/L (95% reference range, 90–154 µg/L) compared with 59 µg/L (95% reference range, 46.4–77.6 µg/L) in whole blood samples as measured by ICP/MS.[85] The LOQ was 7.0 µg/L and 0.19 µg/L, respectively, with inter-assay imprecision ~3–5%. The barium concentrations in these two studies are substantially higher than other studies, suggesting the possibility of methodological issues (e.g., barium contamination from glass containers). Whole blood barium concentrations in human clinical specimens collected before 1996 ranged from 0.5–2.5 µg/L.[86] The mean whole blood Ba concentration in 25 healthy Italians was 1.2 ± 0.26 µg/L (range, 0.47–2.9 µg/L) with a reference range of 0.47–2.4 µg/L as measured by NAA and several AAS techniques.[87] In a study of 130 German volunteers without occupational exposure to barium, the mean whole blood Ba concentration was 0.8 µg/L (95% CI: 0.4–1.2 µg/L) with a range up to 1.9 µg/L as measured by ICP/MS.[88]

Overdose

Approximately 24 hours after the intentional ingestion of barium carbonate, a 39-year-old woman was intubated for respiratory failure and complete flaccid paralysis; her plasma barium concentration was ~2.8 mg/L as measured by inductively coupled plasma/atomic emission spectrometry the potassium concentration was ~2.2 m Eq/L.[55] She survived with intensive supportive care; her peak plasma barium concentration was ~7.8 mg/L. Three hours after the ingestion of an estimated 20 g barium chloride, a 39-year-old woman arrived at the emergency department with cyanosis, confusion, general muscle weakness (serum K+ = 1.3 mEq/L), respiratory failure requiring intubation, and a history of the acute onset of profuse vomiting.[53] On admission, her serum and whole blood barium concentrations were 20.45 and 150 ng/mL as measured by inductively coupled plasma/mass spectrometry; her serum potassium was 1.3 mEq/L. She received hemodialysis within 1 hour of admission; she survived without complications.

Postmortem

A 39-year-old man died ~6 hours after reporting the ingestion of barium despite supportive care and advanced cardiac life support. His postmortem blood (site not specified) drawn 3 hours after death contained 2.16 mg Ba/L.[69] The barium concentration in postmortem blood (site not reported) from a 49-year-old man dying at the scene despite attempted resuscitation following the ingestion of barium chloride was 9.9 mg/L, as electrothermal atomic absorption spectrometry (EC AAS).[89] In a case series of four deaths from barium chloride poisoning, the postmortem blood (site not specified) contained barium concentrations ranging from ~16–22 mg/L (ppm).[70]

Hypokalemia secondary to barium poisoning is difficult to detect at autopsy because of the rapid passive diffusion of intracellular potassium into the blood after death; however, vitreous potassium concentrations are often relatively low when drawn within a few hours after death. Rapid analysis of fresh tissue with electron-probe analysis helps localize intracellular potassium, whereas freezing of tissue interferes with the analysis of the intracellular potassium concentration.

URINE

Barium in urine is usually below 0.05 µmol (~2.8 µg)/24-hour urine volume and 8 µg/L in spot urine samples from the general population.[90] In the 3rd US National Report on Human Exposure to Environmental Chemicals, the geometric mean of barium was 1.43 µg/L with an upper 95% limit of 7.14 µg/L. The mean urinary Ba concentration in 35 healthy, unexposed Italians was 2.7 ± 0.5 µg/L (range, 0.25–10.1 µg/L) with a reference range of 0.25–5.7 µg/L.[87] In a French study of 100 healthy adults, the median Ba concentration in urine samples was 0.89 µg/L (95% reference range, 0.17–3.8 µg/L) as measured by ICP/MS.[85] The LOQ was 0.07 µg/L with inter-assay imprecision of ~8%. The mean Ba concentration in urine samples from 1,437 US patients was 3.5 ± 2.2 µg/L with a range of 1.0–7.0 µg/L as measured by ICP/MS.

Abnormalities

Hypokalemia after overdose may be severe (i.e., <2.0 mEq/L).[91] The total body potassium probably remains relatively stable during barium intoxication; rebound hyperkalemia frequently occurs after treatment of barium intoxication including the use of potassium supplements.[30] During the time the muscles are flaccid from severe hypokalemia, the EMG is electrically silent. Serum magnesium concentrations usually remain normal, but hypophosphatemia may occur rarely along with evidence of rhabdomyolysis (↑ creatine kinase, ↑ myoglobin).[92] Electrophysiological abnormalities during acute barium intoxication include loss of the F waves, loss of the H reflexes, and low-amplitude compound muscle action potentials.[93] These changes indicate involvement of the gamma efferent fibers, the proximal segments of the reflex arch, and the neuromuscular junction. Although barium is not directly cardiotoxic, rare case reports associate severe barium intoxication with elevated serum troponin I concentrations.[7,94] Barium compounds are radiopaque; small concretions appear in the intestine and colon following ingestion of these compounds.

HEALTH SURVEILLANCE

Table 4.6 lists international and US regulations and guidelines related to soluble barium compounds. The Agency for Toxic Substances and Disease Registry derived an intermediate-duration oral minimal risk level (MRL) for barium of 0.2 mg/kg/day based on a No-Observed-Adverse-Effect-Level (NOAEL) of 65 mg Ba/kg/day and a Lowest-Observed-Adverse-Effect-Level (LOAEL) of 115 mg Ba/kg/day for increased kidney weight in female rats exposed to barium chloride during a US National Toxicology Program study;[80] the uncertainty factor was 100 (10-fold, animal to human extrapolation; 10-fold, human variability) with a modifying factor of 3 to account for the lack of an adequate developmental toxicity study. The chronic-duration oral MRL was 0.2 mg/kg/day based on a $BMDL_{05}$ (benchmark dose corresponding to the predicted 5% incidence of the selected effect) of 61 mg

TABLE 4.6. Regulations and guidelines for exposure to soluble barium salts.

Substance	Value
OSHA	
PEL–TWA (8-hour)

Ba/kg/day for nephropathy in male mice from the same study and an uncertainty factor of 100 (10-fold, animal to human extrapolation; 10-fold, human variability).

Although several epidemiological studies suggest an inverse relationship between cardiovascular mortality and barium concentrations of <1 ppm in drinking water,[37,95] a cross-sectional study of residents in an area with relatively high barium concentrations (7–10 ppm) in drinking water demonstrated higher cardiovascular mortality in the study group compared with a nearby area with low barium concentrations. The study did not control for water softness (i.e., high barium concentrations in water are usually associated with high calcium and magnesium concentrations), ethnicity, or other confounders for cardiovascular mortality. A subsequent study of the same area did not detect a statistical difference in blood pressure between residents of the same two areas with high (mean = 7.3 ppm) and low (mean = 0.1 mg/L) barium concentrations in drinking water.[96]

An experimental study of 10 healthy volunteers compared a variety of known risk factors for cardiovascular disease following exposure to the following barium concentrations in drinking water as barium chloride: 2 weeks of 0 ppm, 4 weeks of 5 ppm, and 4 weeks of 10 ppm.[97] There were no statistically significant changes in blood pressure, electrocardiographic monitoring, plasma cholesterol, serum lipoprotein or apolipoprotein, serum potassium or glucose, or urine catecholamine concentrations when compared to baseline (0 ppm).

TREATMENT

Decontamination

The rapid onset of vomiting following the ingestion of barium salts limits the effectiveness of lavage. The oral administration of magnesium or sodium sulfate has the theoretical advantage of precipitating barium salts as insoluble barium sulfate. The intravenous use of magnesium salts has the theoretical concern of precipitating barium in the intravascular spaces. Consequently, oral administration or the addition of 5–10 g of magnesium sulfate to lavage fluid is probably the best decontaminating method. Sodium sulfate (60 g) is an alternate agent for magnesium sulfate. Activated charcoal is probably not effective.

Enhancement of Elimination

Although barium is eliminated primarily through the feces, some case reports suggest renal replacement therapies (e.g., intermittent hemodialysis and continuous venovenous hemodialysis) improve clinical outcomes by aiding the stabilization of serum potassium concentrations; the contribution of enhanced barium elimination from hemodialysis remains unclear. A 22-year-old former chemistry student arrived at the emergency department with altered mental status, *torsade de pointes*, increased muscle tone, and a serum potassium concentration of 1.5 mEq/L.[98] He was treated with infusions of saline, potassium 10–30 mEq/L/hour, sodium bicarbonate, and magnesium sulfate. Ten hours after the presentation, his mental status improved, but he complained of muscle pain and weakness. Four hours of venovenous hemodialysis were associated with rapid resolution of his symptoms along with normalization

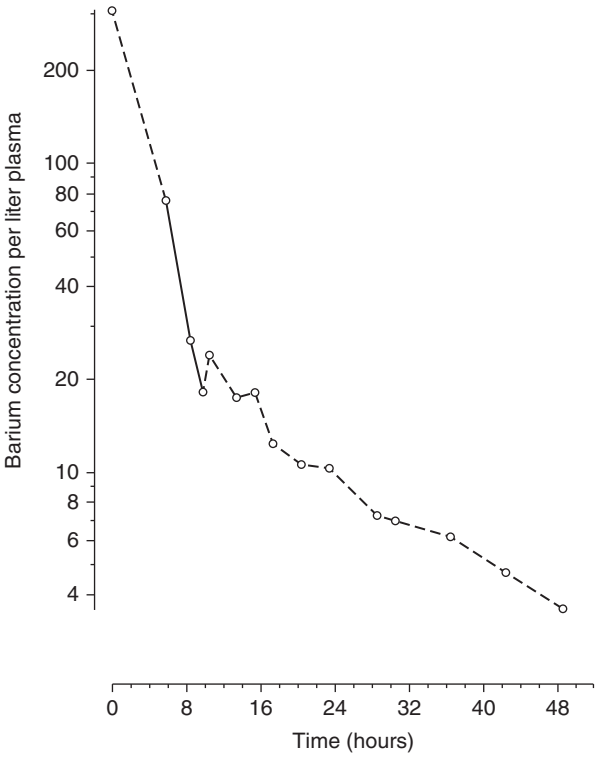

FIGURE 4.1. Plasma barium concentrations in a 22-year-old man after ingesting barium carbonate dissolved in hydrochloric acid. The patient was admitted to the hospital ($t = 0$) about 2 hours after ingestion. The solid line represents the plasma barium concentration during hemodialysis (200 mL/minute) using inductively coupled plasma/optical emission spectroscopy. The dashed line before hemodialysis is the estimated plasma barium concentration before the first measurement, whereas the dashed line after hemodialysis represents the barium concentration measured up to 48 hours after hemodialysis. The approximate plasma barium half-life during hemodialysis was 1.9 hours compared with 18 hours for the half-life after hemodialysis. (Adapted from Schorn et al.).[100]

of his serum potassium and a substantial reduction in his serum barium concentration. Another case report described the rapid improvement in muscle strength and mental status following the use of hemodialysis (dialysate potassium concentration, 4 mEq/L) 3 days after admission.[99] Her serum potassium concentration increased from admission (1.1 mEq/L) to 4 mEq/L following an IV potassium infusion. However, her respiratory failure and profound weakness persisted until the completion of hemodialysis and concomitant reduction in her serum barium concentration.

Although several case reports describe reductions in serum barium concentrations during dialysis, few pharmacokinetic data document barium clearances during hemodialysis. A 22-year-old man arrived at the emergency department 1.5 hours after ingesting barium carbonate dissolved in hydrochloric acid.[100] Hemodialysis began ~7 hours after ingestion with the dialysate containing sodium bicarbonate and 4 mEq/L potassium. As displayed in Figure 4.1, the serum barium half-life during hemodialysis was 1.9 hours compared with a terminal half-life of ~18 hours. The use of continuous venovenous hemodiafiltration during acute barium intoxication reduced the elimination half-life of barium to 6 hours with an ~3-fold increase in the clearance of barium compared with renal elimination.[101] A potential application of hemodialysis in severe barium poisoning is the correction of hypokalemia by the use of high potassium doses in the dialysate (e.g., double the normal dialysate potassium concentration or 7 mEq/L) in the dialysate, particularly in patients with renal dysfunction. Careful monitoring of serum potassium concentrations is necessary in these patients.

Supplemental Care

The mainstay of treatment is the stabilization of vital signs and the aggressive treatment of hypokalemia. Large potassium doses of oral and intravenous potassium may be necessary immediately to correct hypokalemia in patients with severe barium poisoning.[102] Within the first 19 hours of treatment, a 24-year-old man, who intentionally ingested a Ba-containing facial depilatory, received 260 mEq IV potassium; his serum potassium concentration increased from 2.7 mEq/L at admission to 3.9 mEq/L 19 hours after admission.[57] A 30-year-old Ba-intoxicated patient with a markedly widened QRS received 240 mEq/L of IV potassium over 7 hours; his serum potassium increased to 2.0 mEq/L and his ECG normalized.[72] After 4 hours of hemodialysis, he was extubated and his muscle weakness resolved. Monitor the electrocardiogram, the cardiac rhythm, and the serum potassium closely over the first 24 hours.[54] The administration of potassium and continuing barium elimination may cause rebound hyperkalemia;[75] patients generally tolerate mild hypokalemia in the setting of barium poisoning because of the protective effects of barium on cardiotoxicity.[29] Administer generous amounts of fluid replacement while monitoring the urine and serum for evidence of renal failure.

Chapter 5

BERYLLIUM

HISTORY

The French chemist, Vauquelin, discovered beryllium in 1798 while synthesizing beryllium hydroxide. Both Wohler and Bussy isolated the metal in 1828; the latter named the metal glucinium because of the sweet taste of its salt.[1] Commercial production did not begin in the United States until the recognition of the usefulness of beryllium in weapons production, fluorescent lighting, nuclear energy, and aerospace in the 1930s. Beryllium is the lightest among the solid, chemically stable elements with special properties (e.g., extremely hard, nonmagnetic, high electric and thermal conductivity, radiotranslucent) beneficial to modern technology. In 1933, the first medical reports of acute pneumonitis secondary to beryllium exposure appeared in the German literature.[2] The first major use for beryllium in the United States was the production of phosphors (beryllium phosphorus) in fluorescent lighting. During World War II, the first reports of acute chemical pneumonia in US workers extracting beryllium oxide were published.[3] Many cases of acute and chronic lung disease occurred among workers in the early fluorescent lighting industry. The use of beryllium in the fluorescent lighting industry ceased in 1951.

Chronic exposure to beryllium causes a chronic granulomatous pulmonary disease in a small percentage of sensitized, beryllium-exposed workers that is similar to sarcoidosis and miliary tuberculosis.[4,5,6] The term Salem sarcoid was applied to the granulomatous lung disease that appeared in fluorescent lighting manufacturing workers in Salem, Massachusetts.[7,8] Subsequently, Hardy discovered inhaled beryllium as the cause of this disease. The Salem workers also developed granulomatous skin lesions and acute contact dermatitis from exposure to soluble beryllium salts.

In the 1940s, beryllium was used during the development of nuclear weapons and nuclear power.[9] An acute pneumonitis appeared in US workers refining beryllium. Beginning in 1947, chronic beryllium disease developed in some residents living near beryllium production facilities and some family members of beryllium workers, presumably as a result of para-occupational exposure to beryllium-contaminated clothing.[10,11] Implementation of the 1949 recommendations of the Atomic Energy Commission concerning work practices, air concentrations, emissions, and ventilation systems drastically reduced cases of granulomatous disease associated with occupational and environmental exposure to beryllium. Between the 1960 and the early 1990s, only one case of chronic beryllium disease was reported following nonoccupational exposure to beryllium.[12]

In 1951, Harriet Hardy established the US Case Register (for beryllium disease) in Boston. The National Institute for Occupational Safety and Health (NIOSH) now manages this case registry, and the registry now contains over 800 cases.[13] A similar registry in the United Kingdom contains about 60 cases.[14] Exposure of earlier workers to dust and fumes of various beryllium compounds (oxides, fluoride, sulfate) occurred during extraction and fabrication of beryllium, whereas the majority of beryllium exposures in the current work environment occur in industries that fabricate or machine beryllium-containing alloys.[15] Current uses include alloys for space exploration, military equipment, electronics, and nuclear reactors.[16,17] Although

improved work practices and environmental controls have markedly decreased the number of cases of chronic beryllium disease, genetic susceptibility and prolonged Be exposure increase the risk of Be sensitization and chronic beryllium disease in manufacturing processes using beryllium (e.g., beryllium oxide ceramics, nuclear weapons production facilities).[18,19]

PHYSIOCHEMICAL PROPERTIES

Beryllium is an odorless, nonmagnetic, corrosion-resistant metal that possesses the lowest thermal neutron adsorption cross-section of any metal. This strong, lightweight metal has several attractive physiochemical properties including radiotransparency, electrical conductivity, corrosion resistance, and the generation/reflection of neutrons. The stability, exceptional strength, and heat-absorbing properties allow many technological applications. Physicochemical properties affect the toxicity of beryllium ions. Case reports associate acute beryllium disease with exposure to high doses of low-fired beryllium oxide, but not exposure to high-fired (1,540°C) beryllium oxide.[20]

Pure beryllium is a brittle, steel-gray metal that possesses unique properties as the fourth-lightest element in the periodic table. The brittleness of this stiff metal allows the spread of insoluble Be particles during the machining and other beryllium processes. Beryllium occurs naturally only as the ^{9}Be isotope. The physical properties of low absorption of neutrons and high-scattering cross-section favor the use of beryllium as a moderator and reflector of structural material in nuclear plants. Low density along with resistance to oxidation, strength, and high modulus of elasticity produces beryllium alloys that resist high centrifugal forces. However, most alloys contain beryllium concentrations of ~3–4% because of the brittleness of beryllium compounds and the low solubility of most elements in beryllium. The exception is lockalloy (62% Be, 38% Al).

There are two oxidation states, Be^{0} (metallic) and Be^{2+} (divalent). The chemical properties of beryllium and aluminum compounds are similar including a high affinity for oxygen that provides corrosion resistance. The solubility and size of beryllium particles probably affect the risk of developing beryllium sensitization and chronic beryllium disease.[21] Metallic Be is not soluble in water at neutral pH. Water hydrolyzes cationic beryllium salts to form insoluble hydroxides or hydrated complexes at physiological pH of 5–8, but at pH >8 more soluble beryllate salts form. Most beryllium salts (e.g., oxide, carbonate, anhydrous sulfate, hydroxide) are practically insoluble in water, whereas water-soluble beryllium salts include chloride, fluoride, nitrate, phosphate, and sulfate (tetrahydrate). Beryllium salts are odorless. At physiological pH (7.2), beryllium ore materials and beryllium hydroxide are more soluble than beryllium oxide and metallic beryllium. Table 5.1 lists the identifying information and physical properties of beryllium and beryllium compounds.

TABLE 5.1. Identifying information and physical properties of metallic and divalent beryllium. (Based on WHO).[1]

Property	Be	BeF_2	$Be(OH)_2$	BeO	$BeCl_2$	$BeSO_4$	$BeCO_3$
Synonym	Metallic beryllium	Beryllium fluoride	Beryllium hydroxide, dihydroxide, or hydrate	Beryllium oxide or monoxide	Beryllium chloride or dichloride	Beryllium sulfate	Beryllium carbonate (basic)
CAS RN	7440-41-7	7787-49-7	13327-32-7	1304-56-9	7787-47-5	13510-49-1	13106-47-3
Valence	0	2	2	2	2	2	2
Molecular weight (g/mol)	9.012	47.01	43.03	25.01	79.92	105.07	112.05
Color	Gray	Colorless	White	White	Colorless	Colorless	White
Physical state	Solid hexagonal	Glassy, hygroscopic mass	Amorphous powder or crystalline solid	Amorphous powder	Needles	Tetragonal crystals	Powder
Melting point (°C)	1,287–1,292	555	Decomposes with heat	2,508–2,547	405	550–600 (decomposed)	No data
Density (g/mL)	1.846	1.986	1.92	3.016	1.899	2.443	No data
Water solubility (mg/L)	Insoluble	Very soluble	3.44	Very sparingly	Very soluble	Insoluble	Insoluble

EXPOSURE

The principal source of beryllium exposure for the general population is the combustion of fossil fuels, particularly near power plants that burn coal containing high Be concentrations. The highest risk of Be exposure occurs in individuals involved in the manufacturing, fabrication, or reclamation of beryllium. Most studies of workers in these industries involved exposure to materials containing relatively high beryllium concentrations (i.e., 20–65 wt%); however, most beryllium alloys currently contain <4% beryllium (e.g., commercial wrought copper–beryllium) with the exception of lockalloy. As a result of improved work practices and better control of emissions, people living near beryllium-emitting industries have only a slightly increased risk of developing diseases related to Be exposure. Smokers may inhale high concentrations of beryllium depending on the source of the tobacco. Smoking may triple the daily consumption of beryllium.[22] Some mantles from camping lanterns contain high concentrations of beryllium nitrate that volatilize within the first 15 minutes of igniting.[23]

Commercial Processes

The United States is the leading producer of beryllium ores and consumer of Be products.[15] Mining of beryllium occurs primarily from naturally occurring silicates (bertrandite, beryl ore). Production in the United States occurs only in Utah via the SX-carbonate process from bertrandite ($4BeO_2SiO_2\ H_2O$, 15% Be by weight). The United States imports beryllium from Argentina and Brazil, where the main beryllium silicate ore is beryl ($Al_2Be_3Si_6O_{18}$, 5% Be by weight).[24] Byproducts of metallic beryllium production from beryllium-containing ores include beryllium carbonate, tetrahydrate sulfate, and hydroxide. Beryllium sulfate results from the leaching of the ore with sulfuric acid; then, aqueous ammonium carbonate converts the beryllium sulfate to basic beryllium carbonate. The subsequent heating of beryllium carbonate yields beryllium hydroxide, beryllia (starting material for the production of the metal), and beryllium alloys. The arc furnace method is used to form beryllium-copper alloy by reducing beryllium oxide with carbon in the presence of molten copper.

Two other commercial methods called the fluoride and sulfate processes convert the commercial ore, beryl ($Be_3Al_2Si_6O_{18}$), to beryllium hydroxide. The sulfate process involves the alkaline or heat processing of beryl with the addition of strong sulfuric acid, while the fluoride process involves the sintering of beryl with sodium silicofluoride or sodium fluoroferrate and the leaching of the solution with caustic soda. The consumption of beryllium has been decreasing since 1987 because of decreased demand in the defense and aerospace industries as well as concern about the potential health hazards.[1] Examination of the ambient air during beryllium machining operations indicates that >50% of the particles in the breathing zone of the workers are >10 μm in aerodynamic diameter.[25] Using a personal impactor, this study demonstrated median time-weighted beryllium averages ranging from 0.13 $\mu g/m^3$ in lapping processes to 0.74 $\mu g/m^3$ in deburring operations.

Uses

Industrial uses of beryllium involve primarily free metals, beryllium alloys, and beryllium oxide. Beryllium-copper and other alloys account for ~75–80% of Be production as a result of favorable commercial properties (e.g., good electrical/thermal conductivity, high strength and hardness, corrosion/fatigue resistance, non-magnetic, non-sparking).[15] The addition of 2% Be to copper substantially increases the strength of the alloy without reducing thermal or electrical conductivity. Bauxite is the principal source of aluminum, and these aluminum-bearing rocks contain variable amounts of beryllium depending on the source. Emissions from the pot used in the aluminum smelting process may contain beryllium, but the sensitization rate of aluminum smelter workers to beryllium is low compared with beryllium-exposed workers in other industries.[26] Beryllium exposure may occur in industries that do not produce or process this metal including the following: 1) abrasive blasting operations using Be-containing coal or copper slag; 2) welding of specialized Be-copper or other Be-containing electrodes/fluxes; 3) fabrication of Be alloys; or 4) recycling of Be-containing metals.[27] Workers at risk of developing Be sensitization include work involving Be metal production, melting and casting Cu-Be alloy, processing Be-containing rod and wire products, ceramics production, machining Be, Be metal production, and analytical laboratories using Be.[28] Beryl is a gemstone (green emerald, light blue aquamarine, yellow beryl). Beryllium phosphate has no commercial uses. Table 5.2 lists the common uses of specific beryllium compounds.

Sources

Human exposure to beryllium occurs primarily in the workplace. Machinists working directly with beryllium

TABLE 5.2. Commercial uses of metallic beryllium, beryllium alloys, and beryllium oxide. (Based on WHO).[1]

Form	Uses
Metallic Be	Aircraft disc brakes, turbine rotor blades, space vehicles optics and instruments, heat shields, aircraft/satellite structures, missile guidance systems, nuclear reactor neutron reflectors, nuclear warhead triggering devices, nuclear fuel elements, precision instruments, rocket propellants, navigational systems, mirrors, high-speed computers, audio components, X-ray transmission windows
Be-copper alloy	Aircraft engine parts, springs; high-frequency electrical connectors and relays; precision instruments; bushings and bearings in aircraft and heavy machinery; non-sparking tools; submarine cable housing and pivots; wheels and pinions; switches in automobiles; molded plastics; radar; telecommunications; factory automation; computers; home appliances; instrumentation and control systems; tubing in oil and drilling equipment; connectors for fiber optics; and integrated circuits
Be-aluminum alloy	Aircraft and spacecraft construction material
Be-copper-cobalt alloy	Nozzles for gas/oil burners, electronics (springs, switches, contacts, electrodes), bushings, bearings, soldering iron tips
Be-nickel alloy	Aircraft and spacecraft parts, glass molding, diamond drill bits, springs, electrical connectors
Be-nickel-chromium alloy	Crowns and bridges as an alternative to gold
Be oxide	High-technology ceramics, nuclear reactor components, electronic heat sinks, electrical insulators, substrates for high-density electrical circuits, gyroscopes, military vehicle armor, rocket nozzle crucibles, gas lantern mantels, microwave oven components, thermocouple tubing, laser structural components, automotive ignition systems, radar electronic countermeasure systems

metals and alloys are particularly susceptible to developing beryllium sensitization.[29] The general population typically is exposed to trace amounts of beryllium in ambient air, food, and water.

Air

The emission of beryllium from natural sources (volcanic particles, windblown dust) is small compared with the emission from man-made sources. The combustion of coal (average Be content 1.8–2.2 μg/g) in power plants represents the major source (i.e., ~95%) of man-made Be emission.[22] Other anthropogenic sources include metal fabrication, beryllium oxide production, municipal waste combustion, and ore processing. Beryllium enters the atmosphere as beryllium oxide. Potential sources of local elevated ambient Be concentrations include beryllium extraction plants, ceramic plants, foundries, incinerators, machine shops, municipal waste incinerators, propellant plants, and rocket-motor test ranges.

The annual average Be concentration in rural ambient air in the United States is typically nondetectable (<0.03 ng/m^3). Beryllium concentration in urban air is usually higher due primarily to the burning of coal and fuel oil; between 1982–1992, the average annual ambient air concentration of Be in Detroit, Michigan, ranged from 0.02–0.2 ng/m^3 with a median atmospheric Be concentration of ~0.2 ng Be/m^3.[15]

Soil

This metal exists in nature as a component of coal, oil, soil, rocks, and volcanic dust rather than as a pure metal. Beryllium is an uncommon element in soil, present in variable concentrations with average Be soil concentrations of 0.6 mg/kg in the United States,[15] compared with ~2.5–5 mg/kg soil and a range up to 40 mg/kg worldwide.[1,30] The Be concentration usually increases with the increasing content of silica and alkali. Although Be binds strongly to fulvic acid in the soil, beryllium has a stronger affinity for aluminum in clay than iron oxides and most organic materials. The most important source of environmental exposure to beryllium is the burning of coal, typically at concentrations of 100 mg Be/kg coal. Both coal ash and municipal waste ash present in landfills constitute a major source of beryllium in the environment.[15]

Water

The Be concentration in surface waters is in the low ng/L range with the concentration in seawater ~10 times less (i.e., <0.5 ng/L). Anthropogenic sources of beryllium in surface water are primarily the discharge of industrial wastewater effluents. The geometric mean of total beryllium in US surface water is usually <70 ng Be/L. Only 5.4% of the samples of US drinking water contained beryllium concentrations of >10 ng/L; the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mean beryllium concentration in the positive samples was 190 ng/L.[31] In a review of analytical studies of US tap water, the mean Be concentration was ~13 ng/L (range, 10–70 ng/L)[32] compared with <10 ng/L (LOD; range, <10–20 ng/L) in 18 samples of domestic mineral water.[33] Within the pH range (4–8) typically present in the environment, the strong absorption of beryllium into finely dispersed sediment limits the migration of beryllium into groundwater. In general, the bioconcentration of beryllium in plants and animals is low.[15] Existing data suggest that significant bioconcentration of Be in water by aquatic species does not occur.[34]

Diet

There are limited data on the total daily Be intake in the general population. The estimated daily intake of Be in nonsmoking adults ranges from 5–100 μg with the primary source being food (root, tuber, forage crops on acidic soil); typical Be concentrations range from <1– to ~20 μg/kg fresh weight.[32] In a Japanese study of hospital diets, the average daily Be intake was ~84 μg as measured by inductively coupled plasma mass spectrometry.[35] Most plants absorb only small amounts of beryllium from the soil with little Be translocation (i.e., <25 μg/kg fresh weight) to edible parts of the plant. Foods with the highest Be content include kidney beans, crispbread, peas, parsley, and pears.[15] Biologically significant biomagnification of beryllium in plants and animals probably does not occur because the bioconcentration factor is <1,000; limited data suggest this value for beryllium ranges from 19–100.[15]

Lifestyle

Beryllium is a minor constituent of cigarette smoke in some samples with yields in mainstream smoke ranging from nondetectable to 0.0005 μg/cigarette in a review of 12 analytical studies; 8 of these studies had nondetectable quantities of beryllium in mainstream smoke.[36] The source of the beryllium is unclear; there are inadequate data to determine the quantity of beryllium present in commercial mainstream cigarette smoke.

ENVIRONMENTAL FATE

Air

Beryllium enters the atmosphere primarily as beryllium oxide particles. Most of these particles have a mean mass aerodynamic diameter of <2.5 μm; and therefore, the atmospheric life of these particles is short (i.e., about 10 days).[37]

Soil

The reaction of beryllium in soil includes hydrolysis of soluble salts, complexation with ligands (e.g., humic substances), and anion exchange (e.g., sulfate to carbonate). There are little data on the biotransformation of beryllium in soil. In general, beryllium adheres tightly to most types of soil.[30] The common beryllium silicates are highly insoluble in aqueous solutions and relatively resistant to weathering.

Water

The mobility of beryllium in water is low; however, water-soluble complexes of hydroxides form with beryllium at high pH, increasing solubility and mobility. Most beryllium in the aqueous environment is bound either to suspended matter or sediment. Little beryllium is dissolved in natural waters, except in acidic, organic-rich continental river waters.[24] The estimated residence time of beryllium in the ocean is a few hundred years. Most reactions in water involve the conversion of one beryllium salt to another. Hydrolysis of soluble beryllium salts produces beryllium hydroxides that are relatively insoluble at the pH of most natural waters.

DOSE EFFECT

Most of the information relating to dose-response in humans results from observing the effect of the inhalation of beryllium salts in the work environment. Although very little information is available on the dose-response of beryllium following ingestion, the oral route is probably not a significant route for the development of beryllium-associated disease.

Acute Toxicity

Inhalation of beryllium salts (fluoride, sulfate, chloride, oxide, hydroxide) or metallic dust in concentrations of >25–100 μg Be/m^3 may produce acute respiratory symptoms in workers ranging from irritation of the mucous membranes in the nose and throat to acute bronchitis and chemical pneumonitis.[10,38] Almost all

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

workers develop these acute respiratory symptoms at Be concentrations of >1 mg/m^3; these acute symptoms are absent at Be concentrations of <15–25 μg Be/m^3. Although the vast majority of patients recover completely after an acute exposure, animal studies suggest that symptoms of chronic beryllium disease may appear years after a high-dose, acute exposure.[39]

Chronic Toxicity

The prevalence of chronic beryllium disease has declined dramatically since the implementation of an occupational exposure standard of 2 μg Be/m^3; however, significant variability occurs in the latency and the dose-effect relationship of this disease. Although there is currently no consistent association between mean, cumulative, and peak Be exposure and beryllium sensitization and/or chronic beryllium disease, respiratory disease is unlikely following Be exposure of <0.03–0.2 ng/m^3 in ambient air.[15]

Pregnancy may be a risk factor because a majority of the fatal cases in females listed in the US Beryllium Case Registry were pregnant. Cross-sectional studies suggest that beryllium sensitization may occur in a few individuals at mean ambient air concentration of <2 μg Be/m^3, particularly in jobs that involve short-term exposure (i.e., 1 year) to relatively high peak Be concentrations in air.[40] Five cases of chronic beryllium disease occurred among workers exposed to beryllium oxide fumes at a precious metals refinery from 1972–1985.[41] Four of these individuals worked in the furnace area, where the mean Be concentration in time-weighted-average personal air samples collected during 2 weeks in 1983 was 0.52 μg/m^3; however, this cross-sectional analysis of air samples may or may not reflect past or recent beryllium exposure of these workers. Consequently, the current occupational standards may not protect all workers from sensitization and the potential to develop beryllium disease.[1] A study of beryllium workers in a beryllium-copper alloy manufacturing plant did not detect sensitization to beryllium below airborne beryllium concentrations of 0.01 μg/m^3 based on the lymphocyte proliferation test.[42]

TOXICOKINETICS

Absorption

Inhalation is the primary route of exposure to beryllium with the amount absorbed depending on dose, solubility, and particle size; the upper airways filter particles of >5 μm, whereas particles 0.5–5 μm reach the alveoli. The mean mass median aerodynamic diameter of Be particles in various operations of a Be extraction and processing plant was 5.0–9.5 μm as collected by an 8-stage impactor and measured by electrothermal atomic absorption spectrometry;[43] the estimated alveolar Be deposition was 3–5% for nasal breathing and 9–13% for mouth breathing based on the International Commission on Radiological Protection lung model. However, other factors (e.g., beryllium speciation, particle size, surface area) besides airborne Be mass may affect the risk of developing chronic beryllium disease (CBD).[44]

Although few human data are available, animal studies suggest that the lungs retain and slowly adsorb beryllium.[45] The residence time of insoluble Be compounds (e.g., metallic Be) may be years based on the presence of Be in the lungs years after exposure ceases.[15] The gastrointestinal tract poorly absorbs beryllium; animal studies suggest that <1% of an ingested dose crosses the epithelium of the gastrointestinal tract.[46] Dermal absorption of beryllium through intact skin probably contributes little to the total body burden of beryllium unless Be contaminates ulcerated skin.

Distribution

Most beryllium in the blood circulates as a colloidal phosphate rather than as citrate or hydroxide salts. Following inhalation, long-term storage of beryllium occurs in lung tissue, particularly in pulmonary lymph nodes. Most of the retained beryllium eventually deposits in the skeleton. Substantial variation exists in the beryllium concentration between patients with similar exposure; there are more patients with high body burdens of beryllium and no disease than patients with chronic beryllium disease.[47]

Elimination

Although beryllium and beryllium salts are not biotransformed, animal studies suggest that the partial conversion of one salt to another may alter the water solubility of the beryllium compound.[45] Following ingestion, most of the beryllium appears in the feces because of the poor oral absorption of beryllium. The kidney excretes most of the absorbed beryllium in urine. The biological half-life of beryllium following inhalation in a group or by workers exposed to beryllium dust ranged from 2–8 weeks.[48] The residence time of beryllium in the lung lasts up to several years depending on the solubility of the beryllium salt. Animal studies indicate that the ionized soluble forms of beryllium (e.g., citrate) leave the lung rapidly (4 days), whereas non-ionized soluble forms have rapid (1–60 days) and slow (0.6–2.3 years) phases of elimination.[49]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The lung is the primary target organ for beryllium toxicity following inhalation. The role of dermal exposure in beryllium sensitization remains undefined.[50] Two types of pulmonary disease result from the inhalation of beryllium dust and salts: an acute chemical pneumonitis and chronic interstitial granulomatous lung disease. The acute form of the disease probably results from the direct cytotoxic injury caused by exposure to high Be concentrations. Beryllium is a potent inhibitor of phosphorylated enzymes (e.g., alkaline phosphatase). A suspected mechanism for the acute effects of beryllium involves the impairment of key protein phosphorylation. Beryllium probably combines with un phosphorylated enzymes and interferes with the competition of magnesium for these enzymes.[51] Fibrosis is not necessarily a consequence of an acute inflammatory response to beryllium.

An immune reaction to the inhaled beryllium causes chronic beryllium disease (CBD) following the deposition and long-term retention of beryllium in the lungs. The number of antigen-specific T cells (Be-responsive CD4+ T cells) in the blood increases during the transition from Be sensitization to CBD.[52] Following the accumulation of Be-responsive CD4+ T cells in the lungs, granulomas form from cytokine release. Exposure to Be triggers T cell proliferation in these granulomas from the production and release of proinflammatory T helper 1 (Th1) type cytokines (e.g., tumor necrosis factor-α, γ-interferon, interleukin-2).[53] Subsequently, chronic lung inflammation and slowly progressive pulmonary fibrosis develop.

In these patients, beryllium probably acts as a hapten that binds to proteins and peptides in the lungs, resulting in the beryllium–peptide becoming physically associated with a major histocompatibility complex (MHC) Class II molecule. The T cell contains a receptor (T cell antigen receptor) that recognizes the MHC Class II-beryllium–peptide complex; along with CD4+ cells, these T cells produce cell proliferation through the production of lymphocyte growth factor (interleukin-2) and accumulation of beryllium-specific CD4+ (helper/inducer) cells.[54] Special antigen-presenting cell surface molecules (coded by the *HLA-DPB1* gene) facilitate the recognition of beryllium by the T cells.[55] The transition of T cells from a central memory to an effector memory phenotype characterizes the development of chronic beryllium disease (noncaseating granulomas, fibrosis). After T cell activation, the accumulation of inflammatory cytokines (IFN-γ, TNF-α, IL-2, IL-6, IL-10) along with macrophages and activated T cells perpetuates the granulomatous inflammation.

Susceptibility to Be sensitization and chronic beryllium disease has a genetic component; a substantial number of these individuals have the human leukocyte antigen (*HLA*) Class II marker, HLA-DPB1 E69. However, the risk of beryllium sensitization is multifactorial as not all patients with beryllium sensitization have known a HLA mutation. This susceptibility may result from polymorphisms in HLA-DPB1 and DRB1 alleles that cause overrepresentation of HLA-DPB1 alleles with glutamic acid at position 69 of the β chain (E69) as well as polymorphisms in cytokines (*TGF-β1*) and interleukin genes (*IL-1A-1142*, *IL-1A-3769*, *IL-1A-4697*).[56,57] The non-*02 E69 alleles and E69 homozygotes are associated with increased odds for beryllium sensitization and CBD compared with *02 alleles and E69 heterozygotes, respectively. In a study of 386 US workers in a nuclear weapons facility, any E69 carriage increased the odds of developing CBD.[19] Compared with E69 negative genotypes, a single E69 positive *02 allele increased the odds for beryllium sensitization (OR = 12.01, 95% CI: 4.28–33.71) and chronic beryllium disease (OR = 3.46, 95% CI: 1.42–8.43).

Of the 630 known DNA sequence variants of *HLA-DPBI*, 204 are *HLA-DPB1 E69* with at least 1/3 of the US population containing E69 marker. The prevalence of CBD increases substantially in Be workers with any 2 E69 alleles or an E69 allele with the most electronegative charge (i.e., −9) when compared with Be workers not having the E69 allele or only 1 E69 allele.[58] In the US population, the most common E69 allele is *02:01 with a surface charge of −7.[59] Genetic and other factors also affect Be sensitivity and progression to CBD because the prevalence of the supra-allelic E69 marker of genetic risk far exceeds the prevalence of Be sensitization and CBD and ~25% of workers with CBD do not carry the *HLA-DPB1 E69* gene variant.[60] E69 marker is a risk factor for beryllium sensitization, but not chronic beryllium disease; the large prevalence of E69 in the general population indicates the presence of E69 has a low positive predictive value for beryllium sensitization.[61]

Pathological Changes

The acute reaction of tissue to Be is a nonspecific inflammation similar to the reaction of tissue to other mucosal irritants.[20] Similarly, the hallmark of chronic reaction of tissue to Be exposure is a noncaseating epithelioid granuloma that is indistinguishable from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

similar lesions caused by extrinsic allergic alveolitis, sarcoidosis, and other forms of pulmonary inflammation associated with chronic granulomas.[62] Although granulomas may appear in different types of tissue including lymph nodes, spleen, liver, myocardium, kidney, and bone, chronic beryllium disease (CBD) is primarily an interstitial granulomatous disease of the lungs without extrapulmonary lesions.[63] A mononuclear cell interstitial infiltrate and varying degrees of fibrosis are usually present during the examination of lung biopsies of patients with CBD.

Beryllium is an unusual metal that produces cell-mediated immune responses. In animal models, the initial inflammatory response is indistinguishable from the histopathological changes caused by strong irritants.[64] Table 5.3 describes the four phases of histopathological changes seen in CBD. Phases II and III involve the formation of noncaseating granulomas in response to an immunological reaction to beryllium.

The pathological hallmark of chronic beryllium disease is the formation of non-necrotic epithelioid cell granulomas that are indistinguishable histologically from those seen in Crohn's disease, zirconium granulomas (skin only), extrinsic allergic alveolitis, tuberculosis, and sarcoidosis. These granulomas consist of closely-knit epithelioid histiocytes (transformed macrophages) cells with a collar of lymphocytes (predominantly CD4+ T cells), scattered plasma cells, and fibroblasts.[65] Eosinophils are not usually present in these granulomas. Rarely, other metals (aluminum,[66] titanium[67]) have been associated with the formation of noncaseating granulomas and hypersensitivity. The distribution of granulomas in the lung is similar to that of sarcoidosis (subpleural, interlobular septae, around bronchovascular bundles).

TABLE 5.3. Histological phases in chronic beryllium disease (CBD). (Kribel et al.).[9]

Phase	Histological Changes
I	Nonspecific inflammatory responses develop along with cellular exudation, emphysema, and obliteration of the normal lung architecture that may progress to fibrosis. Permanent changes may not occur following mild Be exposure.
II	"Foamy" macrophages appear that contain phagocytized Be particles. Peribronchial lymphoid tissue proliferates with lymphocytes visible in the intracellular septae and around Be particles.
III	Formation of granulomas with focal accumulation of macrophages, epithelioid cells, and multinucleated giant cells.
IV	Interstitial fibrosis occurs along with hyperplasia of alveolar septae.

The epithelioid cells contain a variety of cytoplasmic inclusion bodies.[68] Schaumann bodies are concentrically laminated spherules containing calcium and iron impregnated glycoproteins with central birefringent crystals.[69] The presence of Schaumann bodies in fibrotic lungs indicates the previous presence of granulomatous disease. Schaumann bodies are not pathognomonic for chronic beryllium disease (CBD); these lesions are often present in patients with sarcoidosis, less often in patients with tuberculosis or Crohn's disease, and rarely in patients with extrinsic allergic alveolitis.[68] The final phase is progressive, interstitial fibrosis that is characteristic of many pulmonary toxins. The prominence of alveolitis helps distinguish CBD from sarcoidosis and indicates a poorer prognosis.[63] Beryllium persists for many years in the lung granulomas from patients with CBD, even after occupational Be exposure ceases.[70] Most of the Be in the lungs of patients with CBD resides in the chronic lung granulomas, and Be concentrations in histologically normal lung tissue are similar in Be-exposed patients with and without CBD. The presence of high concentrations of beryllium in postmortem lung tissue helps confirm the diagnosis of CBD in the presence of clinical and radiological findings consistent with CBD. However, high concentrations of beryllium are not required for the diagnosis of CBD; high concentrations of beryllium may be present in lung tissue without CBD.[71]

CLINICAL RESPONSE

Beryllium is a cutaneous sensitizer and primary skin irritant that produces contact dermatitis, skin granulomas, and ulcers.[72] High Be concentrations cause inflammation and edema in the affected tissue including conjunctivitis and periorbital edema. Acute beryllium disease implies that the duration of illness is less than 1 year and that the disease involves inflammation of the skin, the respiratory tract, and the mucous membranes.

Acute Toxicity

Exposure to Be concentrations from 25–100 $\mu g/m^3$ causes a pneumonitis indistinguishable from other causes of chemical pneumonitis along with conjunctivitis, dermatitis, pharyngitis, and laryngotracheobronchitis.[73] Initial symptoms include dry cough and progressive shortness of breath with exertion. Diffuse bilateral alveolar infiltrates may appear on chest X-ray within a few weeks of the onset of symptoms consistent with chemical pneumonitis. The clinical course is often

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mild but may progress rapidly to death; some symptoms may persist over a year.[74] In contrast to chronic beryllium disease and sarcoidosis, the clinical features of acute beryllium disease and acute sarcoidosis (Löfgren syndrome) differ. The latter typically has a benign course that resolves in most patients in contrast to the occasional fulminant pulmonary disease culminating in cor pulmonale associated with acute beryllium disease. Additionally, some systemic effects (e.g., erythema nodosum, acute reactive arthritis, uveoparotitis) occur in sarcoidosis but not in acute beryllium disease.[75]

Environmental Exposure

Soon after the discovery of chronic granulomatous pulmonary disease (CBD) among beryllium manufacturing workers in the 1940s,[7] case reports from 1948–1969 documented the presence of a similar disease in residents of communities surrounding Lorraine, Ohio, associated with para-occupational and/or Be exposure in ambient air.[10] In 1959, a series of 21 cases of community-acquired chronic beryllium disease in residents without occupational Be exposure living up to 8 km from a beryllium facility was published.[76] Similar cases did not appear in the medical literature until a case series of five definite and three probable community-acquired CBD cases diagnosed from 1999–2002 living near a Reading, Pennsylvania, beryllium manufacturing and fabricating facility was published in 2008.[77] All these cases have been long-term residents since the 1950s. The lead author testified in court on behalf of the plaintiff community members.

Beryllium is a lightweight metal that occurs naturally in the soil at low concentrations as beryllium silicate. Extraction of Be salts from the soil and formation of metallic or ceramic Be is associated with beryllium sensitization and chronic beryllium disease; however, insufficient evidence associates these adverse effects with exposure to environmental Be silicates.[63]

Occupational Exposure

Lungs

Acute beryllium disease usually follows within several days of massive Be inhalation or within several weeks following prolonged exposure to high ambient air Be concentrations; resolution typically occurs within several months after cessation of beryllium exposure. Depending on the dose, duration, and type of exposure, signs and symptoms of acute beryllium disease in the lungs range from mucosal irritation to tracheobronchitis, chemical pneumonitis, and fatal noncardiogenic pulmonary edema.[78] Although almost all cases of acute beryllium disease occurred before 1950 as a result of beryllium concentrations (50–100 $\mu g/m^3$) exceeding current workplace standards, sporadic cases of acute beryllium disease still occur.[79] Large exposure to soluble beryllium salts (primarily fluoride) causes upper respiratory tract irritation (conjunctivitis, rhinitis, bronchitis), whereas exposure to the less soluble beryllium salts and oxide fumes produces chemical pneumonitis. Symptoms include progressive cough with sputum, dyspnea, substernal chest pain, malaise, anorexia, and cyanosis. Although most cases of acute beryllium disease recover without sequelae within 1–6 months, some individuals develop chronic beryllium disease years after an acute massive Be exposure.[80,81]

Skin

Cutaneous manifestations of Be exposure include contact dermatitis, dermal granulomas, and beryllium ulcers. Soluble Be salts (fluoride, sulfate, chloride, nitrate) can hydrolyze to free acids causing edema and contact dermatitis (papules, vesicles, pustules, eczematous lesions).[82] Workers exposed to vacuum-cast beryllium metal, pure beryllium metal, and beryllium hydroxide have not developed these skin lesions.[83] Symptoms usually begin within 1–2 weeks, suggesting a delayed allergic reaction. The introduction of either soluble or insoluble beryllium compounds underneath the skin through abrasions or lacerations produces nodular scars and chronic ulcerations. These lesions contain granulomas that are painless; the skin lesions usually appear several years after the introduction of beryllium into the skin.[84] In contrast to sarcoidosis, erythema nodosum is not associated with Be sensitization.

Chronic Beryllium Disease

Chronic beryllium disease (CBD) is a systemic granulomatous disease that is similar to sarcoidosis and principally affects the lungs, lymphatic system, and the skin of sensitized individuals (<15–20% of the exposed population).[15] Most exposed workers do not develop beryllium sensitization or chronic beryllium disease with the incidence varying widely across industries using beryllium. Involvement of organs outside the lungs does not usually occur without the presence of pulmonary lesions; with pulmonary disease, hepatic lesions occur occasionally and cardiac involvement is rare.[85] In contrast to sarcoidosis (e.g., erythema nodosum, uveitis), extrapulmonary manifestations of CBD are rare today.[86] The prevalence of granulomatous interstitial lung disease (CBD) in beryllium industry workers

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

previously averaged ~1–3% with a prevalence of hypersensitivity ranging up to 20% in high-risk industries,[87,88] whereas currently the estimated prevalence of CBD ranges from 0–7.8% and Be sensitization of ~1–15%.[89] The vast majority of cases of CBD occur in the beryllium production industry (machining, lapping, forming, firing); however, rare cases of CBD have developed in workers exposed to copper-beryllium alloys containing Be concentrations as low as 2%.[90,91] In a cross-sectional survey of the latter group of workers, the prevalence of Be sensitization using the beryllium blood lymphocyte test was 1% in comparison to 0.9–10% for beryllium sensitization in workers from the beryllium production industry.[92] This disease may occur in workers at nuclear weapons facilities during the processes of decontamination or decommissioning.[93]

The prevalence of beryllium sensitization is low when the overall Be exposure is low (e.g., workers at conventional munitions facilities).[94] In a case-control study of workers at a nuclear weapons facility, logistic-regression analyses demonstrated a statistically significant relationship between CBD and measures of beryllium exposure (mean, cumulative), whereas Be sensitization was not directly associated with either mean or cumulative Be exposure.[95] Beryllium is a ubiquitous metal; sensitization may occur in new hires without known prior Be exposure.[96] Longer latency periods are associated with less severe disease.[97] Several studies of workers with CBD indicate smoking prevalence is lower in beryllium workers than without CBD.[29] In a cross-sectional study of 895 current workers at a nuclear weapons production plant, 17 workers (1.9%) had Be sensitization (consistently abnormal BeLPT results).[98] The beryllium-sensitized individuals did not significantly differ from the whole cohort in cigarette smoking status or pack-years; additionally, there were no differences in gender, age, history of atopic disease, prevalence of respiratory symptoms, spirometric abnormalities, or profusion of small opacities on chest X-rays.

Stages

Classification of chronic beryllium disease based on sensitive immunological techniques involves the following three stages: 1) beryllium sensitization (positive blood or lung Be lymphocyte proliferation test (BeLPT)) with no other laboratory evidence of disease; 2) subclinical chronic beryllium disease in asymptomatic, sensitized individuals with additional evidence of pathological abnormalities in the lung; and 3) clinical chronic beryllium disease.[99] Beryllium sensitization, as defined by a positive BeLPT result, can progress to chronic beryllium disease; however, not all sensitized individuals develop CBD. Individuals with subclinical chronic beryllium disease are sensitized to beryllium along with histological evidence of lung granulomas in the absence of clinical effects. Some impairment of lung function may be detectable in the absence of symptoms. Slight alterations in lung function during exercise were observed in ~60% of individuals with subclinical CBD; no other consistent alterations in lung function were found. The individuals with clinical CBD have Be sensitization, histological evidence of lung granulomas, respiratory symptoms, abnormal chest X-rays, and/or altered lung function. The disease may progress in the absence of continuing Be exposure.

Presentation

Manifestations of CBD are consistent with an allergic inflammation of the lungs that is associated with secondary changes in other tissues. Chronic beryllium disease usually develops from 10–20 years up to 40 years after the first Be exposure with the onset of symptoms typically ranging from a few months to 25 years.[38,100] The rate of progression from beryllium sensitization to CBD is highly variable, but the rate of sensitization and CBD increases with increasing cumulative exposure.[101] Patients with CBD typically present with nonspecific generalized symptoms or respiratory findings including weight loss, dyspnea, cough, chest pain, fatigue, malaise, night sweats, arthralgias, and cor pulmonale. Dyspnea on exertion is the most common presenting symptom. Physical features depend on the severity of the disease and include bibasilar crackles, hepatosplenomegaly, clubbing, lymphadenopathy, and, in severe cases, cor pulmonale and right-sided heart failure.[102] The cardiac effects probably result from a response to impaired lung function and cor pulmonale rather than a direct effect of beryllium on the heart.

Diagnosis

The combination of adequate Be exposure and evidence of beryllium sensitization (positive beryllium lymphocyte proliferation test) combined with histopathological features of noncaseating granulomas define CBD; however, this pathognomonic histopathological lesion is indistinguishable from similar lesions seen in sarcoidosis. In contrast to sarcoid, ocular involvement, parotid disease, and acute reactive arthritis are absent in chronic beryllium disease. Table 5.4 outlines the diagnostic criteria for beryllium-induced diseases. The route of exposure primarily involves inhalation, although other routes (oral, resuspension from clothing) may contribute to sensitization.[103]

TABLE 5.4. Diagnostic criteria for beryllium-induced health effects. (Adapted from Maier).[100]

Diagnosis	Criteria	Tests	Abnormality
Beryllium sensitization	1. Beryllium sensitization	Blood BeLPT	Positive
	2. Histopathological evidence of CBD	Lung biopsy	None
Subclinical CBD	1. Beryllium sensitization	Blood BeLPT	Positive
	2. Histopathological evidence of CBD	Lung biopsy	Noncaseating granulomas, mononuclear cell infiltrate
	3. No respiratory symptoms or physiological abnormalities		
CBD	1. Beryllium sensitization	Blood BeLPT	Positive
	2. Histological evidence of CBD	Lung biopsy	Noncaseating granulomas, mononuclear cell infiltrate
	3. Clinical symptoms	History	Cough, dyspnea
	4. Physical abnormalities	Physical exam	Crackles
	5. Laboratory abnormalities	PFTs, exercise testing, ABG	Abnormal

Abbreviations: ABGs = arterial blood gases; BeLPT = beryllium lymphocyte proliferation test; CBD = chronic beryllium disease; PFTs = pulmonary function tests.

Carcinogenesis

The US Toxicology Program lists beryllium and beryllium compounds as known human carcinogens based on sufficient evidence of carcinogenicity from studies in humans. Several epidemiological studies of workers indicate a an increased risk (OR = 1.5–2) of lung cancer in workers exposed to beryllium.[104,105] A mortality study of 16,115 Be workers employed from 1925–2008 in seven facilities using soluble/mixed Be and eight facilities using insoluble Be compounds reported increased lung cancer mortality occurring predominantly in workers initially employed before 1955 in two soluble/mixed Be facilities (Lorain, Reading).[106] Be workers employed after 1955 or workers employed at any time in plants using only insoluble Be materials did not experience elevated lung cancer mortality rates.

A meta-analysis of six studies of US male Be workers employed in 1940–1969 and followed through 1988 demonstrated a mean SMR of 1.26 (range, 0.99–1.69) based on US national rates.[30] Interpretation of these studies is complicated by selection bias, confounding with other carcinogens (sulfur mists, cigarette smoking), limited exposure data, and accurate estimation of the expected number of lung cancer deaths. Some,[1] but not all,[107] reviews of these design flaws suggest that a significantly elevated risk of lung cancer probably does exist in cohorts of beryllium workers. A nested case control study of 142 lung cancer cases in beryllium workers associated cumulative, average, and maximum beryllium exposure with lung cancer after a 20-year lag.[108] The study did not adjust for birth year, and direct information on smoking was not available. Reanalysis of this study for the birth year (and presumably for the difference in smoking rates) demonstrated an association between average/maximum beryllium exposure and long-term cancer risk; cumulative beryllium exposure was not associated with a dose-related increase in the risk of lung cancer.[109] Information on smoking was incomplete in most of these studies; therefore, the data do not permit an evaluation of the effects of smoking and Be exposure. Data from the US Beryllium Case Registry suggest a 3-fold increased lung cancer mortality risk (95% CI: 1.0–6.2) for individuals with acute beryllium disease, but there was no statistically significant increased risk (95% CI: 0.1–3.7) in individuals with chronic beryllium disease.[110]

Following a review of beryllium carcinogenicity,[111] the IARC classified beryllium as a Group 1 compound (human carcinogen), in part because of the dose-related increased lung cancer incidence in a retrospective cohort mortality study among 9,225 male workers employed at 7 beryllium processing facilities for at least 2 days from 1940–1969[112] and a cohort mortality study on 689 patients from a case registry with beryllium disease.[113] In the former study, the standardized mortality ratio (SMR) for lung cancer in the total cohort was 1.26 (95% CI: 1.12–1.42), whereas the SMR for the latter study was 2.00 (95% CI: 1.33–2.89). Factors favoring the increased incidence of lung cancer in these cohorts included the following: 1) the highest risk occurred in plants with the highest rate of acute beryllium disease and individuals with acute beryllium disease; 2) workers hired before

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the 1950s had greater excess lung cancer risk and presumably the higher Be exposure; and 3) the consistent excess of lung cancer in most plant locations. The IARC noted several limitations of these studies including the low excess lung cancer risk, poor exposure data, and little adjustment of confounding variables (e.g., smoking); consequently, controversy remains regarding the interpretation of the results. Levy et al. recalculated the data from SMRs for lung cancer in the cohort study of 9,225 beryllium processing workers using city mortality rates rather than county or US rates along with a different indirect method for adjusting for smoking.[114] This reanalysis did not detect statistically significant increases in the incidence of lung cancer among beryllium workers. A subsequent pooled, cause-specific mortality study of 9,192 workers in 7 US Be processing plants demonstrated an increased standardized mortality ratio (SMR) for lung cancer of 1.17 (95% CI: 1.08–1.28). The standardized rate ratios (SRRs) for lung cancer were higher for higher quartiles of cumulative exposure lagged 10 years including the 2nd (1.56), 3rd (1.66), and 4th (1.97) quartiles. Reanalysis of this study indicated the lung cancer risk increased monotonically, but modestly, in the full cohort of three of these Be plants by tenure and most subgroups based on plant and date of hire; however, regression-based point-wise confidence bands did not clearly separate lung cancer risks for low- and high-Be exposure groups.[115] In animals, the development of lung tumors following exposure to beryllium is species-specific. Rats and monkeys are very susceptible, whereas rabbits, hamsters, and guinea pigs do not usually develop lung tumors.[1]

Reproductive Abnormalities

There are few human data on the reproductive and developmental effects of beryllium. Although animal data on these effects is limited, current data do not indicate that beryllium exposure at the current workplace or environmental concentrations causes adverse reproductive effects.

DIAGNOSTIC TESTING

SI Conversion Units

1 nmol/L = 9.012 mg: = 0.009 ng/mL
1 ng/L = 0.111 nmol/L
1 ng/g (blood) ≅ 1 ng/mL

Analytical Methods

Before the 1960s, analytical methods for the determination of Be in biological and environmental samples involved spectrometric, spectrophotometric, and fluorometric techniques. Subsequent use of gas chromatography/electron capture detection allows limits of detection (LOD) in the range of <1 ppb; however, the technique requires skilled technicians and the volatilization of Be to a derivative (e.g., trifluoroacetylacetone).[116] Current methods to measure airborne Be exposure analyze total mass per cubic meter of air by using size separation techniques and atomic absorption spectrometry; standard methods include both inductively coupled plasma/mass spectrometry (ICP/MS, NIOSH 7300 method) and graphite furnace atomic absorption spectrophotometry (GFAAS, NIOSH 7102 method). The limit of detections for these two techniques is 0.005 ppm and 0.03 ppm, respectively. Flame atomic absorption spectrometry and atomic emission spectrometry (AES) lack sufficient sensitivity to quantitate Be concentrations in biological media. High concentrations (500 mg/kg) of aluminum and silicon interfere with beryllium analysis by atomic absorption spectrometry; whereas high iron concentrations interfere with the 243.86 nm beryllium emission line used in ICP-AES.

Methods to evaluate the physiochemical properties of Be include Auger microscopy, scanning electron microscopy (SEM) coupled with X-ray energy-dispersive spectrometry (EDS), transmission electron microscopy (TEM) with EDS or electron energy loss spectroscopy (EELS), X-ray diffraction, and time-of-flight/secondary-ion mass spectrometry (TOF/SIMS) in positive mode. TEM is complementary to SEM as the former analyzes particles of <0.5 μm compared with ≥0.5 μm for the latter. In a study of dust collected by dry-grab sampling technique in four Quebec factories (aluminum smelter, magnesium processing, electrolyte processing, electrolytic pools treatment), only TOF/SIMS, ICP/MS, and GFAAS detected Be in the dust samples.[117] The advantage of TOF/SIMS was the determination of Be particle size distribution at low Be concentrations (<0.01%, range 58–146 ppm) and small particle size (mostly <10 μm).[118] These techniques did not determine the chemical speciation of the beryllium in the dust samples.

Biomarkers

Patients with CBD have an abnormal immune response to Be (lymphocyte proliferation test), and transbronchial biopsies demonstrate evidence of noncaseating granulomas or mononuclear cell interstitial infiltrate. The

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

diagnostic criteria for classic chronic beryllium disease (CBD) include the following: 1) documented exposure to beryllium; 2) consistent clinical and radiographic features; 3) presence of granulomas; 4) evidence of beryllium in tissues; and 5) hypersensitivity to beryllium.[119] The finding of beryllium in granulomas from tissue is diagnostic of chronic beryllium disease. Laser microprobe mass spectrographic analysis allows the detection of beryllium in standard histological sections of granulomas in tissue with light microscopy.[120] Although some studies suggest a difference in the serum concentration of proinflammatory cytokines (IFN-γ, IL-2, IL-6, TNF-α),[121] upregulation of *CD55* or downregulation of *CXCL9*, the evaluation of proinflammatory cytokines with existing technologies (e.g., SELDI-TOF using matrix-assisted laser desorption/ionization time-of-flight mass spectrometry) remains challenging to differentiate chronic beryllium disease, beryllium sensitization, and sarcoidosis.[122] Blood and urine Be concentrations are not currently used as biomarkers of Be exposure.

Blood

Lymphocyte Proliferation Test

The blood or bronchoalveolar lavage from a vast majority of patients with chronic beryllium disease (CBD) demonstrates *in vitro* lymphocyte sensitization when challenged with Be salts; however, some patients with evidence of hypersensitivity may have only subclinical disease.[123] A confirmed abnormal beryllium lymphocyte proliferation test (BeLPT) without evidence of lung disease is diagnostic of beryllium sensitivity, whereas the presence of granulomatous inflammatory response in the lungs with an abnormal BeLPT is diagnostic of chronic beryllium disease. The BeLPT documents the beryllium-specific blast transformation of lung lymphocytes obtained either through peripheral blood or through bronchoalveolar lavage. The sensitivity of a single abnormal BeLPT is relatively low (i.e., 66–88%) and increases with repeat testing.[124] However, the BeLPT is highly specific with low false-positive rates of 1–3% and higher false-negative rates (~30%) depending on the prevalence of beryllium sensitization in the population.[125] Final reports typically involve four options (normal, borderline, abnormal, uninterpretable). A single abnormal result usually should be confirmed with an additional test to establish beryllium sensitization. The demonstration of two abnormal or an abnormal plus a borderline BeLPT minimizes the risk of false-positive results. Uninterpretable or borderline results require repeat testing with subsequent actions (e.g., continued surveillance, referral for clinical evaluation) depending on the results and individual patient factors.[126] Options for inconsistent results in highly suspicious cases include transbronchial biopsies and bronchoalveolar lavage for BeLPT cells.

A substantial portion of workers with a positive BeLPT develop CBD (e.g., 6–8%/year), but studies on the exact rate are inconsistent. In a study of 55 Be-sensitized workers, 17 (31%) developed CBD over a mean of ~4 years (range, 1–9.5 years) of follow-up.[127] The progression rate to CBD was 6–8%/year. Overall, low methodological quality on studies of Be-sensitized workers limits conclusions regarding the exact percentage of BeLPT-positive workers who eventually develop the disease.[128] Additionally, data on the percentage of sensitized workers who develop the disease despite cessation of Be exposure are limited. The BeLPT does not efficiently separate CBD from Be sensitization or predict the progression from Be sensitization to CBD. A study of Beryllium BioBank participants suggests consideration of the intensity and total hours of Be exposure as well as the absolute BeLPT (i.e., rather than positive/negative based on cut points) may improve the predictive value of this test for the development of CBD.[129,130]

The beryllium lymphocyte proliferation test on blood samples (30–40 mL blood in heparinized tubes and shipped to the laboratory within 30–48 hours) is the method of choice for the medical screening of workers for beryllium sensitization. Laboratories with substantial experience for detecting beryllium sensitization include National Jewish Health (Denver, Colorado) and the Oak Ridge Institute for Science and Education the (Oak Ridge, Tennessee). The use of bronchoalveolar lavage fluid is a more sensitive and specific test medium for the diagnosis of Be hypersensitivity than peripheral blood based on studies correlating the degree of blast transformation with the severity of the clinical disease;[131] the presence of a positive beryllium lymphocyte proliferation test on lavage fluid indicates CBD.[18,132] Substantial variation in the sensitivity of the blood lymphocyte transformation test occurs between different laboratories.[133] Slightly positive blood tests may occur in healthy workers with Be exposure and sensitization, but the clinical course of these patients remains variable. Borderline BeLPT results are usually repeated with split samples sent to two different laboratories. Beryllium patch tests historically were an alternate method to diagnose CBD in patients with equivocal blood tests;[134] however, the Be patch test is usually not used currently because of concern about the development of Be sensitization in Be-naïve individuals.[89] Table 5.5 compares the differential features of chronic beryllium disease, sarcoidosis, and extrinsic allergic alveolitis. Poor

TABLE 5.5. Comparison of findings in chronic beryllium disease, sarcoidosis, and extrinsic allergic alveolitis. (Adapted from Jones Williams).[14]

Finding	Chronic Beryllium Disease	Sarcoidosis	Extrinsic Allergic Alveolitis
Occupational exposure	Yes	No	Yes
Beryllium in tissues	Yes	No	No
Erythema nodosum	No	Yes	No
Bilateral hilar adenopathy	Uncommon	Common	No
Bone cysts	No	3%	No
Skin tests			
Tuberculin	Negative	Negative	Unaltered
Kveim	Negative	Positive	Negative
Be lymphocyte transformation test	Positive	Negative	Negative
Circulating precipitins	No	No	Yes
↑ Serum angiotensin-converting enzyme	Not prominent	Common	Uncommon
Granulomas	Yes	Yes	Yes
Alveolitis	Prominent	Inconspicuous	Prominent
Prognosis	Poor	Good	Good

positive predictive value and ethical considerations limit the use of the HLA-DPB1E69 biomarker as a screening test.[135]

Beryllium Concentration

There are few data on blood beryllium concentrations. Typical background Be concentrations in blood are <1 ng/mL (ng/g). In a study of 10 subjects without known occupational exposure to beryllium, the mean serum Be concentration was 1.0 ± 0.4 ng/mL (ng/g) as measured by flameless atomic absorption spectrometry.[136] In a French study of 100 healthy adults, the 95% reference range for beryllium was below the limit of quantitation (0.10–0.14 µg/L) in whole blood and plasma samples as measured by ICP/MS.[137]

Urine

Background urinary beryllium concentrations in the general population is <1 ng/mL. In the Third National Health and Nutrition Examination Survey (NHANE-SIII) of the US population, most urine samples from >5,000 participants contained nondetectable beryllium concentrations (95% CI: <0.13 ng/mL).[138] Similarly, the beryllium concentration in urine samples from 100 healthy French volunteers was below the limit of quantitation (0.05 µg/L) in almost all subjects.[137] A study of 496 US residents without known exposure to beryllium detected urine Be concentrations in 67% of these residents with a mean Be concentration of 0.28 ng/mL (0.22 ng/g creatinine) and an upper 95% limit of 0.79 ng/mL (0.62 ng/g creatinine) as measured by inductively coupled argon plasma mass spectrometry and Zeeman graphite furnace atomic absorption spectrometry (LOD, 0.1 ng/mL).[139] In a study of 10 men without known occupational exposure to beryllium, the urine from smokers of nonfiltered cigarettes contained substantially higher serum Be concentrations (2 ng/mL) than the mean (0.9 ± 0.5 ng/mL) of all subjects as measured by flameless atomic absorption spectrometry.[136]

Abnormalities

Imaging

Beryllium is radiolucent. The classic radiographical feature of chronic beryllium disease is an interstitial disease (i.e., nonnecrotizing granulomas) consistent with a predominant upper lobe fibronodular process (small, round, and reticular opacities) and hilar adenopathy with radiographical abnormalities usually lagging behind the development of symptoms and physiological impairment.[140] Radiographical examinations typically reveal opacities in the lung following chronic Be exposure. There are three radiographical stages of chronic beryllium poisoning as follows: 1) fine diffuse granularity in the lungs; 2) diffuse reticular pattern; and 3) appearance of distinct nodules and honeycombing.[141] Other abnormalities include diffuse, bilateral reticular opacities, and honeycombing. The hilar adenopathy typically is mild, bilateral, and associated with parenchymal changes (linear scars).[142] Typically, the hilar adenopathy

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

is less prominent in CBD than sarcoidosis.[143] Radiographical imaging of the chest is similar in CBD and sarcoidosis.

Pulmonary Physiology

Pulmonary function testing is not a reliable screening test for CBD. Although most epidemiological studies of beryllium workers have not demonstrated decrements in pulmonary function,[4,81,141] a recent cross-sectional study found small decrements in pulmonary function after long-term Be exposure. In this study, a cumulative exposure of 100 μg Be/m^3/year (i.e., 50-year exposure to the current TLV–TWA of 2 μg Be/m^3) was associated with a decrease of 220 mL in the FVC and 150 mL in the FEV_1.[144]

A variety of patterns of pulmonary function abnormalities occur in workers with CBD including obstructive, restrictive, or mixed defects with slowly declining gas exchange (i.e., reduced CO diffusing capacity, DL_{CO}) and a mild obstructive pattern being the most common physiological abnormality in current workers. A study of 41 workers with CBD revealed the following three patterns: 1) restrictive defect (20%); 2) obstructive defect (39%); and 3) isolated reduction of carbon monoxide diffusing capacity (36%).[145] Characteristic changes in advanced disease are a restrictive disease with reduced vital capacity, decreased total lung volume, and a reduction in the DL_{CO}. CBD may be subclinical with normal pulmonary function tests;[146] however, cardiopulmonary exercise testing may reveal abnormalities in early disease when static physiological values are normal.[147]

Direct arterial blood gas measurements during exercise testing may help distinguish between CBD and beryllium sensitization, but the interpretation of pulse oximetry during testing is more complicated because indirect measures of oxygen saturation misclassify some patients. Exercise tolerance testing is the most sensitive indicator of physiological impairment in patients with CBD, particularly exercise capacity.[146] Other abnormalities include elevated dead space to tidal volume ratio (V_d/V_t), low resting PaO_2, low diffusing capacity, and increase in the arterial-alveolar (A-a) gradient at maximum exercise. Abnormalities on bronchoalveolar lavage (BAL) include leukocytosis, lymphocytosis, and an abnormal lymphocyte proliferation test.

Blood

The Kveim test is consistently negative in patients with CBD, but the high false-negative rate of this test in sarcoidosis limits the ability of this test alone to differentiate between sarcoidosis and chronic beryllium disease (CBD). Occasionally, hypercalcemia develops and the appearance of renal stones is common in workers with CBD.[1] In patients with chronic beryllium disease, there are no direct effects on typical blood parameters (white blood cell counts, hematocrit, differential white blood cell percentages) or serum chemistry panels including hepatorenal function.[48,148]

HEALTH SURVEILLANCE

Risk Assessment

The estimated tolerable concentration for the non-cancer health effects of Be is 0.02 μg/m^3 based on the LOAEL for chronic beryllium disease in exposed workers using a total uncertainty factor of 10.[15,30] The inhalation unit risk of 2.4×10^{-3} was derived for Be based on the risk of lung cancer in exposed workers. However, the data were limited by the small increases in lung cancer risks, incomplete smoking histories, lack of control of other potential carcinogens, and limited Be exposure data.[30] The risk of developing chronic beryllium disease is relatively low despite long-term exposure based on cross-sectional studies. In a cross-sectional study of 50 Be sensitized workers from a cohort of 1,875 current/former nuclear weapons research and development facility workers undergoing Be sensitivity testing, the mean duration of employment was ~18 years.[149] Five of the workers had CBD (0.3% of the total cohort), and three had the probable disease. None of these workers had severe diseases. The mean latency from the first possible Be exposure to evaluation was 32 years. Three workers had definite CBD and 2 had probable CBD of 11 sensitized workers in the low Be exposure group, whereas 2 sensitized workers had definite CBD and 1 worker had probable CBD in the moderate Be exposure group of 28 sensitized workers. None of the sensitized workers in the high Be exposure group of nine workers had evidence of CBD. A study of 5,436 US beryllium workers using best-fitting power and categorical models with mean daily weighted average (DWA) beryllium exposure based on job exposure matrices suggested a statistically significant excess lifetime risk of lung cancer following DWA beryllium exposure of 4 μg/m^3.[150] In general, the risk of beryllium sensitization and CBD is substantially less in beryllium mine and ore extraction workers compared with workers exposed to beryllium oxide particles; the occurrence of CBD in workers solely exposed to beryllium at the former facilities is extremely rare.[21,151]

Environmental Monitoring

Table 5.6 lists the standards and regulations for beryllium in the United States. The machining operations involving beryllium alloys produce irregularly shaped particles. A study of these processes demonstrated that the mass median sieve diameters of particles produced by sawing beryllium metal, the beryllium-nickel, and beryllium-copper alloys were 130 μm, 230 μm, and 300 μm, respectively.[152] With the use of high velocity, low volume exhaust systems, and special ventilation shrouds, the ambient air Be concentration was <0.07 μg/m^3; the Be air concentration in the shrouds was <2 μg/m^3. The current Be standards require maintenance of a beryllium work area, respiratory protection (powered air-purifying respirator), protective clothing, and equipment to reduce dermal exposure.[153] The previous standard for beryllium emissions remains unchanged.

The ATSDR recommends a chronic-duration oral minimal risk level (MRL) for Be of 2 μg/kg/day based on benchmark analysis of a chronic dog feeding study involving the administration of beryllium sulfate in the diet to 5 male and 5 female dogs for 143–172 weeks.[154] At Be doses of 12 mg/kg/day (males) and 17 mg/kg/day (females), ulcerative lesions in the small intestine occurred in 9 of 10 dogs, whereas only 1 dog developed similar lesions at 1 mg/kg/day. There were no observable gastrointestinal effects at lower doses. The ATSDR did not recommend a MRL for inhalation because of inadequate data and the lack of animal studies with a reliable no-observed-adverse-effect level (NOAEL) for respiratory effects.

TABLE 5.6. Regulatory and guidelines for beryllium exposure.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	0.2 μg/m^3
Action level	0.1 μg/m^3
STEL–TWA (15-minute)	2 μg/m^3
NIOSH	
REL–TWA (10-hour)	<0.5 μg/m^3
IDLH	4,000 μg/m^3[a,b]
ACGIH	
TLV–TWA (8-hour)	2 μg/m^3
STEL–TWA (15-minute)	10 μg/m^3
US FDA	
Bottled water allowable limit	4 μg/L
US EPA	
RfC (chronic inhalation exposure)	0.02 μg/m^3
RfD (chronic oral exposure)	2 μg/kg/day
EPA carcinogenic unit risk (daily)	4.3 mg/kg (oral)
	2.4×10^{-3} mg/kg (inhalation)
MCL (US Federal drinking water guidelines)	4 μg/L
ATSDR	
MRL (chronic oral)	2 μg/kg/day
MRL (chronic inhalation)	No recommendation

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; MCL = maximum contaminate level; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfC = reference concentration; RfD = reference dose; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency; US FDA = US Food and Drug Administration; WHO = World Health Organization.

[a] As a carcinogen, NIOSH recommends reducing exposure to the lowest concentration feasible; [b] Values are based on the NIOSH Documentation for Immediately Dangerous to Life or Health Concentrations (IDLHs) (1994). As a recognized human carcinogen, the current recommendation is to reduce the concentration to the lowest feasible.

Biological Monitoring

Although the risk of acute beryllium pneumonitis is dose-related, the latency, onset, severity, and progression of chronic beryllium disease (CBD) are highly variable and poorly related to exposure because the disease results from a Type IV hypersensitivity reaction.[155] The immune-mediated etiology of CBD complicates the interpretation of Be concentrations in blood and urine. The detection of beryllium in blood or urine indicates beryllium exposure; however, Be concentrations in biological samples do not correlate well to the total body burden of beryllium or CBD. The blood and urine from patients with CBD may not contain detectable Be concentrations.[156] There are limited data on the use of blood and urine beryllium concentrations as measures of beryllium exposure. Beryllium concentrations in blood and urine of individuals exposed to beryllium range from nondetectable to 3 μg/L.[157,158] In a study of 65 metallurgical workers in steel and copper alloy plants exposed to relatively low ambient air Be concentrations (median = 0.03–0.31 μg/m^3), the urinary Be concentration ranged from <0.03 (LOD)–0.54 μg/L.[159] For workers in the copper alloy plants with median ambient air concentrations of ~0.3 μg Be/m^3, the median urinary Be concentration ranged from 0.2–0.4 μg/L compared with Be concentrations of <0.03 μg/L (LOD) in urine samples from the control group (assembly workers). Based on regression analysis of air and urine samples, inhalable Be dust concentrations of 0.2 μg/m^3 correlated to urine Be concentrations of 0.12–0.15 μg/L.

Medical Screening

The Occupational Safety and Health Administration released an updated final ruling on allowable beryllium exposure and increased requirements for worker screening in 2017 with implementation beginning in 2019 as displayed in Table 5.7.[153] This ruling expanded the beryllium requirements to shipyard and construction industries as well as increasing worker screening requirements.[160] Current final US OSHA rules require repeat Be exposure monitoring within 6 months for Be exposure of $\geq 0.1\,\mu g/m^3$ (action level) and within 3 months if the exposure exceeds the TWA PEL ($0.2\,\mu g/m^3$) or STEL ($2\,\mu g/m^3$).

Preemployment physical examination should include pulmonary function tests, chest X-ray, and a careful history of previous respiratory disease and allergies. However, there is no definite evidence that workers with preexisting diseases are at greater risk of developing CBD.[161] As a screening test for the detection of CBD, the beryllium lymphocyte proliferation test is more sensitive and specific than a chest X-ray, spirometry, or clinical examination.[18] The BeLPT identifies >70% of cases of CBD. Sensitization may occur within a few months of beginning employment in a beryllium machining plant.[162] US OSHA rules require medical examination every 2 years or when exposure exceeds the action level for 30 days/year.

A positive BeLPT requires a repeat test for confirmation. Two positive tests imply sensitization to beryllium, and these workers need further evaluation for the presence chronic beryllium disease (PFTs, chest X-ray, consideration for bronchoalveolar lavage and biopsy). Workers who develop positive LPT probably require removal from further Be exposure. Cohort and case-control studies of beryllium workers with beryllium sensitization and CBD indicate an association between these effects and *HLA-DPB1 E69*.[163] This *HLA-DPB1 E69* genotype encodes a glutamic acid at position 69. HLA markers may regulate the development of sensitization or disease, but the specific alleles (HLA-DPB1 E69, HLA-DRB1 S11) and mechanisms for their effects require further elucidation. Currently, there are inadequate data to use genetic markers (e.g., Glu69) as screening tests for beryllium-related health effects.[143]

TABLE 5.7. Occupational Safety and Health Administration (OSHA) 2017 final ruling for beryllium exposure. (Based on Occupational Safety and Health Administration (OSHA)).[153]

Requirements	Updated Ruling
Industries using beryllium in the workplace	Adds construction and shipyards.
Personal protective equipment	Appropriate protection of skin, eyes, and lungs (negative pressure/powered air-purifying respirators).
Screening requirements	Exposure to $0.1\,\mu g\ Be/m^3$ for >30 days/year.
Screening frequency	Every 2 years or sooner.

TREATMENT

Pulmonary

The first goal of management is the cessation of beryllium exposure. Workers with positive responses to the lymphocyte transformation test may require removal from any environment that contains beryllium. For patients with CBD, corticosteroids are the primary modality of treatment; however, there are no well-controlled clinical trials to determine how the administration of steroids changes the natural history of chronic beryllium disease. Because lifetime treatment with steroids is usually required to provide symptomatic relief and improve lung function, the desirable dose is the lowest effective dose (e.g., alternate daily dose of 20–40 mg prednisone) with dose reductions considered every 2–3 years using PFTs as measures of relapse. Short-term high-dose (60–80 mg prednisone/day) therapy may be necessary. After clinical improvement, the corticosteroid dose may be tapered as tolerated. Clinical improvement usually occurs within 2–3 months of the initiation of steroid treatment.[164] These patients should be monitored closely for the development of opportunistic respiratory infections (e.g., aspergilloma)[165] and right-sided heart failure. Inhaled steroids may be administered early in the disease course with short-acting bronchodilators if needed for symptomatic improvement. Few data are available on the use of methotrexate or newer immunosuppressive therapies (e.g., infliximab)[166] to reduce steroid side effects.

Patients with acute beryllium disease are also treated with high-dose steroid therapy. Controlled clinical trials of steroid treatment in CBD are not available to guide the duration of treatment. Some patients develop prolonged remission after steroid treatment, whereas other patients continue to deteriorate. Methotrexate and other anti-inflammatory agents (azathioprine, cyclophosphamide, mycophenolate, infliximab) are alternative treatments for patients that develop serious adverse reactions or do not respond to steroid treatment with dosages similar to the treatment of sarcoidosis.

General treatment is similar to that for other patients with end-stage lung disease including cessation of smoking and yearly immunizations with pneumococcus and influenza vaccines. There are few clinical data on the use of chelating agents in the treatment of beryllium toxicity. Consequently, there are inadequate data to recommend the use of chelating agents for beryllium toxicity. 1,2-Dihydroxybenzene-3,5-disulfonic acid (Tiron) and calcium disodium EDTA are potential chelating agents based on experimental studies in rodents.[167] There are no data on the use of tumor necrosis factor inhibitors in patients with CBD.

Skin

Wounds contaminated with beryllium should be irrigated copiously and thoroughly debrided. These wounds should be followed closely for the development of delayed healing, chronic ulcerations, and the formation of granulomas. Complete excision is necessary for chronic skin lesions that result from the entrapment of beryllium in the skin. Acute cutaneous eruptions from Be exposure should be treated with soaks or compresses, topical corticosteroids, and the avoidance of further direct contact with beryllium.

Chapter 6

BISMUTH

HISTORY

Both inorganic and organic bismuth have a long tradition of medicinal use. At the beginning of this century until the antibiotic era started, bismuth tartrate and bismuth salicylate in oil were used to treat syphilis, either alone or in combination with organic arsenic compounds. Occasionally, osteoporosis and/or osteomalacia developed in the pelvis, femur, and vertebrae of patients treated with these bismuth compounds. Briefly, in the 1930s, bismuth subnitrate was administered for hypertension and diuresis.[1] An acute, usually reversible, renal failure developed following the oral or intramuscular administration of bismuth triglycollamate and bismuth thioglycollate for stomatitis, upper respiratory tract infections, and warts.[2,3] The use of inorganic bismuth preparations continues for a variety of gastrointestinal complaints (subcarbonate, subgallate, subsalicylate, subnitrate, tartrate), hemorrhoidal irritation (subgallate, resorcinol), and minor skin irritation (subgallate, formic iodide, subnitrate).

In the early 1970s, the first cases of bismuth encephalopathy (confusion, ataxia, myoclonus, psychiatric symptoms) occurred in an Australian patient receiving bismuth subgallate as an ileostomy deodorant.[4] Over the next 5 years, in France and surrounding countries (Austria, Belgium, West Germany), an epidemic of >900 encephalopathies was reported in patients receiving high cumulative, annual doses (i.e., 20 g bismuth over 0.25–20 years) of relatively water-insoluble, lipophilic bismuth salts including bismuth subgallate and bismuth subnitrate.[5,6,7] Most patients recovered fully following the cessation of bismuth therapy. Although the exact source and etiology of this epidemic were never identified, bismuth salts (e.g., subgallate) were withdrawn from several countries. Later cases of bismuth encephalopathy occurred in Turkey and South Africa.[8] Despite higher overall per capita consumption of the same bismuth salts, bismuth encephalopathy was rarely associated with these bismuth salts in the United States.[9] Currently, the administration of bismuth preparations is increasing as a result of the recognition that the use of colloidal bismuth subcitrate and subnitrate promotes the healing of gastroduodenal ulcers and chronic gastritis, in part by antibacterial activity against *Helicobacter pylori*.[10]

PHYSIOCHEMICAL PROPERTIES

Bismuth (CAS RN: 7440-69-9) is a brittle heavy metal (atomic weight, 208.98 g/mol) that belongs to Group 15 (Group Va) of the periodic table along with arsenic and antimony. Bismuth appears as a pinkish-white crystalline structure that possesses high electrical resistance and the lowest thermal conductivity of all metals except mercury. The density of bismuth is 9.7 g/cm^3 with a melting point of 271.3°C. Of the two naturally existing valences (+3, +5), the trivalent form is the most abundant and chemically stable. Most inorganic salts of bismuth are poorly soluble in water, but their solubility increases in the presence of substances (citrate, tartrate, sorbitol) that reduce pH. The composition of most bismuth salts is complex with these compounds appearing as mixtures of salts both in lightly and heavily hydrated forms.[11] Although the exact structure requires further

elucidation, colloidal bismuth subcitrate probably forms a solution containing particles of bismuth, citrate, oxychloride, and hydroxyl group depending on pH.[12]

EXPOSURE

Uses

Commercial

Most bismuth consumed in the United States appears in low-melting alloys and metallurgical additives used in electronic and thermoelectric applications.[13] Bismuth is also a catalyst, an industrial chemical, a pigment in cosmetics, and a substitute for lead in shotgun pellets. Potential nanotechnological uses of Bi include super-structured nanonetworks of BiOCl and nested nanonetworks of Bi_2S_3 as components of electronic devices, sensors, filters, and photocatalysts.[14]

Medicinal

Bismuth is available in a variety of over-the-counter medications for the treatment of indigestion/diarrhea (subsalicylate, subgallate, subcarbonate), hemorrhoids (subcarbonate, subgallate, resorcinol), minor skin irritation (subgallate, formic iodide, subnitrate), and diaper rash. Another indication is the use of colloidal bismuth subcitrate (De-Nol™, bismuth tripotassium dicitrate or tripotassium dicitrate bismuthate) in the treatment of gastric and duodenal ulcers caused by *H. pylori*. Colloidal bismuth subcitrate is a soluble, complex salt of citric acid that precipitates at pH <5. This bismuth preparation inhibits the digestion of protective gastric mucosa, bioactive proteins, epidermal growth factor-induduced proteolysis, and the proliferation of *H. pylori*.[15] Bismuth subsalicylate is an effective agent for the treatment of travelers' diarrhea and dyspepsia. Bismuth iodoform paraffin paste is a wound-packing and hemostatic agent that reduces wound colonization and promotes granulation tissue formation.

Production Processes

Bismuth in ores exists primarily as bismite (bismuth oxide) and bismuthite (bismuth sulfide); these minerals commonly occur in association with tin oxide, lead sulfide, and copper sulfide ores. The most common process for the production of bismuth is pyro-metallurgic separation during lead and copper refining.

Sources

Data on the presence of bismuth in the environment are limited. The daily intake of bismuth from water and food is ~20 µg, whereas the daily inhalation of bismuth is small (<0.01–0.76 µg) as a result of low Bi concentrations in ambient air (i.e., urban air, <0.07 µg/m^3; rural air, <0.001 µg/m^3).[16] Bismuth concentrations in soil average ~1 mg Bi/kg, whereas the bismuth concentration in rocks ranges from 0.1–0.3 mg Bi/kg (ppm) in sandstone.[13] The total Bi concentration in four seawater samples near the San Diego coastline ranged from 0.13–2.0 ng/L as measured by hydride generation/atomic absorption spectrophotometry.[17] The mean total Bi concentration in 164 dissolved river water samples from a summary of 4 Japanese studies was 12.7 ± 43.4 ng/L compared with 28.1 ± 103.2 ng/L in 162 particulate samples from the same area, as measured by inductively coupled plasma/mass spectrometry (ICP/MS).[18] For 24 dissolved and 23 particulate lake water samples, the mean bismuth concentrations were 17.7 ± 82.0 ng/L and 52.7 ± 167.9 ng/L, respectively. The mean bismuth concentrations in 29 dissolved and 23 particulate water samples from coastal seawater were 24.0 ± 34.4 ng/L and 12.1 ± 9.1 ng/L, respectively.

ENVIRONMENTAL FATE

Few data are available on the transportation and distribution of bismuth in the environment. Currently, there is little evidence that bismuth is present in the environment at concentrations that produce toxicity.

DOSE EFFECT

Pharmaceutical Preparations

Most over-the-counter bismuth medications contain 1–2% bismuth. Bismuth subsalicylate (Pepto-Bismol) yields 200 mg Bi/30 mL (1.75% solution), and salicylate intoxication is more likely to develop following an acute overdose of bismuth subsalicylate than bismuth intoxication.[19] One De-Nol (colloidal bismuth subcitrate) tablet contains about 108 mg bismuth. Because most bismuth compounds are poorly absorbed from the gastrointestinal tract, most toxicity results from the chronic ingestion of these compounds. No clinically significant changes in the spectral analysis of the electroencephalogram or nerve conduction studies were detected in 66 patients receiving either colloidal bismuth subcitrate (n = 22; 480 mg/day) or bismuth subnitrate (n = 20;

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

1.8 g/day) for 2 months, when compared with controls ($n = 24$) receiving ampicillin.[20]

Overdose

A 19-year-old recovered from the ingestion of 21 tablets of bismuth triglycollamate (1.5 g bismuth) after a period of renal insufficiency.[3] Renal failure and neuropathy developed after the single ingestion of 11–12 g bismuth (100 De-Nol tablets), but there was no evidence of an encephalopathy; recovery occurred within 2 weeks of ingestion.[21] A 68-year-old man with poor renal function ingested 864 mg bismuth daily for 2 months; he developed mental status changes with hallucinations and ataxia that resolved within 4 months of the cessation of bismuth therapy.[22]

TOXICOKINETICS

Absorption

Although bismuth absorption from the gastrointestinal tract is poor (<0.33%) for most insoluble salts (e.g., nitrate),[23] substantial interindividual and intraindividual variation occurs, probably as a result of differences in factors affecting absorption including gastric emptying, stomach pH, and dissolution rate of tablets.[24] Animal studies suggest that absorption of bismuth occurs in the duodenum.[25] Human data on absorption are limited. Rapid peak plasma bismuth concentrations occur after the ingestion of single oral doses of colloidal bismuth subcitrate (bismuth tripotassium dicitrate, De-Noltab). In a study of 16 healthy adults ingesting 2 De-Noltab (216 mg Bi), median peak bismuth concentration occurred 30 minutes (range, 15–105 minutes) after ingestion; the peak plasma bismuth concentration was >50 μg/L in 14 subjects and >100 μg/L in 9 subjects.[26] The median steady-state bismuth concentration following the ingestion of 4 bismuth tripotassium dicitrate tablets (108 mg Bi/tablet) daily for 6 weeks in plasma samples from 9 patients was 17 μg/L.[27]

The peak plasma Bi concentration is lower after the ingestion of bismuth subsalicylate or bismuth subnitrate than colloidal bismuth subcitrate.[28] In an experimental study of 10 healthy, fasting volunteers, the peak plasma Bi concentration was 1.7 μg/L (range, 0.8–5.3 μg/L) 4 hours after the ingestion of three 30-mL doses of bismuth subsalicylate.[29] Following multiple bismuth subcitrate doses, steady-state plasma Bi concentrations occur after ~4 weeks with plasma Bi concentrations rarely exceeding 50 μg/L.[30] In a study of healthy adults receiving multiple doses of bismuth tripotassium dicitrate, the mean steady-state plasma Bi concentration occurred 18 days (range, 7–29 days) after beginning Bi treatment with mean peak Bi concentration of 38.3 μg/L (range, 7.6–58.3 μg/L).[31] Rodent studies suggest that bismuth in shotgun pellets implanted intraperitoneally is absorbed and distributed throughout the body; the clinical effects of retained bismuth bullets remain unclear.[32,33]

Distribution

In the blood, relatively large amounts of bismuth appear in erythrocytes. The highest concentrations of bismuth occur in the kidney, regardless of the route of administration or the type of salt.[11] An autopsy study of 22 patients given intramuscular injections mostly of bismuth salicylate during the 1930s revealed the following median values in mg/kg (ppm): kidney, 33.3; liver, 6.8; spleen, 1.6; colon, 1.3; lung, 0.9; brain, 0.6; and blood, 0.5.[34] In French patients dying of bismuth encephalopathy, the highest Bi concentrations appeared in the thalamus and cerebellar cortex; the Bi concentration was twice as high in the gray matter as white matter.[35]

Elimination

Bismuth elimination occurs primarily in the urine and, to a lesser extent, in the feces with the Bi concentration 10 times higher in bile than plasma. The exact contribution of renal excretion and biliary secretion of bismuth remains undetermined; the contribution of each route probably depends on the salt and the dose. Bismuth continues to accumulate for up to several months during chronic dosing with bismuth subcitrate. In a study of healthy volunteers, the mean plasma Bi elimination half-life changed from 18 hours after a single Bi dose to 13–22 days (mean = 20.7 days) after up to 4 weeks of multiple colloidal bismuth subcitrate doses.[31] Consequently, a washout period of 8 weeks is recommended between multiple courses of bismuth subcitrate therapy. The International Commission on Radiological Protection (ICRP) recommended the following biological half-lives for bismuth in the body: whole body, 5 days; liver, 15 days; bone, 13.3 days; spleen, 10 days; and kidney, 6 days.[36] In a study of nine patients receiving daily bismuth tripotassium dicitrate for 6 weeks, elevation of urine bismuth concentrations over baseline 12 weeks after cessation of treatment suggested the accumulation of this bismuth dose.[27]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Bismuth is not an essential element for mammals. In general, heavy metals (e.g., bismuth) form strong covalent bonds with sulfhydryl groups on proteins, resulting in the inhibition of vital enzymes. In animal models, bismuth alters the metabolism of certain heavy metals (copper, zinc) and induces the formation of low-molecular-weight metallothionein-like proteins, particularly in the kidney.[37] Animal studies indicate that bismuth produces conformational changes in the membranes of mitochondria in the liver and the proximal tubule of the kidney; these changes occur along with impairment of enzyme activity in these membranes.[38] The etiology and mechanism of toxicity of the encephalopathy that occurred in France following the consumption of bismuth have never been firmly established.

Chronic ingestion of bismuth subsalicylate may produce black pigmentation of the tongue.[39] This compound reacts with hydrogen sulfide produced by anaerobic bacteria in the mouth to form bismuth sulfide. The latter chemical is an insoluble black bismuth salt that discolors the tongue. In contrast to the black, hairy tongue, the acquired pigmentation is not associated with enlargement of the filiform papillae of the tongue.

Pathological Changes

Following an overdose of bismuth subcitrate, a dose-dependent change occurs in the renal tubular epithelial cells of the kidney, beginning with vacuolation and eventually producing necrosis. These renal changes are associated with proximal renal tubular dysfunction (glucosuria, aminoaciduria, phosphaturia); the changes are usually reversible. Intranuclear inclusion bodies are often present in the renal tubular epithelium during autopsies of patients treated with intravenous bismuth for syphilis; these lesions are usually strongly Schiff-positive when stained by PAS and a hematoxylin counterstain.[40] Typically, the inclusion bodies are spherical, hyaline, refractile bodies with a brown tinge, appearing more often in the nuclei than the cytoplasm. Although some studies do not suggest these inclusion bodies are bismuth,[41] animal studies with x-ray microanalysis indicate the presence of bismuth.[42]

There are no pathological changes in the brain or in the kidney that are specific to bismuth toxicity. Postmortem examinations of patients with suspected bismuth-associated encephalopathy demonstrate bismuth accumulation in neurons and glial cells in various parts of the brain (e.g., cerebellum, neocortex, thalamus), particularly in the vascularity of the cerebellum as measured by silver enhancement of bismuth crystallites by autometallography.[43] Gliosis and neuronal loss are usually not present. Electron microscopy demonstrates the presence of bismuth in the vascular basement membranes and lysosomes. Postmortem examination of a 20-year-old woman with bismuth encephalopathy demonstrated nonspecific anoxic lesions (Ammon's horn, cortex, basal ganglia) along with widespread loss of Purkinje cells in the cerebellum; she died after 5 weeks in the hospital from septicemia.[44] The case report did not describe the course of her oxygenation; the thalamus, hypothalamus, subthalamus, and white matter were unremarkable. Autopsies of three patients dying from Bi-associated encephalopathy demonstrated the highest Bi concentrations in the frontal and occipital cortex, thalamus, and cerebellum; Bi concentrations ranged up to 25 μg/g compared with 0.01 μg/g in controls.[35]

CLINICAL RESPONSE

Most examples of bismuth toxicity result from chronic therapeutic use of soluble bismuth compounds. Some bismuth compounds are associated with reversible myoclonus and encephalopathy that require 2–10 weeks to resolve spontaneously.[45] Chronic bismuth ingestion results in stomatitis, black spots in the mucosa and gums (bismuth lines), black pigmentation of the tongue (bismuth subsalicylate), salivation, and pathological fractures.[5]

Medical Therapy

Encephalopathy

Over 1,000 cases of myoclonic, subacute progressive encephalopathy in patients on prolonged courses of bismuth therapy were reported in France in the 1970s, along with isolated cases in Australia,[46] Belgium, Switzerland, Spain, and Germany. The major clinical features included a prolonged prodromal phase characterized by impairment of gait and writing, deterioration of antegrade and retrograde memory, inattentiveness, insomnia, and behavioral changes followed by the subacute development of confusion, dysarthria, ataxic gait, difficulty standing, apraxia, and myoclonus over 24–48 hours. Table 6.1 lists the frequency of signs and symptoms in 698 patients with bismuth encephalopathy. Most patients recovered within 2–6 weeks of cessation

TABLE 6.1. Clinical features in 698 patients with bismuth encephalopathy. (Adapted from Slikkerveer).[11]

Category	Clinical Feature	Percentage of Total Patients
Neurological		
	Myoclonus	80
	Trembling	59
	Memory Disturbances	56
	Writing Disturbances	53
	Dysarthria	52
	Inability to Walk	38
	Unsteady Gait	36
	Insomnia	35
	Sphincter Troubles	30
	Status Epilepticus	28
	Somnolence	25
	Headache	25
	Motor Deficit	20
	Gait Disturbance	20
	Coma	13
	Diplopia	5
Neuropsychiatric		
	Confusion	79
	Poor Concentration	60
	Thought Abnormalities	58
	Mental Disturbance	36
	Excitation	35
	Depression	32
	Anxiety	27
	Hallucination	17
	Delirium	16
Other		
	Shoulder Stiffness	8
	Renal Impairment	5
	Osteonecrosis of Humeral Head	3
	Bismuth Gum Lines	0.3

of bismuth therapy. Some neuropsychological symptoms (affective disorder, reduced cognition, insomnia, tremor) persisted in the most severely affected patients.[5] Case reports associated the chronic use of bismuth nitrate with panic attacks and a major depressive disorder,[47] whereas the prolonged use of colloidal bismuth subcitrate (bismuth tripotassium dicitrate) was linked to the development of neurotic symptoms.[48] However, a definite causal relationship between bismuth compounds and neuropsychiatric symptoms was not clearly established.

Nephropathy

The chronic use of bismuth triglycollamate, bismuth diallyacetate, and bismuth thioglycollamate previously has been associated with reversible impairment of the proximal tubules of the kidney that occasionally leads to renal failure. An 8-year-old girl developed nausea, vomiting, malaise, low-grade fever, and anuria after ingesting an unconfirmed amount of bismuth sodium triglycollamate given to her by her sister; the estimated amount was 18 g (plasma bismuth = 300 μg/L 1 week after admission).[49] The patient recovered after ~1 week of hemodialysis. Renal function and development remained normal at follow-up examination 3 years after the incident. A 16-year-old adolescent girl developed renal failure (serum creatinine = 19.9 mg/dL) 10 days after ingesting 18 g of colloidal bismuth subcitrate; the serum bismuth concentration was 495 μg/L on admission.[50] Normal renal function returned 9 weeks after admission.

Osteoarthropathy

Demineralization and osteonecrosis are reported complications in patients receiving high Bi doses parenterally for syphilis and orally for gastrointestinal symptoms; these complications are usually but not always associated with encephalopathy.[51] These bone lesions occurred primarily in the humeral head, thoracic vertebrae, and, less commonly, the femoral head.[11,52] Typically, these bony lesions occur in patients with severe bismuth-induced myoclonic jerks and encephalopathy. In a case series of 59 cases of bismuth-associated encephalopathy reported in the 1970s, eight women had boney lesions confined to the humeral head and thoracic vertebrae including 6 fractures of the humeral neck and three compression fractures of the thoracic spine.[5] All these patients had serum Bi concentrations exceeding 1,500 μg/L.

Acute Oral Toxicity

Several case reports associated the development of acute renal failure with large, intentional ingestions of colloidal bismuth subcitrate.[21,53] A 17-year-old girl presented to the emergency department with nausea, vomiting, and acute tubular necrosis with anuria 7 days after intentionally ingesting 7.5 g bismuth subcitrate (300 mg Bi).[54] She required hemodialysis for ~1 week. A 22-year-old woman developed Fanconi's syndrome and acute renal failure after the intentional ingestion of 5.4 g of colloidal bismuth subcitrate; she was anuric 3 days after ingestion, requiring 2 weeks of hemodialysis.[55] Within 6 weeks, her renal function was normal. A 2-year-old boy developed renal dysfunction and oliguria 2 days after the ingestion of 28 De-Nol tablets (colloidal bismuth subcitrate 8.4 g).[56] He received 10

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. days of peritoneal dialysis with the return of normal renal function 3 weeks after ingestion. Encephalopathy occurred in none of these patients.

Environmental Exposure

In general, bismuth exposures from the environment are relatively low with little evidence of toxicity from these sources.

Occupational Exposure

Bismuth toxicity in the workplace is not well documented. Even though exposure to bismuth in the work environment occurs commonly, there is little evidence of toxicity resulting from bismuth exposure in industry.[57]

Reproductive Abnormalities

Although human and animal data are limited, there is no current evidence to indicate that Bi is a reproductive toxin at concentrations normally present in the environment or during medical treatment with Bi compounds. In a case series of 45 patients with Bi-associated encephalopathy, three women were pregnant and delivered normal neonates.[58] Presumably, the fetus was exposed to high Bi concentrations throughout pregnancy; the estimated Bi concentration in cord blood from one neonate was 250 μg/L.

Carcinogenesis

Although data are limited, there is no evidence that bismuth compounds are carcinogenic in animals or humans. Neither the IARC nor the US National Toxicology Program list bismuth or bismuth compounds as suspected carcinogens.

DIAGNOSTIC TESTING

SI Conversion Units

1 μM = 208.98 μg/L

1 μg = 0.00478 μmol

Analytical Methods

The current method of choice for the determination of bismuth concentrations in biological samples includes inductively coupled plasma/mass spectrometry (LOD, 0.007 μg/L; RSD 5–14%),[59] electrothermal atomic absorption spectrophotometry (ET/AAS), inductively coupled argon plasma/atomic emission spectrometry (LOD, 0.04 μg/L, RSD, <6%),[60] and atomic absorption spectrophotometry with hydride generation (HG/AAS; LOD, 0.225 μg/L).[61] Interpretation of Bi concentrations using ET/AAS is complicated by the volatility of Bi at temperatures necessary to remove the matrix. The use of electrothermal/atomic absorption spectrometry with platinum as a matrix modifier to decrease Bi volatility allows a limit of detection of 25 ng/g wet weight.[62] In a study of trace elements in urine, temperature (frozen, refrigerated, room temperature) and chemical additives (dilute hydrochloric acid, nitric acid, boric acid, potassium pyrosulfate) did not significantly change the bismuth concentrations when stored over 65 days as measured by inductively coupled plasma/mass spectrometry.[63]

Biomarkers

Blood

Medical Therapy

The interpretation of studies on bismuth blood concentrations is complicated by the lack of standardized analytical techniques, variation in types of blood samples (whole blood, serum, plasma), insufficient size of study groups, and the failure to distinguish normal from therapeutic concentrations.[64] Currently, there are inadequate data to determine the difference in Bi concentrations between different types of blood samples. In a study of 75 healthy adult subjects, the reference range for bismuth in plasma was <0.1 (LOD) to 3.5 μg/L.[65] In general, blood bismuth concentrations are <50 μg/L during therapy with the current regimen of bismuth compounds.[66] In a study of healthy volunteers receiving either colloidal bismuth subcitrate (480 mg/day) or bismuth subnitrate (1.8 g/day) for two months, the mean, posttreatment serum Bi concentrations were 17.2 ± 9.7 μg/L and 5.4 ± 2.8 μg/L, respectively, as measured by electrothermal/atomic absorption spectrometry.[20] The baseline serum Bi concentration in controls and treated patients was <1 μg/L. In a study of 19 healthy volunteers, the serum bismuth concentration ranged from <0.007 (LOD) to 0.67 ng/L with the serum from 10 of these volunteers being below the LOD as measured by ICP/MS.[59]

Overdose

Toxicity may occur in patients with blood Bi concentrations of >100 μg/L; patients with Bi-associated encephalopathy have large variations in the blood Bi concentration. A chronically ill, 76-year-old woman

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

presented with confusion, poor appetite, insomnia, myoclonus, and malnutrition.[67] She had a history of chronic bismuth subsalicylate use; serum bismuth was 242 μg/L ~1 week after admission. Improvement began ~1 month after admission; her mental status returned to normal 18 months after admission with a normal activity level. A 56-year-old woman presented with two weeks of progressive confusion, difficulty concentrating, myoclonic jerks, hand tremors, gait instability, and visual hallucinations.[68] A blood bismuth concentration during her workup was 397 μg/L; her myoclonus, rigidity, and visual hallucinations (but not her mental status) resolved by discharge 10 days after admission. In a case series of 45 patients with Bi-associated myoclonus and encephalopathy, the serum Bi patients with bismuth encephalopathy was ~680–700 μg/L.[69] In a patient with renal dysfunction, behavioral changes, incontinence, visual hallucination, and ataxia developed after the ingestion of 48 g Bi over 2 months.[22] The whole blood Bi concentration was 880 μg/L. Fifty days after admission, his whole blood Bi concentration was 46 μg/L, and his neurological exam and electroencephalogram returned to normal.

Urine

The elimination half-life of bismuth is longer in urine (20–30 days) than plasma.[11] In a study of 75 healthy adult subjects, the reference range for bismuth in urine was 0.3–4.6 μg/L.[65] The LOD was 0.1 μg/L as measured by hydride generation/atomic absorption spectrophotometry (HG/AAS).[61] The mean bismuth concentration in urine samples from 14 students and laboratory employees was 1.94 ± 1.26 μg/L with a range of 0.52–3.89 μg/L as measured by HG/AAS. In a case series of 45 patients with Bi-associated myoclonus and encephalopathy, the urine Bi concentration ranged from 200–9,600 μg/L.[58] A 67-year-old man with sacral chondroma developed myoclonus and encephalopathy (confusion, disorientation, delusions, agitation) within 10 days after debridement and packing of his extensive sacral tumor with bismuth iodoform paraffin paste.[70] His urine Bi concentration 14 days after packing and prior to chelation with DMPS was 2,800 μg/L.

Spinal Fluid

Substantial interindividual variation also occurs in CSF bismuth concentrations in patients with Bi-associated encephalopathy averaging ~50–60 μg Bi/L. In a case series of 45 patients with Bi-associated myoclonus and encephalopathy, the CSF Bi concentration ranged from 10–100 μg/L.[58]

Abnormalities

The electroencephalogram (EEG) is characteristic of bismuth encephalopathy in most cases with generalized spike-wave complexes suggestive of myoclonus that is epileptic in origin.[71] Monomorphic waves at 3–5 Hz appear in the temporal-rolandic and frontal areas, unaffected by eye opening or photostimulation.[58] This rhythm spreads to the occipital regions where alpha rhythms disappear. A diffuse beta rhythm of low voltage develops in most patients, but spikes or other features of paroxysmal activity are usually absent. In a case series of 70 French patients with Bi-associated encephalopathy and myoclonus, paroxysmal phenomena on the EEG and generalized clonic epileptic seizures occurred only when the serum Bi concentration was <1,500 μg/L.[72] Bismuth is radiopaque; increased density may appear in the cortex of the cerebral hemispheres and the basal ganglia along with residual Bi in the gastrointestinal tract. No significant changes occurred in the CSF.

HEALTH SURVEILLANCE

There are no well-defined environmental or biological exposure limits for Bi or Bi compounds with the exception of the intermetallic compound, bismuth telluride (Bi_2Te_3), used in the semiconductor industry. The ACGIH TLV–TWA for selenium sulfide-doped bismuth telluride is 5 and 10 mg/m^3 for undoped bismuth telluride. The NIOSH REL–TWA is 10 mg/m^3 (total, un-doped Bi_2Te_3) and 5 mg/m^3 for respirable Bi_2Te_3, whereas the OSHA PEL–TWA is 15 mg/m^3 (total Bi_2Te_3) and 5 mg/m^3 for respirable Bi_2Te_3. Typical urine Bi concentrations in subjects without occupational exposure are <20 μg/L; Bi toxicity is rare in subjects with blood Bi concentrations of <50–100 μg/L.

TREATMENT

The main treatment for bismuth intoxication is the cessation of bismuth therapy along with supportive care. Decontamination measures may be effective for large single ingestions within the first 1–2 hours post-ingestion, but little data are available to guide treatment. Whole bowel irrigation is a potential decontamination measure if the abdominal x-ray indicates large quantities of bismuth in the intestines.

Little data are available to determine the optimal treatment. Symptomatic patients with blood bismuth concentrations exceeding 200–300 Bi/L are candidates for chelation. Based on animal studies and limited human data,[22,73] DMPS (2,3-dimercapto-propane-1-

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. sulfonic acid) and DMSA (2,3-dimercaptosuccinic acid) given in doses of 30 mg/kg/day until symptoms abate are the chelating agents of choice.[74] Case reports document increased urinary Bi following treatment with DMPS,[70] but the absence of pharmacokinetic data and the presence of other factors affecting clinical symptoms (e.g., removal of Bi packing, hemodialysis) prevent conclusions regarding the efficacy of chelation therapy in cases of Bi encephalopathy. Sixteen hours of hemodialysis preceded by the intravenous administration of DMPS removed 4.7 mg of Bi, whereas hemodialysis alone did not increase Bi clearance.[73] In some case reports, DMPS was stopped because of clinical deterioration despite substantial reduction in plasma Bi concentrations and increased urinary Bi excretion.[71]

Although renal clearance of bismuth increases after the administration of BAL, the clinical effectiveness of BAL (dimercaprol) for bismuth toxicity has been inconsistent.[75] In a study of rats receiving 250 µmol/kg of 1 of 6 chelators (BAL, deferoxamine, DMPS, DMSA, sodium-calcium EDTA, D-penicillamine, thiopronine) daily for 3 days, BAL and DMPS produced the highest urinary Bi elimination.[74] BAL was the only chelator that effectively lowered brain bismuth concentrations, whereas EDTA increased brain bismuth. The authors opined that DMPS and DSMA were possibly the most useful chelators of bismuth with BAL reserved for very severe intoxications. In a study of 24 volunteers receiving either 30 mg/kg DMSA or DMPS after 28 days of colloidal bismuth subcitrate (480 mg/day) therapy, the blood bismuth concentration increased within the first 4 hours (DMSA > DMPS), followed by a ~50-fold increase in the urine bismuth concentration during the first 24 hours.[76] Treatment with BAL should be reserved for severely intoxicated patients without peanut allergies. Animal studies do not support the use of D-penicillamine.[77] Hemodialysis does not significantly increase Bi elimination; treatment with hemodialysis should be limited to patients with renal failure.[21]

Chapter 7

BORON AND BORON COMPOUNDS

BORON AND BORATES

HISTORY

The Babylonians imported borax (sodium tetraborate) over 4,000 years ago as a flux for shaping gold.[1] Borax has been a cleaning agent since the Greek and Roman Empires. Although its use in mummifying, metallurgy, and medicine has been attributed to the Egyptians, the first documented use of borax occurred in the 8th century, when Arab traders brought the mineral tincal to Mecca and Medina. Tibetan lakes are probably the earliest sources of borax that were shipped over the Himalayas to India. As early as the 12th century, European goldsmiths used borax flux. Gay-Lussac and Sir Humphry Davey independently isolated and identified elemental boron in 1808 by heating boron oxide with metallic potassium. Reports of boric acid poisoning appeared in the late 19th century as a result of the use of this compound as an anticonvulsant.[2] Borax was a common food preservative prior to the 20th century, particularly in meat. Dr. Harvey Wiley was the chief of the United States Department of Agriculture Bureau of Chemistry (forerunner of the US Food and Drug Administration) when food manufacturing became a mass production industry in the early 1900s.[3] Under the authority of the Pure Food and Drug Act of 1906, he banned the use of borax as a preservative; his decision was upheld by the US Supreme Court in 1911.

PHYSIOCHEMICAL PROPERTIES

Elemental boron is the only metalloid and electron-deficient, nonmetallic element in Group 3 (Group IIIb) of the periodic table that includes aluminum, gallium, indium, and thallium. At room temperature, pure boron is a hard, brittle metalloid that functions as a semiconductor. The chemistry of boron is complex with the interaction of boron with other compounds resembling the chemistry of silicon and carbon. As a result of the high affinity of boron for electronegative atoms (e.g., oxygen), elemental boron occurs primarily as inorganic salts (i.e., borates) rather than elemental boron in nature. The two stable isotopes of boron are ^{10}B and ^{11}B. In its natural state, boron (B) exists as a mixture of about 20% ^{10}B and the remainder as ^{11}B isotopes.

Boron has a high affinity for oxygen, resulting in the formation of borates; reduced boron compounds (alkyls, aryls, halides, hydrides) readily oxidize and hydrolyze, limiting the commercial value of these compounds.[4] Hence, boron exposure primarily involves inorganic boron compounds. In water, at temperatures above 100°C, boron forms boric acid and other boron compounds. The theoretical composition of borax is 52.7% sodium tetraborate, $Na_2B_4O_7$ (36.5% boric oxide, 16.25% sodium oxide), and 47.24% water of crystallization; borax hydrolyzes in solutions to produce a mildly alkaline solution of $Na_2(B_4O_5(OH)_4)\cdot 8H_2O$. At 20°C, the pH of a 5% solution of borax is ~9.3 compared with 11.4 for a 5% solution of sodium metaborate ($NaBO_2\cdot_nH_2O$, CAS RN: 7775-19-1). Sodium perborate

Melting point (°C)	2,075	450	75 (decomposes)	743
Boiling point (°C)	4,000	1,500	NA	1,575 (decomposes)
Density (g/mL)	2.35[a] (25°C)	1.8[a]	1.73	2.367
Water solubility	Insoluble	4% (20°C)	59.3 g/L (25°C)	3.1% (25°C)

Abbreviations: CAS RN = Chemical Abstract Service Registry Number; NA = not available.
[a]Amorphous form.

($NaBO_3$, CAS RN: 7632-04-4) is the hydrolytically unstable persalt of boron that reacts with water to form stable sodium metaborate and hydrogen peroxide. The addition of activators to solutions of perborate compounds at normal washing temperatures allows the use of these compounds as bleaches. The multi-center nature of boron results in the formation of a diverse array of covalent networks, rings, cages, and clusters that produces strong covalent bonds with electronegative elements (e.g., fluorine, oxygen). The vapor pressure of boron and borates at room temperature is negligible. Table 7.1 lists some identifying characteristics and physiochemical properties of boron and boron compounds.

EXPOSURE

Production Processes

Turkey is the largest producer of borate products in the world, exporting mineral concentrates including ulexite ($Na_2O{\cdot}CaO{\cdot}5B_2O_3{\cdot}16H_2O$), colemanite ($2CaO{\cdot}3B_2O_3{\cdot}5H_2O$), and tincal ($Na_2B_4O_7{\cdot}10H_2O$) as well as other refined borax products. In the United States, the entire production of borates occurs in the Mohave Desert of Southern California from the Kramer deposit at Boron, California. This deposit is the largest borate deposit outside of Turkey. The production of boron results from the chemical reduction of boron-containing ores by reactive metals, either by nonaqueous electrolytic reduction or through thermal decomposition. In the latter process, ore collected from open-pit mines is crushed and dissolved with steam with the resulting borax solution crystallized, washed, and kiln-dried after the removal of insoluble compounds by sedimentation. This process produces borax with either 5 or 10 mol of water, depending on the temperature at crystallization. Heating the hydrated form of borax to molten glass followed by cooling produces anhydrous borax, as does pulverizing the glass to a fine powder.

Uses

Fiberglass accounts for about 77% of the production of boron minerals with ~2/3 produced for fiberglass insulation and ~1/3 for fiberglass textiles. In fiberglass, boric oxides increase mechanical strength and chemical durability. The production of low-thermal expansion glasses and heat-resistant Pyrex accounts for ~18% of boron production compared with ~5% for enamels, ceramic glazes, and frits. The addition of borates to glass removes bubbles and improves the formation of finished glass products. Elemental boron is used as a neutron absorber in nuclear reactors. Boron also appears in cosmetics, soaps and cleansers, fertilizers for boron-deficient plants (apples, sugar beets, oil palms, alfalfa), leather tanning, and antifreeze.[5] Borax contributes to the softening of hard water by precipitating calcium to form calcium borates as well as reacting as a buffering and mild alkalinizing agent. Sodium perborate is an effective bleach, but activators (e.g., organic acyl derivatives) are necessary to hydrolyze perborate at temperatures <60°C.[1] Previously, boron was a food preservative in Europe and Asia. Boron trichloride is part of the chemical vapor deposition process for the production of boron filaments, whereas boron tribromide is a catalyst in the manufacture of proprietary pharmaceuticals.

Product Formulations

Sources of boron in products include insecticides (e.g., Harris Famous Roach Tablets (boric acid), Roach-Pruf (orthoborate)), soaps (e.g., Boraxo Powdered Hand Soap), and contact lens solutions. Sodium borate, sodium biborate, sodium pyroborate, and sodium tetraborate (borax cleaners) contain 21.5% boron by weight. Sodium borate solutions (Dobell's) contain 1.5 g sodium borate, 1.5 g sodium bicarbonate, and 0.3 mL liquified phenol. Boric anhydride, boron oxide, boron

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

trioxide, boric oxide, boron sesquioxide, borax, and tincal (tinkal) are 33% boron by weight. The following is the percentage by weight of other boron compounds: sodium perborate (oxidizer in tooth powders and toothpastes), 7.3%; sodium metaborate, 16.44%; magnesium perborate, 14%.

Sources

Borates are the most common boron-containing compounds in sediments and sedimentary rock as a result of the highly stable bonds formed between boron and (electronegative) oxygen species. The weathering of these formations probably accounts for greater exposure of the general population to boron than releases from a limited number of industrial sources.[6] Except for boric acid and sodium borate, the limited solubility of boron compounds substantially reduces their bioavailability. Ingestion of food (primarily fruits and vegetables) and water are the major sources of boron for the general population. Exposure to boron-containing insecticides and cosmetics may increase boron exposure. The western United States contains boron-rich deposits; therefore, this population probably has a relatively higher boron exposure than residents of other parts of the United States.

Air

Natural sources of borates in the atmosphere include oceans and geothermal steam. Evaporation of seawater is the biggest contributor of boron to ambient air.[4] The release of boron compounds occurs from natural and anthropogenic sources. The latter sources include coal-fired and geothermal steam power plants, fiberglass manufacturing facilities, and rockets. There are few data on the boron concentration in ambient air; however, air is probably an insignificant source of boron exposure for the general population. Estimated boron concentration in air averages $\sim 2 \times 10^{-5}$ mg/m^3 with a range of $<5 \times 10^{-7}$–8×10^{-5} mg/m^3.[7]

Soil

The concentration of elemental boron in the earth's crust is ~10 ppm. A study of US soils revealed that boron concentrations ranged up to 300 mg/kg with a geometric mean of 26 mg/kg.[5] Boron-containing ores include the following: borax, colemanite, kernite, tincalconite, tourmaline, and sassolite. Boron is released to the soil both from natural sources (rainfall, weathering, desorption, or decay of boron-containing matter) and from man-made sources (fertilizers, pesticides, fly ash, sewage sludge).[8] Boron is an essential nutrient for plants at concentrations of ~0.5 ppm boron.

Water

The major source of boron in water is the weathering of clay-rich sedimentary rocks containing boron; boron concentrations in natural waters depend on the geographic location of boron-rich deposits.[6] Some contamination of water occurs as a result of run-off from industrial and agricultural uses of boron-containing materials. High boron concentrations exist naturally in marine sediments and sedimentary rocks in the form of borosilicates. The average boron concentration in samples of sewage effluent in California was 1 mg/L. In England, a study of municipal sewage from a treatment plant revealed boron concentrations ranging from 2.5–6.5 mg/L.[9]

Typically, the boron concentration in surface freshwater is <0.1–0.5 mg/L.[7] Unusually high boron concentrations (e.g., 0.31–15.2 mg/L) occur in the water supplies of northern Chile,[10] while the water supplies of the Kutahya Province of Turkey contain boron concentrations in water samples ranging from 2.05–29 mg/L.[11] In the San Joaquin Valley of California, where groundwater is near boron-rich soils of marine origin, the median boron concentration was 4 mg/L with a range up to 120 mg/L.[6]

Diet

The range of the average estimated daily intake from all sources of boron in the United States ranges from 0.5–3 mg with a mean of 1.5–2 mg.[12] In a study of US diets (Continuing Survey of Food Intakes by Individuals), the reported mean daily intake of boron for male and female adults were 1.17 mg and 0.96 mg, respectively, with a range of 0.02 to over 9 mg.[13] The median daily boron intake in adult male vegetarians is higher (1.47 mg) than in the general population. In areas with high boron content in drinking water (e.g., northern Chile), daily boron intake may reach 27 mg (0.45 mg/kg).[14]

Food is the primary source of exposure to boron for the general population, particularly fruits (avocado), grains, wine, legumes, nuts, and vegetables. Plant-based foods are a richer source of boron than animal-based foods. Boron is an essential plant nutrient, occurring naturally in all plant foods. Milk and coffee account for the largest contribution of boron to the diet because of the volume of these items in the diet.[15] Analysis of foods with the highest boron content demonstrated the following concentrations (wet weight): raisins,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

2.20 mg/100 g; peanut butter, 1.45 mg/100 g; peanuts, 1.70 mg/100 g; dried fruits, 1.87 mg/100 g; and avocados, 1.22 mg/100 g.[13] Dairy products, meats, fish, and most grains are poor sources of boron. Wine consumption may add several mg of boron daily.

Most surveys of drinking water do not report boron concentrations. Existing data suggest that boron concentrations in drinking water are highly variable depending on the geographical source of the water. Analysis of US public water supplies indicates that drinking water typically contains <1 mg B/L with maximum boron concentrations ranging up to 3–4 mg/L.[16] Boron in US drinking waters probably does not pose any significant human health risk in most locations. Conventional water treatment methods (coagulation, filtration, sedimentation) do not remove significant amounts of boron.

ENVIRONMENTAL FATE

Boron is a nonvolatile metalloid compound that combines with most other elements. Although changes in the specific form of boron may occur during transport through the environment, transformation and degradation of boron do not occur in the environment.

Air

Boron released to the atmosphere may exist in the form of aerosols or particulate matter as borates, boron oxides, borides, boranes, borazines, or organoboron compounds.[5] Borates are relatively water soluble; therefore, wet or dry deposition releases these compounds to the surface of the earth relatively quickly. The atmospheric half-life of boron compounds is probably measured in days, depending on atmospheric conditions and particle sizes.

Soil

The extent of adsorption to soil depends on pH and the chemical composition of the soil with maximum adsorption occurring in the range of 7.5–9.[17] The greatest adsorption results from soils that contain high concentrations of aluminum oxides, iron oxides, and hydroxides. The adsorption of boron in some soils may not be reversible. Most boron compounds are transformed into borates in the soil as a result of the presence of moisture. Water leaching and incorporation into plants remove these borate compounds from soils.

Water

In natural waters, boron compounds readily hydrolyze to form the weak monobasic acid (H_3BO_3) and the monovalent anion $B(OH)_4^-$. Because borate ions in solution are fully oxidized, aerobic processes are unlikely to affect speciation; therefore, biotransformation does not affect the behavior of boron species in the environment. The adsorption of boron by clays is the main mechanism for removal of boron from natural waters.[6] Bioconcentration of boron by organisms from water is unlikely because of the low octanol/water partition coefficient (0.175) of boron. Boron does accumulate in aquatic and terrestrial plants, but biomagnification of boron in the food chain does not occur.[4]

DOSE EFFECT

Like carbon and silicon, the chemistry of this metalloid is very complex depending on temperature, pH, and the interaction of borates with oxygen. In aqueous solutions, boron forms $B(OH)_3$ (boric acid); presumably, the toxicokinetics and toxicity of boron relate to the effects of boric acid. However, the amount of boric acid formed will vary depending on local environmental conditions and the type of boron product. Hydrated borax typically contains 52.7% sodium tetraborate, $Na_2B_4O_7$ (36.5% boric oxide, 16.25% sodium oxide), and 47.24% water of crystallization.

Acute Toxicity

Borax is an alkaline salt that is an irritant to the upper respiratory tract in sufficient doses. In a study of 629 borax workers, inhalation of borax dust (boric oxide, sodium tetraborate) at ambient air concentrations exceeding 4–14.6 mg/m^3 was associated with acute irritation of the upper airway as measured by weighted mean total particulate borax in personal samples.[18] Symptoms included eye irritation, dryness of the upper respiratory tract, dry or productive cough, epistaxis, chest tightness, and sore throat, primarily in the higher exposure categories. Borax concentrations of <1.1 mg/m^3 as total particulate were not associated with signs or symptoms of acute irritation. A study of 79 workers exposed to sodium tetraborate dust did not demonstrate any significant differences in the potency of anhydrous sodium borates compared with other sodium borates at a geometric mean of ~3 mg/m^3, total dust.[19]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Chronic Toxicity

In the older medical literature, a review of 175 cases associated the daily ingestion of 6–20 g of borax for several months with a wide range of toxicity.[20] These doses correspond to 2.12 g boron/day. The clinical details and differential diagnoses in these case reports were limited using obsolete analytical techniques. A prospective study of 303 workers exposed to an arithmetic mean daily boron concentration of 0.45 mg/m^3, total dust (0.02 mg boron/m^3) did not detect any significant change in the FEV_1 over a period of 7 hours.[21]

TOXICOKINETICS

Absorption

Uptake of boron occurs almost exclusively (i.e., >98%) as undissociated boric acid regardless of the form of inorganic borate (e.g., boric acid, borax, boron in the diet) because of the high pKa of boron. Absorption from the following procedures is sufficient to produce toxicity: irrigation of skin with altered permeability, irrigation of serous cavities, enemas, and intravenous injections. Limited human data indicate that intact skin absorbs little boron; however, significant amounts of boron may be absorbed across broken skin or across mucous membranes. In an *in vitro* study with human skin and a dose simulating bathing conditions in 5% borax, the mean absorption was 0.41% of the applied dose.[22] In volunteers administered ^{10}B-enriched 5% borax and 10% disodium octaborate tetrahydrate (DOT) aqueous solutions topically, the mean percent dose absorbed was 0.210 ± 0.194% for the borax solution and 0.122 ± 0.108% for the DOT solution as determined by urinary boron concentrations.[23] The flux and permeability constant for the borax solution were 0.009 µg/cm^2/hour and 1.8×10^{-7} cm/hour compared with 0.01 µg/cm^2/hour and 1.0×10^{-7} cm/hour, respectively, for the DOT solution.

Distribution

The distribution of boron occurs throughout the body by passive diffusion, particularly to the brain, liver, and kidneys.[24] The volume of distribution of boron is relatively small (i.e., <total body water). In animals, boron does not accumulate in soft tissue or fat; bone is a repository for absorbed boron with relatively high boron concentrations compared with other tissues.[25,26]

Elimination

The kidney excretes almost all (i.e., >90%) of the absorbed dose of boron with a relatively rapid excretion rate. The kidneys excrete ~50% of an absorbed dose during the first 24 hours with most of the rest of the dose eliminated in 5–7 days. Little, if any, metabolism of borax occurs in the body.

Maternal–Fetal Kinetics

No data are available on the kinetics of boron in the fetus. Boron occurs in the milk of lactating mothers with concentrations typically ranging from ~11–110 µg/L milk depending on boron concentrations in the environment. In a St. Johns, Canada, study of 28 lactating mothers within 12 weeks of delivery, the mean boron concentration in breast milk was relatively stable, ranging from 10–60 ng/mL (mean = ~30 ng/mL).[27] In a study of 35 lactating mothers from areas in Chile and Argentina with high environmental boron concentrations, the geometric mean breast milk/blood boron ratios from 3 cohorts residing in different areas were ~60–80%.[28] The geometric mean boron concentration in drinking water samples ranged from ~5,000 ng/mL (San Antonio de los Cobres, $n = 4$) to ~8,000 ng/mL (Arica, $n = 9$) with marked interindividual variation compared with 187 ng/mL in the control city (Santiago, $n = 6$). The study used whole blood samples for mothers in San Antonio de los Cobres (GM = 430 ng/mL), whereas plasma samples were collected in Arica (GM = 380 ng/mL) and Santiago (GM = 35 ng/mL). However, the erythrocyte and plasma boron concentrations were highly correlated ($r_s = 0.99$).

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Current evidence suggests but does not provide definitive proof that boron is an essential element in humans with suspected effects on cell membrane function, hormone metabolism, normal bone growth, calcium metabolism, and enzyme reactions.[29] In some bacteria, boron-containing biomolecules are involved in cell-to-cell communication; several important biomolecules in humans have a high affinity for boron including *S*-adenosylmethionine and NAD^+. Some studies suggest homeostatic control of boron in humans.[30] Boron is an essential element in vascular plants, particularly for plant growth and cross-linking in cellular membranes/extracellular matrix.[31,32]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The mechanism of boron toxicity is not known. The most sensitive endpoints of toxicity in animals are developmental and reproductive toxicity. In rats that ingested boron for 10–14 weeks, cerebral succinate dehydrogenase activity was increased, suggesting that alterations in electron transfer in the respiratory chain of the mitochondria may contribute to the boron toxicity.[33]

CLINICAL RESPONSE

Acute Oral Toxicity

The oral toxicity of borates is relatively low depending on the amount of boric acid formed and primarily involves irritant effects.

Occupational Exposure

The presence of excessive ambient air boron concentrations exceeding 4 mg/m^3 has been associated with acute irritant effects including dryness of the upper respiratory tract, productive cough, epistaxis, chest tightness, and sore throat.[18] To date, long-term adverse pulmonary effects (radio graphical abnormalities, reduced FEV_1, FVC) have not been detected in studies of workers exposed to boron compounds.[5,18] Animal studies suggest that boron trifluoride is a more severe pulmonary irritant than other boron compounds,[34] but little human data are available. Contact dermatitis occurred in workers exposed to alkanolamine borate compounds used in metalworking fluids at concentrations of 10–30%; the dermatological effects appeared independent of the alkalinity of these compounds.[35]

Reproduction Abnormalities

Although exposure of animals to high doses of boron as boric acid causes reproductive abnormalities in rodents, there are few data on similar effects in workers exposed to borates. A cross-sectional study of 500 male workers exposed to average ambient air concentrations of 17.6–44.8 mg boron/m^3 as sodium borate for a mean of 18 years did not detect an effect on fertility as measured by the standard birth ratio.[36]

Carcinogenesis

Neither the International Agency for Research on Cancer nor the US National Toxicology Program lists boron or boron compounds as carcinogenic agents. There are little data on the carcinogenicity of boron. To date, *in vitro* studies do not indicate that boron is genotoxic.[37,38] A study of mice fed boron for 103 weeks did not detect a significantly increased incidence in the number of tumors.[39] A 2-year study of mice ingesting 400–500 mg boric acid/kg/day (low dose) and 1,100–1,200 mg boric acid/kg/day (high dose) did not demonstrate any significant excessive incidence of tumors.[40]

DIAGNOSTIC TESTING

SI Conversion Units

1 g borax = 10.5 mmol boron = 0.113 g boron
1 g anhydrous borax = 0.215 g boron
1 ppm boron = 0.4421 mg boron/m^3
1 mg boron/m^3 = 2.262 ppm boron

Analytical Methods

Several issues specific to boron compounds complicate the interpretation of analytical results for boron in biological samples. Boron concentrations are usually reported either as total boron or boron species (borates). As a result of the lack of convenient, commercial methods to speciate boron in borate, the percentage of boron in borate species is inferred from the percentage of boron in the borate species being analyzed. Consequently, susceptibility of borates to weight change from uptake/loss of water (i.e., instability of hydration state) and the type of sampler will affect the accuracy of analytical results.[41] The latter issue involves the difference in weight measured as total dust (NIOSH Method 0500) and inhalable particles (Institute of Occupational Medicine sampler).[42] Complications in sample preparation result from the ubiquity of boron in the environment, the low boron concentration in biological samples, and the volatility of boron compounds. These difficulties include certification and preparation of standards, contamination from Teflon vessels during microwave digestion, boron losses during freeze-drying, B isotopic variations, reagent backgrounds, and instrumental interferences.[43]

The most common analytical procedure to analyze boron in biological materials involves digestion of the sample in hot acid or base, followed by an analysis of the resulting solution by inductively coupled plasma/atomic emission spectrometry (ICP/AES). High-temperature atomic spectrometric methods (e.g., ICP/AES) are sensitive methods for the detection of boron in biological

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. and environmental materials. The limit of detection for boron in air samples using NIOSH method 7303 (hot acid digestion followed by ICP/AES) is 9.4 ng/L. Inductively coupled plasma/mass spectrometry (ICP/MS) is a more rapid method requiring a small sample size with limits of quantitation in blood samples near 1 µg/L (inter-assay imprecision, ~3–5%) and 0.25 µg/L (inter-assay imprecision, ~1%) in urine samples.[44]

The measurement of the $^{10}B/^{11}B$ isotopic ratio allows the separation of anthropogenically derived boron from natural sources of boron in groundwater.[45] The natural abundance of ^{10}B and ^{11}B is specific to a location; thus, the $^{10}B/^{11}B$ isotopic ratio varies depending on the anthropogenic and groundwater sources of boron.[46] Atomic absorption analysis is not an effective method, and colorimetric curcumin and carmine methods are outdated.[5] The turmeric paper test (i.e., turning the yellow turmeric paper red in the presence of boric acid and hydrochloric acid) lacks specificity as a result of many false-positive reactions.[24]

Biomarkers

Blood

The geometric means for serum samples from 397 healthy, urban male and 583 female Japanese residents were 79.8 µg/L (95% CI: 33.3–191.2 µg/L) and 67.9 µg/L (95% CI: 29.5–154.9 µg/L), respectively, as measured by ICP/AES (LOD, 5 µg/L).[47] With the exception of the 50–69-year-old age group, the boron concentrations increased with age. In a convenience sample of 15 Chinese workers employed at boron mines or processing plants producing borax or boric acid, the mean serum boron concentration was 499 ± 790 ppb (µg/L; range, 20–3,569 ppb) compared with 96 ± 91 ppb (range, 3–536 ppb) for community controls from the same area of high environmental boron concentrations.[48] The mean serum concentration for a convenience sample of 15 Chinese residents without occupational boron exposure from a different area (i.e., low environmental boron exposure controls from the same study) was 48 ± 24 ppb (range, 8–113 ppb) as measured as elemental boron by inductively coupled plasma/mass spectrometry. There are few data on the ratio of boron concentrations in plasma/serum and whole blood. In a French study of 100 healthy adults, the median boron concentration in plasma samples was 36 µg/L (95% reference range, 19–79 µg/L) compared with 26 µg/L (95% reference range, 14–44 µg/L) in whole blood samples as measured by ICP/MS.[44]

Urine

The presence of elevated total boron concentrations in the urine reflects recent exposure (i.e., several days). In a study from the early 1960s, the boron concentration in urine samples from 148 healthy working adults without known exposure to boron compounds ranged from 40–6,600 µg/L (mean = 919 µg/L; median = 715 µg/L) as measured by a spectrographic method after acid digestion.[49] In a study of 102 Japanese electronic workers without occupational boron exposure, the distribution of boron concentrations in urine samples was lognormal with a geometric mean of 798 µg/L (95% CI: 398–1,599 µg/L).[50] The urine was normalized to a specific gravity of 1.024. The mean total boron concentration in urine samples from 118 Italian residents was 1,890 µg/L (95% CI: 490–3,290 µg/L) as measured by ICP/AES.[51] The maximum urine boron concentration was 7,800 µg/L. A Chinese study compared post-shift urine boron concentrations in 15 workers producing borax and boric acid with those of 15 unexposed control workers living near the plant.[48] The mean post-shift urine boron concentration in the exposed workers was 19.3 mg/g creatine (range, 1.4–168 mg/g creatinine) compared with 4.8 mg/g creatinine (range, 0.8–50.7 mg/g creatinine) for local controls. The estimated daily boron intake for the exposed workers was ~41 mg compared with ~3 mg for local controls; however, the study did not separately report the inhalable boron concentration in workplace personal air samples. The mean end-of-shift total boron concentrations in urine samples from 14 workers exposed to airborne borax concentrations (range, 3.3–18 mg/m^3) measured gravimetrically ranged from 3.16–10.72 µg/mg creatinine.[52]

HEALTH SURVEILLANCE

Environmental Monitoring

Table 7.2 lists the guidelines and regulations for occupational exposure to boron compounds. Gravimetric analysis of air samples for boron concentrations may be misleading compared with direct measurement of boron content because certain boron species can rapidly hydrate following the collection of air samples.[41] These guidelines are based on the irritation of boron to the skin, eyes, and respiratory tract. The lower concentrations recommended for the trifluoride and tribromide compounds reflect the greater pulmonary toxicity that occurs in animal studies when compared with other boron compounds.

TABLE 7.2. Regulations and guidelines for exposure to boron compounds.

Substance	Level
OSHA	
PEL–TWA (8-hour)	
Boron oxide	
(total dust)	10 mg/m^3
(respirable fraction)	5 mg/m^3
Sodium tetraborates	10 mg/m^3
Ceiling	
Boron tribromide	10 mg/m^3 (1 ppm)
Boron trifluoride	3 mg/m^3 (1 ppm)
ACGIH	
TLV–TWA (8-hour)	
Sodium tetraborates	
Anhydrous	1 mg/m^3
Pentahydrate	1 mg/m^3
Decahydrate	5 mg/m^3
Boron oxide	10 mg/m^3
Ceiling	
Boron tribromide	1 ppm (10 mg/m^3)
Boron trifluoride	1 ppm (3 mg/m^3)
MRL Inhalation	
Acute-duration (≤14 days)	0.3 mg/m^3
MRL Oral	
Acute-duration (≤14 days)	0.2 mg B/kg/day
Intermediate-duration (15–365 days)	0.2 mg B/kg/day
NIOSH	
IDLH (30 minute)	
Boron trifluoride	100 ppm
WHO	
ADI	13 mg (adult)
IPCS	
TDI	0.4 mg/kg

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ADI = acceptable daily intake; IDLH = immediately dangerous to life and health; IPCS = International Programme on Chemical Safety; MRL = Minimum risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; TDI = tolerable daily intake; TLV = threshold limit value; TWA = time-weighted average; WHO = World Health Organization.

Biological Monitoring

There are no official biological guidelines for exposure to boron. Creatinine-corrected, post-shift urine boron concentrations are biomarkers for workers exposed to borax and boric acid; however, there are inadequate data to determine a reliable biological exposure limit. In a study of Chinese workers exposed to borax and boric acid in boron mines and processing plants, total boron concentration in post-shift spot urine samples correlated with total boron concentrations in 24-hour urine samples (Pearson correlation coefficient = 0.85, $P < 0.0001$) and with total boron concentrations in personal air monitoring (Pearson correlation coefficient = 0.83, $P < 0.0001$) as measured ICP/MS.[48] The mean post-shift urine boron concentration for 60 Chinese boron workers was 16 mg/g creatinine (range, 0.7–235.7 mg/g creatinine).[48] In this study, the post-shift boron concentration correlated well to total estimated boron exposure for the workers (Pearson correlation coefficient 0.90, $P < 0.0001$) and community comparisons (Pearson correlation coefficient 0.48, $P < 0.008$), but not for residents from areas of low boron exposure. Over the work week, there was no evidence of accumulation of boron in the body following these exposures.[52]

TREATMENT

Treatment is supportive.

BORIC ACID

HISTORY

Arabian physicians used boric acid as a cleansing agent in the first millennium. In the early 18th century, boric acid was administered in Europe as a sedative (Homberg's sedative salt), an anti-spasmodic, and an analgesic. Lister introduced the use of boric acid as an antiseptic in 1875;[53] since that time, this compound has also been a common constituent of ointments, skin lotions, medicinal powders, toothpaste, mouthwashes, topical astringents, and water softeners. Medicinal uses of boric acid solution included irrigation of pleural cavity, bladder, lower bowel, abscesses, inflamed joints, skin ulcers, and inflamed mucous membranes. Reports of boric acid poisoning appeared in the late 19th century as a result of the copious irrigation of internal organs with boric acid.[54] Routes of poisoning from boric acid include ingestion, intravenous, lavage of cavities, dermal (topical wound care, diaper dermatitis), and enemas. Fatalities have been associated with the accidental administration of boric acid to infants[55] and the ingestion of boric acid-contaminated food by adults.[56]

PHYSIOCHEMICAL PROPERTIES

Boric acid is a colorless, odorless compound that appears in the form of crystals, white powder, or granules. This very weak monobasic acid is soluble in water, glycerin, and alcohol (~5%); chemically, this substance is a Lewis acid accepting OH^- rather than a proton donor. The chemical behavior of boron in aqueous media depends on pH and boron concentration.[1] Dilute aqueous solutions of boric acid at pH <7 contain primarily undissociated boric acid [$B(OH)_3$] and metaborates [$B(OH)_4^-$] species. In biological systems, boron associates with one or more hydroxyl groups. A teaspoon of 100% boric acid crystals contains about 2.9–4.4 g boric acid.

Because boric acid is weakly acidic (pKa 9.42), over 98% of boric acid exists in the form of $B(OH)_3$ in human blood at pH 7.4. Above pH 10, metaborate anion is the main species in the solution. Boric acid is stable to dehydration under all conditions in contrast to borax and low-hydrated borates.[41] Boric acid does not hydrate because there are no known higher hydrates. At elevated temperatures, boric acid dehydrates to form one of three metaboric acid crystal modifications ($B_2O_3 \cdot H_2O$). Table 7.3 lists some identifying data and physical properties of boric acid. Saturated solutions of boric acid contain 5.55% boron by weight.

EXPOSURE

Although used as a pH buffer in aqueous ophthalmic irrigation solutions, boric acid is no longer a common antiseptic agent. Uses of boric acid include the formulation of cosmetics, pharmaceuticals, and toiletries as well as the reduction of flammability of cellulose insulation, cotton mattresses, and wood composites. Boric acid and related sodium salts (sodium tetraborate decahydrate, sodium tetraborate pentahydrate, anhydrous sodium tetraborate, disodium octaborate tetrahydrate, anhydrous disodium octaborate, sodium metaborate) are constituents of registered pesticide products in the United States. The concentration of boric acid in seawater is ~4.5–5.5 mg/L with about 76% of the total inorganic boron in the undissociated form of boric acid.[38] At neutral pH (7.0), 98% of boric acid in dilute solution is present in the undissociated form. In water, boric acid is in equilibrium with borates, depending on water pH.

TABLE 7.3. Physical properties and identifying information of boric acid.

Physical Characteristic	Value
CAS RN	11113-50-1, 10043-35-3
Molecular formula	$B(OH)_3$
Molecular weight (g/mol)	61.83
%B (by weight)	17.5
Color	White
Physical state	Crystals, powder, granules
Odor	Odorless
Melting point (°C)	170.9
Density (g/mL)	1.435 (15°C)
Water solubility (g/L)	47.2 (20°C)
Vapor pressure	Negligible (20°C)

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number.

DOSE EFFECT

Acute Toxicity

A single ingestion of boric acid is frequently asymptomatic. Linden et al. documented several accidental ingestions that produced minimal systemic toxicity.[57] In this study, a 14-month-old child ingested an estimated 20 g of 50% boric acid without developing signs of intoxication. A 2-year-old child ingested 10 g boric acid; his only sign of intoxication was spontaneous emesis for 3 hours. A 28-year-old female ingested an estimated 297 g of 99% boric acid; she developed spontaneous vomiting within 1 hour. She received gut decontamination measures, and she was released the following day asymptomatic.

Human case reports suggest that the minimum lethal dose of boron (as boric acid) is ~2–3 g in infants, 5–6 g in children, and 15–20 g in adults; however, as noted above, symptoms based on the estimated dose are highly variable.[58,59] The estimated fatal dose of boric acid in 5 infants ranged from 4.5–14 g.[55] With supportive care, infants survived an estimated ingestion of 1.95–20 g boric acid.[55,57,60] A 77-year-old female presented to the hospital 23 hours after ingesting an estimated 30 g boric acid; she developed acute renal and cardiac failure.[61] Despite the use of hemodialysis and charcoal hemoperfusion, she died. An 82-year-old man accidentally ingested 30 g boric acid that was sold to him as magnesium sulfate by a pharmacist.[62] He developed headache, agitation, nausea, vomiting, and mild hypertension; he survived with supportive care and hemodialysis. Inhalation of borax and boric acid at ambient air levels of 4–14.6 mg/m^3 has been associated with acute

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

irritation of the upper airway in the occupational setting.[63]

Chronic Toxicity

Valdes-Dapena et al. reported boron poisoning from the daily ingestion of 4–5 g boric acid for 3–4 weeks; however, they did not describe the clinical features of intoxication.[20] This dose corresponds to 2.12 g boron/day. In animals, the most sensitive toxic effect of boron is developmental toxicity in rats with a lowest-observed-adverse-effect level (LOAEL) of 13.3 mg/kg/day and a no-adverse-effect level (NOAEL) of 9.6 mg/kg/day.[64]

TOXICOKINETICS

Absorption

Boric acid is almost completely absorbed from the gastrointestinal tract. In a pharmacokinetic study of volunteers, ~94% of the ingested dose was recovered in the urine within the first 96 hours.[65] Limited human data indicate that intact skin absorbs little boron; however, significant amounts of boron may be absorbed across broken skin or across mucous membranes. No increase in the urinary excretion of boron occurred following the application of 15 g boric acid to a forearm for 4 hours.[66] An *in vitro* study on human skin demonstrated percutaneous flux values for the following boric acid solutions: 0.05%, 0.25 μg/cm^2/hour; 0.5%, 0.58 μg/cm^2/hour; and 5.0%, 14.58 μg/cm^2/hour.[22]

Distribution

Boric acid distributes rapidly after absorption via passive diffusion; the volume of distribution of boric acid is relatively small (i.e., <total body water).[67] In a study of eight young adult male volunteers receiving an intravenous boric acid dose of 562–611 mg, the distribution phases of the three-compartment model were 0.251 ± 0.099 , 0.456 ± 0.067 , and 0.340 ± 0.128 L/kg.[68]

Elimination

Boric acid is not metabolized in the human body. The kidneys excrete almost all of the absorbed dose of boric acid in the urine unchanged; therefore, renal clearance is the major determinant of the elimination half-life. Following the ingestion of boric acid solutions, the elimination half-life of boric acid is ~1 day.[67,69] In a study of eight young adult male volunteers receiving an intravenous boric acid dose of 562–611 mg (100–108 mg B), the mean plasma elimination half-life was ~21 ± 5 hours based on a three-compartment model.[68] The mean total renal clearance was 54.6 mg/minute/1.73 m^2 using the area under the curve. The mean renal clearance of dietary boron over 24 hours in 16 pregnant women was ~61 ± 37 mg/minute/1.73 m^2) compared with ~44 ± 22 mg /minute/1.73 m^2 for 15 nonpregnant women.[70] An analysis of 9 cases of boric acid poisoning revealed a mean serum half-life of 13.4 hours (range, 4–27 hours).[71]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanism of toxicity following boric acid poisoning is unknown. Postmortem findings in patients dying from boron toxicity are nonspecific (e.g., cerebral edema, pulmonary congestion).[72] Extensive vascular congestion, intravascular thrombosis, and widespread perivascular hemorrhage, along with degenerative changes in the neurons of the CNS appeared in autopsies of infants dying after ingesting boron-contaminated formula.[55] In addition, these autopsies demonstrated exfoliative dermatitis, neutrophilic infiltrate in the lamina propria of the small bowel, intracytoplasmic inclusion bodies in pancreatic acinar cells, renal tubular damage, liver congestion, and parenchymatous degeneration of the liver.[20] Some of these changes may be pre-terminal pathology rather than a direct effect of boron toxicity.

CLINICAL RESPONSE

Medical Therapy

Following repeated application of boric acid-containing ointments for diaper rash, chronic boron poisoning developed characterized by exfoliative dermatitis and renal toxicity (oliguria, renal tubular necrosis, renal failure).[20,24,73] Hyperthermia and hypothermia may occur. Neonates and young infants appear more susceptible than adults to chronic boron poisoning.

Acute Oral Toxicity

Irritation of the gastrointestinal tract (nausea, vomiting, blue-green diarrhea) begins within 1–2 hours following the ingestion of toxic amounts of boric acid. Although most accidental ingestions produce no symptoms, persistent vomiting and diarrhea may cause dehydration, shock, and coma following severe ingestion. A

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

45-year-old man presented with vomiting, blue-green diarrhea, and dehydration 2 days after ingesting an estimated 280 g boric acid.[72] Seventeen hours after admission, he died after developing persistent hypotension, metabolic acidosis, oliguric renal failure, and pulseless electrical activity in his heart.

Classically, serious boric acid toxicity is associated with the "boiled lobster" syndrome, characterized by exfoliative dermatitis (erythema, desquamation 1–2 days post-ingestion).[74] The erythema is generalized; the rash usually resolves within 1–3 days. The rash may localize to the hands, feet, buttocks, scrotum, or face in less serious cases. Clinical features of serious boron toxicity in neonates and infants receiving large doses of boric acid include weakness, lethargy, irritability, restlessness, opisthotonus, tremors, hyperexcitability, delirium, convulsions, and coma.[55] After the intentional ingestion of a roach powder containing boric acid, a 56-year-old man developed desquamative dermatitis involving the axilla, inguinal crease, sacral area, and gluteal cleft with sparing of the palms and soles.[75] There were no genital or oral lesions; Nikolsky's sign was positive.

Environmental Exposure

There are few data on the toxicity of boric acid exposure to the environment.

Reproductive Abnormalities

Animals

Developmental studies in animal species (mice, rats, rabbits) indicate that high doses of boric acid cause developmental effects when fed to these animals at doses causing maternal toxicity. Several animal studies also demonstrate adverse reproductive effects on sperm formation when animals are fed high doses (1,750 ppm) of boron in the diet over 90 days.[76] These high doses of boric acid cause epithelial disorganization and loss of germ cells as well as decreases in the basal serum testosterone concentrations.[77] No developmental toxicity was observed in mice fed 55 mg boric acid/kg/day from gestational day 0–20[64] or in rabbits fed 125 mg boric acid/kg/day from gestational day 6–19.[78] The rat is the most sensitive species with a NOAEL of 9.6 mg B/kg/day for developmental toxicity, whereas the NOAEL for rabbits and mice were 22 mg B/kg/day and 43 mg B/kg/day, respectively.[79] The latter study demonstrated mild maternal effects and severe developmental toxicity (cardiovascular malformations) in rabbits fed 250 mg boric acid/kg/day. Inhibition of the release of mature sperm and testicular atrophy was seen in male mice feed >4,500 ppm boric acid over 9 weeks;[80] however, a threshold effect was observed at 2,000 ppm boric acid.

Human

Although boron affects male reproduction in laboratory animals following exposure to high boron doses, there is no clear evidence of male reproductive effects attributable to boron in studies of highly exposed workers. In a Chinese study of 945 men working in boron mining or processing including a subset of 16 heavily exposed workers with a mean estimated daily boron intake of 125 mg, there was no significant difference in reproductive outcomes between the workers' wives and the wives of 249 background control men after adjustment for potential confounders.[81] Additionally, there were no statistically significant differences in semen characteristics between all exposure groups and controls except for a reduction in the sperm Y:X ratio of boron workers. In a cross-sectional study of a nonrandom sample of 102 workers at plants producing borax, boric acid, and sodium perborate, analysis of sperm and hormone concentrations (FSH, LH, testosterone) did not detect any significant difference between controls, low exposure group, and high exposure group.[82] The estimated mean daily boron exposure of the highly exposed group was 14.45 ± 6.57 mg (range, 3.32–35.62 mg).

DIAGNOSTIC TESTING

SI Conversion Units

1 g boric acid = 16.2 mmol boron = 0.175 g boron

Biomarkers

Serum and plasma concentrations of boric acid are similar.[61]

General Population

Often, concentrations are reported as boric acid (borate) rather than boron. Because boron has an atomic weight of 10.81 compared with 61.8 for boric acid, the boric acid concentration is ~5.7 times heavier than an equivalent concentration of boron (i.e., 100 g boric acid/L = 17.5 g B/L). Therefore, 1 g boric acid contains 0.175 g boron. The mean whole blood concentration in 7 healthy adults was about 0.01 mg boron/L.[83]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Overdose

Serum and urine boron concentrations document exposure, but the prediction of clinical effects based on boron concentrations must be done cautiously. A 14-month-old child remained asymptomatic with a serum boric acid concentration of 80 mg/L (14 mg boron/L) 4 hours after ingestion. Emesis developed in patients with the following serum boric acid concentrations: 530 mg/L 1 hour after ingestion; 580 mg/L 7 hours after ingestion; and 2,320 mg/L 1 hour post-ingestion.[57] Two hours after ingesting 75 g boric acid, a 45-year-old man was vomiting continuously with stable vital signs.[84] At that time, his serum boric acid concentration was 167.4 mg/L. He survived without sequelae after supportive care and hemodialysis. The serum boric acid concentration of an 82-year-old was 1,800 mg/L 3 hours after accidentally ingesting 30 g boric acid.[62] He survived with supportive care and hemodialysis without developing metabolic acidosis, hypotension, or renal dysfunction. Fifty-two hours after the ingestion of 280 g boric acid, a 45-year-old adult had a whole blood boric acid concentration of 450 mg boric acid/L.[72] The patient died shortly thereafter.

Postmortem

The blood borate concentration in a postmortem heart blood sample from an 18-month-old child was 83.16 mg/L.[85] The child was found in cardiopulmonary arrest at home after apparently ingesting roach powder containing boric acid; she was pronounced dead in the emergency department. The gastric contents from this child contained 60.48 mg borate/L.

Abnormalities

Dehydration may cause electrolyte (e.g., hypernatremia, hyperchloremia) and metabolic (e.g., acidosis) abnormalities following an overdose of boric acid.[55] Occasionally, evidence of renal damage (elevated serum creatinine) and liver damage (elevated aspartate and alanine aminotransferases) may develop after boron toxicity.[75,86]

HEALTH SURVEILLANCE

In rodents, the lowest-observed-adverse-effect level (LOAEL) was the development of reduced fetal body weight, minor skeletal changes, and a slight delay in maturation seen in rats fed 13.6 mg boron/kg/day as boric acid during gestation days 0–20.[87] Developmental toxicity in animal studies appears before reproductive toxicity. Based on the LOAEL value of 13.6 mg boron/kg/day as boric acid for developmental toxicity, an intermediate oral minimal risk level (MRL) of 0.01 mg boron/kg/day was derived using an uncertainty factor of 1000 (10 for extrapolation from animals to humans, 10 for human variability, and 10 for a LOAEL).[5] A study of rats fed diets containing doses of up to 8.75 mg boron/kg/day for 2 years did not detect any adverse effects (i.e., NOAEL).[76] The International Program on Chemical Safety Task Group from the World Health Organization derived a tolerable daily intake level of 0.04 mg B/kg/day using a NOAEL (no-observable-adverse-effect level) of 9.6 mg boron/kg/day from a similar developmental study[64] and an uncertainty factor of 25.[88] Using a benchmark dose for 5% reduction in fetal body weight of 10.3 mg B/kg/day based on the rat developmental toxicity data and an uncertainty factor of 78, Hasegawa et al. calculated a tolerable daily intake of 0.13 mg B/kg.[89]

The WHO provisional guideline for boron in water is 0.5 mg/L based on an NOAEL of 9.6 mg/kg/day in development studies, an uncertainty factor of 60, and a subsequent tolerable daily intake (TDI) of 0.16 mg/kg/day.[90] Ten percent of the TDI is allocated to drinking water (60 kg adult consuming 2 L water/day). Although there are few data, the chronic ingestion of boron exceeding these guidelines has not been associated with specific diseases.[11]

TREATMENT

Gut Decontamination

The effectiveness of gut decontamination in boron toxicity has not been studied. Most accidental ingestions (<200 mg boric acid/kg) of boron compounds (i.e., boric acid) require no measures of decontamination.[71] There are no data to confirm the efficacy of lavage in this setting. *In vitro* data indicate that activated charcoal does not adsorb boric acid well enough to be a practical alternative to other methods of decontamination.[91]

Enhancement of Elimination

Although the pharmacokinetic properties (i.e., low molecular weight, small volume of distribution) of boric acid suggest a potential role for hemodialysis, there are limited pharmacokinetic data on the efficacy of hemodialysis during the treatment of boric acid poisoning. Following the suicidal ingestion of an estimated

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

21 g boric acid, 2 sessions of hemodialysis eliminated about 24% (5 g) of the estimated dose of boric acid.[92] The calculated total body clearance of boric acid during hemodialysis was 3.53 L/hour compared with 0.99 L/hour without dialysis. The serum half-life of boric acid decreased from 13.46 hours to 3.76 hours during dialysis. The renal clearance of boric acid following the suicidal ingestion of 75 g boric acid averaged 274 mL/minute during 2.5 hours of hemodialysis with a high-flux, high-efficiency polysulfone hemodialysis membrane (blood flow rate 400 mL/minute).[84] The serum boric acid concentration decreased from 15.44 to 1.83 mg/dL during this time period. The hemodialysis clearance of boric acid in an 82-year-old man with acute boric acid toxicity was 235 mL/minute with an extraction ratio of 70%.[62] In two young infants accidentally given boric acid in their formula, plasma boric acid concentrations decreased from 257 mg/L and 171.6 mg/L to <10 mg/L during continuous venovenous hemodialysis in 16 hours and 10 hours, respectively.[93] Removal of boric acid was 767 mg (mean clearance, 167 mL/minute/1.73 m^2) and 214 mg (mean clearance, 131 mL/minute/1.73 m^2), respectively.

Antidotes

There are no recognized antidotes for boron poisoning. Experimental data in rats suggest that *N*-acetylcysteine may reduce the renal toxicity of boric acid, but there are no human data.[94]

Supplemental Care

Patients with serious boron intoxications are frequently dehydrated; these patients should receive generous fluid replacement with close monitoring of renal function and electrolyte status. Diazepam (adult, slowly up to 10 mg intravenously; child, 0.1–0.3 mg/kg), lorazepam (adult, 1–2 mg IV), or midazolam are the drugs of choice to treat seizures. Respiratory insufficiency usually results from altered consciousness, except following direct pulmonary toxicity from exposure to boron trifluoride or boron tribromide.

BORANES

PHYSIOCHEMICAL PROPERTIES

Borane compounds (boron hydrides) have the general formula, B_nH_{n+4}; these compounds exist as very different structures than corresponding hydrocarbons as a result of the ability of boron to form multicenter bonds that are exclusively covalent. Pentaborane is a highly volatile, flammable liquid and a strong reducing agent that is highly toxic. Dimethylamine borane is a white solid with an amine odor at room temperature. In contact with water, this substance releases a flammable gas, whereas decomposition into unstable peroxides occurs after prolonged exposure to air. Diborane is a gas, and pentaborane is a volatile liquid, both with poor odor warning properties.[95] Based on studies from the 1950s, the median odor thresholds for boranes are as follows: decaborane, 0.3 mg/m^3; diborane, 2–4 mg/m^3; and pentaborane, ~2.5 mg/m^3.[96] Table 7.4 lists the physiochemical properties of the most common borane compounds.

EXPOSURE

Borane compounds are active reducing compounds previously used in the production of rocket fuel. Other uses for diborane include doping agent, rubber vulcanizer, accelerator of flame speed, and catalyst (olefin polymerization). Decaborane is also a catalyst for olefin polymerization. Pentaborane currently has no commercial uses. Manufacturing processes using dimethylamine borane include the production of thin-metal film, semiconductors, high-temperature printed circuit boards, floppy disks, and power transistors. Exposure to these compounds depends on their form.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The mechanism of toxicity is not well-defined. Rodent and *in vitro* studies suggest that exposure to decaborane inhibits pyridoxal phosphate-requiring enzymes, possibly as a result of the reduction of pyridoxal phosphate by a substance formed non-enzymatically from the presence of decaborane in the aqueous environment of the body.[97] Animal studies indicate that decaborane exposure produces hypertension initially followed by hypotension, bradycardia, and myocardial depression (↓ myocardial contractile force).[98] In rodent studies, inhalation of high diborane concentrations produces primarily pulmonary damage.[99] Histological changes include vascular congestion, alveolar hemorrhage, atelectasis, degeneration of mucosal cells, and sloughing of the mucosal epithelium of the bronchi and bronchioles.

TABLE 7.4. Physical properties and identifying characteristics of borane compounds.

Physical Characteristic	Decaborane	Diborane	Pentaborane
CAS RN	17702-41-9	19287-45-7	19624-22-7
Molecular formula	$B_{10}H_{14}$	B_2H_6	B_5H_9
Molecular weight (g/mol)	122.31	27.69	63.12
Color	Colorless	Colorless	Colorless
Physical state (standard temperature/pressure)	Crystalline solid	Gas	Liquid, volatile
Odor		Offensive, sweet	Pungent
Melting point (°C)	99.6	−165	−46.6
Boiling point (°C)	213	−92.5	60
Specific gravity	0.94 (25°C)	0.96 (air = 1)[a]	0.61 (0°C)
Water solubility (25°C)	Slightly soluble[b]	Insoluble[c]	Decomposes
Vapor pressure (mmHg)	0.05 (25°C)	>760	171 (20°C)
Odor threshold (mg/m^3, air)[96]	0.3 (0.06 ppm)	2–4 (2.2–4.4 ppm)	2.5 (1 ppm)

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number.
[a]Vapor density; [b]Decomposes in hot water; [c]Hydrolyzes in water to boric acid and hydrogen gas (H_2).

CLINICAL RESPONSE

The central nervous system is the primary target organ for borane compounds with varying severity of respiratory tract irritation. Most of the reports on the clinical effects of exposure to borane compounds used data from the 1940s and 1950s with very little analytical confirmation of workplace exposure. These clinical reports document dizziness, nausea, headache, and drowsiness as common symptoms of excessive exposure to these compounds; chest tightness and cough occurred more frequently after diborane exposure than decaborane or pentaborane exposure.[100] Additional symptoms of toxicity include muscle spasm, nervousness, restlessness, fatigue, tremor, ataxia, and convulsions.[101,102] Symptoms may develop soon after exposure to the volatile liquid, pentaborane, whereas symptoms (e.g., nausea, headache, dizziness) following decaborane exposure may be delayed 24–48 hours depending on the intensity of exposure. Respiratory tract irritation developed in two workers within 15 minutes of acute exposure to pentaborane, followed shortly thereafter by seizures, metabolic acidosis, coma, and cardiac arrest.[103] One worker died, and the other worker sustained postanoxic brain damage. Common symptoms reported in coworkers with milder exposure to pentaborane included lightheadedness, confusion, lethargy, insomnia, difficulty concentrating, nightmares, muscle jerks, headaches, and numbness. Separating the effects of post-traumatic stress from the direct effects of pentaborane was difficult; neuropsychological testing suggested the presence of some minimal brain dysfunction and major affective disorders 4–12 weeks after the incident.[104]

TABLE 7.5. Regulations and guidelines for exposure to borane compounds.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	
Decaborane[a,b]	0.3 mg/m^3 (0.05 ppm)
Diborane	0.1 mg/m^3 (0.1 ppm)
Pentaborane	0.01 mg/m^3 (0.005 ppm)
NIOSH	
REL–TWA (10-hour)	
Decaborane[a]	0.3 mg/m^3 (0.05 ppm)
Diborane	0.1 mg/m^3 (0.1 ppm)
Pentaborane	0.01 mg/m^3 (0.005 ppm)
REL–STEL (15-minute)	
Decaborane[a]	0.9 mg/m^3 (0.15 ppm)
Pentaborane	0.03 mg/m^3 (0.015 ppm)
IDLH	
Decaborane[a]	15 mg/m^3
Diborane	17 mg/m^3 (15 ppm)
Pentaborane	2 mg/m^3 (1 ppm)
ACGIH	
TLV–TWA (8-hour)	
Decaborane[a]	0.25 mg/m^3 (0.05 ppm)
Diborane	0.115 mg/m^3 (0.1 ppm)
Pentaborane	0.013 mg/m^3 (0.005 ppm)
STEL–TWA (15-minute)	
Decaborane[a]	0.75 mg/m^3 (0.15 ppm)
Pentaborane	0.039 mg/m^3 (0.015 ppm)

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average.

A case report associated the development of an axonal polyneuropathy with accidental exposure of a chemical worker to liquid dimethylamine borane.[105] Five days after being soaked with dimethylamine borane ($C_2H_{10}BN$, CAS RN: 74-94-2) following a pipe blowout, a 38-year-old man developed numbness and weakness in the distal limbs, dysphagia, slurred speech, and poor concentration. Nerve conduction studies and sural nerve biopsy confirmed axonal polyneuropathy. Some residual muscle weakness and sensory impairment persisted 1½ years after exposure.

DIAGNOSTIC TESTING

Conversion factors for borane compounds at 25°C and 760 mm Hg include the following: decaborane 1 ppm = 4.99 mg/m^3; 1 mg/m^3 = 0.200 ppm; diborane 1 ppm = 1.15 mg/m^3; 1 mg/m^3 = 0.873 ppm; and pentaborane 1 ppm = 2.58 mg/m^3; 1 mg/m^3 = 0.388 ppm. The recommended analytical method for diborane in ambient air is plasma emission spectrometry (NIOSH method 6006) at 249.8 nm with an accuracy of ±21.5% in the range of 0.06–0.25 mg/m^3.[106] There are currently no recommendations for the analysis of decaborane or pentaborane.

HEALTH SURVEILLANCE

Table 7.5 lists the regulations and guidelines for airborne exposure to borane compounds. There are no official biological exposure limits for these compounds.

TREATMENT

Treatment is supportive. The primary risk following severe acute exposure to high doses of borane compounds is central nervous system depression and suppression of the respiratory drive. Patients should be removed from further exposure, and contaminated skin should be washed thoroughly with soap and water after the removal of contaminated clothes. Case reports document symptoms of borane toxicity in first responders after providing medical care to workers with borane toxicity.[103] Appropriate protective gear should be worn when removing exposed patients from the source of borane toxicity. Symptomatic patients should be monitored for respiratory depression and cardiac dysrhythmias. Patients with altered consciousness may require respiratory support (supplemental oxygen, assisted ventilation). There are no antidotes for borane toxicity.

Chapter 8

CADMIUM

HISTORY

The discovery of cadmium as a separate element occurred in 1814.[1] Early cases of cadmium toxicity primarily involved industrial exposure to cadmium dust in the latter 1800s and accidental ingestion of toxic cadmium salts (e.g., bromide).[2] By the early 1900s, cadmium toxicity was a recognized complication of the use of cadmium as an antiseptic and anthelmintic.[3] The industrial output of cadmium was relatively low until the early 1920s because cadmium is a byproduct of zinc production. The rapid expansion of the industrial uses of cadmium began in the 1940s, primarily as a result of the use of cadmium in electroplating; consequently, the body burden of cadmium in the general population has increased dramatically since 1900.[4] In 1946, inhabitants (primarily middle-aged women with low calcium and vitamin D intake) of the Jinzu River basin in Toyama Prefecture, Japan, began developing *itai-itai* (ouch-ouch) disease characterized by severe arthralgia, renal dysfunction, and osteomalacia.[5,6] This disease resulted from consumption of water and rice contaminated by cadmium from the discharges of a local zinc-mining operation, primarily affecting women. The use of traditional Japanese dress with wide hats to screen out sunlight with subsequent reduction in vitamin D synthesis contributed to the musculoskeletal symptoms of *itai-itai* in these women.[7] Gastrointestinal symptoms and renal dysfunction were relatively less prominent than musculoskeletal complications (osteomalacia, compression fractures of the spine). The full syndrome occurred only in postmenopausal women with a history of several pregnancies. Renal dysfunction usually involved the excretion of low-molecular-weight proteins, rarely involving impairment of urine concentrating ability.[8] Other incidents of environmental cadmium contamination include the Mae Sot District, Tak Province, Thailand, where discharges from a zinc mine contaminated local rice fields.[9]

PHYSIOCHEMICAL PROPERTIES

Cadmium (Cd) is a silver-white, soft, odorless metal that belongs to Group 12 (Group IIa) of the periodic table along with zinc and mercury. Cadmium rarely occurs in its metallic state because this metal readily forms a number of divalent inorganic salts. There is no evidence that cadmium forms stable covalent bonds with carbon in nature; therefore, organic cadmium compounds are not toxicologically important compounds.[10] Proteins bind most cadmium in mammals as inorganic salts. Table 8.1 lists the properties and identifying information of metallic cadmium and cadmium salts. Several cadmium salts (acetate, chloride, fluoride, nitrate, sulfate) are very soluble in water, whereas other salts (carbonate, oxide, sulfide) and metallic Cd are insoluble. In nature, the presence of oxygen and acids increases the solubility of cadmium salts. Cadmium has a relatively high vapor pressure compared with other metals, and cadmium oxides form quickly after the evaporation of cadmium. Cadmium is more volatile than lead. The presence of reactive gases (carbon dioxide, hydrogen chloride, sulfur dioxide, sulfur trioxide, water vapor) in the immediate

environment encourages the formation of cadmium salts (carbonate, chloride, sulfite, sulfate, hydroxide). The heating of cadmium alloys above 321°C produces a golden yellow smoke composed of cadmium oxide fumes compared with gray smoke from zinc fumes.[11] The relatively low melting point, excellent corrosion resistance, high thermoelectric conductivity, and high ductility favor the industrial use of cadmium.

EXPOSURE

Uses

The primary industrial application of cadmium salts is the use of cadmium hydroxide in electrode material of Ni–Cd rechargeable batteries; less commonly, cadmium is a constituent of pigments in plastic and glass as well as a component of protective metal plating on steel. Cadmium sulfide is a yellow to deep-maroon pigment present in some paints, glazes, ceramics, glass, and fireworks. The use of cadmium (Cd laurate, Cd stearate) as a stabilizer in plastics (PVC) and components of alloys has declined significantly. Uncommonly, cadmium is a constituent of semiconductors, ceramic glazes, phosphors for television sets and X-ray screens, and a neutron absorbant in nuclear reactors. A cadmium-containing Asian herbal preparation (*chui-fong tokwan*) was distributed illegally in the United States.

Commercial Process

Cadmium exists in nature primarily in association with zinc sulfide deposits (greenockite, sphalerite) at cadmium/zinc ratios of 1/100–1/1,000. Exposure to cadmium may occur at nonferrous foundries as a contaminant in special high-grade zinc, particularly in finishing workers and furnace operators.[12] A variety of products may contain cadmium as an impurity including phosphate fertilizers, cement, fossil fuels, iron, steel, and nonferrous metals (copper, lead, zinc). The production of cadmium (as cadmium oxide) is a byproduct of roasting of zinc-bearing ores with coke or the refining of lead and copper sulfide ores (galena, malachite). The separation of cadmium occurs by distillation or electrodeposition. Cadmium readily volatilizes during smelting, forming respirable cadmium oxide fumes that may cause cadmium toxicity.[13] This metal is also recovered from recycled, Cd-containing batteries.

Sources

Air

Volcanic activity is the primary natural source of cadmium in the air; however, anthropogenic sources (e.g., mining/smelting zinc and lead, fuel combustion, phosphate fertilizers, waste disposal, pigment manufacturing plants) account for most of the cadmium present in ambient air. Mean total cadmium concentrations in air range from <1 ng/m^3 in remote areas[14] to 5–40 ng/m^3 in urban and industrial areas; emissions near anthropogenic sources may exceed 100 ng/m^3.[15] The main sources of airborne cadmium in the United States are the burning of fossil fuels and the incineration of municipal waste that contains rechargeable batteries and plastic.[16] Less common sources include the abrasive blasting of steel bridges.[17] The chemical form of cadmium in the air after combustion from the burning of fossil fuels, including tobacco smoke, is primarily a cadmium oxide aerosol.

Soil

The extensive natural distribution of cadmium in the soil occurs with Cd concentrations averaging ~0.1–0.5 mg/kg (ppm) soil, primarily in association with copper, lead, and zinc ores. In a study of agricultural soil remote from Cd sources, the Cd concentrations averaged 0.27 mg/kg.[18] Phosphate fertilizers contain 3–100 µg Cd/g fertilizer; these phosphate fertilizers are the major source of cadmium in agricultural soils.[12] Other sources of terrestrial cadmium include the land disposal of cadmium-containing waste and the application of sewage sludge containing cadmium. Soil Cd concentrations near long-established smelters may exceed 100 mg Cd/kg soil; contamination of the food chain may occur in areas surrounding these facilities.[19] The deposition of cadmium from the air may contribute significant amounts of cadmium to the soil near point sources of cadmium (e.g., smelters and pigment manufacturing plants).[20] In England, contaminated soil from cadmium mines (average, 87 ppm; range, 2–520 ppm) was not associated with adverse health effects, but local conditions may affect the translocation of cadmium from the soil through the food chain to humans.[21,22]

Water

Cadmium concentration in seawater is typically <0.1 µg/L; however, runoff from point sources of Cd may increase seawater Cd concentrations near harbors and estuaries.[23] In a study of the Spring River Basin containing lead and zinc mining and ore processing in the central United States, Cd concentrations in samples of surface waters under peak flow conditions ranged from <1.0–24 µg/L, whereas samples collected during base flow conditions contained Cd concentrations of <1.0–75.0 µg/L.[24] Groundwater seldom contains detectable concentrations of cadmium, unless local industrial or mining wastes contaminate these waters. Typical cadmium concentrations in drinking water are <1 µg/L (ppb) unless point sources of cadmium are nearby.[25] Soft or acidic water increases the leaching of cadmium and lead from distribution and household pipes, but drinking water contributes minor amounts to the total body burden of cadmium.

Diet

The estimated age-weighted daily intakes of cadmium in nonsmoking adult males and females living in the United States are 0.35 µg/kg/day and 0.30 µg/kg/day, respectively.[26] The difference primarily results from differences in gastrointestinal absorption. Total Diet Study by the US Food and Drug Administration during the early 1980s also indicates that the estimated daily amount of Cd ingested by the average US adult is ~30 µg Cd.[27] Food is the major source of cadmium exposure for the general population, with most foods containing some cadmium. Drinking water and ambient air (<0.5 µg Cd/day) are minor sources of cadmium in the diet for the general population, with the exception of tobacco smoke.[28] Cadmium typically occurs in its free ionic form in water, whereas Cd usually exists as a complex with a variety of ligands (e.g., metallothionein) in food.[29] In general, plant foods (e.g., rice, wheat, green leafy vegetables, potatoes, carrots) contain higher cadmium concentrations than eggs, milk, meat, and fish muscle. Soybeans, peanuts, and sunflower seeds have naturally high cadmium concentrations.

Rice is a leading source of increased Cd exposure in the Japanese population compared with the US population. The average daily intake of Cd in the Japanese diet decreased from ~37 µg during the 1977–1981 period to ~25 µg during the 1991–1997 period.[30] The amount of Cd in the Japanese diet correlated strongly to rice consumption. The actual daily contribution of food (1–3 µg Cd/day) to the total body burden of cadmium is much less than the total daily intake because of the limited bioavailability of cadmium. High-fiber diets and diets rich in shellfish increase the uptake of cadmium relative to the general population.[31] Some foods (e.g., kidney and liver (0.2–1.3 ppm), shellfish (0.1–4.7 ppm), leafy vegetables (0.01–0.06 ppm), potatoes, grains, and cereals) readily absorb cadmium from soil contaminated by phosphate fertilizers, polluted water, or sewage sludge.[1]

The total Cd concentrations are typically higher in the following situations: 1) marine than terrestrial organisms, 2) older than younger organisms, 3) hepatorenal than other tissue, and 4) organisms living near than far away from point sources of cadmium.

The persistence of cadmium in the environment and the long biological half-life (10–30 years) of cadmium account for the accumulation of cadmium in the body with age. The scarcity of chromium in the 1940s resulted in the use of cadmium plating. Acute cadmium poisoning resulted from the acid leaching of cadmium from cadmium alloys in cooking utensils and containers.[32] Most ceramic wares do not now contain acid-leachable Cd concentrations that exceed US FDA standards (0.5 μg/mL).

Lifestyle

Tobacco plants accumulate cadmium depending on soil characteristics; consequently, measurable amounts of cadmium occur in tobacco leaves and mainstream cigarette smoke. Typically, tobacco leaves contain 1–2 μg Cd/g dry weight, resulting in ~0.5–1 μg Cd/cigarette.[33] The mean Cd content of 331 samples of cigarette tobacco from 20 different countries was 1.15 μg/g (range, 0.29–3.38 μg/g), as measured by flameless atomic absorption spectrophotometry after wet digestion with nitric, sulfuric, and perchloric acids.[34] Analysis of tobacco samples in commercial Finnish cigarettes produced from 1920–1984 suggests that the Cd content in tobacco remained relatively stable over those decades.[35]

Tobacco smoking is a significant cadmium source in the form of cadmium oxide for cigarette smokers because mainstream smoke from a cigarette yields 0–6.67 μg Cd depending on the Cd content in the tobacco and smoking characteristics (frequency, duration, intensity).[36] Cd occurs primarily in the particulate phase of smoke. In a study of Saudi Arabian cigarettes with a mean Cd content of 1.81 μg/g dry weight (range, 0.83–2.78 μg/g dry weight), the estimated Cd intake from smoking one pack of cigarettes ranged from 0.22–0.78 μg.[37] Smoking one pack of cigarettes per day doubles the daily intake of cadmium, in part because of the increased uptake of cadmium from the lungs compared with the gastrointestinal tract.[38] The inhalation of passive smoke apparently does not significantly increase blood cadmium concentrations.[39] In contrast to chromium, preliminary studies suggest that lung clearance reduces pulmonary cadmium concentrations after cessation of smoking. In a Finnish study of 45 autopsies, the mean cadmium concentration in the lungs of nonsmokers was 0.4 ± 0.4 μg/g dry weight compared with 3.0 ± 2.2 μg/g dry weight in smokers.[40] The Cd concentration in former smokers decreased to concentrations present in nonsmokers ~20 years after cessation of smoking.

Environmental Fate

Similar to other heavy metals, cadmium is not biodegradable; therefore, the environmental fate of cadmium depends on its physicochemical form.

Air

Cadmium and cadmium salts have negligible vapor pressures; however, combustion processes (e.g., municipal waste incinerators, nonferrous metal production) release small particles in the respirable range (<10 μm). These particles have a residence time of 1–10 days in the atmosphere that allows long-range deposition up to a few thousand kilometers.[23] Deposition of cadmium in urban areas is ~1 order of magnitude greater than the deposition of cadmium in rural areas. Dry deposition and precipitation remove cadmium from the atmosphere. Cadmium and cadmium compounds exist in the air as suspended particles derived from ocean spray, industrial emissions, volcanic discharges, and erosion of soil. Most cadmium appears in the air as cadmium oxide, but other compounds (sulfate, sulfide, chloride) may occur in the atmosphere. These cadmium compounds are stable and do not undergo photochemical reactions.

Soil

Cadmium does not form volatile compounds; therefore, partitioning of cadmium from soil to air does not occur, except through the erosion of cadmium-containing soil. Cadmium is relatively more mobile than most heavy metals (e.g., lead, mercury) with some cadmium leaching from the soil into water, especially under acidic conditions. The strong binding of cadmium to organic matter limits the mobility of Cd in soil.[41] Migration of cadmium depends on soil pH and the presence of organic matter; insoluble Cd salts disperse into sediments, whereas soluble Cd salts are mobile, potentially migrating into water sources. Cadmium accumulates at all levels of the food chain, particularly in plant leaves; however, experimental data suggest that the amount of Cd available for translocation decreases as the total soil Cd concentration increases.[42] Therefore, Cd soil concentrations are not directly correlated to Cd in the food chain unless extremely contaminated soil exists in the area. The binding of cadmium is relatively stronger in wetland than upland soils; thus, Cd is relatively more bioavailable under upland conditions.[43]

Water

Cadmium is more mobile in an aqueous environment compared with other heavy metals (lead, mercury). Similar to the soil, the Cd concentration in water is inversely related to pH and the amount of organic material. Particulate matter rapidly adsorbs most cadmium released into freshwater, and the listed local conditions determine the amount of cadmium that precipitates onto the river bottom. The reducing and oxidizing potential of water does not affect the concentration of cadmium in water because cadmium exists almost exclusively in the 2+ (soluble) state. Photolysis is not an important mechanism for cadmium degradation in an aquatic environment. The partition of cadmium from water to the atmosphere is probably very limited as a result of the poor volatility of cadmium.

Biomagnification requires the transfer of the toxicant through the food chain by ingestion, whereas bioaccumulation involves the direct uptake of cadmium by each level of the food chain, independent of the uptake of lower levels in the food chain. The extent of the bioaccumulation of cadmium depends on the following factors: the physicochemical properties of the species of cadmium, the presence of other metals, physical conditions (pH, salinity, water temperature), the cation exchange capacity of the soil, and the plant species.[1] Aquatic and terrestrial organisms bioaccumulate and bioconcentrate cadmium, depending on water pH and humic content. Although cadmium accumulates at a variety of levels in the food chain, biomagnification of cadmium in the food chain does not occur because of the low bioavailability of cadmium and the tendency of cadmium to concentrate in the liver and kidney rather than muscle.[44]

DOSE EFFECT

Following both acute and chronic exposures to airborne cadmium, the accumulated dose rather than the deposited dose correlates best with a dose-effect relationship.[45]

Acute Toxicity

Inhalation

Case reports associate fatalities from acute chemical pneumonitis and pulmonary edema from estimated exposure to 50 mg Cd oxide/m^3 for 1 hour[46] and 8.6 mg Cd oxide/m^3 for 5 hours;[47] however, these calculations are questionable because the authors based these values on extrapolations from postmortem Cd concentrations in the lung rather than direct measurement of ambient air exposures. Animal studies suggest that exposure to cadmium at concentrations of >0.5 mg/m^3 may produce alterations in the epithelial cells of the lungs.[48]

Ingestion

Gastrointestinal symptoms develop after exposure to oral doses exceeding 0.07 mg Cd/kg.[23] The gastroenteritis produced by cadmium ingestion and the poor bioavailability of oral cadmium doses limit the acute systemic Cd toxicity, depending on the dose.[49] The estimated ingestion of 150 g cadmium chloride by a 17-year-old girl caused hypotension, respiratory arrest, metabolic acidosis, oliguria, and death, despite intensive care including chelation and intubation.[50]

Chronic Toxicity

Long-term exposure to high concentrations of airborne cadmium causes primarily pulmonary and renal effects. An increased prevalence of the urinary excretion of low-molecular-weight proteins occurs in workers exposed to 20–50 μg Cd/m^3 for 10–20 years and in some individuals in the general population ingesting 140–260 μg Cd/day.[51] Diabetic patients may be more susceptible to cadmium-induced renal proximal tubule dysfunction than nondiabetic patients based on the synergistic effect of diabetes and the cadmium body burden on the urinary excretion of β_2-microblobulin and *N*-acetyl-D-glucosaminidase in a cross-sectional European (Cadmibel) study of 2,327 residents of Cd-polluted and non-polluted areas.[52] In a Swedish population-based study of morning urine samples from 813 middle-aged women, regression analysis indicated an interaction between urinary *N*-acetyl-D-glucosaminidase concentrations and insulin-dependent diabetes (β = 2.3, P = 0.042), but not with non-diabetics (β = 0.8). However, the number of diabetics was insufficient to determine the lowest observed effect level. The estimate of the critical concentration in the renal cortex associated with probable kidney dysfunction in 50% of the general population is ~250 μg Cd/g tissue, whereas the critical level associated with renal dysfunction in 10% of the population is ~200 μg Cd/g tissue.[53,54] Pulmonary effects from exposure to cadmium occur exclusively following inhalation in the work environment with evidence of renal dysfunction. Host and nutritional factors influence the development of cadmium-induced bone changes that occur only after very high cadmium exposure.[51]

TOXICOKINETICS

Absorption

The two main routes of Cd absorption are the lungs and gastrointestinal tract. Although limited human data are available, animal studies indicate that percutaneous absorption of cadmium is negligible, except under extreme circumstances. Dermal absorption of Cd is limited. The application of soluble cadmium compounds to the skin of guinea pigs resulted in the absorption of 1.8% of the cadmium over 5 hours.[55]

Inhalation

The uptake of cadmium from the lungs averages ~25% (range, ~10–50%) depending on a number of factors, particularly particle size.[51] The relatively greater cadmium absorption from cigarette smoke than ambient air probably results from small particle sizes and high alveolar deposition based on data from animal studies.[56] Atmospheric cadmium exists primarily as suspended particulates; therefore, particle size is the major determinant of cadmium deposition in the alveoli and pulmonary absorption. Less important factors include mucociliary and alveolar clearance, solubility, and transport through the epithelial lining of the lung. Soluble cadmium salts (chloride, sulfate) pass through the alveolar membrane more quickly than less soluble salts (oxides), but the majority (50–100%) of the cadmium dose delivered to the alveoli eventually will be absorbed, regardless of the solubility of the particular cadmium compound.

Ingestion

In general, absorption of metals in humans is variable depending on multiple factors including chemical species, environmental matrix that surrounds the metal, contents of the gastrointestinal tract, diet, age, and nutritional status (e.g., low iron stores). Limited observations of humans indicate that the bioavailability of cadmium compounds ranges from 2.2–9.0% with an average of ~3–5%.[10,57] Animal studies suggest that the presence of metallothionein-bound cadmium in food reduces Cd absorption and changes cadmium distribution;[58] however, the role of metallothionein in the gastrointestinal absorption of cadmium is probably minimal. Mice fed metallothionein-bound cadmium have higher cadmium concentrations in the kidney compared with mice fed similar amounts of cadmium chloride; these metallothionein-bound Cd-fed mice have comparatively lower Cd concentrations in blood and liver.[59,60] Patients with deficiencies of calcium, protein, iron, or zinc absorb relatively more cadmium than patients with normal concentrations of these elements. In a study of volunteers, the average absorption of 25 μg ^{115m}Cd from a test meal was 8.9 ± 2.0% in 10 subjects with low body iron stores (serum ferritin <20 ng/mL) compared with 2.3 ± 0.3% in 12 subjects with normal iron stores (serum ferritin >23 ng/mL).[61]

Distribution

The body burden of cadmium increases throughout life from ~1 μg at birth to ~20–30 mg by age 50, depending on environmental exposure and smoking. The body burden of Cd in workers exposed to high cadmium concentrations ranges up to 200–300 mg. Most cadmium in the body is bound to a small-molecular-weight, cysteine-rich protein (metallothionein).[62] In the blood, metallothionein binds cadmium, concentrating Cd primarily in the erythrocytes. Transport of Cd by the portal circulation results in the uptake of Cd by the hepatocytes, where the presence of Cd induces metallothionein synthesis, resulting in the sequestration of Cd as Cd–metallothionein complex. Although some uptake of the Cd–metallothionein complex occurs in the kidney, most Cd bound to metallothionein is not available for uptake by the tissues in the body. Cd is also loosely bound to other proteins (albumin, amino acids) and sulfhydryl compounds (glutathione, cysteine) in the blood; metallothionein binds a majority (~60%) of the cadmium in the red cells.

After chronic, low-dose cadmium exposure, about one-half of the body burden of cadmium exists in the kidneys and much smaller amounts (i.e., 20-fold less) in the liver. Autopsy data indicate that the body burden varies with age, sex, race, cigarette smoking, and cause of death.[63] The average Cd concentration in the renal cortex ranges from 11–100 mg/kg wet weight with the 90th percentile being about twice the median Cd concentration.[51] After exposure to the relatively higher Cd concentration in the workplace, the liver stores a greater portion of the cadmium burden. The development of cadmium-induced renal dysfunction results in the loss of cadmium from the renal cortex; in these situations, the cadmium concentration in the liver may substantially exceed the cadmium concentration in the kidney. Even in workers dying from the inhalation of cadmium fumes, the cadmium concentration in the lungs is less than renal or hepatic Cd concentrations.[64] Brain, bone, and fat contain relatively low cadmium concentrations. Postmortem examinations indicate that bone is not a major repository for cadmium, with Cd concentrations in bone being ~1,000-fold less

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. than those in the renal cortex, depending on age and smoking status.[65]

Elimination

Cadmium does not undergo any direct metabolic conversion (e.g., oxidation, reduction, alkylation). The limited oral bioavailability (i.e., <5–10%) of cadmium results in the excretion of the majority of the ingested dose in the feces. Of the adsorbed cadmium dose, excretion occurs approximately equally in the urine and bile. Renal cadmium excretion is very slow and dose-dependent, probably as a result of the reabsorption of the metallothionein–cadmium complex by the epithelial cells of the proximal tubule at low Cd exposures. Biological half-lives of cadmium in the body are several decades. The amount of cadmium in the urine depends on the total body burden of cadmium, the presence of renal dysfunction, and, to a lesser extent, recent exposure. Increased urinary cadmium excretion occurs when proteinuria develops; high Cd concentrations exist in the absence of proteinuria only after short-term, high-dose exposure to cadmium.[66] The elimination of cadmium from blood follows a 2-compartment model with an initial whole blood elimination half-life of 2–4 months that reflects recent exposure and a slow compartment with a half-life of years (e.g., 7–16 years) reflecting the total body burden of cadmium.[67] Figure 8.1 demonstrates the cadmium elimination curve for a nonsmoking copper-cadmium alloy factory worker with renal tubular damage and a currently smoking worker without evidence of tubular dysfunction. Both workers were followed for up to 13 years after the cessation of cadmium exposure.

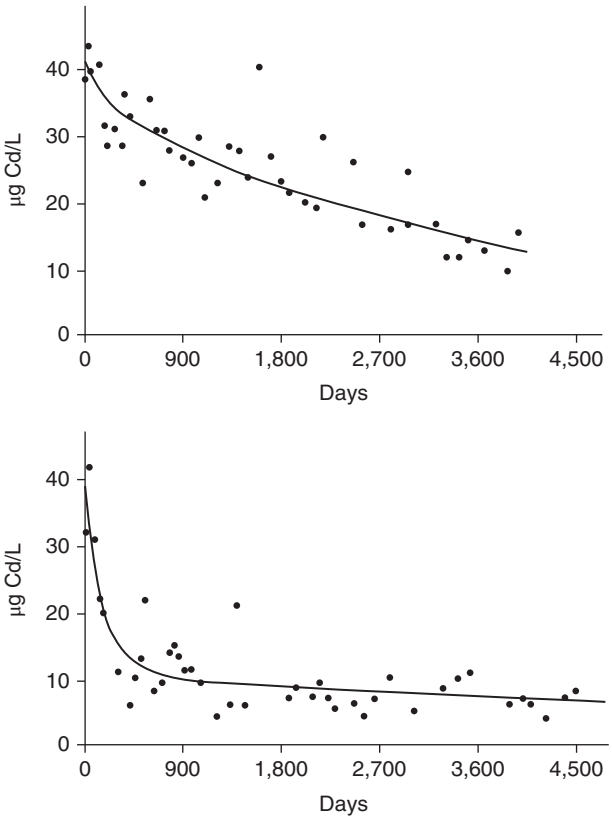

FIGURE 8.1. Blood cadmium elimination curve of two copper-cadmium alloy factory workers followed up to 13 years after cessation of cadmium exposure as measured by spectrophotometric and later atomic absorption methods. (Redrawn from Järup et al.).[67]

Maternal–Fetal Kinetics

There is a maternal–fetal gradient for blood cadmium, with the cadmium concentration in cord blood of neonates generally being lower than maternal Cd concentrations. In contrast to lead and mercury, the placenta is a selective barrier to the transplacental transport of cadmium through the synthesis of metallothionein.[68] This process reduces the cadmium concentration in newborn children to <50% of the maternal concentration.[69,70] Although the placenta selectively retains cadmium because of the synthesis of metallothionein, the placenta limits the transfer of cadmium from the mother to the fetus. In a study of mothers living in Chinese farmland containing cadmium concentrations up to ~9 mg/kg, the maternal blood to cord blood ratio ranged from ~1–99.[71] The cadmium concentration in maternal blood ranged from 0.8–25.2 μg/L with a median of 1.72 μg/L, whereas the cord blood cadmium concentration ranged from 0.02–1.48 μg/L with a median of 0.4 μg/L. Cadmium concentrations in human milk are 5–10% of the concentrations present in maternal blood.[72] In a study of the four stages of breast milk production (colostrums, transitional milk, early mature milk, mature milk), the concentrations of microelements decreased with advancing lactation stages.[73] The mean cadmium concentration in samples from 45 lactating women in each lactation stage ranged from 1.37 ± 0.94 ng/mL in colostrum samples to 0.34 ± 0.19 ng/mL in mature breast milk samples. Analysis of breast milk from smoking mothers suggests that the cadmium concentration in colostrums was significantly higher in smoking than never-smoking mothers; however, the sample size was small.

Chemical Interactions

Reduced iron stores increase cadmium absorption,[61] whereas oral zinc supplements reduce cadmium

absorption. Increased susceptibility to cadmium-induced bone toxicity is associated with vitamin D, calcium, and protein deficiencies.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

Cadmium is a nonessential trace metal that progressively accumulates in the body. The exact mechanism of toxicity for cadmium is unclear. Suspected mechanisms include cadmium binding to sulfhydryl groups on important enzymes, autophagy dysfunction, competition with essential trace elements (zinc, selenium), and interference with calcium-binding sites on regulatory proteins (e.g., calmodulin).[74]

Pathological Changes

Kidney

The kidney is the main target organ following chronic cadmium exposure as a result of the accumulation of Cd in the epithelial cells of the proximal tubule; the subsequent disruption of the resorptive capacity of the proximal tubule causes polyuria, glucosuria, and low-molecular-weight proteinuria. A low-molecular-weight cytosolic protein (metallothionein) selectively binds heavy metal ions including essential trace elements (copper, zinc) and more toxic metals (cadmium, mercury). Metallothionein is an important transport and storage protein that provides some protection against the toxic effects of cadmium in both the kidney and liver[75] as well as regulating the metabolism and function of copper and zinc.[76] In the blood, metallothionein binds cadmium; the glomerulus readily filters cadmium-metallothionein complex followed by reabsorption of the complex by the proximal tubule. Uptake of Cd-metallothionein by lysosomes in the epithelial cells of the proximal tubules results in the degradation of the complex and the release of Cd within the epithelial cell. When the free Cd^{2+} concentrations exceed 50–300 μg/g wet weight in the renal cortex, the free Cd^{2+} interacts with sulfhydryl groups on intracellular proteins to directly alter protein functions (e.g., metal-dependent enzymes), activates calmodulin, and induces oxidative stress leading to cell injury by either necrotic or apoptotic cell death.[77] Early changes induced by excess renal Cd may include alteration of cell–cell adhesion, cellular signaling pathways, and autophagic responses. Subsequently, cytosolic contents of the injured cells are shed into the urine and the reparative process begins in the damaged area where dedifferentiated cells migrate to the denuded area of the basement membrane and replace the injured cells. Animal studies suggest that increased β_2-microglobulinuria begins when the urine concentration of non-metallothionein-bound Cd exceeds 2 ppm, which corresponds to renal cortical Cd concentrations of 150–200 ppm (μg/g).[78] Cd-induced proteinuria progresses slowly and is probably irreversible following continued exposure to high Cd concentrations.[79] The initial renal lesion is proximal tubular dysfunction characterized first by proteinuria, and later by aminoaciduria and glycosuria. Renal failure is rare.[80]

Lungs

Acute exposure to Cd concentrations exceeding 5 mg/m^3 has been associated with the destruction of pulmonary epithelium and the development of tracheobronchitis, pneumonitis, and pulmonary edema. Abnormalities at the cellular level are similar to the damage caused by oxidative stress with alteration of multiple enzymes including catalase, glucose-6-phosphate dehydrogenase, glutathione peroxidase, and superoxide dismutase. Necrosis of Type I alveolar pneumocytes occurs with subsequent hyperplasia of Type II alveolar pneumocytes.

Cadmium is a probable lung carcinogen. Although the mechanism of toxicity is not clear, cadmium is a poor mutagen; this carcinogen probably acts indirectly through non-genotoxic mechanisms. Cadmium potentially induces cancer by multiple mechanisms including inhibition of DNA damage repair, aberrant gene expression, and inhibition of apoptosis. Although the generation of reactive oxygen species by cadmium-induced oxidative stress probably does not directly cause carcinogenic effects, reactive oxygen species play a central role in cadmium carcinogenesis by promoting the above mechanisms.[81]

Bone

Reduction in bone mineral density and increased risk of osteoporosis are complications in residents of cadmium-polluted areas, primarily in subjects with poor nutrition. Animal studies suggest a direct toxic effect of Cd on the bone, resulting in increased bone turnover and decreased bone mineralization. Usually, these subjects have renal toxicity with associated loss

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of calcium and phosphate along with alteration of vitamin D metabolism that may contribute to the formation of structural weakness in the bones. However, several studies suggest that cadmium may have a direct effect on bone resorption based on a correlation between bone resorption biomarkers (urinary hydroxylysylpyridinoline, lysylpyridinoline) and cadmium exposure, particularly in menopausal women.[82] In these studies, reduction in serum parathyroid hormone indicated that cadmium-associated calciuria results from bone resorption rather than decreased tubular resorption.

Postmortem Examination

An autopsy of a worker dying 12 days after exposure to high concentrations of yellow-brown smoke from the melting of copper scrap metal demonstrated diffuse alveolar damage characterized by an exudation of pneumocytes, organized exudate filling the alveolar sacs, interstitial fibrosis, and intra-alveolar hemorrhages. Presumably, this smoke contained high Cd concentrations; however, no analysis of the workplace exposure was reported.[83] The Cd concentration in the right upper lobe was 1.06 μg/g wet weight; no other postmortem values were reported. A 53-year-old steel erector died 5 days after melting cadmium-plated nuts and bolts in a closed space.[47] The postmortem examination demonstrated abnormalities in the respiratory tract and kidneys without significant changes in other organs. There was massive pulmonary edema, hyperemic trachea and bronchi, small pleural effusions, pulmonary consolidation, acute emphysema, and renal cortical necrosis. Histological examination of the kidneys demonstrated bilateral cortical necrosis with thrombosis of the intralobular arteries and afferent arterioles along with thrombotic occlusion of capillary tufts and infarction of many glomeruli. A 55-year-old man died 7 days after welding a cadmium-coated metal fixture that emitted a colored fume.[84] He developed cough and malaise followed by fever, chills, and respiratory distress 3 days later, which progressed despite penicillin therapy and supplemental oxygen. There was no analysis of cadmium concentrations or welding fumes to confirm the extent of cadmium exposure. Postmortem examination demonstrated marked pulmonary edema, thickened, edematous alveolar septae with lymphocytic infiltration and early fibrosis, and hyperplasia of the epithelial lining of the bronchi. The kidneys had occasional pigmented casts in the tubules, but no evidence of cortical damage.

CLINICAL RESPONSE

Acute Inhalation

The clinical features of cadmium-induced metal fume fever include fever, headache, dyspnea, pleuritic chest pain, conjunctivitis, rhinitis, sore throat, and cough developing 4–12 hours after exposure. Although this presentation is similar to acute illnesses caused by inhaling copper, zinc, and other metallic fumes, cadmium-induced metal fume fever may progress to a severe illness. At higher cadmium concentrations, acute chemical pneumonitis may progress to a fatal, acute respiratory distress syndrome.[85,86] Respiratory failure may occur 3–10 days later.[47,87] A 78-year-old nonsmoking man died of respiratory insufficiency 25 days after developing the clinical features of metal fume fever shortly after welding with solder containing 20–30% cadmium.[88] His autopsy demonstrated an elevated blood cadmium concentration (59.4 μg/L) and diffuse bronchopneumonia along with interstitial, perivascular and peribronchial fibrosis. The latter finding suggested preexisting pulmonary disease. Although pulmonary abnormalities on chest X-ray may persist for several months, most acute cases of cadmium-induced respiratory injury recover without sequelae.[89] The 4-year follow-up of a 34-year-old worker with a history of cadmium pneumonitis (cough, dyspnea, myalgia, fever) after a 1-hour exposure to cadmium fumes from welding revealed a normal physical examination and no respiratory complaints.[90] His single-breath diffusing capacity returned to normal, but his total lung capacity was somewhat decreased. A 51-year-old welder developed metal fume fever after welding plates of cadmium silver alloy; he returned to work at the same facility for the next 13 years without further cadmium exposure.[91] Subsequently, he developed progressive pulmonary fibrosis manifested by dyspnea, finger clubbing, basal crepitations, and chest X-ray abnormalities (nodules, diffuse patchy shadowing).

Acute Ingestion

Acute gastroenteritis after Cd ingestion is characterized by the sudden onset of vomiting, diarrhea, and abdominal pain. A large (150 g) ingestion of cadmium chloride produced facial edema, vomiting, hypotension, respiratory arrest, metabolic acidosis, pulmonary edema, oliguria, and ultimately death 30 hours after the ingestion.[50]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Environmental Exposure

Investigation of the effect of excessive cadmium exposure in the general environment primarily involves the examination of the health effects of residents in several cadmium-polluted areas of Japan and China. These studies indicate that the primary target organs are the kidney and bones. The main source of cadmium for these cohorts was chronic ingestion of Cd-contaminated food in the diet. A cross-sectional study of morning spot urine samples from 1,753 middle-aged Japanese women (mostly aged 35–60 years) did not demonstrate clear evidence of renal tubular dysfunction in the general population without exposure to Cd-polluted areas.[92] Although urinary α_1-microglobulin and β_2-microglobulin concentrations were higher in residents with high urine Cd concentrations than residents with lower urine Cd concentrations, the prevalence of residents with microprotein concentrations above standard cutoffs was similar between residents with high and low cadmium concentrations.

Kidney

The earliest manifestation of Cd-induced renal damage in residents of Cd-polluted areas is the increased excretion of low-molecular-weight proteins (β_2-microglobulin, retinol-binding protein, α_1-microglobulin) along with urinary markers of cytolysis (e.g., *N*-acetyl-β-D-glucosaminidase). The health consequences of proximal renal tubular damage remain controversial including the reversibility of these elevated urinary biomarkers. Most environmental studies on Cd-related kidney injury are observational (i.e., case series) with several prospective cohort studies;[93,94,95] a review of these studies did not detect convincing evidence supporting a risk of progression to chronic renal disease or renal failure following environmental cadmium exposure as measured by declining glomerular filtration rate (GFR).[96] Some studies suggest the increased excretion of these markers is irreversible in some residents, but the concentrations may stabilize with a reduction in Cd exposure.[97] A prospective follow-up study of 102 Japanese residents from Cd-polluted areas of Nagasaki, Japan, suggested that these changes are irreversible in some residents.[98] From 1979–1989, the geometric mean urinary β_2-microglobulin of 28 residents over the age of 40 years increased from 1,135.8 μg/g creatinine to 1,999.7 μg/g creatinine ($P = 0.01$), despite the reduction in the urinary cadmium concentrations during this period as a result of soil remediation. In 1979, 29 residents had urinary β_2-microglobulin concentrations exceeding 1,000 μg/g creatinine; by 1989, 25 of these residents had urinary β_2-microglobulin concentrations exceeding 1,000 μg/g creatinine and 21 residents had higher Cd concentrations than the initial 1979 value.

Tubular proteinuria is frequently asymptomatic. Chronic exposure to very high cadmium concentrations may cause glomerular damage, resulting in decreases in glomerular filtration and reduced creatinine clearance. Some follow-up studies suggest that glomerular damage may also develop in residents of Cd-polluted areas. A follow-up study of 29 Japanese residents demonstrated an increase in the urinary protein concentration and a reduction in creatinine clearance during the study period, despite soil remediation and a reduction in the urinary cadmium concentrations.[99] Although the creatinine clearance did not improve during the 10-year study, the serum creatinine concentrations remained in the upper limits of normal reference ranges. The clinical significance of these values was not evaluated. Japanese cohort studies of the cadmium-contaminated Nagasaki Prefecture also suggest that cadmium-induced renal dysfunction is associated with increased mortality (SMR = 1.41, 95% CI: 1.07–1.83), but this association disappears as the cadmium exposure decreases.[100]

Current observational studies do not support a causal relationship between increased kidney stone risk and environmental or dietary Cd exposure based on urine and blood Cd concentrations.[101] In a Swedish population-based prospective cohort study using a self-administered questionnaire on diet and lifestyle at baseline to estimate dietary data and cadmium concentrations in food, the adjusted hazard ratios for kidney stones did not support a strong association between dietary cadmium and kidney stone risk in men (aHR = 0.97, 95% CI: 0.77–1.23, $n = 707$ cases) or women (aHR = 0.99, 95% CI: 0.89–1.43, $n = 290$ cases).[102]

Bone

Bone abnormalities (osteomalacia, decreased bone mineral density, osteoporosis) occur late in the course of chronic cadmium poisoning, usually in association with nutritional deficiencies associated with alterations in serum vitamin D and increased urinary loss of calcium and phosphorus with alteration of parathyroid hormone concentrations. Itai-itai disease (severe arthralgias, renal dysfunction, osteomalacia, alteration of long bones, multiple fractures) was endemic in the heavily Cd-polluted mining area in the Toyama Prefecture of Japan; this disease occurred primarily in malnourished residents and postmenopausal women. Urinary excretion of cadmium was high (30 μg/g creatinine), and stress fractures were common in these

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

patients. Osteomalacia and osteoporosis as measured by a microdensitometer also occurred in Cd-exposed men with renal dysfunction, when compared with non-exposed male subjects; however, the difference in bone density between Cd-exposed and nonexposed men is substantially less than that between Cd-exposed and nonexposed women.[103]

Chronic low-level Cd exposure may also enhance renal loss of calcium and reductions in bone mineral density in populations outside Japan. In postmenopausal Belgian women living near zinc smelters (mean Cd soil concentration, 0.8–14.7 ppm Cd), a 2-fold increase in urinary cadmium correlated to a statistically significant ($P < 0.02$) reduction of 0.01 g/cm^2 in bone density.[104] A doubling of the urinary cadmium was associated with an increase (mean = 1.73, 95% CI: 1.16–2.57) in the relative risk of fractures in women. For women with urinary cadmium concentrations >1 μg/day, the incidence of bone fracture was 13.5/1,000 person-years. A study of 1,021 Swedish residents living in Cd-polluted areas near nickel-cadmium battery production plants demonstrated an ~3-fold increased risk of low forearm bone mineral density in the group with urinary cadmium of >3 nmol/mmol creatinine when compared with the lowest exposure group.[105] There was also a dose-response relationship between increasing cadmium concentrations in the group over 50 years of age and the risk of forearm fractures. In a population-based study of 820 upper-middle-aged Swedish women, multiple linear regression analysis detected significant negative associations between urinary Cd (median = 0.52 μg/L, 95% CI: 0.24–1.3 μg/L) adjusted to density (1.015 g/mL) and bone mineral density ($P = 0.047$).[106] The bone mineral density of women in the upper 99th percentile of urinary Cd concentrations averaged 5–6% lower than women in the bottom 1% of Cd exposure. Increasing urinary Cd was also associated with increasing bone resorption (urine deoxypyridinoline) and decreasing serum parathyroid hormone.

Cardiovascular System

Hypertension

Although some studies suggest an association between modest elevations in systolic blood pressure (1–2 mm Hg)[107] and blood cadmium concentrations, particularly in women,[108] there is no conclusive evidence that cadmium contributes to the development of essential hypertension in the general population.[109,110] Some studies suggest an elevated blood cadmium concentration in hypertensive patients compared with normotensive patients,[111] whereas other studies demonstrated no statistically significant difference in blood cadmium concentrations between the two groups.[80] Existing positive studies indicate that the effect of cadmium on blood pressure is relatively small compared with other confounding variables. The association between blood cadmium concentrations and blood pressure in the positive studies is stronger in never-smoking participants than in former smokers or current smokers. A study of 33,333 Swedish women did not detect an association between cadmium in the diet and cardiovascular disease (myocardial infarction, total cardiovascular disease, stroke).[112] For myocardial infarction, the multivariable-adjusted RR comparing the highest and lowest quartiles of cadmium exposure in the diet was 1.07 (0.88–1.29).

Cardiovascular Disease Mortality

Studies of the effect of cadmium exposure on cardiovascular mortality in the general population are inconclusive. A Belgian study of residents living near cadmium-producing plants did not detect a statistically significant increase in cardiovascular mortality among residents near the plants.[113] Cross-sectional analysis on data from the National Health and Nutrition Examination Surveys (NHANES), 1988–1994 survey, followed for mortality through 2,000 suggested associations between elevated cadmium exposure and increased risk of cardiovascular mortality in men, but not women. Among adult participants, the multivariable-adjusted hazard ratios associated with a 2-fold increase in creatinine-corrected urinary cadmium were 1.21 (95% CI: 1.07–1.36) in men and 0.93 (95% CI: 0.84–1.04) in women.[114] The hazard ratios for cardiovascular disease mortality were 1.36 (95% CI: 1.11–1.66) and 0.82 (95% CI: 0.76–0.89), respectively. Adjusted variables included smoking. Analysis of data from 8,989 participants in the US National Health and Nutrition Examination Survey followed for 4.8 years suggested that environmental cadmium concentrations were associated with increased cardiovascular mortality using Cox regression to analyze the cause of death based on death certificates.[115] Comparing cardiovascular disease mortality in patients with cadmium concentrations in the 80th (0.80 μg/L) and 20th (0.22 μg/L) percentiles, the multivariable-adjusted (smoking status, recent smoking, cumulative smoking dose, sociodemographic/cardiovascular disease risk) hazard ratio was 1.69 (95% CI: 1.03–2.77) for blood cadmium and 1.74 (95% CI: 1.06–2.83) for urine cadmium. Cadmium concentrations were strongly associated with smoking; study limitations (e.g., reliance on death certificates for outcome) prevent conclusions about causation. A meta-analysis of prospective studies on Cd blood concentrations and mortality from cardiovascular disease demonstrated an association of higher

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

blood Cd concentrations with increased cardiovascular disease-related deaths (HR = 1.60, 95% CI: 1.21–2.10; I^2 = 21.4%); however, increasing urine Cd concentrations did not correlate to increased mortality from cardiovascular disease (HR = 1.27, 95% CI: 0.84–1.93; I^2 = 81.1%).[116] Cumulative Cd body burdens correlate better to urine than blood Cd concentrations. In this meta-analysis, estimated Cd intake was not associated with increased coronary heart disease mortality (HR = 1.02, 95% CI: 0.88–1.30).

Nervous System

Several studies have associated hair cadmium concentrations with disruptive behavior including children and US Navy recruits.[117] In a study of 149 children aged 5–16 years in a rural Maryland public school system, hair cadmium correlated inversely to intelligence (verbal IQ) and social achievement scores, but not motor function.[118] Interpretation of these studies is complicated by numerous study limitations including lack of control of confounding variables (home environment, parental IQ, lead exposure) and use of a weak cadmium biomarker (hair cadmium). In a prospective cohort study of 106 Chinese children followed for 4.5 years, cadmium umbilical cord concentrations correlated negatively with the Wechsler Preschool and Primary Scale of Intelligence Revised Edition after controlling for confounding variables. However, most studies of environmental cadmium exposure do not demonstrate a negative association between biomarkers of Cd exposure and neurodevelopment (IQ, behavior). A randomized clinical control trial did not demonstrate any statistically significant decrease in scores on intelligence quotient, neuropsychological function or behavior, and blood Cd concentration at 2 years of age, adjusted for concurrent blood lead, caregivers' IQ, and socioeconomic factors.[119] The median whole blood Cd concentration was 0.21 μg/L as measured by inductively coupled plasma/mass spectrometry. Separating the children into categories based on the whole blood Cd concentrations did not demonstrate any statistically significant differences between the groups, with the exception of the California Verbal Learning Test for Children.

Liver

Although cadmium accumulates in the liver, there is little evidence that liver damage occurs in humans exposed to cadmium commonly present in the environment.[120] A Japanese study of 607 nonsmoking and nondrinking women between the ages of 19–78 demonstrated no correlation between blood cadmium concentrations and serum hepatic transaminases.[121] The geometric mean values for the daily Cd intake and the serum cadmium concentration were 24.7 μg and 1.76 μg/L, respectively.

Occupational Exposure

The primary form of cadmium in occupational exposures is cadmium oxide with the primary target organs being the lungs and kidneys.[23] Following inhalation, the toxicity of different cadmium compounds is similar, despite some differences in solubility (e.g., cadmium sulfide, cadmium selenium sulfide). Chronic rhinitis and anosmia are frequent complaints among workers chronically exposed to cadmium. In a non-blinded study of 16 referents and 55 workers exposed to cadmium fumes during brazing, evaluation of olfactory function indicated that 13% of the workers were moderately or severely hyposmic compared with none in the referent group based on butanol detection threshold (local receptors in nasal epithelium) and odor identification (central processing).[122] Forty-four percent (n = 24) of the cadmium-exposed workers were mildly hyposmic compared with 31% (n = 5) of the referent group. The study did not exclude confounding factors (e.g., smoking); the smoking history of the referents was unknown. Yellowing of the teeth is a potential marker of chronic cadmium oxide exposure.

Lungs

Chronic obstructive pulmonary disease occurs frequently in workers exposed to cadmium, but the association between Cd exposure and the development of emphysema remains inconclusive, particularly in cigarette smokers exposed to multiple carcinogens in tobacco smoke.[123] Methodological considerations (e.g., small sample size, healthy worker effect, limited exposure data, diagnostic accuracy, confounding exposure to pulmonary toxins) limit conclusions from these studies. Early studies that did not control for confounding variables (e.g., smoking) demonstrated a significantly increased incidence of emphysema and chronic bronchitis in cadmium workers,[124] but several subsequent studies did not confirm an excess prevalence of respiratory disease.[125] In a study of 57 male workers using cadmium-containing solder (median calculated cumulative dose = 1.7 mg Cd-year/m^3; range, 0.34–9.9 mg Cd-year/m^3) and 31 referents matched for age and height, there was no statistically significant difference in pulmonary function (FVC, FEV_1, FEV%,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

single-breath nitrogen washout) between the two groups despite the presence of elevated β_2-microglobulinuria in 42% of the exposed workers.[126] Separation of the exposed group into exposure categories did not reveal any dose-response relationships between cadmium exposure and pulmonary function. More recent evidence favors some pulmonary effects from cadmium exposure, albeit small.[127,128] In a study of pulmonary function in 69 smoking and nonsmoking male volunteers (mean = 45 years) exposed to ambient air Cd concentrations of 0.008–1.53 mg/m^3 over several years in a cadmium alloy plant, the residual volume of the Cd-exposed workers averaged 8% higher than controls.[129] Workers with the highest cumulative Cd exposure had slightly larger differences (i.e., 10%). There were no statistically significant differences in the values of FVC, FEV_1, or diffusing capacity. In a study of lung function in 101 copper-cadmium alloy manufacturing workers with ≥1-year exposure to cadmium and referents matched for age, sex, and employment status, decrements in diffusing capacity (transfer coefficient) increased with cumulative cadmium exposure.[130] The FEV_1, FEV_1/FVC%, or both were ≥1.96 SD below published reference values in 33% of the cadmium workers and 17% of the references ($P < 0.05$), whereas the transfer factor was below those values in 19% of the cadmium workers and 3% of the referents ($P < 0.01$). Cigarette consumption was similar in the two groups. Estimation of the cumulative exposures of workers in these studies indicated that the ambient air concentrations of cadmium in these facilities were substantially higher than current workplace standards.

Kidney

The kidney is the main target and most sensitive marker of excessive chronic cadmium exposure. Renal tubular dysfunction is an early marker of renal dysfunction in cadmium workers, and low-molecular-weight proteinuria using sensitive markers (β_2-microglobulin, retinol-binding protein, α_1-microglobulin) is a frequent early finding.[131] Subtle defects in glomerular filtration may precede the onset of proximal tubular impairment as detected by increased urinary concentrations of transferrin and protein;[132] however, the presence of high molecular weight proteinuria usually occurs after the development of renal tubular dysfunction.

A case report associated an increased age-related decline in workers with evidence of proteinuria and/or evidence of renal tubular dysfunction; however, evidence of chronic kidney disease as measured by declining GFR is conflicting.[133] A review of 34 Cd-exposed groups including >3,000 subjects did not find consistent evidence of a rapid decline in GFR, despite the inclusion of older workers with proteinuria and heavy Cd exposure.[96] Heterogeneity, the risk of bias, and a lack of information on methods precluded a meta-analysis of the data from these studies. In a 5-year follow-up study of 23 workers removed from workplace exposure to cadmium because of increased urinary excretion of β_2-microglobulin and/or retinol-binding protein, the estimated reduction in glomerular filtration rate (GFR) over the 5 years was 31 mL/minute/1.73 m^2.[134] Direct measurement of the GFR was not available. The low-molecular-weight proteinuria associated with cadmium exposure is slowly progressive and may be irreversible despite cessation of exposure.[54,135] The hypercalcinuria following high cadmium exposures may increase urolithiasis risks; however, observational studies are inconsistent. In a cross-sectional study of 765 Swedish battery workers using the lowest tercile of cumulative cadmium exposure as referents (<250 μg-years/m^3), the incident rate ratio for self-reported kidney stones in workers with the highest cumulative Cd exposure (>5,000 μg-years/m^3) was elevated (incidence rate ratio, IRR = 3.0, 95% CI: 1.3–6.8), but not in the middle tercile (IRR = 1.6, 95% CI: 0.7–3.4).[136] The results were adjusted for age and calendar time, but not for additional risk factors; overall, the quality of the study was low. A meta-analysis of two cross-sectional and two case-control studies comparing the highest and lowest cadmium exposures on renal stone risks reported a summary odds ratio of 1.56 (95% CI: 1.13–2.14, $I^2 = 56.1\%$, $P_{\text{heterogeneity}} = 0.077$).[137] The few studies and substantial heterogeneity indicate the results may not reflect true causation.

Cardiovascular System

Most studies of workers exposed to cadmium have not detected increased mortality from cardiovascular disease. The exact role of cadmium in the development of hypertension in workers with renal dysfunction remains undetermined. In a study of 6,958 cadmium-exposed workers followed for 41 years (mean duration exposure = 12 years), there was no statistically significant increased mortality from hypertensive diseases (SMR = 119, 95% CI: 85–152), when compared with standardized mortality rates for England and Wales.[138] The SMR for circulatory diseases was 89 (95% CI: 84–94) for the total study period, whereas the SMR for ischemic heart disease was 92 (95% CI: 85–98) for the same period. There was also a statistically significant inverse association between cadmium exposure and cerebrovascular mortality. In a study of US cadmium production workers with cadmium exposure for at

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

least 6 months, 1940–1969 and followed through 1978, mortality from diseases of the circulatory system in this cohort was lower than expected (SMR = 65, 95% CI: 49–85) including heart disease.[139]

Nervous System

Data on Cd-induced neurological injury are limited, with few data to document occupational exposure to cadmium as a cause of neurological abnormalities. Neurological injuries are not typically associated with cadmium toxicity. Several case reports associate cadmium exposure with neurological changes. A case report associated the development of sensorimotor peripheral neuropathy with cadmium exposure during work as a pipe fitter based on physical examination.[140] The nerve conduction studies and electromyogram were normal with the exception of slightly reduced recruitment of normal-appearing motor units. However, the association with cadmium was based on elevated hair cadmium concentrations that are poor biomarkers of occupational cadmium exposure. The urine cadmium concentration was 5 μg/L. A double-blinded epidemiological survey of 13 retired long-term Cd-exposed workers and 19 age-matched controls reported the presence of peripheral neuropathy in 7 (54%) exposed workers and 2 (11%) controls based on symptoms, physical examination (areflexia, anesthesia), and neurophysiological testing; the diagnosis of a peripheral neuropathy required abnormalities in only 2 of the 4 areas.[141] Multiple regression analysis indicated a correlation (OR = 1.26, 95% CI: 1.04–1.51) between the diagnosis of peripheral neuropathy and urinary Cd.

Reproductive Abnormalities

No conclusive evidence associates cadmium with teratogenic effects, either in animals or humans. Limited evidence in humans suggests the possibility that cadmium exposure causes a reduction in birth weight,[142] decreased height,[71] or prematurity.[143] However, there is no consistent pattern of reproductive abnormalities between various studies of the effect of environmental concentrations of cadmium on fetal development.[144,145] Although near-fatal doses of cadmium cause testicular necrosis in several animal species, a small study of male workers exposed to cadmium oxide fumes did not demonstrate decreased testicular hormones.[146] In a study of 83 Belgian smelter workers with a mean urine Cd concentration of 6.94 μg/g creatinine, the probability of a live birth did not differ between the exposed and 138 unexposed controls.[147] About 25% of the workers had evidence of microproteinuria. Fertility was similar in the two groups based on questionnaires regarding live births, age of the family, and date of marriage. The wives were not interviewed to determine confounding variables. Studies on the effect of cadmium exposure on sex hormones are also inconsistent. A study of 40 infertile Nigerian men with oligozoospermia (<20 million/cm^3) and 20 with azoospermia compared various measures of spermatogenesis with serum Cd concentrations as measured by atomic absorption spectrometry.[148] The serum Cd concentration correlated negatively to several measures of spermatogenesis (e.g., sperm density, motility, viability, morphology) and positively to serum testosterone, follicle-stimulating hormone, luteinizing hormone, and prolactin. The study did not control smoking. A population-based study of 263 Chinese men from Cd-polluted areas did not support the correlation between blood Cd and these sex hormones after adjustment for smoking, body mass index, and alcohol consumption.[149]

Carcinogenesis

The International Agency for Research on Cancer listed cadmium and cadmium compounds as human carcinogens (IARC Group 1) in 1993[150] and the US National Toxicology Program as a compound known to be a human carcinogen in 2000[151] based primarily on an increased risk of lung cancer in some occupational cohorts exposed to cadmium. The US EPA classifies cadmium as a probable human carcinogen (Group B1) by inhalation based on limited evidence of increased lung cancer in humans and sufficient evidence of lung cancer in rats. Mortality studies of cadmium exposure and an increased risk of lung cancer are inconsistent with both positive and negative results. Inadequate controls for confounding factors (e.g., smoking, co-exposure to metallic carcinogens), small numbers of lung cancer deaths, and poor correlation between lung cancer mortality and cumulative Cd exposure complicate the interpretation of these studies. Strong evidence from rat studies indicates that cadmium inhalation can cause lung cancer (pulmonary adenocarcinomas), but the evidence is less convincing in other animal species.

Lungs

Occupational Exposure

In several cohorts of workers exposed to cadmium (cadmium recycling facilities, nickel-cadmium battery plants, cadmium smelters/processing plants), the risk of death

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from lung cancer increased; however, a clear association between specific cumulative Cd exposure levels and lung cancer risk remains uncertain. In a meta-analysis of five occupational cohort studies following a mean of 31 years, the weighted relative risk for lung cancer was 0.68 (95% CI: 0.33–1.41) when comparing the highest and lowest cadmium exposure categories; the RR for three occupational case-control studies was 1.61 (95% CI: 0.94–2.75).[152] The lung cancer data do not demonstrate a linear dose-response.

Many epidemiological studies of occupational cadmium exposure are small with no control for confounding variables (e.g., smoking, arsenic, nickel).[153] Exposure to cigarette smoke significantly increases the whole blood cadmium concentrations; therefore, exposure to cigarette smoke is a confounding variable in epidemiological studies of workers exposed to cadmium. Reevaluation of the US smelter data indicated that cadmium is carcinogenic only in the presence of concomitant exposure to arsenic. After adjustment for age attained, year of hire, and Hispanic ethnicity, a reanalysis of the smelter data indicated a significant positive trend ($P < 0.05$) between cumulative Cd exposure and the risk of lung cancer mortality.[154] The trend was not significant in the absence of concurrent exposure to arsenic trioxide. The number of lung cancer deaths in this study was small ($n = 21$). A study of Swedish battery workers exposed to nickel hydroxide and cadmium oxide detected an increased overall risk of lung cancer (SMR 176, 95% CI: 101–287).[155] However, there was a significant dose-related increase in the risk of lung cancer only for combined exposure to cadmium and arsenic. A study of 926 male nickel-cadmium battery workers in the United Kingdom detected a statistically, nonsignificant elevation of the SMR (111, 95% CI: 81–148) for the exposed cohort, but the risk of lung cancer was not related to estimated cumulative cadmium exposure.[156] Although a review of these data suggested that the carcinogenic classification of probable human carcinogen would be more appropriate than human carcinogen,[157] the International Agency for Research on Cancer reaffirmed the designation of cadmium as a human carcinogen in 2012, primarily based on studies of American smelter workers.[158]

Environmental Exposure

Although a meta-analysis of three prospective population studies of lifetime environmental cadmium exposure based on urine cadmium concentrations and adjustment of lung cancer risk for age and smoking suggested a positive association (RR = 1.68, 95% CI: 1.47–1.92; $P < 0.0001$), the association between lung cancer and chronic cadmium inhalation by residents living near point sources of cadmium is inconsistent. In a meta-analysis of three cohort studies of the general population following a mean of 15 years, the weighted relative lung cancer risk comparing the highest and lowest cadmium exposure groups was 1.42 with a 95% CI of 0.91–2.23.[152] The lung cancer data do not demonstrate a linear dose-response. An increased cancer incidence has not been detected following the ingestion of cadmium in water and food including studies of high cadmium contamination in Japan. A mortality study in the English village of Shipham, where high cadmium concentrations occur in the soil, did not detect a significantly increased cancer incidence when compared with the cancer rates from an adjacent village.[159] The cadmium concentration in garden soil from Shipham ranged up to 360 ppm; these concentrations are substantially higher than cadmium concentrations (i.e., 3 ppm) typically found in polluted Japanese soils. A 17-year observational study of residents near Belgian zinc smelters suggested an association between environmental cadmium exposure (24-hour urinary cadmium excretion) and lung cancer.[160] The adjusted hazard ratio for lung cancer was 1.70 (95% CI: 1.13–2.57, $P = 0.011$) for a doubling of the 24-hour urinary cadmium excretion and 1.57 (95% CI: 1.11–2.24, $P = 0.012$) for a doubling of cadmium concentration in the soil. Adjustments for confounders included smoking and arsenic exposure; however, arsenic concentrations were calculated for only 26% of the study population. The association between lung cancer and cadmium exposure remained statistically significant only when calculating arsenic exposure by the geometric mean arsenic excretion within the 10 districts of the study and not with multiple-regression analysis. Based on a single urinary cadmium concentration at baseline and cancer mortality followed for up to 20 years, the Strong Heart Study of 3,792 American Indians compared baseline urine cadmium concentrations with annual cancer mortality.[161] The adjusted hazard ratio (aHR) comparing the 80th vs. the 20th percentiles of urine cadmium for lung cancer mortality was 2.27 (95% CI: 1.58–3.27) after adjusting for sex, age, smoking status, cigarette pack-years, and body mass index. Urine cadmium concentrations of the study group were not followed during the course of the study.

Prostate

The causal association between cadmium exposure and an increased cancer incidence in tissues other than the lungs is not definitive. The association of cadmium with prostatic cancer is relatively weak and inconsistent;[162,163] however, experimental animal studies

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

indicate high cadmium doses produce tumors in multiple tissues of several species and strains by different routes of exposure, including the prostate.[164,165] Some early European epidemiological studies detected an increased risk of prostate cancer following cadmium exposure in the workplace, but more recent studies have not confirmed this relationship. In a cohort mortality study of 522 Swedish men exposed to cadmium for at least 1 year between 1940–1980 in a cadmium-nickel battery factory, the SMR for prostate cancer was 108 ($n = 4$) for all workers; however, the SMR for 295 workers with at least 5 years of Cd exposure and 20 years of latency (i.e., with substantially higher Cd exposure in earlier years) was 148 ($n = 4$). The latter was statistically significant. Several case-control studies of workers exposed to cadmium demonstrate marginal increases in the incidence of prostatic cancer among cadmium workers.[128,166] Other case-control studies did not associate an increased risk of prostate cancer with cadmium exposure.[167,168] The Strong Heart Study did not detect an association between baseline urine cadmium concentrations in the American Indian cohort and prostate cancer mortality during the 20-year study.[161] Rodent studies indicate that chronic inhalation of cadmium produces prostate tumors following cadmium exposure below the Cd concentrations necessary to cause testicular toxicity.[169] Accumulation and retention of prostatic cadmium appear highly androgen-dependent in these studies. Cadmium concentrations high enough to cause testicular necrosis are required to produce Leydig cell tumors in rodents.[170] Higher cadmium doses produce an increased incidence of prostate tumors in animals only following the preservation of testicular function by zinc treatment. Most oral studies in laboratory animals have not found significant increases in cancer incidence.[171] In animal studies, preneoplastic lesions of the prostate appeared in male rats, but these lesions were not dose-related.[169] A meta-analysis of cadmium exposure and the risk of prostate cancer suggests the risk is higher following occupational rather than environmental exposure; however, substantial heterogeneity among studies limits conclusions.[162]

Kidney

Several hypothesis-generating case-control studies suggest that chronic occupational exposure to high cadmium doses (i.e., exceeding current workplace standards) increases the risk of renal cancer, with typical relative risk estimates in the range of 1.3–2.0.[172,173] However, these epidemiological studies examined many types of exposure, and the cadmium exposure estimates were based primarily on questionnaires.

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.0089 μmol/L = 8.9 nmol/L
1 μmol/L = 112.4 μg/L
1 nmol/L = 0.112 ng/L
1 nmol/mmol creatinine ≈ 1.12 μg/g creatinine

Analytical Methods

Electrothermal atomic absorption spectrometry (ET/AAS) and inductively coupled plasma/atomic emission spectrometry (ICP/AES) are the most common methods for the determination of cadmium in biological and environmental samples; the limit of detection for the former is ~0.1 μg/L in blood and 1–10 μg/kg (ppb) in food and tissue.[1,51] The limit of detection (LOD) for biological samples using ICP/AES and microwave digestion was 0.15 μg/L.[174] Quality assurance programs (e.g., acid-washing, double-distilled water rinsing, reduced volatilization during analysis) are necessary to ensure that interference, contamination, and analyte loss do not invalidate the measurement of samples with low cadmium concentrations. Although the LOD of neutron activation analysis is relatively low (0.1–1 mg Cd/L), methodological problems limit the use of this analytical technique except for the determination of Cd in tissues (kidney, liver).[175] NIOSH Method 7300 for the determination of cadmium in ambient air (membrane filter, digestion with nitric and perchloric acid) has a LOD of 0.3 μg/L. EPA Method 1638 using inductively coupled plasma/mass spectrometry with nitric acid digestion can detect Cd in water samples with an LOD of 0.025 μg/L. Whole blood specimens should be collected in acid-cleaned, heparinized containers (glass or plastic) that do not contain heavy metal contamination; the specimens should be refrigerated until analysis.[176]

Biomarkers

Blood

Although the total body burden of cadmium is difficult to assess without a renal biopsy, the blood cadmium concentration is the best measure of recent (within the last several months) exposure with some contribution from long-term body burden.[177,178] Blood is typically superior to urine in the assessment of body burden for metals with long biological half-lives (i.e., cadmium) as a result of reduced variability in cadmium concentrations.[179]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The plasma contains much lower cadmium concentrations than whole blood because most cadmium in whole blood resides in erythrocytes. In the general population, the plasma contains only ~30% of the cadmium in whole blood.[180,181] For workers chronically exposed to cadmium, the plasma contains substantially less Cd (i.e., ~13%) than whole blood, reflecting the increased contribution of the cadmium body burden.[182]

General Population

The whole blood Cd concentration in the unexposed general population is usually <0.5 μg/L with Cd concentrations exceeding 1 μg/L suggesting environmental or dietary Cd exposure. In the Canadian Health Measures Survey, the geometric mean cadmium concentration in adults was 0.42 μg/L (95% CI: 0.37–0.48 μg/L), similar to the geometric mean blood cadmium concentrations in adults from the US NHANES (men, 0.37 μg/L; women, 0.41 μg/L) and Germany (0.58 μg/L) studies.[183] The mean and median blood cadmium concentrations in the Korean National Health and Nutrition Examination Survey (958 men, 944 women) were 1.67 μg/L and 1.55 μg/L, respectively.[184] In a study of 588 nonsmoking Japanese women from 1991–1997, the geometric mean whole blood Cd concentration was 1.90 ± 1.86 μg/L. Whole blood Cd concentrations are relatively lower in children because of the slow excretion of Cd from the body and the accumulation of Cd with age. The median whole blood Cd concentration in a study of ~4,000 urban and rural German children was ~0.1–0.2 μg/L with an upper 95th percentile of <0.4 μg/L.[185]

Relatively higher whole blood cadmium concentrations occur in smokers and subjects with low iron stores than nonsmokers with normal iron stores. Analysis of US NHANES data from 1999–2006 demonstrated a statistically significant difference in the whole blood Cd concentration between cigarette smokers (GM = 0.95 μg/L) and nontobacco consumers (GM = 0.31 μg/L) after adjustment for gender, body mass index, age, ethnicity, and survey year.[186] The whole blood Cd concentrations were not significantly different between smokeless tobacco consumers and nontobacco users. In a regression model using NHANES data from 1999–2010, a history of smoking within the last 5 days was associated with an increase in the geometric mean blood Cd concentration of 55% (range, 40–71%); there was no statistically significant increase in the urine Cd concentration.[187] In a study of 1,811 New York City adults, the geometric mean whole blood Cd concentration was 0.77 μg/L (95% CI: 0.75–0.80 μg/L) compared with 1.53 μg/L in heavy smokers.[188]

Substantial geographical variation occurs in the blood cadmium of middle-aged men 40–59 years of age. An Italian study of urban residents demonstrated 95th percentile cadmium concentrations in nonsmokers and smokers of 1.4 μg/L and 2.3 μg/L, respectively, as measured by graphite furnace atomic absorption spectrophotometry.[189] A study of this age group indicated that the 95th percentile for nonsmokers was <2.0 μg Cd/L, whereas the whole blood cadmium concentration in 1% of men smoking >1 ppd exceeds 7 μg/L.[190]

Toxicity

Biological monitoring equivalents (BEs) are concentrations in blood or urine that correspond to the maximum existing health-based exposure guidelines. The calculated BEs in whole blood for the US EPA chronic RfD and the ATSDR chronic MRL are 5.3 μg/L and 4.4 μg/L, respectively;[191] these concentrations substantially exceed the blood cadmium concentrations in most individuals in the general population.

Postmortem

Case reports of antemortem and postmortem blood suggest the occurrence of postmortem redistribution.[192] In a study of 66 autopsies of adults (mean = 45.6 years) without known excessive Cd exposure, the geometric mean Cd concentration in postmortem femoral and cardiac blood was 2.59 μg/L and 11.81 μg/L, respectively.[193] Nine cases had postmortem blood cadmium concentrations ranging from 82–600 μg/L, as measured by inductively coupled plasma/dynamic reaction cell/mass spectrometry. Regression modeling indicated that the blood cadmium concentration increased with the postmortem interval ($P < 0.006$); the mean time between death and blood collection was 13.3 hours (range, 0.5–24.5 hours). The postmortem Cd concentrations were statistically higher than reference values in the general population. The smoking history was mostly unknown.

Urine

Urine Cd is predominately a measure of cumulative Cd exposure and renal Cd concentrations, but the urine Cd concentration does respond somewhat to recent Cd exposure. Following low cadmium exposures (i.e., general environmental, moderate occupational) in subjects with normal renal function, the urine cadmium concentration reflects total body burden.[194] In a study of 109 renal biopsies from healthy renal transplant donors, kidney Cd concentrations were strongly associated ($r_p = 0.70$, $P < 0.001$) with urine Cd concentrations adjusted for creatinine.[195] The relationship was nonlinear with relatively lower urine Cd concentrations at higher kidney Cd concentrations. The association between kidney Cd and whole blood

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Cd concentrations was weaker ($r_p = 0.44$, $P < 0.001$) than creatinine-adjusted urine Cd concentrations. Following high cadmium exposure, urine cadmium concentrations reflect recent exposure. Urine cadmium concentrations increase substantially when renal tubular damage releases intrarenal cadmium and reduces the further uptake of cadmium in the renal cortex.[196]

General Population

The most important determinants of urine cadmium concentrations in the general population are increasing age, smoking (>10 cigarettes/day), and residence in Cd-polluted areas (e.g., eating vegetables in Cd-contaminated soil).[197] Urine cadmium concentrations usually increase up to the age of 50 years and then decrease.[198] Typical urine Cd concentrations in residents from areas without excessive Cd exposure range from 0.4–1.0 μg/L (3.5–8.9 nmol/L) for nonsmokers and from 1.4–4.0 μg/L (12.5–35.6 nmol/L) in smokers; smoking approximately doubles the baseline urine Cd concentrations. In a Swiss study of 1,409 subjects over the age of 15 years, the median Cd concentration in 24-hour urine samples was 0.13 μg/L; the median Cd concentration for smokers was 0.19 μg/L compared with 0.11 μg/L for never-smokers.[199] The median Cd amount excreted in the 24-hour urine samples was 0.23 μg (95% upper CI: 0.81 μg). In the US NHANES III study (1988–1994) of 22,162 participants (6–>70 years), the mean value for urine cadmium was 0.57 μg/L (0.48 μg/g creatinine). In 7,970 urine samples from the 1999–2002 NHANES survey, the mean Cd concentration was 0.41 μg/L with an upper 95th percentile of 1.3 μg/L. These Cd concentrations were not associated with subclinical renal tubular dysfunction. In 2,848 urine samples from the US adult population in NHANES IV (2009–2010), the geometric mean was 0.179 μg/L and the median was 0.180 μg/L with a 95th percentile of 1.03 μg/L.[200] Urine cadmium concentrations increase with age and smoking. Urine cadmium concentrations averaged 1–2 μg/L in Japanese women from non-polluted areas; samples from other countries demonstrate lower mean urinary cadmium concentrations (0.54–0.88 μg/L).[198] A study of 588 nonsmoking women from 27 locations throughout Japan demonstrated a geometric mean urinary Cd concentration of 2.50 ± 2.14 μg/L compared with 4.39 ± 1.96 μg/g creatinine and 2.59 ± 1.92 μg/L for results corrected to a specific gravity of 1.016.[30] In a study of spot urine samples from middle-aged Japanese women, the grand geometric mean of the urine Cd concentration was 1.3 μg/g creatinine with a range of 0.8–3.2 μg/g creatinine.[92]

Toxicity

Early adverse effects of cadmium toxicity primarily involve the kidney and to a lesser extent the bones. Cadmium-induced renal dysfunction is unlikely in subjects with urine cadmium concentrations of <2 μg/L.[201] However, chronic exposure to low Cd concentrations (<2.0 μg/g creatinine) may cause subclinical increases in the urinary excretion of high molecular mass enzymes and low-molecular-weight proteins,[202] but the threshold concentration of elevated microproteins varies substantially between different studies and populations. In general, 5 μg Cd/g creatinine corresponds to ~100 μg/g renal cortex wet weight.[23] The following classes of proteins are measured in order to assess the effects of cadmium on the kidney: 1) high molecular mass enzymes (alanine aminopeptidase, AAP; *N*-acetyl-β-D-glucosaminidase, NAG), 2) intermediate molecular mass proteins (albumin, transferrin), and 3) low molecular mass proteins (β_2-microglobulin, β_2-M; retinol-binding protein, RBP; α_1-microglobulin, protein HC or α_1-M). Low molecular mass (M_r) proteins easily pass through the glomerulus and are reabsorbed by the proximal tubules. The earliest manifestation of renal tubular toxicity is the increased excretion of low molecular mass proteins (β_2-M, α_1-M, RBP) in the range of 0.5–3 μg Cd/g creatinine, reflecting subclinical dysfunction of proximal renal tubule reabsorption.[203,204] The intermediate M_r proteins (albumin, transferrin) measure glomerular filtration because under normal circumstances only small amounts of these proteins appear in the urine; however, defects in tubular reabsorption also increase the amount of these proteins in the urine because some of these proteins are filtered by the glomerulus and reabsorbed by the renal tubules. The high M_r proteins originate in the proximal renal tubular tissue, and these proteins (NAG, AAP) are usually more sensitive indicators of renal damage than the low M_r proteins (β_2-M, RBP, α_1-M).[205] A variety of factors affect the urinary concentration of these biomarkers including sex, age, body surface area, blood pressure, circadian rhythms, inter-day variability, aspirin, diabetes mellitus, hypertension, and rheumatoid arthritis.[206] Hence, the upper limits of normal depend on the reference population and individual characteristics. Some controversy exists over whether these measures of proximal renal function detect dysfunction before the impairment becomes irreversible.

In a study of 74 Japanese inhabitants with elevated urinary β_2-microglobulin concentrations followed 5 years after cessation of excessive Cd, the urinary β_2-microglobulin continued to increase during the 5-year follow-up in subjects with urine β_2-microglobulin concentrations exceeding 1,000 μg/g creatinine. The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

β_2-microglobulin concentrations in the other inhabitants remained stable (but did not decline).[207] Complications in establishing a definitive threshold concentration at which cadmium-induced renal toxicity begins include the ubiquity of cadmium and confounding factors (diet, individual kinetics, preexisting disease, vitamin deficiencies) that contribute to the development of renal disease following cadmium exposure.[208] Cadmium exposure increases urinary calcium concentrations by decreasing the uptake of calcium by renal tubules;[209] however, there are limited data correlating urine calcium concentrations and renal dysfunction.

Hair

Hair Cd concentrations are qualitative, but not quantitative measures of the body burden of cadmium. Although analysis of cadmium in hair has theoretical advantages, hair cadmium concentrations are not reliable predictors of toxicity or excessive occupational exposure as a result of external contamination and individual variation from differences in hair acidity.[210,211] Hair cadmium concentrations may be helpful as a screening test for the general population,[212] but the weak correlation between Cd body burden and hair concentrations limits the use of this test. In a study of 40 residents of a Cd-polluted area of Japan, hair cadmium concentrations correlated weakly or moderately to body burden; blood cadmium concentrations were much better measures of the cumulative cadmium dose.[213] A study of Cd hair concentrations in maternal and newborn hair suggested that the median cadmium hair concentration in newborns of currently smoking mothers was higher than that in newborns of maternal nonsmokers or past-smokers (i.e., stopped before the third trimester).[214] However, the confidence intervals were wide and Cd hair concentration did not discriminate between the groups on an individual basis. The median hair Cd concentration was not significantly different in another arm of the study comparing light smokers (9.1 ± 5.1 cigarettes/day) and nonsmokers.

Abnormalities

Blood/Urine

Microcytic anemia may develop in heavily exposed workers who usually, but not always, respond to iron therapy. Studies of populations exposed to high Cd concentrations in the diet have not detected evidence of a correlation between cadmium exposure and the presence of anemia.[215] Urine calcium concentrations may increase in patients with chronic exposure to high Cd concentrations.

Neuropsychological Testing

A cross-sectional study of 42 active and retired cadmium workers demonstrated slowing of visuomotor function and simple reaction time along with an increase in complaints consistent with peripheral neuropathy and equilibrium when compared with a nonexposed control group from the same company.[216] These abnormalities were correlated to the maximum urine cadmium concentration measured during the course of their employment. There were no statistically significant differences in neuropsychological scores for switching reaction times, finger tapping, or digit span. The neuropsychological test scores were adjusted for years in school, but not for other, more robust measures of intelligence (e.g., vocabulary). The study did not report nerve conduction studies in the exposed workers; therefore, the neurological complaints could not be correlated to objective evidence of peripheral nerve dysfunction. Neuropsychological testing demonstrated abnormalities of coordination, peripheral sensation, and prolonged reaction times in two workers exposed to cadmium during a fire when compared with reference norms.[217] There were no preexposure neuropsychological test scores to determine any postexposure changes or analyses of ambient air including no ambient cadmium concentrations. Because of the difficulties inherent in comparing neuropsychological test scores between groups, more studies are necessary to define the neurological effects of cadmium.

HEALTH SURVEILLANCE

Risk Assessment

Studies on the benchmark dose for estimating cadmium reference levels indicate that both renal function and osteoporosis are critical reference points. The World Health Organization established a lower 95% confidence limit of the benchmark reference dose (BMDL) for environmental cadmium exposure of 5.0 μg/g creatinine in urine. A review of Japanese data suggested a lower BMDL for cadmium of 1.5–3.2 μg/g creatinine in urine.[218] In a Chinese study of 83 female controls, 104 women from moderately Cd-polluted areas and 151 women from heavily Cd-polluted areas, the BMDL of urine cadmium associated with osteoporosis was 3.78–6.36 μg/g creatinine based on z-scores below −2 from dual-energy X-ray absorptiometry of the nondominant wrist.[219] The BMDL for low bone mass was somewhat lower (2.14–3.99 μg/g creatinine). The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

BMDL of urine cadmium for osteoporosis was substantially lower in women > 60 years of age than in women <60 years of age.

The ATSDR calculated the acute inhalation minimal risk level from a LOAEL of 0.088 mg Cd/m^3 as cadmium oxide based on a study of 5 male and 5 female F344 rats exposed to 0, 0.1, 0.3, 1, 3, or 10 mg cadmium oxide/m^3 (0, 0.088, 0.26, 0.88, 2.6, or 8.8 mg Cd/m^3) 6.2 hours/day, 5 days/week for 2 weeks.[220] The earliest histological abnormalities were alveolar histiocytic infiltrate along with focal inflammation and minimal fibrosis in alveolar septa in rats exposed to Cd concentrations of ≥0.088 mg Cd/m^3. The uncertainty factor was 300 based on factors of 10 for the use of a LOAEL, 3 for extrapolation from animals to humans with dosimetric adjustments, and 10 for human variability. The data were unsuitable for benchmark dose analysis because of the lack of data on the shape of the dose-response relationship below the 100% response level. To derive the chronic-duration inhalation MRL, the ATSDR used an analysis of European environmental exposure studies to estimate the internal dose (urinary cadmium expressed as μg/g creatinine) corresponding to a 10% excess risk of low-molecular-weight proteinuria (urinary cadmium dose, UCD_{10}).[23] The 95% lower confidence limit of the UCD_{10} ($UCDL_{10}$) was 0.5 μg/g creatinine; the estimated inhalation exposure to produce this value (in addition to dietary exposure) was 0.1 μg Cd/m^3. The MRL was derived from an uncertainty factor of 10 for human variability and the lack of human data. The chronic inhalation MRL was derived from the 95% lower confidence limit benchmark dose associated with a change of one standard deviation from the control that produced bone mineral density changes in rodents and an uncertainty factor of 100, whereas the ATSDR based the chronic oral MRL on the lower 95% confidence interval of the benchmark dose for low-molecular-weight proteinuria in human studies. The US EPA based their reference doses for water and food on the estimated chronic intake necessary to produce a kidney Cd concentration of 200 μg/g kidney tissue wet weight.

Environmental Monitoring

Airborne cadmium concentrations in the workplace vary substantially, depending on the type of industrial processes, engineering design, and working conditions. Historical estimates of occupational cadmium exposure indicate substantial decreases in ambient air concentrations in most industries since the mid-20th century. Examination of static area sampling results in a study of 926 UK nickel-cadmium battery workers demonstrated the highest mean Cd concentrations (range, 0.35–1.29 mg/m^3) from 1954–1963 compared with the lowest concentration from 1989–1992 (range, 0.002–0.03 mg/m^3).[156] In a study of Chinese Ni-Cd battery factory workers with renal damage and Cd exposure, the geometric mean of area sample was 2.17 mg/m^3 (range, 0.1–32.8 mg/m^3) as Cd oxide dust.[221] Based on reviews of airborne Cd concentrations in 697 areas and 236 personal samples of copper-cadmium alloy workers from 1951–1983, the estimated Cd exposure decreased from 0.6 mg/m^3 in 1926 to 0.056 mg/m^3 in 1980.[222] The US Occupational Safety and Health Administration (OSHA) reduced the permissible exposure limits (PEL) for cadmium by 95% to 5 μg Cd/m^3 for all cadmium compounds in 1992. Table 8.2 lists regulatory standards and recommended guidelines for cadmium exposure in air, water, diet, and biological samples.

Biological Monitoring

The most widely used measure of chronic cadmium exposure is urinary cadmium concentrations, but urine Cd concentrations do not reflect recent changes in cadmium exposure (e.g., first year of occupational Cd exposure) unless the recent Cd exposure is very high. The blood cadmium concentration is a better measure of current (i.e., within several months) exposure; therefore, this biomarker is the preferred biological exposure index during the first year of exposure and during changes in cadmium exposure.[223] Although cadmium is an IARC Group 1 (human) carcinogen, studies associating cytogenetic endpoints and cadmium exposure are inconsistent. As a result of study limitations (small sample size, selection bias, inadequate control of confounders, insufficient exposure data), there currently are inadequate data to correlate cadmium exposure to cytogenetic endpoints.[224]

Urine

Standard practice indicates that cadmium urine concentrations should be measured in μg Cd/g creatinine to correct for dilution, but there is controversy regarding the importance of adjusting the cadmium concentrations for urine density.[225,226] Dilute urine samples (i.e., specific gravity <1.010, urine creatinine <0.3 g/L) should not be used routinely for biological monitoring. Random urine sampling is sufficient because of the long urinary elimination half-life of cadmium. Urine

TABLE 8.2. Regulations and guidelines for exposure to cadmium and cadmium compounds (as cadmium).

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	5 μg/m^3 (action level 2.5 μg/m^3)
PEL-Ceiling	None
PEL-acceptable maximum concentration (30 minutes maximum during 8-hour shift)	None
NIOSH	
REL–TWA (10-hour)	Potential carcinogen[a]
REL–STEL (15-minute)	Potential carcinogen[a]
IDLH	9 mg/m^3
ACGIH	
TLV–TWA (8-hour)	10 μg Cd/m^3 as Cd for total particulate[b]
STEL (15-minute TWA)	None
Biological exposure indices	
Urine	5 μg/g creatinine
Blood	5 μg/L
US FDA	
Bottled water allowable limit	5 μg/L
US EPA	
RfC (chronic inhalation exposure)	None
RfD (chronic oral exposure)	
Food	1 μg/kg/day
Water	0.5 μg/kg/day
Carcinogenic inhalation unit risk	1.8×10^{-3} per μg/m^3
MCL water	5 μg/L
WHO	
Air quality guidelines	0.005 μg/m^3
Water quality guidelines	3 μg/L
ATSDR	
MRL Acute inhalation (<14 days)	0.03 μg/kg/day
Chronic inhalation (≥1 year)	0.01 μg/kg/day
Intermediate oral (15–364 days)	0.5 μg/kg/day
Chronic oral	0.1 μg/kg/day

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; EPA = (US) Environmental Protection Agency; FDA = (US) Food and Drug Administration; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; MCLG = maximum contaminate level goal; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfC = reference concentration; RfD = reference dose; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average.
[a] Lowest feasible concentration; [b] 2 μg Cd/m^3 for the respirable particulate fraction.

specimens should be collected in acid-cleaned plastic or glass bottles, while avoiding the use of rubber or colored plastic. Sampling should occur outside the workplace after removing work clothes and showering to reduce Cd contamination. The pH of the container used for collecting urine samples to analyze β_2-microglobulin concentrations should remain above pH 5.5 because this enzyme degrades below pH 5.5.

Cadmium and Metallothionein

At low cadmium exposure (i.e., general environment, low-moderate occupational exposure), the Cd-binding proteins (e.g., metallothionein) are not saturated and the urine cadmium concentration reflects the body burden of cadmium and the critical target organ (kidney) concentrations.[227] Urine cadmium concentrations reflect recent exposure when the metallothionein binding sites

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

are saturated during very high Cd exposures. As the intracellular Cd concentrations increase in the proximal renal tubule, epithelial cell injury develops resulting in substantially increased renal Cd and metallothionein excretion. Consequently, polyuria and proteinuria develop; then, urinary cadmium concentrations reflect substantial amounts of current exposure rather than total body burden.[182] Measurements of urine cadmium concentrations in workers with renal dysfunction do not accurately reflect workplace exposure. Cadmium follows the same transport pathways as intestinal absorption of essential elements and plasma proteins for urinary excretion; consequently, essential metal deficiencies and proteinuria may confound interpretation of the renal effects of cadmium at low concentrations, particularly in the presence of altered renal physiology.[228]

Metallothionein binds most urinary cadmium; therefore, metallothionein is a potentially sensitive indicator of the body burden of cadmium without the disadvantage of interference with external contamination.[229] A urine metallothionein concentration of 300 μg/g creatinine correlates to a urine Cd concentration of 3 μg/g creatinine; however, urine cadmium concentrations with or without correction for density remain the urine biomarker of choice for measuring cadmium body burden. The utility of using chelating agents to monitor cadmium burden remains unclear.

Low-Molecular-Weight Proteins

Classification of urinary proteins includes the following: 1) high-molecular-weight enzymes (microsomal alanine aminopeptidase, *N*-acetyl-β-D-glucosaminidase), 2) intermediate-molecular-weight proteins (albumin, transferrin), and 3) low-molecular-weight proteins (β_2-microglobulin, retinol-binding protein, α_1-microglobulin). The presence of excessive urinary concentrations of low-molecular-weight proteins is a biomarker of proximal renal tubule dysfunction, whereas increased urinary concentrations of intermediate-molecular-weight proteins indicate dysfunction in glomerular filtration. Beta$_2$-microglobulin is the most common measure of proximal renal tubular function; however, this biomarker is unstable in acidic urine and precautions are necessary to prevent degradation during storage. Urinary β_2-microglobulin concentrations of 300–1,000 μg/g creatinine confirm an excessive cadmium exposure with potentially reversible renal tubular dysfunction following cessation of Cd exposure, whereas concentrations ranging from 10,000–100,000 μg/g creatinine imply renal damage.[227] The presence of increased β_2-microglobulin is not specific for Cd-induced renal disease because the elevation of this microprotein occurs in renal disease (e.g., chronic pyelonephritis, urinary tract infections), increasing age, and other disease processes (e.g., congenital Fanconi syndrome).[230]

Urinary retinol-binding protein is also a sensitive indicator of decreased tubular reabsorption, but this low-molecular-weight protein is not specific for cadmium-induced damage in the kidney.[231] Retinol-binding proteins increase in the urine when proximal tubular reabsorption decreases for any cause; therefore, this nonspecific, low-molecular-weight protein supports but does not confirm an excessive cadmium exposure. At urine cadmium concentrations below 10 μg Cd/g creatinine, α_1-microglobulin (protein HC) and *N*-acetyl-β-D-glucosaminidase (NAG) isoenzymes may be sensitive markers of proximal renal tubular dysfunction.[232,233,234] In biological fluids, NAG is present in two major enzymatic forms (A or acidic, B or basic) and several minor forms (I_1, I_2, As, P). Although the B isoform is a more sensitive and reliable biomarker of Cd-induced renal damage than the isoenzyme A form, most analytical methods measure the sum of both forms. Total *N*-acetyl-β-D-glucosaminidase (NAG) is a secretory product (lysosomal enzyme) of the kidney that is a nonspecific marker of renal toxicity. Protein HC is a more stable marker in acidic urine than β_2-microglobulin;[235] however, the lack of data necessary to estimate the predictive value of these measures regarding the clinical course of renal function in subjects with early elevations of these markers limits the routine use of these biomarkers to assess cadmium-induced renal damage. Renal injury following chronic cadmium exposure is usually nonreversible.[236]

Biological Exposure Indices

US OSHA standards require biological monitoring of all cadmium-exposed workers at least annually.[237] If the urine Cd concentration exceeds 3 μg/g creatinine or the urinary β_2-microglobulin concentration exceeds 300 μg/g creatinine, the worker should receive a medical evaluation, the biological monitoring should be increased to every 6 months, and source of increased Cd exposure identified and remediated. Removal from cadmium exposure is required when the urine cadmium concentrations exceed 15 μg/g creatinine or urine Cd concentrations exceed 3 μg/g creatinine in the presence of elevated urinary β_2-microglobulin. United States OSHA standards also require removal from cadmium exposure when the urinary β_2-microglobulin exceeds 1,500 μg/g creatinine.

The World Health Organization recommends an exposure limit of 10 μg Cd/g creatinine and the introduction of control measures at an action level of 5 μg Cd/g creatinine. The presence of biomarkers

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of renal dysfunction (i.e., low-molecular-weight or high-molecular-weight proteinuria) occurs consistently at urine cadmium concentrations exceeding 10 μg Cd/g creatinine; this value corresponds to a cadmium concentration of 200 ppm (μg/g tissue) in the renal cortex.[238] Several studies suggest an increase in low-molecular-weight proteins (β_2-microglobulin, retinol-binding protein) when the urine cadmium concentrations exceed 5 μg Cd/g creatinine.[231,239,240] In a study of 65 Chinese smelter workers exposed to airborne Cd oxide concentrations ranging from 4–187 μg/m^3, 9 workers (13%) had low- or marginally low-molecular-weight proteins and/or high β_2-microglobulin values.[241] Of these nine workers, four had urine Cd concentrations of 5–10 μg/g creatinine (mean exposure duration = 11.6 years, range 2.5–1.2 years). Even though these changes are subclinical, studies suggest that Cd exposures producing these urine Cd concentrations may increase the age-related decline in renal function (i.e., glomerular filtration) even after cessation of Cd exposure.[28] The risk of permanent renal dysfunction at these urine Cd concentrations increases significantly, especially when urinary β_2-microglobulin concentrations exceed 300 μg/g creatinine.[227] The ACGIH recommended lowering the biological exposure indices to 5 μg Cd/g creatinine in 1993. The basis for this lower level of cadmium exposure is the prevention of early biochemical changes in the kidney; however, a direct link between the appearance of these biochemical changes and the subsequent development of permanent kidney damage remains controversial.[242]

Blood

Concentrations

Whole blood cadmium concentrations reflect both recent and long-term cadmium exposure; after exposure creases, the initial half-life is ~2–4 months followed by the terminal half-life of several decades. Several years after exposure ceases, the whole blood Cd concentrations reflect the total body burden. Elevated blood Cd concentrations occur within weeks of acute exposure and stabilize within a few months in the presence of continuing Cd exposure. The whole blood Cd concentration reflects the intensity of exposure.[157] In a study of 17 newly hired Swedish Cd-Ni battery factory workers, the whole blood Cd concentration increased for the first 3 months and then plateaued.[243] Typical whole blood Cd concentrations in Cd-exposed workers range from 5–50 μg/L with high-dose exposures producing whole blood concentrations up to 100–300 μg/L. In workers with moderate Cd exposure (whole blood <10 μg/L), the blood cadmium concentration reflects the amount of cadmium exposure within the last several months; however, as the body burden of cadmium increases from prolonged exposure, a greater portion of the blood cadmium results from contributions from the body burden of cadmium. Consequently, the blood cadmium concentration is most useful to assess recent changes in exposure to cadmium in workers with moderate exposures and evaluate the risk of renal damage after cadmium exposure ceases in workers with large body burdens of cadmium. Smokers have higher whole blood Cd concentrations than nonsmokers. In a study of 158 cadmium workers, the mean whole blood cadmium concentration in active smokers was 0.97 μg/L compared with 0.85 μg/L in nonsmoking workers without passive smoke exposure; the effect of smoking on blood Cd concentrations is greatest at Cd concentrations near the concentrations present following typical environmental exposure.[244] Blood cadmium concentrations also increase with age. Cumulative cadmium in the blood is a better measure of cumulative dose than the retrospective estimation of historical air cadmium concentrations.[245]

In a study of 18 men (9 smokers, 9 nonsmokers) employed in an alkaline battery factory with a mean duration of employment of 10 years (range, 2–29 years), the mean airborne Cd concentration collected in personal samplers was 7.6 μg/m^3 (95% CI: 7.1–8.8 μg/m^3), whereas the mean whole blood Cd concentration was 14.1 μg/L (CV = 17%). There was a statistically significant difference in the whole blood Cd concentration between smokers and nonsmokers, with the former being ~2-fold higher than the latter. Cadmium exposure exceeding whole blood Cd concentrations of 10 μg/L for 20 years was associated with an increased incidence of renal dysfunction. A study of cadmium workers revealed that 10% of the workers with blood concentrations of 10 μg Cd/L for 30–40 years had elevated excretion of low-molecular-weight proteins in their urine.[246]

Biological Exposure Indices

US OSHA standards require biological monitoring of all cadmium-exposed workers at least annually for urine cadmium, urine β_2-microglobulin, and blood cadmium.[237] Removal from cadmium exposure is required when the whole blood cadmium concentrations exceed 15 μg/L. If the whole Cd concentration exceeds 5 μg/L, the biological monitoring should be increased to every 6 months and the source of increased Cd exposure identified and remediated. The World Health Organization recommends an action level of 5 μg Cd/L and an upper limit of exposure of 10 μg Cd/L. Recently, the ACGIH recommended lowering the biological exposure index for cadmium from 10 μg Cd/L

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to 5 μg Cd/L. The new US OSHA standards require removal from exposure to cadmium when the blood cadmium concentration exceeds 15 μg Cd/L or the blood cadmium concentration exceeds 5 μg Cd/L in the presence of an elevation of urinary β_2-microglobulin. The German Biological Tolerance Value (BAT) is 15 μg Cd/L and is a temporary guideline for medical examination.

Medical monitoring

The purpose of the medical surveillance program is the periodic monitoring of cadmium workers for recent cadmium exposure, cadmium body burden, and potential or current kidney damage. The preplacement examination should include a comprehensive work and medical history with a careful record of smoking history, diet, and prior renal disease (e.g., chronic pyelonephritis, diabetes-associated renal dysfunction), prostate exam, screening pulmonary function tests, chest X-ray, and a complete blood panel (complete blood count, BUN, creatinine, alanine aminotransferase). Analysis of the urine should include cadmium concentration, albumin, glucose, and total and low-molecular-weight protein concentrations. Follow-up medical examinations depend on the results of biological monitoring. If the results are normal, the workers should be re-examined in 1 year and then biennially thereafter.

TREATMENT

Stabilization

The primary risk following severe acute exposure to very high cadmium oxide fumes is the development of metal fume fever (cough, upper respiratory tract irritation), the delayed development of pneumonitis, and potentially fatal pulmonary insufficiency. Patients should be removed from further cadmium exposure, and contaminated skin should be washed thoroughly with soap and water after the removal of contaminated clothing. Symptomatic patients should be monitored for respiratory insufficiency with pulse oximetry.

Gut Decontamination

Vomiting usually occurs after the ingestion of toxicologically significant amounts of cadmium. There is no evidence that cadmium binds to charcoal. Treatment is supportive with the replacement of fluid loss and antiemetic medication for nausea and vomiting. There are few human data to guide therapy following the ingestion of large doses of soluble cadmium compounds.

Elimination Enhancement

There are inadequate human or animal data to support the use of hemodialysis to increase the removal of cadmium. In a study of 100 male smokers on maintenance hemodialysis for chronic renal failure, the mean whole blood Cd concentration before hemodialysis was 6.22 ± 1.24 μg/L (95% CI: 5.45–6.99 μg/L) compared with 4.07 ± 1.53 μg/L (95% CI: 3.36–4.78 μg/L).[247] *In vitro* studies suggest that extra-corporeal complexing hemodialysis as an adjunct to chelation therapy may reduce the exposure of the kidney to the toxicity of chelating agents (e.g., EDTA); however, inadequate data are available to recommend this therapy.[248]

Chelation

Inadequate data are available to determine the effectiveness of chelating agents for acute or chronic cadmium poisoning; common antidotes tested include British Anti-Lewisite (BAL), calcium disodium ethylenediaminetetraacetic acid ($CaNa_2EDTA$), 2,3-dimercaptosuccinic acid (DMSA), 2,3-dimercapto-1-propanesulfmonic acid (DMPS), and dithiocarbamate compounds (diethyldithiocarbamate, dimethyldithiocarbamate).[249] Animal studies suggest $CaNa_2EDTA$ and DMSA are effective chelating agents for acute cadmium toxicity when administered within 2–8 hours,[250,251] but the issues of unproven clinical efficacy and redistribution to other tissues (e.g., brain, kidney) remain a concern, particularly with $CaNa_2EDTA$.[252,253] The efficacy of chelating agents for improving chronic cadmium toxicity (i.e., renal dysfunction) is unproven. Binding of most plasma cadmium to proteins and other molecules (albumin, macroglobulin, metallothionein) limits the ability of chelating agents to eliminate cadmium from target organs of toxicity.[77]

British anti-Lewisite (BAL) increases cadmium nephrotoxicity; therefore, this chelator is not recommended for cadmium toxicity. As a result of the lack of effective chelating agents, chronic cadmium exposures require no chelation; treatment involves the removal of the person from sources of cadmium contamination. In a study of 17 workers removed from cadmium exposure for elevated urine cadmium and β_2-microglobulin concentrations, periodic administration of ethylenediaminetetraacetic acid (0.5 g IV EDTA/day for 3 days once a year) did not reduce chronic Cd-induced renal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. dysfunction.[254] Chelation therapy was administered 1989–1999 with the exception of 1992–1994. The reversibility of renal dysfunction was associated with urine Cd concentration below 10 μg/g creatinine at the time of removal from Cd exposure, whereas there was no reduction in Cd-induced renal damage in the workers with urine cadmium concentration above that value. The annual administration of EDTA had no beneficial effect on renal tubular dysfunction as measured by urinary β_2-microglobulin concentrations. Because of the lack of any clinically effective chelating agent, experimental work continues on new chelating agents (THP-12-ane N_4, monoesters of DMSA).[255,256] *In vitro* studies suggest that DMSA is superior to DMPS and *N*-acetyl-cysteine as a chelating agent to efficiently bind the Cd-metallothionein complex and theoretically enhance the urinary Cd excretion; however, these chelating agents also removed zinc.[257]

Supportive Care

Treatment of acute poisoning from cadmium fumes remains supportive with attention toward fluid and electrolyte balance, oxygenation, and the detection of chemical pneumonitis with respiratory failure. Screening tests include serum creatinine, urine analysis (creatinine, protein, glucose, amino acids, calcium), chest X-ray, arterial blood gases, and complete blood count. The treatment for chronic cadmium toxicity primarily involves supportive care and removal from exposure to cadmium sources.

Chapter 9

CHROMIUM

The most stable and common form of chromium is the trivalent state (Cr^{3+}), whereas the most common commercial form of chromium is the strongly oxidizing, hexavalent state (Cr^{6+}). Elemental chromium (0) does not occur naturally on earth. Trivalent chromium is an essential trace metal necessary for the formation of glucose tolerance factors and the metabolism of insulin that has commercial applications in tanning and pigments. Commercial applications of Cr^{6+} compounds include corrosion inhibition, plating, glassware-cleaning solutions, wood preservatives, manufacture of safety matches, metal finishing, and the production of pigments.

TRIVALENT

HISTORY

In 1798, Vaquelin discovered the element chromium in the Siberian red lead ore, crocoite ($PbCrO_4$). Chromium is the sixth-most abundant element in the earth's crust. This metal always occurs in combination with other elements, displaying a wide variety of colors. Only meteorites contain free chromium; most chromium exists in chromite (Cr^{3+}) ore along with iron and oxygen.[1] The mining of chromite ore in the United States ceased in 1961; subsequently, the United States became totally dependent on foreign sources of chromium by 1985, until surface mining of chromite resumed in the late 2000s.[2]

PHYSICOCHEMICAL PROPERTIES

Table 9.1 lists the identifying information and physical properties of elemental and trivalent chromium. Although the oxidation states of chromium range from 2− to 6+, the important valences are Cr^{3+} and Cr^{6+}. Elemental chromium (Cr^0) does not occur naturally on earth. Most chromium compounds exist as halides, oxides, or sulfides. Most naturally occurring chromium exists in the trivalent state, predominantly combined with iron or other metal oxides. The most stable form of chromium is the trivalent oxide form that has low solubility and limited reactivity, resulting in limited mobility in the environment and low toxicity.[3] The divalent (chromous) form is a strong reductant; this form of chromium rapidly decomposes in air or water to the chromic (trivalent) state. Cr^{4+} (chromium oxide, CrO_2) and Cr^{5+} compounds are relatively unstable and occur infrequently in nature.

As indicated in Table 9.1, most trivalent chromium compounds are poorly water-soluble in pH 4–11 except acetate, chloride (hexahydrate), and nitrate salts. In alkaline media, trivalent chromium easily oxidizes to hexavalent chromium. Basic chromium sulfate is an unusual hexa-coordinate, a corrosive form of trivalent chromium that liberates up to 6 mol of hydrogen ions per mole and avidly binds proteins in tissues.[4] Although there is no direct evidence that biological systems can

convert trivalent compounds to hexavalent compounds,[5] *in vitro* studies suggest the possibility of the conversion of Cr^{3+} to Cr^{6+} by H_2O_2 or the glucose oxidase system.[6]

EXPOSURE

Production Processes

Chromite ore (Cr^{3+}) is the major source of chromium with the highest grade of ore ($FeOCr_2O_3$) containing slightly more than 50% chromic oxide (Cr^{3+}). Production of chromium metal involves the reduction of chromite ore with aluminum, carbon, or silicon followed by purification. Commercial production of basic chromic sulfate for the tanning industry typically involves the reduction of sodium dichromate with organic compounds (e.g., molasses) in the presence of sulfuric acid or the reduction of dichromate with sulfur dioxide. Limited amounts of chromite ores are mined in Oregon, but most chromite for the use of chromium in the United States is imported (South Africa, Kazakhstan, Russia, Zimbabwe).

Uses

The primary users of chromium compounds are the chemical, metallurgical (stainless steel, mild steel, high alloy steel), and refractory industries (heat-resistant). Commercial applications of trivalent chromium primarily involve leather tanning and the production of green, orange, red, and yellow pigments. The steel industry is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a major consumer of chromium metal during the production of stainless steel. In addition to stainless steel, chromium applications in the metallurgical industry include the use of ferrochromium intermediates in cast irons and nonferrous alloys. The high melting point of chromium and its resistance to acid and alkali are ideal characteristics in the refractory industry. Chromium is a component of chrome and chrome-magnesite castables, chrome-magnesite firebricks in furnaces, and granular chromite in various heat-resistant applications. Trivalent chromium picolinate is an ergogenic aid and a dietary supplement for insulin-dependent diabetes mellitus and hypoglycemia; however, the use of chromium for these indications remains equivocal.[7,8] A meta-analysis of seven randomized clinical trials of patients with type 2 diabetes mellitus using >250 μg Cr^{3+}/day for 3 months suggested that Cr^{3+} supplementation reduced fasting blood sugar compared with placebo; HbA1c, body mass index, and lipids remained unchanged.[9] Although the commercial applications of natural isotopes (^{50}Cr, ^{52}Cr, ^{53}Cr, ^{54}Cr) are limited, radioactive isotope ^{51}Cr is commonly used in biomedicine.

Sources

Although air is the major route of occupational exposure to chromium, inhalation is a minor route of exposure for the general population.[10] Most chromium released into the environment results from human activities at stationary point sources (waste incineration, fuel combustion, industrial processes). Combustion and the processing of ore discharge mostly trivalent chromium into the environment as chromium oxide;[11] however, small amounts of hexavalent chromium occur in fly ash from coal-fired power plants[12] and soil near chromate manufacturing sites.

Almost all of the exposure of the general population to chromium results from the chromium in the diet with food and water accounting for a mean daily intake of ~60 μg and 2 μg, respectively.[2] The estimated mean daily intake of chromium from air is <0.2–0.4. Chromium picolinate is a popular supplement for weight loss and bodybuilding, despite the lack of proven efficacy.[13,14] This compound is also an experimental drug for the treatment of atypical depression.[15]

Air

Total chromium concentrations in US outdoor ambient air are usually low (median, <0.02 μg/m^3).[16] Typical total chromium concentrations in rural areas of the United States are <0.01 μg Cr/m^3, whereas concentrations in urban areas average 0.01–0.03 μg/m^3 with a range up to 0.6 μg/m^3.[17] Stationary fuel combustion accounted for slightly less than half of the total airborne emissions of chromium in Los Angeles between 1976–1980; releases from metal industries accounted for 26–45%.[18] Total chromium in fly ash typically ranges from about 300–600 μg/g fly ash.[19] Although hexavalent chromium (CrO_2Cl_2, CrO_3) is present in fly ash from coal-fired power plants, most chromium emitted into the ambient air from combustion processes and ore processing industries exists as Cr_2O_3 (Cr^{3+}).[10] Chromium is a constituent of cigarettes;[20] the presence of chromium in cigarette smoke may increase chromium concentrations in indoor air substantially above outdoor ambient air concentrations of chromium.

Soil

Chromium concentrations vary widely in soil depending on the composition of parent rocks. A collection of US soil samples demonstrated total chromium concentrations ranging from 1–2,000 mg/kg with a geometric mean of ~37 ± 2.37 mg/kg (estimated arithmetic mean, 54 mg/kg).[21] Deposition of commercial products containing chromium accounts for a majority of the chromium in soil; very high chromium concentrations in soil may result from the deposition of these commercial products in local areas (e.g., landfills).[22] Fertilizers may contain chromium as well as other metals (e.g., arsenic, cadmium, lead, nickel). In a study of Canadian tree planting operations using commercial bulk fertilizers, the total chromium concentration in six samples ranged from 50–114 μg/g (ppm) as measured by inductive coupled plasma/mass spectrometry.[23] The average soil concentration of total chromium underneath wood decks treated with a chromate-containing wood preservative was 43 mg/kg.[24] Most chromium in soil occurs as insoluble trivalent salts (oxide, carbonate). Bioaccumulation of chromium from soil to plants is relatively low, and biomagnification of chromium up the terrestrial food chain is unlikely.[25]

Water

Shallow ground water in the United States typically contains total chromium concentrations ranging from 2–10 μg/L compared with a mean chromium concentration of 0.3 μg/L in sea water.[26] The total chromium concentrations in US rivers range from <1–30 μg/L with a median of ~10 μg/L.[27] Chromium in the aquatic phase exists either in solubilized solution or suspended particles. Soluble chromium accounts for a small amount of the total chromium in water as both hexavalent and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. trivalent chromium. The major source of chromium in aquatic systems is domestic wastewater effluents. Less important sources of chromium in aquatic systems include the following sources in the order of importance: metal manufacturing, ocean dumping of sewage, chemical manufacturing, processing nonferrous metals, and atmospheric fallout.[22]

Diet

Food (e.g., meat, fish, fruits, vegetables) is the major source of chromium for most individuals; drinking water does not contribute significant amounts of chromium (<4 μg) to the diet unless total chromium concentrations exceed 25 μg/L.[10] The typical total chromium concentration in US drinking water averages 0.4–8.0 μg/L with a mean value of 1.8 μg/L; most values are below 5 μg/L.[28] Corrosion of the water pipes may increase the total chromium concentration up to 15 μg/L;[29] however, contaminated wells near anthropogenic sources of chromium may contain substantially higher chromium concentrations. The contribution of airborne chromium to the daily intake of chromium in persons without occupational chromium exposure is minimal (<0.2–0.6 μg) because of the very low total chromium concentrations in ambient air.

Trivalent chromium is probably an essential nutrient with an adequate daily intake of 20–45 μg in healthy adolescents and adults;[2] this value corresponds to the recommended daily intake of trivalent chromium for adults by the US Institute of Medicine in the National Academy of Sciences.[30] The US Food and Drug Administration recommends daily intake of total chromium is 120 μg. Studies of the US diet indicate that the amount of total chromium ranges from 25–224 μg/day with a mean of 60–79 μg/day.[31,32] A study of 32 volunteers indicated that the average daily diet of most people ranges from 10–40 μg Cr; the bioavailability of dietary chromium was dose dependent, ranging from 2% at 10 μg/day to 0.5% at 40 μg/day.[33]

The estimated daily oral intake of total chromium for UK infants (1 year), children (11 years), and adults is 33–45 μg, 123–171 μg, and 246–343 μg, respectively.[10] The reported daily intake of total chromium from the diet has decreased over the last few decades as a result of improved instrumentation and a reduction in contamination from sources (e.g., stainless steel containers).[34] Most fresh foods contain low total chromium concentrations including vegetables (20–50 μg/kg), fruits (20 μg/kg), and grains/cereals (40 μg/kg).[17] Foods high in chromium include green beans, broccoli, high-bran breakfast cereals, and some brands of beer and wine.[35] Frozen or canned vegetables, canned fruits, chicken eggs, seafood, and meat may contain up to 200 μg Cr/kg.[16] In a study of fish from 167 Northeastern US lakes, the mean total chromium concentration was 0.19 μg/g with a range of 0.03–1.46 μg/g.[36]

ENVIRONMENTAL FATE

Although there are limited data on the speciation of chromium, trivalent chromium is the predominant species in the environment.[10] The environmental fate of chromium depends on its chemical species. Trivalent chromium forms relatively inert precipitates, and this form of chromium may persist in soil or sediments. However, the bioavailability of trivalent chromium is limited.

Air

Chromium particles in air possess mass median diameters of ~1 μm.[37] Removal of chromium from the atmosphere occurs primarily by dry deposition and to a lesser extent wet deposition. Based on the size of chromium particles, the expected residence time in the air is <10–14 days. Chromium compounds do not volatilize from water. Canadian studies suggest that most (>90%) of the chromium in air is trivalent chromium.[10]

Soil

The mobility of trivalent chromium (i.e., predominant oxidation state) in soil is relatively poor, especially compared with other metals.[38] The fate of chromium in soil depends on the redox potential and pH of the soil. The presence of low levels of organic matter, oxygen, manganese dioxide, moisture, and brush fires facilitates the conversion of the trivalent form to the hexavalent form.[39] In most soils, chromium occurs primarily in the trivalent state (i.e., insoluble carbonate or oxide) that is relatively immobile because of its strong adsorption to organic particles.[40] Soluble chromium compounds are more mobile in soil, and the solubility of trivalent chromium in soil may increase as a result of the formation of soluble complexes with organic matter in acidic soil. Available evidence indicates that biomagnification of chromium in the aquatic food chain (water → marine organism) and bioaccumulation in plants (soil → above ground plant parts) are not clinically significant; most chromium absorbed from soil to roots is not translocated to above ground plant parts.[41] Additionally, biomagnification in the terrestrial food chain (soil → plants → animals) is unlikely.[2,26]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Water

Chromium compounds do not volatilize from surface water to air; most of the aqueous chromium in surface water ultimately deposits in the sediment with residence times up to 18 years in lake water based on an analysis of water in the Great Lakes.[42] Soluble chromium accounts for a very small percentage (i.e., <0.002%) of the total chromium in water, and particles (iron oxide, clay, organic) suspended in water absorb most chromium.[2] The valence state of chromium in water depends on pH and redox potential in the aquifer. Trivalent chromium predominates under reducing conditions, typical of the more acidic conditions in deep groundwater. Although the oxidation of trivalent chromium to hexavalent chromium may occur in aerobic water, the oxidation half-life is very long (in years).[43] Biomagnification of chromium along the terrestrial food chain is unlikely because of the low bioavailability of chromium due to the formation of complexes with humic acid and the limited translocation of chromium to edible plant parts.[41,44]

DOSE EFFECT

Ingestion

Other than the corrosive chromium sulfate, trivalent chromium compounds are relatively nontoxic. In nutritional studies, no signs of toxicity occurred following the ingestion of up to 1 mg trivalent chromium/day.[45] In a Chinese study of the effects of trivalent chromium on cholesterol and glucose concentrations in type 2 diabetics, the daily administration of 1 mg chromium picolinate was associated with a reduction in the cholesterol and glucose concentrations.[46] Plasma chromium concentrations and the incidence of side effects were not reported in the study.

After intentionally ingesting 48 g basic chromium sulfate ($CrOHSO_4$), a 41-year-old woman developed hemorrhagic gastroenteritis, severe pancreatitis, renal failure, hypovolemia, and intractable cardiogenic shock; she died despite intensive care including hemodialysis.[4] A postmortem examination demonstrated erosive gastroenteritis of the entire gut, severe hemorrhagic pancreatitis, pulmonary congestion, and peritonitis. Basic chromium sulfate has unique chemical properties including the liberation of up to 6 mol hydrogen/mol and high affinity for proteins.

Dermal

Dermal penetration is much lower for trivalent than hexavalent chromium with dermal toxicity much lower for the former than the latter; however, dermal absorption rates alone do not explain the difference in sensitization potency.[47] The penetration rate depends on the time of exposure, pH, and concentration of the chromium solution, as well as the innate penetrating property of the individual chromium compound.[48,49] For trivalent chromium compounds, the penetrating property varies substantially between individual compounds (chloride > sulfate or nitrate). Trivalent chromium is the form that binds immune cells of the skin because hexavalent chromium is converted to trivalent chromium after skin penetration. Trivalent chromium has not been associated with dermatitis, whereas exposure to hexavalent chromium produces both a primary irritant dermatitis and a type IV hypersensitivity reaction.[50]

TOXICOKINETICS

Absorption of chromium occurs in the gastrointestinal tract and the lungs. Urinary excretion may take more than 14 days. The toxicity of chromium compounds is apparently related to the powerful oxidizing action of the hexavalent compound, which the acid milieu of the stomach converts to the less toxic trivalent form. Chromium is stored in all body tissues. The kidney excretes about 60% of the absorbed chromate dose within 8 hours after ingestion.[51] Elimination also occurs via the gastrointestinal tract. Small amounts of chromium are excreted in breast milk.[52]

Absorption

Inhalation

The exact bioavailability of respirable chromium particles (0.2–10 μm) is not known, but the lung probably absorbs soluble chromium compounds well based on the increased renal excretion of chromium following exposure to chromium lignosulfonate (Cr^{3+}).[53] The actual amount of absorption of chromium into the blood depends on a number of factors, including oxidation state, size, solubility, and the phagocytic activity of alveolar macrophages. In most cases, hexavalent compounds are more easily absorbed through the lungs compared with trivalent compounds, in part because of the relatively greater ease with which hexavalent chromium compounds traverse biological membranes. Animal studies suggest that the lungs absorb ~5–30% of respirable trivalent chromium particles.[2]

Ingestion

The absorption of chromium compounds from the gut is poor, averaging ~0.5–2% based on urinary excretion

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

studies.[33] In contrast to Cr^{6+}, the large, octahedral complexes of trivalent chromium limit the transport of Cr^{3+} into cells via the ubiquitous nonspecific anion exchangers.[54] Based on the renal excretion of chromium, volunteers absorbed about 0.4% of a dose of chromium chloride (Cr^{3+}).[55] The absorption fraction of soluble trivalent chromium in chromium picolinate is greater than $CrCl_3$ based on renal excretion studies.[56]

Dermal

Trivalent chromium penetrates skin to a very limited extent, except following massive exposure to hot, acidic chromium sulfate that produces thermal and chemical burns.[57] In clinical studies, trivalent chromium penetrates human skin in variable amounts depending on several factors (concentration, pH, time of exposure, individual variability). Chromium sulfate traverses excised intact human epidermis very slowly compared with chromium chloride.[58]

Distribution

The body reduces most hexavalent chromium entering the body; thus, trivalent chromium accounts for the vast majority of total chromium in the body. After absorption, trivalent chromium binds to transferrin in plasma and distributes widely throughout the body with the exception of erythrocytes. *In vitro* studies indicate hexavalent chromium easily crosses erythrocyte cell membranes via anion carrier proteins, whereas little penetration of Cr^{3+} into erythrocytes occurs.[59,60] In an intravenous radioactive $^{50}Cr^{3+}$ tracer study in six volunteers, the trivalent chromium was distributed primarily to liver, spleen, soft tissue, and bone.[61] With the exception of the lungs, chromium concentrations in all other tissues decrease with age.[62] A study of autopsies of smelter workers revealed higher concentrations of total chromium in the lungs of the workers compared with controls, but the concentration of chromium in the liver and kidneys was similar to controls.[63] The excess concentrations of chromium in the lungs decreased as the period between death and retirement lengthened. Bone is also a potential repository for the long-term storage of chromium.

Elimination

Chromium exists in the body primarily as Cr^{3+}. The kidney rapidly excretes most of the absorbed chromium as trivalent chromium with little retention of chromium in tissues.[64] Biliary excretion accounts for ~10% of the elimination of chromium with smaller amounts of chromium appearing in sweat, milk, nails, and hair.[65] Renal excretion of chromium is rapid following exposure of workers to dust containing chromium lignosulfonate (Cr^{3+}).[53] In the urine of these workers, the half-time for trivalent chromium was 4–10 hours based on an open, one-compartment kinetic model. These urinary half-times are substantially shorter for trivalent chromium than for workers exposed to hexavalent chromium (15–41 hours)[66] or volunteers ingesting hexavalent chromium (mean = 39 hours).[67] Experimental studies on trivalent chromium kinetics in volunteers suggest a three-compartment model with the delayed release of chromium from a slow compartment ($t_{1/2}$ = months–few years). Following the intravenous administration of $^{51}Cr^{3+}$ to six healthy volunteers, the kinetic data fit a model with the plasma in equilibrium with fast ($t_{1/2}$ = 0.5–12 hours), medium ($t_{1/2}$ = 1–14 days), and slow ($t_{1/2}$ = 3–12 months) compartments as measured by a whole-body scintillation scanner.[61]

Maternal–Fetal Kinetics

Trivalent chromium traverses the placenta and occurs in all tissue with the exception of the lungs. The chromium concentrations in most tissues clear rapidly with the exception of the liver and kidneys; these organs retain neonatal tissue concentrations until the second decade of life.[68] In a case series of 10 pregnant women with MoM hip arthroplasties, the maternal whole blood chromium concentration at delivery was 1.28 ± 0.28 µg/L compared with 0.378 µg/L ± 0.17 in cord blood; the difference was statistically significant ($P < 0.01$).[69] The placental transfer rate for chromium was 29%, suggesting the placenta modulates the chromium transfer to the fetus. Most samples of breast milk from lactating women on regular diets contained <0.4 µg Cr/L with a mean of about 0.3 µg/L.[52]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

While current evidence suggests trivalent chromium is an essential trace metal necessary for the normal metabolism of cholesterol, fat, and glucose, the data are not definitive.[70] Rare case reports suggest that insufficient dietary intake of chromium produces a disease similar to adult-onset diabetes and cardiovascular disease;[33] however, there are no well-defined chromium-deficiency diseases in humans. The

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. development of insulin-resistant diabetes in patients on parenteral nutrition that responds to supplementation with trivalent chromium suggests that Cr^{3+} is essential for normal energy metabolism.[71] The naturally occurring, low-molecular-weight oligopeptide, chromodulin (glucose tolerance factor), binds four equivalents of trivalent chromium. This complex may be involved in the auto-amplification mechanism in insulin signaling, but the role of chromodulin in energy metabolism remains unclear. Chromodulin binds chromic ions in response to an insulin-mediated chromic ion flux, and activation of tyrosine kinase activity occurs when the chromodulin-chromium complex binds to an insulin-stimulated insulin receptor.[72] Although trivalent chromium has the potential to form complexes with proteins and nucleic acids, hexavalent chromium first must be converted to the trivalent state before it combines with nucleic acids and proteins.[2] Trivalent chromium forms tight bonds with oxygen- and sulfur-containing ligands; some chromium complexes with histidine and cysteine are relatively inert because of these tight bonds.[73] Trivalent chromium potentiates the action of insulin, probably through a glutathione-like complex composed of niacin, trivalent chromium, and amino acids.[74] Chromium deficiencies in the diet could potentially produce elevated circulating insulin concentrations, hyperglycemia, hypercholesterolemia, elevated body fat, decreased sperm counts, reduced fertility, and a shortened life span.

Mechanism of Toxicity

Trivalent chromium is a weak sensitizing agent that may produce allergic dermatitis; however, *in vitro* studies indicate that the poor dermal penetration of trivalent chromium significantly limits cases of allergic dermatitis.[75] Although trivalent chromium is not a good sensitizer, case reports document positive bronchial provocation tests to trivalent chromium sulfate and nickel sulfate in an electroplater developing asthma symptoms within 1 week of starting employment.[76] Trivalent chromium is a mild pulmonary irritant compared with hexavalent chromium; however, chromium sulfate is a strong corrosive capable of causing direct damage to skin and mucous membranes. There is no apparent association of renal dysfunction with exposure to trivalent or metallic chromium.[2]

CLINICAL RESPONSE

Trivalent compounds generally have low oral toxicity with poor gastrointestinal absorption.

Acute Toxicity

A case report associated thrombocytopenia, anemia, hemolysis, liver dysfunction, and acute renal failure with the ingestion of 1.2–2.4 mg chromium picolinate (Cr^{3+})/day for 4–5 months by a 33-year-old woman.[77] The initial plasma chromium concentration during the second day of hospitalization was 4.6 μg/L (laboratory norm: 0.1–2.1 μg/L). No renal biopsy was performed to determine the cause of the renal failure other than hemolysis; therefore, the effect of chromium on the clinical features of this case report is unclear. Other case reports associate renal dysfunction with the use of dietary supplements containing chromium picolinate;[78] however, the lack of blood chromium concentrations and analysis of the supplements limits conclusions about causation.

Environmental Exposure

In addition to irritating effects, chromium compounds produce an allergic contact dermatitis characterized by acute or chronic eczema. A 63-year-old man developed chronic eczema after handling old chromium dioxide (Cr^{4+}) magnetic cassette tapes;[79] analysis of CrO_2 dust suggests that these tapes may release small amounts of Cr^{3+} and Cr^{6+} following prolonged contact with water or sweat.[80] Hexavalent chromium salts are the main skin sensitizers because they penetrate skin more easily than the trivalent compounds.[75] Consequently, Cr^{3+} sensitivity is much less common than Cr^{6+} sensitivity, primarily involving leather goods.[81] Leather products are a common source of chromium sensitization, particularly leather shoes;[82] both Cr^{3+} and Cr^{6+} are present in leather goods. In a study of 2,211 consecutive patients with suspected allergic contact dermatitis patch tested with 0.5% potassium dichromate (Cr^{6+}) and 13% chromium trichloride (Cr^{3+}), 71 (3.2%) patients had a positive reaction to Cr^{6+} and 31 (1.3%) had a positive reaction to Cr^{3+}.[83] No hexavalent-negative patients had a positive reaction to trivalent chromium.

In a study of 55 lifetime residents (30 men, 25 women) without clinical evidence of renal disease living near a chromium-contaminated landfill in New Jersey, analysis of four urine biomarkers (intestinal alkaline phosphatase, tissue nonspecific alkaline phosphatase, *N*-acetyl-β-D-glucosaminidase, microalbumin) did not demonstrate elevated values compared with reference concentrations.[84] The mean urinary total chromium concentration in 53 women and men was 0.3 ± 0.2 μg/L (0.3 ± 0.8 μg/g creatinine) with no statistically significant difference between women and men.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. A case report associated the use of chromium polynicotinate in combination with multiple vegetable extracts as a weight reduction program with the development of hepatitis (ALT 4371 IU/L, total bilirubin 20 mg/dL).[85] The liver biopsy demonstrated intralobular hepatocyte necrosis and a mixed intralobular and portal cellular inflammatory infiltrate with many eosinophils. The hepatitis resolved within 3 months after cessation of all supplements. The presence of confounding factors (e.g., *Peumus boldus*) limits conclusions regarding causation.

Occupational Exposure

Interpretation of the health effects associated with exposure to Cr^{3+} is complicated by concomitant occupational exposures to Cr^{6+} or other compounds that can induce adverse health effects including respiratory tract irritation. In studies of workers exposed primarily to trivalent chromium, the primary target organs are the immune and respiratory systems. Exposure of 236 workers to trivalent chromium in a ferroalloy metallurgy plant (mean airborne Cr^{3+}, 0.075 mg/m^3; Cr^{6+}, <0.001 mg/m^3)[86] and to metallic chromium in an alloy steel plant (mean = 0.61 mg Cr^0/m^3; mean = 7 years)[87] was not associated with adverse renal effects based on analysis of urinary biomarkers (total protein, albumin, retinol binding protein, renal tubular antigens, β_2-microglobulin alanine-aminopeptidase, *N*-acetyl-β-D-glucosaminidase, γ-glutamyl-transpeptidase, and β-galactosidase activities). A German mortality and morbidity study of trivalent chromium oxide and chromium sulfate production workers did not demonstrate an excess incidence of liver disease.[88] There are few data associating trivalent chromium exposure with alterations of the nervous system. A cohort study of 3,408 US chromate production workers processing chromite ore (mixed Cr^{3+} and Cr^{6+} exposure) did not detect an increased incidence of vascular lesions in the central nervous system of exposed workers; the proportionate mortality ratios for Caucasian and African American men were 78 (95% CI: 61– 98, $P < 0.05$) and 68 (95% CI: 44–101), respectively.[89] Current workers in chromium-related industries are typically exposed to chromium concentrations two orders of magnitude higher than the general population.[2]

Trivalent chromium has significantly lower dermal toxicity than hexavalent chromium as a result of the relatively slower penetration of the dermis compared with Cr^{6+};[47] consequently, trivalent chromium does not usually cause skin ulcers unless converted to the hexavalent form.[90] Trivalent basic chromium sulfate ($CrOHSO_4$) is an exception that may produce direct skin or mucous membrane damage following direct contact. Although Cr^{6+} is the species typically associated with allergic contact dermatitis, Cr^{6+} transforms to Cr^{3+} following penetration of the skin; the latter species binds to immune cells and produces dermal toxicity. Sensitivity to chromium may occur in some workers exposed to high concentrations of trivalent chromium compounds based on patch testing.[91]

Reproductive Abnormalities

Trivalent chromium is not a recognized reproductive toxin. Histological studies of rats exposed to 15.5 mg Cr^{4+}/m^3 for 2 years did not demonstrate pathological changes in the sex organs.[92]

Carcinogenesis

The International Agency for Research on Cancer (IARC) lists hexavalent chromium as a human carcinogen (Group 1), whereas metallic chromium and trivalent chromium are not classifiable as to human carcinogenicity (Group 3). Although chromium workers are often exposed to both trivalent and hexavalent chromium, there is no clear evidence that trivalent chromium exposure in these workers increases the lung cancer rate. The epidemiological studies of workers in the ferrochromium alloy industry exposed to Cr^0 and Cr^{3+} along with small amounts of hexavalent chromium are inconsistent,[93] whereas studies of workers exposed to Cr^{3+} in the tanning industry did not demonstrate an association between exposure to trivalent chromium and an increased incidence of lung cancer. In a US retrospective mortality study of 9,365 workers exposed to Cr^{3+} in 2 chrome leather tanneries from 1940 and followed to 1982, the standardized mortality rate (SMR) for tracheal and bronchial lung cancer in the 2 tanneries was 67 (95% CI: 40–106) and 93 (95% CI: 67–126) when compared to local cancer rates.[94] There was no increase in lung cancer rates with increasing duration of employment.

In a study of 2,357 chromate production workers exposed to both trivalent and hexavalent chromium, the relative risk of lung cancer mortality adjusted for smoking was similar for Cr^{3+} (RR = 1.32, 95% CI: 1.15–1.51) and Cr^{6+} (RR = 1.38, 95% CI: 1.20–1.63).[95] However, exposure to the two chromium species was highly correlated, and analysis of exposure to individual chromium species indicated that hexavalent chromium was the cause of the increased lung cancer risk. In combined proportional hazards models of $\log_{10}$ cumulative exposure for each 10-fold increase in cumulative

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

exposure to Cr^{3+} and Cr^{6+}, the relative risk for Cr^{6+} exposure remained significant (RR = 1.66, $P = 0.045$), whereas the relative risk for Cr^{3+} was not statistically significant (RR = 0.17, $P = 0.449$).

Based on animal studies, there is inadequate evidence of carcinogenicity for metallic chromium (Cr^0) and some Cr^{3+} compounds (chromic oxide, chromium acetate). In experimental studies, trivalent chromium compounds produce genetic changes only in acellular or subcellular systems. Trivalent chromium compounds exhibit no genetic activity in cellular systems, probably because these compounds do not cross cell membranes.[96]

DIAGNOSTIC TESTING

SI Conversion Units

1 μmol/L = 52 μg/L
1 nmol/L = 0.052 μg/L
1 μg/L = 0.01923 μmol/L = 19.23 nmol/L
1 nmol/mmol creatinine ≈ 0.52 μg/g creatinine

Analytical Methods

Methods to quantitate chromium in biological media include graphite furnace atomic absorption spectrometry, neutron activation analysis, inductively coupled plasma/atomic emission spectrometry, gas chromatography/electron capture detection, and mass spectrometry. The former three methods are also used to quantitate chromium in environmental samples. Graphite furnace atomic absorption spectrometry is the most common method used to determine chromium concentrations in biological samples, but appropriate background correction methods (e.g., Zeeman effect background correction, continuum source echelle monochromator wavelength modulation) are necessary to ensure accuracy.[97] Available techniques typically do not separate trivalent chromium from hexavalent chromium. The use of acid digestion followed by quantitation with atomic absorption spectrophotometry allows the determination of hexavalent chromium concentrations in environmental samples (e.g., sediment, sludge, soil).[98]

Matrix interference, the previous lack of Standard Reference Materials, and very low Cr concentrations complicate the analysis of total chromium in biological samples. Prior to the mid-1970s, the inability of conventional atomic absorption spectrometry systems (e.g., electrothermal/atomic absorption spectrometry) to correct for the high nonspecific background absorption resulted in numerous erroneous values for chromium concentrations in biological samples (i.e., whole blood, serum, urine). Newer techniques (ICP/MS equipped with a dynamic reaction cell)[99] and the release of standard material by the National Institute of Standards and Technology improve the precision and accuracy of current chromium measurements.

The ubiquitous presence of chromium in laboratories and the low sensitivity of most methods require careful handling of the biological sample in the laboratory. Some plastic containers contain significant amounts of leachable chromium; therefore, special acid-washed specimen containers are necessary. Stainless steel utensils, scalpels, or trays should not be used to collect tissue specimens for analysis of chromium concentrations; plastic intravenous cannulas are preferable needles for drawing blood samples. Case reports suggest that 2-fold increases in whole blood chromium concentrations may occur following the use of metal cannulas containing chromium.[100] Trace-element-certified containers are often unavailable. Commonly available collection tubes for anticoagulated samples typically contain either ethylenediaminetetraacetic acid (EDTA) or sodium heparin (less often sodium lithium). Red cell lysis may occur after a few days of storage; hence, coagulated serum samples are preferable to plasma samples for the determination of chromium concentrations.

Biomarkers

Concentrations of chromium in the blood and urine document the extent of absorbed chromium when collected within 2 days of exposure and analyzed as discussed above. One study of tannery workers suggested that chromium hair concentrations were a determinate of exposure to trivalent chromium; however, external contamination complicates the interpretation of total chromium concentrations in hair samples.[101]

Blood

Plasma or serum chromium concentrations reflect recent exposure to hexavalent and trivalent chromium, whereas intracellular chromium concentrations reflect the burden of hexavalent chromium because only Cr^{6+} penetrates red blood cells. Three days after the ingestion of a wood preservative containing hexavalent chromium and arsenic, the erythrocyte Cr^{6+} concentration was 4,540 μg/L compared with total chromium concentrations of 2,180 μg/L in whole blood and 1,070 μg/L in plasma.[102] The patient underwent successful liver transplantation 6 days after admission.

General Population

Prior to 1970, published serum total chromium concentrations in the general population were substantially higher than current values, probably from contamination (e.g., stainless steel needles) and less accurate analytical methods. In a review of analytical data from the 1970s and 1980s, typical serum total chromium concentrations for individuals in the general population with no hip implants or occupational exposure to chromium were 1–3 nmol/L (0.052–0.156 μg/L).[103,104] In a recent French study of 106 healthy adults without occupational exposure to chromium, the median whole blood total chromium concentration was 0.55 μg/L (upper 95%: 0.87 μg/L) compared with <0.29 μg/L (upper 95%: 0.79 μg/L) in plasma.[105] The mean whole blood chromium concentration in 519 healthy Italian adults without occupational chromium exposure was 0.23 ± 0.01 μg/L (estimated upper reference value, 0.45 μg/L), whereas 530 serum samples contained a mean total chromium concentration of 0.17 ± 0.01 μg/L (estimated upper reference range, 0.41 μg/L).[106]

Chromium-Cobalt Hip Implants

The concentration of chromium in blood samples from patients with long-term metal-on-metal total hip prostheses substantially exceeds values for the general population, but there are few data on the adverse effects of these elevated concentrations; the clinical significance of elevated chromium concentrations in these patients is unclear.[107,108] Typically, serum concentrations in patients with metal implants are elevated less for chromium (i.e., <1–5 ng/mL) than cobalt.[109,110] In an analysis of 43 studies representing 16 different metal-on-metal (MoM) implants with at least a mean follow-up of 1 year, the mean total chromium concentrations ranged from 1.3–2.2 μg/L in whole blood and 1.6–5.1 μg/L in serum. The median total chromium concentrations in whole blood ranged from 0.5–2.5 μg/L compared with 0.8–4.6 μg/L in serum.[111] This study did not detect any clear difference in chromium concentrations between the different implants; exclusion criteria included single-case reports and bilateral implants. In a 2-year follow-up study of 91 patients with unilateral hip arthroplasty, the median preoperative and 2-year postoperative erythrocyte chromium concentrations were not statistically different despite a mean increase of 1.15 ng/mL (range, 0.62–1.43 ng/mL) in the serum chromium concentration in individual patients with metal-on-metal, porous-coated chrome-cobalt femoral implants (DePuy Orthopaedics, Warsaw, IN).[112] The lack of a statistically significant difference between serum and erythrocyte chromium concentrations suggests that the increased serum chromium concentration resulted from trivalent rather than hexavalent chromium.

In a study of 29 patients with normal functioning unilateral hip protheses (54-mm femoral Birmingham Hip, Smith & Nephew, London, UK) followed 5–29 months after implantation, most of the chromium occurred in the serum and plasma fractions with minimal chromium concentrations in erythrocytes.[113] The mean chromium serum/whole blood ratio was ~2.3 with serum containing about 10 times higher chromium concentration than erythrocytes. *In vitro* and *in vivo* studies suggest the possibility that corrosion of stainless steel or cobalt-chromium (18–30% chromium) hip prostheses may produce Cr^{6+}, but the intracellular hexavalent chromium would be rapidly reduced to Cr^{3+} by the acidic medium of lysosomes based on Amberlite resin separation.[114] *Ex vivo* analysis of periprosthetic capsular tissue obtained during revision of MoM hip implants indicates that trivalent chromium phosphate (Cr_2O_3) is the predominant species in the tissue.[115]

In a 5-year follow-up study, the mean serum chromium concentration in patients with total hip arthroplasties was ~10-fold higher than controls without hip implants.[116] There was no statistically significant difference in the serum chromium concentrations between patients with metal-on-metal Birmingham hip resurfacing and metal-on-metal total hip arthroplasties. Similar elevations in serum chromium concentrations do not usually occur in patients with cobalt-chromium total knee arthroplasties.[117] Table 9.2 lists the erythrocyte and serum chromium preoperatively and 2-years postoperatively from this study. Both cup abduction angle and head size affect serum chromium concentrations after femoral implants.[118,119] Serum chromium concentrations in these patients decrease after the removal of the implant.[120]

Occupational Exposure

Case reports suggest that serum chromium concentrations increase substantially following the accumulation of chromium during occupational exposure, particularly following the inhalation of fumes containing chromium. After cessation of heavy exposure to chromium during the plasma cutting of stainless steel, the serum chromium concentrations of a stainless steel cutter decreased from 10.35 μg/L to 1.87 μg/L 8 years later with a half-life of 40–43 months, as measured by electrothermic atomic absorption spectrometry.[121] His major complaints were mucous membrane irritation and eczema. He developed a minor stroke 4 days after stopping work.

Urine

Urine chromium concentrations reflect absorption of total chromium (i.e., Cr^{3+} and Cr^{6+}) primarily over the last 1–2 days, depending on the amount of prior exposure to chromium compounds. As a result of reduction of hexavalent chromium in the airways and blood after absorption, only trivalent chromium appears in the urine. Consequently, urinary chromium represents exposure to either or both of these species. Most analytical methods do not distinguish between trivalent and hexavalent chromium. Although trivalent chromium does contribute somewhat to the total chromium concentration, substantial portions of the total chromium may result from the reduction of hexavalent chromium. The use of organic chromium supplements (e.g., trivalent chromium picolinate) increases the renal excretion of chromium above background concentrations.[122] Although tobacco contains variable amounts of chromium, the impact of smoking on urine chromium concentrations is not well defined.

General Population

In recent studies of the general population with typical exposure to chromium, the *mean* total chromium concentrations in urine are usually <0.5 μg/L with a range of ~0.2–1.8 μg/L.[104,123] The estimated upper 95% CI for total Cr in urine samples from 189 adult Danish subjects was 0.68 μg/L.[124] The upper 95% reference limit in Finnish subjects without occupational exposure to chromium was 0.52 μg (0.01 μmol)/L.[125] In the National Health and Nutrition Examination Survey (NHANES III) of the US population, the mean total chromium concentration in urine was 0.22 μg/L (0.21 μg/g creatinine) with a 95 upper percentile concentration of 0.7 μg/L (0.60 μg/g creatinine) as measured by inductively coupled argon plasma/mass spectrometry.[126]

Occupational Exposure

The mean concentration in the urine of nonexposed workers was 0.11 ± 0.04 μg Cr/g creatinine as measured by graphite furnace atomic absorption spectrophotometry (GF/AAS).[127] In a study of 45 Chinese cement workers, the average urinary chromium concentration was ~6 times higher (45.5 μg/L) in nonsmoking workers with hand eczema than in nonsmoking workers with no skin disease (7.6 μg/L).[128] Multiple regression analysis of 890 volunteers from 8 different areas of Italy without occupational exposure to chromium did not detect a significant effect of smoking on urine chromium concentrations.[129]

HEALTH SURVEILLANCE

Environmental Monitoring

Incidental ingestion is the most important route of exposure to trivalent chromium, unless people consume garden vegetables grown in chromium-contaminated soil.[130] There is no clear evidence that exposure of the general population to chromium concentrations present in the United Kingdom produces adverse health effects.[10] Trivalent chromium possesses negligible risk because of its low inherent toxicity and low bioavailability.[131] The data on dose-response relationships for chromium compounds are very limited; the use of reference dose for trivalent data based on data for hexavalent chromium may lead to highly inaccurate assessments of risk.[132]

The ATSDR intermediate-duration inhalation minimal risk level (MRL) for insoluble trivalent chromium particulate compounds is 5 μg Cr^{3+}/m^3 based on a minimal LOAEL of 3 mg Cr^{3+}/m^3 for trace-to-mild septal cell hyperplasia and chronic interstitial inflammation in the lung of rats in a 13-week study.[133] The intermediate-duration inhalation MRL for soluble

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

trivalent chromium compounds MRL is 0.1 μg Cr^{3+}/m^3 based on the previous study. The US EPA reference dose (RfD) for oral exposure to insoluble trivalent chromium salts (i.e., chromium oxide/sulfate) of 1.5 mg/kg/day based on a NOAEL derived from administering 5% chromic trioxide (C_2O_3; 1,800 mgCr^{3+}/kg/day) to rats for over 2 years.[134] The current US EPA maximum contaminant level (MCL) of total chromium in drinking water is 50 μg/L.

Biological Monitoring

Although the absorption of trivalent chromium compounds is poor, increased urinary excretion of chromium occurs in limited studies of tannery workers exposed to trivalent chromium compounds.[53,135] Biological monitoring studies suggest that end-of-shift urinary chromium concentrations do not correlate well to trivalent chromium concentration in ambient air.[136]

TREATMENT

Treatment is supportive because trivalent chromium compounds are less toxic and generally not corrosive compared with hexavalent chromium compounds (e.g., chronic acid). Consequently, standard first aid measures are appropriate for decontaminating skin exposed to trivalent chromium. Dilution is the preferred first aid measure for the ingestion of corrosive trivalent chromium compounds (e.g., acidic chromium sulfate).

HEXAVALENT

HISTORY

Cummings first described the skin ulcers (chrome holes) associated with dermal exposure to hexavalent chromium (potassium dichromate) in 1827.[137] In 1928, Blair reported the development of skin and nasal ulcerations in 12 chrome platers.[138] The carcinogenesis of hexavalent chromium compounds was recognized in the late 19th century when nasal tumors were described in Scottish chrome pigment workers.[139] Case reports in the 1930s focused attention on the incidence of lung cancer in chromate workers; in 1936, lung cancer became an accepted work-related disease in German chromate workers.[140] In the 1960s and 1970s, chromium-containing slag was a substantial component of landfills in a variety of residential and commercial settings in Hudson County, New Jersey. Health concerns about exposure to this soil were based on experience with workers exposed to chromium. Epidemiological studies of chromate workers indicate an increased risk of death from lung cancer in workers exposed to hexavalent chromium (Cr^{6+}) compounds.[141,142] Hexavalent chromium compounds are both skin and pulmonary sensitizers, producing a generalized irritation of the conjunctiva and mucous membranes, nasal perforations,[143] and a dry, fissured contact dermatitis (e.g., blackjack disease in card players exposed to dichromate salts used to dye green felt).[144]

PHYSIOCHEMICAL PROPERTIES

Hexavalent chromium occurs in nature rarely, primarily in crocoite ($PbCrO_4$); therefore, most hexavalent chromates exist as a result of commercial production. The hexavalent compounds usually exist as oxides or oxohalides; however, at physiological pH, hexavalent chromium typically exists as an oxyanion $(CrO_4)^{-2}$ that resembles sulfate and phosphate oxyanions. The hexavalent form (chromate, Cr^{6+}) is a strong oxidizing agent, particularly in acidic media. The anionic transport system moves $(CrO_4)^{-2}$ into cells, where various intracellular reducing agents (e.g., ascorbic acid, cysteine, glutathione) ultimately reduce this oxyanion to trivalent chromium.[54] The reduction of dichromates to trivalent chromium increases with decreasing pH in the range 2–6, particularly in the presence of oxidizable organic matter.

Hexavalent chromium compounds (e.g., chromic acid, chromic trioxide, ammonium, potassium, and sodium dichromate) are soluble in water. In general, dichromates are more soluble than the corresponding chromate.[145] *Soluble* hexavalent chromium compounds traverse cell membranes and reduce spontaneously to trivalent compounds.[146] The pH of chromium compounds ranges from 0.5 (chromic acid) to 13 (ammonium dichromate). Table 9.3 lists identifying information and physical properties of hexavalent chromium compounds.

EXPOSURE

Production Processes

The roasting of chromite ore with soda ash produces sodium chromate and dichromate. The latter two compounds are the starting mixtures for most other hexavalent chromium compounds. The commercial production of lead chromate for use as a pigment involves the reaction of sodium chromate with lead nitrate or a reaction of lead monoxide with chromic acid solution.

Uses

Exposure to hexavalent chromium compounds occurs primarily in the chemical, metallurgical, and refractory (heat-resistant) industries with the stainless steel industry accounting for the largest consumption of chromium. Commercial applications include corrosion inhibition, plating, glassware-cleaning solutions, wood preservatives, safety match manufacture, metal finishing, and pigments. The inclusion of chromium alloys and stainless steel increases hardness and resistance to corrosion with chromium concentrations typically ranging ~11–30%. Exposure to hexavalent chromium varies with and within occupations. In a German study of welders, spray painting, shielded metal arch welding, and flux-core arc welding of stainless steel were associated with geometric mean airborne exposure to hexavalent chromium of >5 μg/m^3, whereas the geometric mean Cr^{6+} exposure for gas metal arc welding of stainless steel, cutting, hard-chromium plating, and metal spraying in the chemical chromium industry was 1–5 μg/m^3.[147]

There are two types of chrome plating: 1) decorative plating where the base metal (e.g., nickel) receives a thin layer (0.5–1 μm) of chromium, and 2) hard plating where the layer is more corrosion-resistant and thicker (5–10 μm). Sufficient water-soluble chromates leach from zinc potassium chromate in primer paints to produce allergic reactions; the chromium concentrations in primers are much higher than water-soluble chromates in cement (0.0002–0.0008%).[148] Since 2000, the use of chromates in pigments for US paints, coatings, printing inks, ceramics, glass, plastic, and construction materials has declined.

Sources

Combustion and the processing of ore discharge primarily trivalent chromium into the environment as chromium oxide;[11] however, small amounts of hexavalent chromium occur in fly ash from coal-fired power plants[12] and in soil near chromate manufacturing sites. The highest exposure to hexavalent chromium occurs during chromate production, ferrochrome and chrome pigment production, chrome plating, and stainless steel welding.[2] The chromium produced by the chemical industry exists primarily as hexavalent chromium; treatment of the waste requires conversion to trivalent chromium (i.e., Cr_2O_3) by reduction and precipitation of the hydrous oxide with lime or caustic soda.[2]

The composition of welding fumes is complex with the composition of these fumes varying depending on the type of welding, oxygen concentration, air contaminants, and the composition of the metal, fluxes, and electrodes.[149] Stainless steel is an alloy of iron, nickel, and chromium, whereas mild steel is an alloy of iron, carbon, and silicon. Consequently, the contribution of fumes from mild steel and high alloy steel welding to the chromium burden is minimal, whereas the fumes from the welding of stainless steel potentially contain chromium (Cr^{6+}) and smaller amounts of nickel.[150] Although stainless steel welding produces rapid uptake of presumably soluble hexavalent chromium compounds along with rapid (i.e., same day) excretion of these chromium compounds, the contribution of chromium in welding fumes to the total body burden of chromium is relatively small.[151] Biological monitoring of workers exposed to fumes from both metal inert gas and the manual metal arc methods of welding stainless steel indicates that these workers are exposed to relatively high total chromium concentrations compared with the tungsten inert gas process.[152] However, the metal inert gas method produces relatively smaller amounts of total chromium primarily as insoluble elemental and trivalent chromium compounds in contrast to the relatively high-soluble hexavalent chromium compounds produced by the manual metal arc method. In general, the increase in the systemic bioavailability of hexavalent chromium is very small to negligible for all welders.

Airborne sampling data suggest high blood Cr^{6+} occurs in workers grinding chromium-containing metal or near chromium electroplating tanks.[153] Most of the chromium particles in electroplating tanks are hexavalent (i.e., ~98%) with substantial variation in size ranging from small, respirable particles to large, unrespirable particles.[154] In a study of air samples from seven chromium electroplating factories, the geometric mean Cr^{6+} concentration was 89.7 μg/m^3 with a range of 0.7–168.3 μg/m^3.[155]

Air

The emission of hexavalent chromium from fossil fuel combustion and steel production accounts for ~2/3 of the airborne chromium in some urban areas.[156] The remaining chromium in air is in trivalent form. The speciation of chromium released from specific sources depends on a variety of factors including temperature and reactions with other elements.[157] The US EPA estimates that up to ~1/3 of the chromium released from anthropogenic sources into the atmosphere occurs as hexavalent chromium depending on the specific source.[158] Ambient air in the United States usually contains small amounts of *total* chromium with most airborne samples containing <100 ng/m^3 (median, <20 ng/m^3).[16]

In a study of 21 industrial sites containing chromate ore processing residues, the arithmetic mean hexavalent chromium concentration in particulates from outdoor air samples averaged 9.9 ng/m^3 with a range of 0.13–110 ng/m^3.[159] The mean ratio of hexavalent to total chromium averaged ~21% with a range of 4–60%. The mean background hexavalent chromium concentration of ambient air monitoring samples from Hudson County, NJ, was 1.2 ng/m^3 with a range of 0.2–3.8 ng/m^3.[160] Chromite ore processing residue was a fill material in several areas in Hudson County, NJ, with hexavalent chromium typically accounting for ~1–5% (maximum, 7%). The mean background concentration of total chromium was 4.5 ng/m^3 with a range of 1.5–10 ng/m^3. Although oxidation of trivalent chromium to hexavalent chromium can occur in the presence of manganese, simulation models suggest that typical conditions in the atmosphere favor the reduction of hexavalent chromium to trivalent chromium.[161]

Typically, indoor hexavalent chromium concentrations in ambient indoor air from nonsmoking households are lower (i.e., <1/2) than outdoor ambient air; smoking substantially increases indoor air concentrations of chromium. In a study of 24-hour ambient air samples from 33 residences in Hamilton, Canada, the geometric mean of the hexavalent chromium concentration was 0.20 ng/m^3 (range, 0.1–0.6 ng/m^3) in indoor air compared with 0.55 ng/m^3 (0.1–1.6 ng/m^3) in outdoor air.[162] Hexavalent chromium represented about 20% of the total chromium fraction in the ambient air samples.

Soil

Chromium in the aquatic phase of sediment exists either in solubilized solution or suspended particles. Soluble

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

chromium accounts for a small amount of the total chromium in water as both hexavalent and trivalent chromium. Total chromium concentrations in Canadian soils ranged from 5–1,500 mg/kg with a mean of 43 mg/kg; however, few data on Cr^{6+} were reported.[26] A smaller percentage of total chromium in soil exists as the more mobile and soluble Cr^{6+} than Cr^{3+}. Higher Cr^{6+} concentrations in soil do not necessarily result in higher airborne Cr^{6+} concentrations based on an analysis of soil and indoor/outdoor air chromium samples in a study of 25 industrial sites in Hudson County, NJ.[163] Hexavalent and total chromium concentrations in indoor industrial air samples were 0.23–11 ng/m^3 and 4.1–130 ng/m^3, respectively, compared with 0.013–15.3 ng/m^3 and 1.9–84.5 ng/m^3, respectively, in outdoor industrial air samples.

Water

Total chromium concentrations in US rivers range from <1–30 μg/L (median, ~10 μg/L); however, analytical data on the concentrations of Cr^{6+} are limited. Chromium in the aquatic phase exists either in solubilized solution or suspended particles. Soluble chromium accounts for a small amount of the total chromium in water as both hexavalent and trivalent chromium. In a study of winter water samples from the Delaware River in Pennsylvania, the dissolved total chromium concentrations ranged from 0.57–1.30 μg/L with Cr^{6+} representing up to ~30% of the total Cr concentrations.[164] The total chromium concentrations decreased to 0.03–0.23 μg/L in the spring. Older studies suggest that Cr^{6+} concentrations in well water near point sources (e.g., chrome plating plants) may substantially exceed typical concentrations in groundwater.[165]

Diet

Total chromium concentrations in food are usually very low (i.e., <20–50 ppm).[17] Little data are available on the bioavailability or speciation of chromium compounds.

Although chromium may leach into some acidic foods that are in contact with stainless steel surfaces during harvesting, processing, or preparation, processing typically removes a large percentage of chromium from foods.[2] Typical total chromium concentrations in edible plants range from 0.02–0.05 μg/L with few data on Cr^{6+} concentrations.[17] Fish do not bioconcentrate chromium. The mean total chromium concentration in fish from 167 Northeastern US lakes was 0.19 μg/g (range, 0.03–1.46 μg/g).[36] In a monitoring survey of ~4,400 community and noncommunity water systems by the California Department of Public Health, 86% of the 2,432 samples contained Cr^{6+} concentration of ≤10 μg/L.[166] Only four water samples exceeded 50 μg/L. Sampling did not include agricultural wells, monitoring wells, or treatment facilities with both raw and treated samples. Total chromium concentrations in tobacco range widely between various sources (e.g., 0.24–14.6 μg/g); however, data on the valence and amount of chromium absorbed into the body as a result of smoking is limited. Typically, chromium content in tobacco smoke is higher than that of other metals (e.g., arsenic, beryllium, cadmium, chromium, cobalt, lead, manganese, mercury nickel).[167] In a study of Brazilian cigarettes, the mean total chromium content was 1.43 ± 0.63 μg/g dry weight as measured by graphite furnace atomic absorption spectrometry after desiccation and microwave-assisted digestion.[20] The content of chromium was the highest of five metals analyzed (As, Cd, Cr, Ni, Pb).

ENVIRONMENTAL FATE

Air

The primary process for the removal of chromium from the atmosphere is precipitation and subsequent deposition on the earth's surface. Although there are limited data on the persistence of chromium in the atmosphere, the estimated residence time is <10 days based on modeling, depending on the particle size. Experimental studies indicate that the presence of chlorine, MnO_2, and oxygen increases the formation of hexavalent chromium, whereas the presence of hydrogen, sulfur, sodium, and calcium inhibits the formation of hexavalent chromium.[168] In the atmosphere, hexavalent chromium may be reduced to trivalent chromium by various airborne ions including, in order of highest reducing power, hydrogen sulfide, sulfur, iron sulfide, ammonium, and nitrate.[169] The presence of vanadium and trivalent arsenic also enhances the reduction of Cr^{6+} to Cr^{3+}. Hydrogen and iron sulfide are particularly effective reducing agents in anaerobic environments with reducing half-lives of less than a few days. The estimated atmospheric half-life for this reduction is ~1–5 days.[169]

Soil

Hexavalent chromium is usually water-soluble and a potent oxidizer. Consequently, the mobility in soil is greater for hexavalent chromium than trivalent chromium.[170] Soluble hexavalent chromium compounds are more mobile in the soil than insoluble hexavalent compounds, but organic matter eventually reduces the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. hexavalent form to insoluble (and less mobile) trivalent chromic oxide (Cr_2O_3).[39]

Water

The migration of Cr^{6+} into groundwater is complex, depending on local soil conditions including soil characteristics (e.g., clay) and the presence of reducing agents (i.e., Fe^{2+}-containing minerals, organic matter).[171] The leachability of hexavalent chromium in the soil increases as the soil pH increases. The valence of chromium in water depends on the pH and the redox potential in the aquifer. As commonly occurs in drinking water, hexavalent chromium predominates in conditions of relative high pH that favor oxidation (shallow groundwater with pH 6–8). Although hexavalent chromium may persist in surface waters for extended periods (e.g., 4–18 years), ultimately organic matter and other reducing agents convert the hexavalent chromium to trivalent chromium with subsequent deposition in sediments.[42] Although oxidation of Cr^{3+} to Cr^{6+} can occur in aerobic environments (shallow, oxygenated aquifers), the process is slow. In an experimental study, the oxidation half-life of conversion of Cr^{3+} in lake water to Cr^{6+} was 9 years; the addition of MnO_2 reduced the oxidation half-life to 2 years.[43] Trivalent chromium predominates in the reducing conditions of deep, anaerobic groundwater. The chlorination of drinking water probably does not produce any significant amounts of Cr^{6+} as a result of the presence of complexing organic matter and low chromium concentrations.

DOSE EFFECT

Ingestion

Hexavalent chromium toxicity results from oxidizing and corrosive properties of the individual chromium compounds. An average lethal dose is ~1–3 g chromium compound depending on these physiochemical properties.

Chromic Acid

The intentional ingestion of an estimated 125 mL chromic acid by a 33-year-old electroplating worker was associated with refractory hypotension, acute renal tubular necrosis, and hepatic failure.[172] Electroplating fluid usually contains 20–40% chromic acid (no blood chromium concentration reported). He died 2 days after ingestion. Case reports document the survival of patients ingesting an estimated chromic acid dose of 5–15 g with intensive care including hemodialysis.[51,173]

Dichromate

The estimated ingestion of 1 g ammonium dichromate (~100 mg/kg) by a 22-month-old child was associated with severe gastroenteritis, acute renal tubular necrosis, hepatic injury with coagulopathy, hypotension, respiratory failure, and death 48 hours after ingestion.[174] The intentional ingestion of 2–3 g potassium dichromate (40–60 mg/kg) by a 17-year-old adolescent caused vomiting, nonbloody diarrhea, and epigastric pain; endoscopy demonstrated a small ulcer in the gastric fundus.[175] She developed renal tubular dysfunction based on substantially elevated urinary β_2-microglobulin and retinol-binding protein concentrations; however, glomerular filtration, creatinine clearance, and hepatic function remained normal.

A 17-year-old male died 18 hours after the estimated ingestion of 29 mg Cr^{6+}/kg (i.e., ~5 g $K_2Cr_2O_7$).[176] Prior to death, he developed methemoglobinemia, respiratory failure, hyperkalemia, severe erosion of the stomach and duodenum, disseminated intravascular coagulation (DIC), and gastrointestinal hemorrhage that failed to respond to intensive care. An 18-year-old man ingested ~5 g of potassium dichromate by history.[176] On admission, he was hypotensive and cyanotic (22% methemoglobinemia); shortly thereafter, a coagulopathy, hemorrhage, and cardiac arrest occurred. The initial blood chromium level was 58 mg/L.

Some case reports suggest that the lethal dose of hexavalent chromium may be somewhat lower (0.5–0.8 g). A 14-year-old boy developed an acute gastroenteritis and toxic hepatitis with renal failure, leading to anuria and death 8 days after ingesting 7.5 mg Cr^{6+}/kg body weight.[177] The use of dimercaprol (BAL), ascorbic acid, exchange transfusion, and peritoneal dialysis did not alter his clinical course. Postmortem examination demonstrated extensive liver and kidney damage along with high chromium tissue concentrations. Based on clinical reports, renal damage occurs following smaller Cr^{6+} doses than hepatic necrosis.[173,178]

Survival has been reported after large ingestions of hexavalent chromium. A 20-year-old man ingested about 45 g of a powder containing 70% $K_2Cr_2O_7$ (31.5 g potassium dichromate).[179] He immediately developed gastrointestinal symptoms (vomiting, hematemesis, diarrhea) and hypotension. He recovered after a prolonged hospital course that included hepatorenal failure and gastrointestinal bleeding. The estimated ingestion of 22.5 g potassium dichromate by a 48-year-old man was associated with vomiting, upper gastrointestinal bleeding, and anemia (Hct = 25%); he survived with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

mild elevation of hepatic transaminases and serum creatinine.[180] The serum chromium concentration 7 hours after ingestion was ~0.7 mg/L.

Dermal

The risk of sensitization to hexavalent chromium depends on the duration and amount of exposure. A review of the current medical literature indicated that the prevalence of chromium sensitization in cement workers chronically exposed to 10–20 ppm hexavalent chromium for years is about 4–5% compared with 0.5% in the general European population without occupational exposure to chromium.[181] Exposure to 20 ppm hexavalent chromium potentially may cause skin ulcers in nonsensitized workers. A substantial decrease in the number of sensitized cement workers occurred after the concentration of water-soluble chromate (Cr^{6+}) decreased to <2 μg/g (ppm) cement.[182] Based on patch testing, the release of <0.3 μg leachable chromates/cm^2 is associated with minimal sensitization of workers exposed to hexavalent chromium.[183] Experimental studies in humans indicate that exposure to 25–29 mg Cr^{6+}/L water[184] and 1,240 mg Cr/kg soil[185] should not cause allergic contact dermatitis in Cr^{6+}-sensitized individuals.

TOXICOKINETICS

Absorption

Inhalation

The precise bioavailability of respirable chromium particles (0.2–10 μm) is not known, but the lung probably absorbs soluble chromium compounds well. The actual amount of chromium absorbed into the blood depends on a number of factors, including oxidation state, size, solubility, and the phagocytic activity of alveolar macrophages. In most cases, hexavalent compounds are more easily absorbed through the lungs compared with trivalent compounds, in part because of the relatively greater ease with which hexavalent chromium compounds traverse biological membranes. Animal studies suggest that the lungs absorb ~53–85% of respirable hexavalent chromium particles (<5 μm).[2]

Ingestion

Following the ingestion of chromium doses normally present in the diet, the poor bioavailability of hexavalent chromium results from the reduction of hexavalent chromium to trivalent chromium in the stomach.[186] In a study of adult volunteers receiving single 10 mg doses of Cr^{6+} in 1 L drinking water, endogenous reducing agents within the upper gastrointestinal tract and the blood reduced virtually all (>99.7%) of the ingested dose of Cr^{6+} to Cr^{3+} prior to absorption into the blood.[67] Consequently, large doses of hexavalent chromium are required to bypass the reducing capacity of the stomach and enter the blood in toxicologically significant amounts. In a study of six volunteers ingesting chromite ore processing residue at a dose of up to 200 μg total chromium/day for 3 days, monitoring of the urine detected no significant change in the urine chromium concentration.[187] The residue contained ~10% hexavalent chromium.

Dermal

Hexavalent chromium penetration is limited, except following massive exposure that typically includes thermal and chemical burns. In clinical studies, potassium dichromate penetrates human skin;[188] the rates of absorption of sodium chromate (Cr^{6+}) from occluded patches on volunteers were concentration-dependent. One study demonstrated the following absorptive rates for Cr^{6+}: 1.1 μg/cm^2/hour for a 0.01 M solution, 6.4 μg/cm^2/hour for a 0.1 M solution, and 10 μg/cm^2/hour for a 0.2 M solution.[49] Immersion of four volunteers below their shoulders for 3 hours in a warm aqueous bath (91° ± 2.5°F) containing 22 mg Cr^{6+}/L as potassium dichromate resulted in the estimated total chromium absorption of $\sim 3.3 \times 10^{-5}$–4.1×10^{-4} μg/cm^2/hour based on analysis of urine chromium concentration over 5 days.[189] The lack of elevated plasma and erythrocyte chromium concentrations beyond the first day is consistent with the rapid penetration of hexavalent chromium in the dermis and conversion to trivalent state.

Distribution

In contrast to Cr^{3+}, hexavalent chromium rapidly penetrates red cells, where it binds to the β-chain of hemoglobin.[190] The hexavalent chromium complexes are sufficiently stable to persist for a substantial portion of the erythrocyte lifecycle. Within the erythrocyte, hexavalent chromium is reduced to trivalent chromium. This process may produce reactive intermediates, DNA- and protein-chromium adducts, and free radicals. Following ingestion of Cr^{6+}, chromium concentrates in white blood cells and the liver with the kidney and brain containing lower hexavalent chromium concentrations than leukocytes and liver.[177,191]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Elimination

The half-life for chromium in urine following the ingestion of hexavalent chromium is longer than exposure to trivalent chromium with urinary half-times of workers exposed to hexavalent chromium ranging from 15–41 hours.[66] After ingestion of 0.05 mg Cr^{6+} as potassium dichromate in drinking water, the mean urinary excretion half-life of chromium in four volunteers was 39 hours.[67] About ¾ of the total dose was excreted in the first 4 days. The urine chromium concentration returned to baseline by 14 days after cessation of dosing. The relatively longer excretion half-lives following dosing with hexavalent chromium probably reflect incomplete reduction of Cr^{6+} to Cr^{3+} and the relatively longer retention of hexavalent chromium in the tissues.

Case reports suggest that serum chromium concentrations follow a two-compartment model after ingestion of high doses of hexavalent chromium. After an intentional ingestion of 22.5 g potassium dichromate, the serum chromium half-lives for the initial and terminal phases over 16 days were 3.16 ± 2.63 hours and 50 ± 27 hours, respectively, as measured by atomic absorption spectrometry.[180] The plasma half-lives of chromium after the accidental ingestion of potassium dichromate for these two phases over the 49-day-study were 5.6 hours and 191 hours, respectively.[192] Erythrocytes release hexavalent chromium slowly; the RBC chromium elimination half-life was >2-fold greater (440 hours) than the plasma elimination half-life. At the end of the study (49 days), the plasma and RBC chromium concentrations remained elevated. Kinetic studies in workers exposed to hexavalent chromium suggest the delayed release of chromium from a slow compartment ($t_{1/2}$ = months to a few years). In a study of four stainless steel manual metal arc welders exposed to soluble hexavalent chromium fumes, analysis of urinary chromium excretion suggested an exponential two-compartment model with a biological half-life in the slow compartment of 14 days to infinity.[193] Evidence for this slow compartment was not present in kinetic studies of patients with acute chromium toxicity when followed for 16 days.

Substantial individual variation in urine chromium concentrations occurs between individuals as a result of variations in individual reductive capacity for hexavalent chromium as well as confounders such as smoking, nutritional supplements, and beer consumption.[194] All three confounders increase urinary chromium. Consequently, in a *selected* population of "strong reducers," relatively high urine chromium concentrations may reflect more efficient elimination processes rather than a higher risk of toxicity. In chrome platers exposed to much higher hexavalent chromium concentrations compared with the general population, the renal elimination half-life of chromium was 2–3 days followed by a slow phase characterized by a renal elimination half-life of ~1 month.[195] Case reports suggest that the urinary elimination half-life of chromium may be prolonged in some workers exposed to heavy concentrations of fumes containing chromium. The half-life of chromium in urine samples obtained from a plasma cutter of stainless steel after he stopped working was ~129 months.[121]

Maternal–Fetal Kinetics

Hexavalent chromium traverses the placenta; the maximum chromium concentrations in most tissues are present at birth, with the exception of the lungs.[68]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Toxicity

The mechanism of chromium toxicity is complex. *In vitro*, hexavalent chromium, but not trivalent chromium, produces strong oxidative and cytotoxic effects, resulting in DNA, protein, and membrane injury along with dose-dependent loss of cell viability.[196] The major defense against the action of hexavalent chromium in the lungs and stomach is the reduction of hexavalent chromium to trivalent chromium via an NADPH-dependent mechanism involving ascorbate. Animal studies indicate that glutathione plays an important role in the reduction of hexavalent chromium in erythrocytes; this compound also provides some reducing capacity in the lungs.[197] Mechanisms for renal tubular injury following acute ingestion of hexavalent chromium (dichromate, chromic acid) include hypotension, intravascular hemolysis, and a direct toxic effect of chromium on the tubular epithelial cells.

Skin

Hexavalent chromium is a skin and mucous membrane irritant as well as a powerful oxidizing agent. Some hexavalent chromium compounds (chromic acid, ammonium or potassium dichromate) are strong corrosives.[198] Sensitivity to chromium compounds depends on valence ($Cr^{6+} \gg Cr^{3+}$), water solubility, pH, amount, and the presence of reducing agents (e.g., iron sulfate).[199] Hexavalent chromium is a strong sensitizing agent capable of producing allergic dermatitis, particularly in the cement industry, where the dermal

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

absorption of Cr^{6+} substantially increases when the pH exceeds 10.[75] The addition of iron sulfate during the kiln process reduces the conversion of Cr^{3+} in cement to Cr^{6+}.[200] Chromium sensitivity is a classic delayed-type (class IV) hypersensitivity reaction. A lag phase of 14 days is necessary for sensitized, antigen-specific T cells to form in the lymphatic system and diffuse into the skin. Subsequent dermal exposure to chromium releases cytokines and cytotoxic T cells, which produce dermal inflammation. The primary risk factors for the development of chromium sensitization are prior irritation of the skin and the chromium concentration present at the surface of the skin. Co-exposure to other metals (cobalt, nickel) is not a prerequisite for the development of chromium sensitization, although sensitization to these metals may occur in the same individual.

Carcinogenesis

Although most carcinogenic metals act primarily as epigenetic agents and weak mutagens, *in vitro* studies indicate Cr^{6+} is a genotoxic metal capable of forming DNA adducts and inducing mutations.[201] The production of oxidative DNA damage probably contributes to the human genotoxicity of hexavalent chromium compounds.[139] Cytotoxicity from deposition and excessive accumulation of particulate hexavalent chromium in the pulmonary bifurcation contribute to Cr^{6+}-associated lung cancer following intracellular Cr^{6+} absorption.[202] Intracellular reduction of hexavalent chromium produces oxidative stress, tissue inflammation, cytotoxicity, and subsequent DNA/protein damage; however, *in vitro* studies also indicate Cr^{6+} has epigenetic effects including DNA methylation and histone posttranslational modifications involving chromatin compaction and gene silencing. Increased cell proliferation enhances changes in DNA methylation and/or sequence substitutions.[201,203]

Hexavalent chromium is the primary species responsible for chromium toxicity,[204] although molecular damage probably results from the intracellular reduction of Cr^{6+} to intermediates (Cr^{5+}, Cr^{4+}, carbon-based radicals) and Cr^{3+} via nonenzymatic (ascorbate, cysteine, reduced glutathione) and enzymatic (cytochrome P450 reductase, glutathione reductase, mitochondrial electron transport complexes, aldehyde oxidase) antioxidants.[146,205] The greater potency of hexavalent chromium probably results from the higher redox potential of Cr^{6+} and the easier penetration of Cr^{6+} into cells.[206] The tetrahedral chromate ion more closely resembles the permeable sulfate and phosphate ions than the octahedral complexes of trivalent chromium. The higher redox potential of Cr^{6+} causes the rapid reduction of hexavalent chromium to reactive intermediates (Cr^{5+}, Cr^{4+}) and then to trivalent chromium. Oxidative reactions form complexes with critical macromolecules (peptides, proteins, DNA) that cause DNA stand breaks, DNA-protein crosslinks, and disruption of cellular signaling pathways.[207] Trivalent chromium may participate in some of these intracellular processes.

Pathological Changes

Lung

Hexavalent chromium is a strong pulmonary irritant that produces hyperemia,[208] thick nasal discharge, nasal ulcerations, and other inflammatory changes in the mucosa of the respiratory tract following exposure to high concentrations of chromium trioxide fumes.[209] Additionally, hexavalent chromium compounds are pulmonary sensitizers that cause bronchospasm and anaphylactoid reactions in sensitized workers.[210]

Hexavalent chromium compounds are recognized as human carcinogens. Although all pathological types of lung cancer occur following exposure to hexavalent chromium, small cell carcinomas and, to a lesser extent, poorly differentiated cancers predominate in post-mortem investigations of chromium workers dying of lung cancer.[211] In a Japanese study of 84 chromate production workers from a plant that ceased operation in 1975, autopsies of 13 ex-workers were performed before 1993.[212] Nine of the ex-workers had 16 lung tumors (13 squamous cell types and 3 small cell types). The incidence of squamous cell tumors was twice as frequent as age-matched controls with lung tumors. A majority of the lung tumors in these workers developed in central parts of the lung, particularly near major bifurcations where inhaled chromate particles are chronically retained.

Kidney

The acute ingestion of large amounts of hexavalent chromium produces acute tubular necrosis, marked interstitial changes, and renal failure.[213,214] The association of renal tubular dysfunction with exposure of workers to hexavalent chromium compounds is equivocal.[2] The glomeruli usually remain intact.[215]

Liver

Centrilobular hepatic necrosis, hepatic coma, and death occur after the acute ingestion of very large, acute

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

doses of hexavalent chromium.[177] Postmortem analysis of a patient dying of hepatorenal failure 26 hours after receiving a purgative containing high hexavalent chromium concentrations demonstrated hepatic chromium concentration 20 times higher than in other tissues.[216]

A study of five workers in the chrome plating industry associated histological changes (lymphocytic and histiocytic infiltrates, hyperplasia of Kupffer's cells, necrosis) in the liver with exposure to hexavalent chromium.[217] However, most epidemiological studies of workers have not detected an increased incidence of liver damage.[155]

Postmortem Examination

Hexavalent chromium is a strong oxidizing agent that causes ulceration of the skin and gastrointestinal mucosa. The autopsy of a fatal ingestion of chromic acid demonstrated extensive necrosis of the gastrointestinal tract with esophageal perforation and a mediastinal hematoma anterior to the upper esophagus.[218] Histological examination of the liver revealed necrosis in 80% of the hepatocytes and fatty degeneration. Renal injury included dilated, atrophic renal tubules without necrosis and dilated glomeruli. Postmortem examination of other fatalities demonstrates centrilobular necrosis of the liver, pulmonary hemorrhage, hemoperitoneum, necrosis of the mucosal lining in the stomach,[176] and extensive cortical proximal convoluted renal tubular cell necrosis;[172] glomeruli appear relatively normal.[174]

CLINICAL RESPONSE

Acute Oral Toxicity

The ingestion of large doses of hexavalent chromium causes vertigo, thirst, abdominal pain, bloody diarrhea, and, in severe cases, coma and death. Serious complications include hepatorenal syndrome,[179] severe coagulopathy,[176] and intravascular hemolysis.[219] If the patient survives, the initial phase of shock, hepatic, and renal failure may develop within 1–2 days. Occasionally, renal dysfunction may persist after recovery from an acute overdose of hexavalent chromium.[216]

Although suicidal chromic acid ingestions are usually fatal, patients may survive the accidental ingestion of chromic acid with intensive care including hemodialysis.[51] Serious complications of an acute chromic acid ingestion include severe hemorrhagic gastroenteritis with yellow-green vomitus or hematemesis, hepatic necrosis, gastrointestinal hemorrhage and perforation, and acute tubular necrosis with renal failure.[51,173] Although chromic acid is a strong mineral acid that causes direct skin and extensive gastrointestinal tract ulcerations, serious end organ failure, and gastric hemorrhage may develop despite the absence of lesions in the mouth, larynx, or esophagus on endoscopy.[220] An intravenous chromic acid exposure resulted in nausea, vomiting, dark red urine, loose reddish stool, and renal failure that required temporary hemodialysis.[178]

Environmental Exposure

Ecological studies of populations exposed to hexavalent chromium as measured by chromium concentration in drinking water or geographical location near point sources are inconsistent; overall, most studies do not strongly support an association between cancer mortality and environmental chromium exposures. An ecological study of JinZhou Chinese province containing a ferrochromium plant compared mortality rates in four areas with low total chromium concentrations in drinking water (<0.001 mg/L) and five areas with relatively high chromium concentrations from 1970–1978.[221] Discharge from the plant to surface and drinking water began in 1961. In 1965, total chromium concentrations in well water samples from the high-chromium areas ranged from 0.6–20 mg/L with 15% of the well water containing <2 mg/L. Comparing high and low chromium exposure areas, the age-adjusted cancer mortality rate ratio for stomach cancer was elevated at 1.82 (95% CI: 1.11–2.91), whereas the rate ratio for lung cancer of 1.15 (95% CI: 0.62–2.05) and all cancers of 1.13 (95% CI: 0.86–1.46) were not significantly elevated. Re-analysis of cancer rates in the region by dividing the province into the industrial town of TangHeZi where the plant was located, unexposed agricultural village residents, and exposed agricultural residents did not confirm the elevated rate of stomach cancer deaths when using local rather than provincial rates.[222] The relative risks of lung and stomach cancers were similar for the chromium-exposed residents and residents of agricultural villages without chromium contamination; average total chromium concentrations in drinking water did not correlate to stomach or lung cancer rates.

Hexavalent chromium compounds were additives at water-cooling towers in three southern California, gas compressor facilities in the decades from the 1950s–1980s. An ecological study in Kings County and San Bernardino County, California compared cancer mortality in locations near natural gas compressor plants with areas distant from the plants based on zip codes.[223] Age-adjusted cancer mortality rate ratios (i.e., rate (areas near the plant)/rate (distant areas)) for

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

1989–1998 were 1.03 (95% CI: 0.90–1.17) for lung cancer deaths, 0.93 (95% CI: 0.87–1.00) for all cancer deaths, and 0.98 (95% CI: 0.95– 1.02) for all deaths.

Occupational Exposure

The main target organs of hexavalent chromium toxicity are the skin and respiratory tract. A French mortality study of 4,227 stainless steel production workers from 1968–1984 detected excess deaths from liver cirrhosis compared to expected deaths (SMR = 174, 95% CI: 131–226; Observed/Expected = 55/31.6) based on national rates and matched for age, sex, and calendar time.[224] The study reported no measures of chromium exposure or regression analysis for potential confounding variables. Most mortality and morbidity studies of workers in the production of chromium compounds have not demonstrated an excess prevalence of liver disease.[142]

Kidney

Studies of renal function in chrome platers suggest the possibility that Cr^{6+} exposure exceeding $4\,\mu g/m^3$ may produce renal tubular dysfunction manifested by increased urinary excretion of β_2-microglobulin.[225] In a cross-sectional study of 115 Chinese chromate production workers with mean duration of chromium exposure of ~13 years and 60 local controls without Cr exposure, the incidence of urinary *N*-acetyl-β-D-glucosaminidase activity and β_2-microglobulin concentration above reference values was increased compared with controls.[226] Despite the mandatory use of personal protective equipment (M40 masks, rubber gloves/boots) and the lack of any airborne chromium concentrations exceeding $50\,\mu g/m^3$, the airborne chromium concentrations correlated to urine total chromium concentrations (mean = 17.41 μg/g creatinine); the airborne chromium concentration was not speciated. Therefore, the chromium exposure may have exceeded current workplace standards. The study did not report confounding variables. Other studies have not detected an increased prevalence of renal tubular dysfunction or reduced creatinine clearance. A cross-sectional Swedish study of 24 current chrome platers, 27 ex-chrome platers, and 37 referents demonstrated an increased incidence of elevated urinary β_2-microglobulin concentrations in current chrome platers (mean = 5.3 years), but not ex-chrome platers with >1 year Cr^{6+} exposure in the chrome plating plants followed 1940–1968.[227] Other epidemiological studies on chrome platers[228] and on stainless steel welders[229] have not consistently associated renal tubular dysfunction or reduced glomerular filtration with occupational Cr^{6+} exposure. In a study of 3,408 US chromate production workers processing chromite ore and followed 1937–1971, mortality from genitourinary disease was not significantly increased with a proportionate mortality ratio for Caucasian workers of 71 (95% CI: 40–117).[89] Chromium exposure and smoking data were not available.

Skin

Hexavalent chromium is a skin and mucous membrane irritant with some hexavalent compounds being strong corrosive agents. Chromic acid is a corrosive that produces inflammation and ulceration of the skin as well as allergic contact dermatitis in sensitized individuals. In addition, chromic acid burns can cause systemic toxicity even following relatively small burns. External burns of 10% of the total body surface caused by chromic acid may be fatal, whereas a 19-year-old man survived a 20% burn after developing hepatic damage, acute renal failure, and normochromic and normocytic anemia.[230]

In addition to the corrosive injuries produced by chromic acid, Cr^{6+} may cause allergic contact dermatitis or skin ulcers in sensitive individuals. Skin ulcers (chrome holes) develop slowly in exposed areas of the body (nasal septum, extremities) following exposure to hexavalent chromium, particularly in areas of the skin with loss of dermal integrity (e.g., index, middle fingers). These painless ulcers are usually well-circumscribed craters with intense inflammation and tenacious crusts.[231,232] These lesions heal in a few weeks following cessation of chromium exposure, often with atrophic or occasionally hypertrophic scars.

Immune System and Asthma

Occupational exposure to hexavalent chromium compounds may produce an allergic contact dermatitis characterized by eczema.[233] Chromium sensitization is a common cause of contact dermatitis in workers presenting to allergy and occupational clinics, particularly among workers in the building trades.[234] Although the chromium concentration in cement is low (<0.2%), chromium sensitivity is the most common type of sensitivity reaction in cement workers. As many as 8–9% of cement workers have positive patch tests for hexavalent chromium compounds, even though the incidence of allergic dermatitis is much less.[235] A study of volunteers from a referral clinic indicated that sensitivity to chromates (Cr^{6+}) in that population averaged 1.7%,[236] but the actual incidence for patients with normal skin and normal sensitivity is probably much less (0.1%). In a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

study of 230 automobile workers handling nuts and bolts coated with Cr^{6+}-containing chrome and diagnosed with skin disease (eczema, dermatitis), positive patch tests to potassium chromate occurred in 56 (24.3%) of exposed workers compared with 1 (0.15%) of 66 controls.[237] Among construction workers, hexavalent chromate in cement is the most common cause of allergic contact dermatitis; however, over the last several decades, the prevalence of allergic contact dermatitis in cement workers has decreased as a result of the reduction of hexavalent chromium concentrations in cement.[238]

Case reports associate the development of occupational asthma in chromium-sensitized workers with a variety of hexavalent chromium compounds including chromic acid vapors[210,239] metal plating with chromium,[76] chromate spray paint,[240] zinc chromate primer paint,[239] and chromium (Cr^{6+}) fumes from stainless steel welding.[241] Although the chromium content of cement is minute, case reports associate the development of allergic contact dermatitis and occupational asthma with cement exposure, particularly in smokers.[242,243] Nickel electroplating is more efficient compared with chromium electroplating that generates minimal amounts of Cr^{6+}. Some cross-reactivity to nickel may occur in electroplating workers with chrome-induced occupational asthma.[244] Sensitization to chromium may occur in occupational environments, where air concentrations to chromium are below permissible occupational limits.

The wide variation in lymphocyte subpopulations and modulation of cell populations by a wide variety of effectors limits interpretation of the effect of chromium on the immune system. In general, studies do not support the suppression of the immune system by chromium compounds. Comparison of a convenience sample of 15 plastics workers exposed to lead chromate (Cr^{6+}) demonstrates a 30–50% reduction in measures of CD4+ helper-inducer and natural killer lymphocytes compared with 15 healthy, unexposed controls; serum chromium concentrations and serum immunoglobulins IgA, IgG, and IgM were not significantly different between the two groups.[245] In an Italian study of 84 shoe, hide, and leather workers exposed to hexavalent chromium, the lymphocyte subpopulations (CD4+, CD8+, CD19+, CD16+/CD56+, CD4/CD8) were similar in exposed and unexposed workers.[246] An earlier study of 20 Italian tannery workers detected an increased proliferative response of peripheral blood mononuclear cells to concanavalin A, but the distribution of lymphocyte subsets (e.g., T cells, T helper lymphocytes, T cytotoxic lymphocytes, B cells, natural killer cells) was similar between the exposed and unexposed workers.[247] Personal air samplings of Cr^{6+} concentrations were not reported, but analysis of airborne total Cr and Cr^{6+} concentrations in similar factories suggested TWA concentrations of 90–100 $\mu g/m^3$ and 1–2 $\mu g/m^3$, respectively.

Respiratory Tract

Chronic exposures to chromate dusts and chromic acid fumes may cause conjunctivitis, lacrimation, sneezing, nose and throat irritation, rhinitis, cough, epistaxis, nasal obstruction, or ulceration, and/or perforation of the nasal septum.[155,248,249] Older studies of chromate production workers associated high exposure to dichromate and chromium trioxide (>10 Cr^{6+} $\mu g/m^3$) with an increased incidence of sinusitis, laryngitis, nasal polyps, and bronchitis; airborne chromium concentrations were not well-defined but involved both Cr^{3+} and Cr^{6+}.[250,251] In a cross-sectional study of 27 Korean electroplaters and 34 controls (male clerks from the same factory), the prevalence of nasal complaints (dry nose, crusting, nasal obstruction) was significantly increased in chromium workers compared with controls based on questionnaires.[252] Olfactometry testing demonstrated reduced olfactory thresholds in exposed workers without nasal complaints. Chemicals used in electroplating included chromic acid, sodium and potassium dichromate, hydrogen chloride, nitrous oxide, sulfuric acid, and nickel carbonate with the airborne concentration of Cr^{3+} and Cr^{6+} near or slightly above current workplace standards.

A statistically significant excess of deaths (SMR = 143; observed/expected, 41/28.66; $P < 0.05$) due to chronic obstructive pulmonary disease (COPD) was detected in UK chromate production workers first employed before 1945 based on national rates adjusted for geographical area and social class; there was no excess mortality from COPD in workers employed after that date.[253] The SMR for workers employed after process changes to reduce dust and chromate exposure demonstrated a significantly reduced SMR for COPD (SMR = 17; observed/expected, 1/5.88; $P < 0.05$). In a retrospective mortality study of 2,689 UK nickel/chromium platers employed at least 6 months 1946–1983, the SMR for mortality from respiratory diseases excluding cancer was 127 (observed/expected, 97/76.4; $P < 0.05$) based on national rates.[254] The primary exposure was chromium trioxide, but the chromium concentrations were not well documented. There was no direct correlation between the presence of chromates and the development of chronic obstructive pulmonary disease in a cross-sectional study of ferrochromium workers.[255] Methodological issues in these studies prevent the establishment of a definitive cause–effect relationship

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. between chromate exposure and mortality from noncancerous pulmonary diseases, particularly the lack of smoking, chromium speciation, and confounder data.

Reproductive Abnormalities

Reproductive data on the effect of hexavalent chromium on human reproduction are limited, particularly for studies with analyses of airborne Cr^{6+} concentrations. In the current medical literature, the association between Cr^{6+} exposure and adverse child outcomes (birth defects, autism spectrum disorder, prematurity, small for gestational age) is weak.[256] A study of 30 tungsten inert gas stainless steel welders exposed to low concentrations of hexavalent chromium did not detect a statistically significant increase in sperm morphology, sperm mobility, or sex hormones (testosterone, follicle-stimulating hormone, luteinizing hormone) compared with referents.[257] In a study of women undergoing *in vitro* fertilization, the number of spontaneous abortions before 28 weeks in IVF-treated women impregnated by men exposed to stainless steel welding fumes ($n = 91$, 18%) and mild steel welding fumes ($n = 128$, 25%) was similar to controls ($n = 819$, 28%).[258] The risk ratio for pregnancies with paternal exposure to stainless steel was 0.6 (95% CI: 0.4–1.0). The same group earlier studied the occurrence of spontaneous abortions among 2,520 pregnancies of 1,715 married to metal workers in 1977–1987. The odds ratio of spontaneous abortions in couples with fathers exposed to stainless steel welding fumes was 0.78 (95% CI: 0.55–1.1) when compared with couples of unexposed fathers.[259] Occupational histories were based on questionnaires, and the occurrence of spontaneous abortions was confirmed on medical registries; no chromium concentrations were reported. A study of stainless steel and mild steel welders did not detect statistically significant differences in sperm morphology, sperm motility, or sex hormones (follicle-stimulating hormone, luteinizing hormone, testosterone) between welders and referents.[260] The study did not assess airborne concentrations of metals to determine dose-response.

Toxic oral doses of potassium dichromate (57 mg Cr^{6+}/kg/day) in drinking water caused severe developmental and fetal toxicity in rats including increased post-implantation loss, decreased cranial ossification, and decreased fetal weight.[261]

Carcinogenesis

The International Agency for Research on Cancer (IARC) and the US Toxicology Program recognize hexavalent chromium as a known human carcinogen. Increased risk of lung cancer occurs primarily in workers exposed to hexavalent chromium dust during the refining of chromite ore and the production of chromate pigments. Although individual studies suggest the possibility of an excess incidence of cancer at sites outside the lung, the results from these studies are inconsistent. Studies of chrome platers exposed to Cr^{6+} and other carcinogenic chemicals (e.g., nickel, sulfuric acid) found a significantly increased lung cancer risk in association with surrogate measures of Cr^{6+} exposure (e.g., duration of employment at jobs involving Cr^{6+} exposure); however, data on estimates of attributable risk of Cr^{6+} exposure remain unclear. Similarly, lung cancer rates are elevated in studies of chromate production workers with the rates declining as improved industrial hygiene methods reduced Cr^{6+} exposure. Results of studies of lung cancer rates in stainless steel welders exposed to Cr^{6+} and other potential carcinogens are inconclusive.

Lung

Based on positive responses in assays for genotoxicity, hexavalent chromium is the most potent genotoxic chromium species.[139] The solubility of these hexavalent compounds is a significant risk factor with the moderately soluble compounds (e.g., strontium and zinc chromates) associated with the greatest risk of lung cancer. The dose-related, increased risk of lung cancer is associated with the inhalation of hexavalent chromium in the occupational setting, primarily in populations of workers refining chromite ore or producing chromate pigments with high exposures to hexavalent chromium.[262,263] No increased risk of lung cancer was detected in a population-based, case-control study of tobacco-using workers with low to medium exposure to hexavalent chromium as determined by job history; however, the odds ratio of lung cancer among nonsmokers or former smokers was elevated (OR = 2.4, 95% CI: 1.2–4.8).[264] In the 1950s and 1960s, process modifications (i.e., elimination of calcium chromate by changing to lime-free processes) and improved environmental controls reduced exposure to hexavalent chromium compounds. A meta-analysis of cancer studies post-modification did not demonstrate a statistically significant excess of lung cancer; however, the combined studies lacked sufficient statistical power to exclude a moderate increase in the risk of lung cancer.[265] This risk of lung cancer decreases to baseline levels for the working population when newer technologies for reducing the amount of lime in the roast mix result in hexavalent chromium concentrations in ambient air of <1–5 $\mu g/m^3$.[266]

Squamous cell and small cell carcinomas are the predominant cell types with the development of small cell carcinomas occurring after more intense exposures over shorter periods of time compared with the appearance of squamous cell carcinomas.[139]

The mean latency period for developing lung cancer in these workers ranged from ~13–30 years, although a few cases have appeared following 5 years of exposure to chromates.[267] In general, the minimal latency period for lung cancer is 10–15 years. Similar latency periods for the development of lung cancer have been reported in chromium chemical production workers (chromic acid mists) and workers exposed to lead and zinc chromates.[268,269]

Chromate Production

Epidemiological studies of chromate production workers demonstrate an increased risk of lung cancer mortality that has declined with improved industrial hygiene methods. These studies indicate that the risk of lung cancer increases with increasing cumulative exposure to hexavalent chromium.[270] An increased incidence of lung cancer (adjusted SMR = 197; observed deaths, 175) occurred in 1,422 workers exposed to hexavalent chromium in chromate production employed before changes to production processes in the late 1950s decreased hexavalent chromium exposure.[253] The study demonstrated no excess lung cancer deaths (adjusted SMR = 102, 95% CI: 56–171; observed deaths, 14) in 677 men employed after the changes in production processes. An etiological research study of 398 chromate workers at a new facility, where >99% of the personal breathing zone samples were <50 μg Cr^{6+}/m^3, did not demonstrate increased mortality.[271] The number of subjects was small, and the follow-up period was relatively short (15 years). A meta-analysis of 49 epidemiological studies of cancer outcomes primarily among chromate production workers employed after improvements in the production process demonstrated a SMR of 141 (95% CI: 135–147).[272] Limiting the analysis to high-quality studies controlled for smoking indicated that current hexavalent chromium exposure is a relatively weak carcinogen as the overall SMR for lung cancer decreased to 112 (95% CI: 104–119).

Chrome Plating

Some epidemiological studies demonstrated elevated lung cancer rates in chrome bath workers exposed primarily to soluble hexavalent chromium (i.e., chromic acid mists) when compared with referent populations. In these studies, the risk of lung cancer following exposure to chromic acid mists increased with the duration of exposure after adjustment for sex, age, and period from the first chrome work.[273] The risk of developing lung cancer is smaller and less consistent in chrome platers than in chromate production workers. In a study of 1,087 chrome platers exposed to chromic acid mist, the SMR was 185 (95% CI: 141–238; observed deaths, 60; $P < 0.001$) when compared to the general population in England and Wales.[274] However, there was no statistically significant difference in the SMR for lung cancer when comparing the exposed workers with a group of workers without known exposure to hexavalent chromium. In a prospective cohort study of 1,193 Japanese metal platers (626 chrome platers, 587 non-chromium platers), the overall SMR for all platers was 179 (95% CI: 102–290; observed deaths, 16).[275] However, there was no statistically significant difference in the SMR between the subgroups of chromium and non-chromium platers. The chromium platers worked in small-scale chromium plating plants in Tokyo, Japan, for at least 6 months. Extending the follow-up to 27 years resulted in an increased lung cancer mortality of borderline statistical significance (SMR = 146, 95% CI: 0.98–2.04; observed deaths, 28); the SMR was 1.09 (95% CI: 0.67–1.60; observed deaths, 20) in non-chromium platers.[276] Higher lung cancer risk occurred in chromium platers with earlier exposure, but not with increased duration of employment as a chromium plater. Smoking histories were not available.

Chrome Pigment Production

Some epidemiological studies suggest an increased incidence of lung cancer in workers exposed to hexavalent chromium (e.g., lead and zinc chromates) during chromium pigment production.[141] In some of these studies, the rate of lung cancer mortality increased (SMR = 190, 95% CI: 111–295) for workers with hexavalent chromium exposure over 30 years (1940–1982), but not with shorter Cr^{6+} exposure or the whole cohort.[277] Monitoring airborne chromium concentrations in later years indicated total chromium exposure for the cohort was >500 μg/m^3 with highly exposed workers exceeding 2,000 μg/m^3. The lack of control for confounders (smoking, nickel exposure) and poor exposure data (i.e., lack of speciation) limits conclusions regarding the contribution of hexavalent chromium to lung cancer rates.[278,279] In general, water-soluble chromates (sodium and potassium chromate, dichromates) are more potent carcinogens than less-soluble chromate compounds with the exception of calcium and zinc chromates.[280] Studies of end users of chromate (e.g., painting operations using chromate pigments) do not demonstrate a strong association between exposure to chromium compounds and the development of lung cancer.[281]

Stainless Steel Welding

Workers in the stainless steel welding industry are exposed to hexavalent chromium and other potential carcinogens (e.g., nickel and asbestos); epidemiological studies of workers in this industry are inconsistent with increased lung cancer mortality rates in some sections of the industry.[282] Although a meta-analysis of five epidemiological studies suggested an increased pooled relative risk of lung cancer in stainless steel welders of 1.94 (95% CI: 1.28–2.93),[283] the differences in lung cancer risks between exposed welders and referents in four of the studies were not statistically significant. A historical follow-up study of arc welders exposed to fumes containing chromium and nickel demonstrated a nonstatistically significant increase (~20–30%) in the mortality from lung cancer compared with controls, but most of this excess mortality was attributed to smoking and asbestos exposure.[284] The ~30–40% increase in the incidence of lung cancer in welders does not correlate well with exposure to hexavalent chromium; a study of welders demonstrated little difference in the rates of lung cancer between stainless steel welders (chromium, nickel exposure) and mild steel welders (no chromium, nickel exposure).[285] In a Swedish study of 234 stainless steel welders with at least 5 years of exposure 1950–1965 and followed through 1984, the SMR for trachea, bronchus, and lung tumors was 2.49 (95% CI: 0.80–5.81; observed/expected, 5/2).[286] The median time-weighted average airborne total chromium concentration was 110 μg/m^3 ranging up to 750 μg/m^3. Eighty-five percent of the chromium measurements exceeded current workplace standards.

Environmental Exposure

There is little evidence that chromium causes lung cancer following lifetime exposure to hexavalent chromium in drinking water or airborne chromium exposure near point sources. In a mortality study of residents near gas compressor facilities that used hexavalent chromium as water-cooling additives, there was no significant increase in the mortality rates of cancer at any site when compared with mortality rates in surrounding communities.[223] In an ecological study of five Chinese agricultural villages with and four nearby villages without Cr^{6+} in their drinking water, the mortality rates from lung cancer, stomach cancer, and all cancers were similar without evidence of a dose-response relationship.[222] The risk of cancer from dermal or oral exposures to hexavalent chromium compounds is not well documented.[10] Hexavalent compounds for which there is evidence in animal studies for carcinogenicity include the following: barium chromate, calcium chromate, chromium trioxide, lead chromate, sodium dichromate, and strontium chromate.

Other Sites

Currently, there is a lack of conclusive evidence to associate hexavalent chromium exposure with an excess of cancer outside the respiratory tract.[287] Although individual studies suggest the possibility of an excess incidence of cancer at sites outside the lungs (nose, gastrointestinal tract), results from these studies are inconsistent.[253,288] In a study of 2,354 workers employed at a chromate production plant in 1950–1974, lung cancer mortality was elevated (SMR = 1.63, 95% CI: 1.42–1.86) using US mortality rates without evidence of increased mortality rates from other cancer sites.[289] A review of the carcinogenicity of hexavalent chromium reported suggestive evidence of an increased risk of cancer in nonpulmonary sites including bone, stomach, prostate, genital, renal, bladder, and blood (lymphoma, Hodgkin's disease, leukemia).[290] However, the evidence cited for this conclusion primarily involves mortality studies, many of which demonstrated nonsignificant increases in the SMR. Furthermore, the author failed to discuss the inherent weakness of mortality studies (selection bias, accuracy of exposure data, confounding) and the lack of well-designed cohort studies to support the development of cancer at sites distant from the sites of administration. Most of the studies cited for stomach cancer contained small numbers of observed cases and nonsignificant increases in the SMR.[291,292] A review of the chromium data in 1997 indicated that heterogeneity of reporting and reporting bias precluded the use of meta-analysis to determine the incidence of cancer at sites outside the lung.[265] Additionally, confounding complicates the interpretation of these studies including smoking, dietary factors, alcohol consumption, and socioeconomic status. Co-exposure to sawdust confounded the previous causal relationship between sinonasal cancer and chromates.[293] A more recent meta-analysis of 32 studies of gastrointestinal tract cancers detected an elevated meta-SMR of 1.49 only for esophageal cancer among four US cohorts (meta-SMR = 1.49, 95% CI: 1.06–2.09) with relatively high Cr^{6+} exposure.[294] Calculated meta-analysis summary relative risk (95% CI) using random effects models and inverse variance weighting methods was as follows: oral cavity = 1.02 (0.77–1.34), esophagus = 1.17 (0.90–1.51), stomach = 1.09 (0.93–1.28), colon = 0.89 (0.70–1.12), and rectum = 1.17 (0.98–1.39). A meta-analysis of 56 cohort and case-control studies and 74 individual relative risk estimates on stomach cancer suggested an association

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

between hexavalent chromium exposure and stomach cancer.[295] The summary relative risk (sumRR) was 1.27 (95% CI: 1.18–1.38); these studies included workers in chrome plating, chromium production, leather works, and jobs with exposure to Portland cement. The sumRR for studies with increased risk of lung cancer was higher (sumRR = 1.41, 95% CI: 1.18–1.69), suggesting increased risk of stomach cancer following higher chromium exposure. Few studies controlled for confounding variables (e.g., smoking).

DIAGNOSTIC TESTING

Analytical Methods

In biological media, techniques for the determination of hexavalent chromium include complexation with diphenylcarbazide followed by solvent extraction and analysis by electrothermal/absorption atomic spectrometry (LOD, 0.2–0.5 μg/L)[296] and capillary electrophoresis/inductively coupled plasma/sector field/mass spectrometry.[297]

In environmental samples, ion chromatography is the most common technique for separating hexavalent chromium from environmental samples with flow-injection analysis a less common technique.[298] Techniques for quantitating hexavalent chromium in environmental samples include ion chromatography followed by ultraviolet–visible (UV–VIS) spectroscopy (air, NIOSH method 7605; water, EPA method 7199 or 218.7 for dissolved Cr^{6+}), complexation of chromate ions with 1,5-diphenylcarbazide (DPC) in strongly acidic solution followed by spectrophotometry (540 nm),[299] anion-exchange fast protein/liquid chromatography/electrothermal atomic absorption spectrometry (LOD, 0.035 μg Cr^{6+}/m^3),[300] absorptive stripping voltammetry,[301] complexation with pyrocatechol violet and *N*-(2-hydroxyethyl)ethylenendiamine-*N*,*N*′,*N*′-triacetic acid coupled with differential pulse adsorptive stripping voltammetry,[302] flow injection on-line sorbent extraction followed by complexation with sodium diethyldithiocarbamate and quantitation by electrothermal/atomic absorption spectrometry (LOD, 16 ng Cr^{6+}/L and 18 ng Cr^{3+}/L),[303] ion chromatography coupled with inductively coupled plasma/atomic emission spectrometry,[304] and complexation with ammonium pyrrolidinedithiocarbamate followed by high-pressure liquid chromatography with UV detection.[305,306] The limit of detection for hexavalent chromium using the latter method is 2.2 μg/L. Although the reaction of DPC with chromate is highly specific for Cr^{6+}, the presence of other metals (Cu^2, Fe^3, Hg^2, Mo^6, V^5) may compete with Cr^{6+} for the colorimetric reagent and lower the quantitative value of hexavalent chromium. Additionally, the use of spectrophotometry for the quantitation of Cr^{6+} (e.g., welding fumes) is usually inappropriate because the highly acidic solutions in the presence of magnetite (Fe_3O_4) reduce most of the Cr^{6+} to Cr^{3+}.[298] The use of a sampling filter impregnated with alkali decreases the reduction of Cr^{6+} when analyzing chromic acid mists, but the addition of magnesium hydroxide is important to prevent the air oxidation of trivalent chromium species to Cr^{6+}. Proper storage of water samples requires a pH ≥ 8 with ammonium ion-containing buffers to complex free chlorine; the presence of free chlorine oxidizes Cr^{3+} to Cr^{6+}.

Biomarkers

Blood

Plasma or serum chromium concentrations reflect recent exposure to hexavalent and trivalent chromium, whereas RBC chromium concentrations reflect the burden of hexavalent chromium because only Cr^{6+} penetrates red blood cells. Chromium concentrations in erythrocytes indicate the extent of hexavalent chromium exposure during the lifetime of the red blood cell. Low RBC chromium concentrations imply that the concentration of Cr^{6+} did not significantly exceed the reducing capacity for Cr^{6+} in the plasma, whereas RBC Cr concentrations often exceed plasma Cr concentrations ~3–5 fold several days after severe acute Cr^{6+} poisoning.[216] On the day of admission after accidentally ingesting potassium dichromate, the plasma and RBC chromium concentrations in blood samples from a 58-year-old man were 1,657 μg/L and 631 μg/L, respectively.[192] By 49 days postingestion, values were 5 μg/L and 129 μg/L, respectively.

The ratio of whole blood/plasma total chromium concentrations varies substantially with time after an acute ingestion as chromium diffuses into erythrocytes. In a fatal chromic acid ingestion complicated by massive gastrointestinal hemorrhage, the whole blood/plasma total chromium ratio was 2.1 3 hours after ingestion (Hct = 53%) compared with 1.75 11 hours after ingestion (Hct = 17%).[218] She died 1 hour later. The whole blood/plasma chromium ratio was ~2–3 several days after the use of dichromate-containing purgatives.[216]

General Population

There are few data on Cr^{6+} concentrations in whole blood samples from the general population, primarily because of the low hexavalent chromium exposure for individuals without occupational exposure to Cr^{6+}.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Toxicity

Whole blood chromium concentrations above 2–3 mg/L are potentially lethal following acute exposure to hexavalent chromium.[217] Most case reports do not speciate blood chromium concentrations. A 15-year-old girl ingested potassium dichromate, vomited, and soon became comatose; she died within 12 hours of ingestion. The admission blood sample contained 35 mg Cr/L.[307] A 17-year-old adolescent died 18 hours after the ingestion of potassium dichromate from hypotension, DIC, and severe gastrointestinal hemorrhage, despite intensive care including the use of hemodialysis, hemoperfusion, and dimercaprol.[176] The whole blood chromium concentrations 3 hours and 13 hours after ingestion were 58 mg/L and ~27 mg/L, respectively. The total serum chromium concentration 7 hours after the intentional ingestion of potassium dichromate by a 48-year-old man was ~0.7 mg/L.[180] He survived after developing tarry stools, abdominal pain, diarrhea, chest pain, and mild elevation of his serum creatinine. The serum chromium concentration 1 day after the deliberate ingestion of potassium dichromate by a 16-year-old adolescent was ~2.4 mg/L.[308] Within 2 days, he developed hepatorenal failure requiring liver transplantation. He survived without hepatorenal dysfunction for at least 2 years after transplant. On admission to the emergency department with diarrhea and abdominal pain, the plasma chromium concentration in a 58-year-old man who accidentally ingested potassium dichromate was 2.09 mg/L.[192] He survived without developing hepatorenal dysfunction. A 55-year-old man survived the accidental ingestion of chromic acid after developing hemorrhagic gastroenteritis and hepatorenal dysfunction that required several days of hemofiltration.[220] Five hours after ingestion, his blood chromium concentration (sample type not reported) was 3.4 mg/L.

Urine

Urine chromium concentrations reflect absorption of chromium primarily over the last 1–2 days in patients without prior occupational exposure to chromium. As a result of reduction of hexavalent chromium in the airways and blood, only trivalent chromium appears in the urine. Consequently, urinary chromium represents exposure to either or both of these species. Most analytical methods do not distinguish between trivalent and hexavalent chromium. Although trivalent chromium does contribute somewhat to the total chromium concentration, substantial portions of the total chromium result from the reduction of hexavalent chromium.

Hair

External contamination of hair complicates the use of this biomarker as a measure of the severity and timing of hexavalent chromium exposure. Analysis of hair chromium could not distinguish the timing of an acute, accidental exposure to potassium dichromate in a woodworker using chromium as a pigment.[218] The use of hair analysis in the occupational setting is complicated by the difficulty of distinguishing chromium bound to the hair after absorption from external contamination. External contamination of the hair prevented the identification of the time of an acute ingestion of potassium dichromate. Chromium concentrations in hair are up to 1,000 times higher than serum chromium concentrations.

Abnormalities

Some hexavalent chromium compounds are strong oxidizing agents; therefore, methemoglobinemia potentially may develop. In a fatal case of potassium dichromate poisoning, methemoglobinemia occurred along with respiratory failure, gastrointestinal hemorrhage, and coagulopathy.[176] A case series of chromium-sensitized workers indicates that inhalational challenges with potassium dichromate produce a variety of reactions (immediate, dual, late) in response to the bronchial provocation tests including angioedema, erythema, pruritus, cough, wheezing, and bronchospasm.[309] Not all chromium-exposed patients with positive bronchial provocation tests have positive skin prick tests for potassium dichromate.[310]

HEALTH SURVEILLANCE

Risk Assessment

Occupational Exposure

Hexavalent chromium is a recognized lung carcinogen that causes elevated lung cancer rates in exposed workers (e.g., chromate and chromate pigment production), whereas no increased risk of lung cancer was detected in workers in the ferrochromium industry exposed to trivalent chromium.[53] In general, estimates of excess lifetime occupational risks of developing lung cancer in chromate production workers range from ~0.002–0.005 per μg Cr^{6+}/m^3. Based on Poisson and Cox regression analysis of the Painesville cohort at a chromate production facility, the estimated lifetime additional risk of lung cancer mortality associated with 45 years of occupational exposure to 1 μg Cr^{6+}/m^3

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

was 0.00205 (90% CI: 0.00134–0.00291) for the relative risk model assuming a linear dose-response for cumulative exposure with a 5-year lag.[270] Extrapolating these data to a continuous environmental exposure resulted in an environmental unit risk of 0.00978 (90% CI: 0.00640–0.0138). Statistical tests did not detect a statistically significant increased risk of lung cancer below lifetime cumulative occupational exposures to hexavalent chromium below 1 mg/m^3-year. The exclusion of short-term workers defined by <1 year of employment limited information in the low exposure range. In an updated mortality study of 714 Painesville workers including 198 short-term workers, the standardized mortality ratio (SMR) remained elevated (SMR = 186, 95% CI: 145–228) for workers with cumulative exposure of >1.41 mg/m^3-years.[311] Using linear Cox model with unlagged cumulative exposure, the occupational unit risk was 20% lower (0.00166, 95% CI: 0.000713–0.00349) and the environmental unit risk was 15% lower (0.00832, 95% CI: 0.00359–0.0174) than in the previous study.

Extrapolation of exposure data from 2,372 men hired at a chromate manufacturing plant from August 1, 1950 to December 31, 1974 with mean cumulative exposure to hexavalent chromium of 0.134 mg/m^3-year indicated an estimated rate ratio of 2.44 (95% CI: 1.54–3.83) for a cumulative hexavalent chromium exposure of 1 mg/m^3-year as CrO_3.[312] The estimated excess lifetime risk of lung cancer mortality from exposure to 0.1 mg/m^3 (OSHA PEL) was 255 per 1000 (95% CI: 109–416).

Currently, there is substantial scientific debate about the following: 1) the mode of action (i.e., cytotoxic vs. genotoxic) of Cr^{6+}-induced cancer; and 2) the validity of extrapolating from high oral doses in rodents to chromium concentrations typically present in the environment using a linear model rather than a nonlinear threshold model reflecting the Cr^{6+} reductive capacity in the gastrointestinal tract.[313,314]

Using the multistage, low-dose linear extrapolation, the US EPA calculated an inhalation unit risk factor for airborne Cr^{6+} exposure of 0.012 per μg/m^3.[315,316] This value correlates to an upper 95% confidence limit of 1/1,000,000 for an airborne Cr^{6+} concentration of 8×10^{-5} μg/m^3. Revaluation of the inhalation unit risk factor by the Texas Commission on Environmental Quality using dosimetric adjustments and an uncertainty factor of 30 to points of departure with respect to tumor formation resulted in a value of 0.24 μg Cr^{6+}/m^3 (i.e., ~300 times higher than the US EPA estimate).[317] In this study, analysis of data from Crump et al.[270] and Luippold et al.[263] suggested possible threshold values of 1.00–2.70 mg/m^3 year for cumulative Cr^{6+} exposure; the most conservative point of departure selected for derivation of the cancer-based chronic inhalation reference value was 0.195 mg/m^3 year. In the Luippold study, over ¾ of the exposed cohort smoked. There are inadequate data to evaluate the effect of combined exposure to tobacco smoke and chromium on the risk of developing lung cancer.[318]

Environmental Exposure

The inhalation of Cr^{6+}-contaminated dust is a carcinogenic hazard; however, there is limited evidence causally linking oral or dermal environmental exposure to Cr^{6+} and increased lung cancer. Risk analyses of soil contaminated with hexavalent chromium indicate that soil concentrations limited to the range of 130–450 ppm Cr provide adequate protection against the development of allergic contact dermatitis, respiratory cancer, and systemic toxicity.[319] For persons living in residential properties, the estimated risk of lung cancer is <1:1,000,000 when the concentration of total chromium in the soil is <180 mg/kg (ppm). Risk analysis by an expert panel concluded that soils containing Cr^{6+} concentrations below 75 ppm or total chromium concentrations below 1,000 ppm with 5% Cr^{6+} did not pose a significant health hazard to nearby residents.[320] Studies of residents exposed to hexavalent chromium in ambient air have not detected an excess incidence of lung cancer in these subjects.[223,321]

The body possesses mechanisms in the lung and stomach to reduce hexavalent chromium to the less toxic trivalent chromium. Thus, at low levels of Cr^{6+} exposure, the body has the potential to reduce Cr^{6+} to Cr^{3+} before the former compound can interact with DNA. Current evidence, including the decline in the incidence of lung cancer in chromate workers after reduction in Cr^{6+} concentrations, suggests the possibility that a threshold for the carcinogenic potential of hexavalent chromium in humans may exist; however, the existence of a Cr^{6+} threshold for cancer remains controversial.[322]

Environmental Monitoring

Inhalation

The ATSDR MRL (minimal risk level) for intermediate- and chronic-duration inhalation exposure to Cr^{6+} as chromium trioxide mist or other dissolved hexavalent chromium aerosols and mists is 0.005 μg Cr^{6+}/m^3 based on a LOAEL of 0.002 mg Cr^{6+}/m^3 for upper respiratory effects in workers.[143] The MRL for intermediate-duration inhalation exposure to Cr^{6+} as particulate hexavalent chromium compounds is

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

0.3 μg Cr^{6+}/m^3 based on a benchmark concentration of 0.016 mg Cr^{6+}/m^3 for increased lactate dehydrogenase activity in lung lavage fluid from rats.[323]

Oral

The ASTDR MRL for intermediate-duration oral exposure to Cr^{6+} is 5 μg/kg/day based on hematological changes (e.g., microcytic and hypochromic anemia) in rats,[324] whereas the MRL for chronic-duration oral exposure to Cr^{6+} is 0.9 μg/kg/day based on a benchmark dose of 0.9 μg Cr^{6+}/kg/day for diffuse epithelial hyperplasia of the duodenum in mice.[324]

The US EPA chronic oral reference dose (RfD) for soluble Cr^{6+} salts (e.g., potassium or sodium chromate, potassium or sodium dichromate) is 3 μg Cr^{6+}/kg/day based on a NOAEL for systemic effects in rats exposed to 2.5 mg Cr^{6+}/kg/day as potassium chromate in the drinking water for 1 year.[325] By inputting recent toxicology and mode of action data into physiologically-based pharmacokinetic and benchmark dose models, a reevaluation supported the current oral RfD of 3 μg Cr^{6+}/kg/day.[326]

Biological Monitoring

Table 9.4 lists the recommendations and standards for exposure to chromium, including the recommendations of the ACGIH for biological monitoring.

Urine

Urine chromium concentrations are the most practical method of monitoring occupational exposure to hexavalent chromium. Total chromium concentrations in urine samples from individuals without occupational exposure to chromium are usually <5 μg/g creatinine. Total chromium concentrations in the urine of workers must be interpreted cautiously because of the low sensitivity of current methods and because of the ubiquity of chromium in laboratories (i.e., cross-contamination). These methods do not routinely speciate chromium because chromium in urine is primarily Cr^{3+}; consequently, the urine chromium concentration reflects exposure to dietary and environmental Cr^{3+} as well as hexavalent chromium. End-of-shift urine chromium concentrations correlate to soluble hexavalent chromium concentrations, but not to insoluble hexavalent chromate or trivalent chromium compounds.[327] The pre-shift urine chromium concentration reflects both current and past chromium exposure as some accumulation of chromium occurs during the workweek that decreases slowly following cessation of exposure. In a study of a retired plasma cutter of stainless steel followed for 8 years, the urinary chromium half-life was 129 months.[121]

After several weeks of exposure to water-soluble hexavalent chromium, the end-of-shift, end-of-work week urinary chromium concentration should not exceed 30 μg Cr/g creatinine and the increase during a shift should not exceed 10 μg Cr/g creatinine.[328] In a study of 16 workers from an aircraft construction factory using hexavalent chromium adhesives (magnesium chromate) to finish off joints, exposure to airborne total chromium was low (0.2–1.5 μg Cr/m^3).[127] The corresponding amount of total chromium in the urine also was low (0.16–7.74 μg/g creatinine). Urine total chromium concentrations between 10–40 μg/L correlate with external exposure to 100 μg Cr^{6+}/m^3 based on studies of stainless steel welders using manual arc (MMA) and metal inert gas (MIG) methods, resulting in exposure to chromium trioxide concentrations up to 80 μg/m^3.[329] The median hexavalent chromium concentration in personal air samples of MIG welders was slightly higher (10 μg/m^3) compared with MMA welders (<4 μgm^3). The mean total chromium concentration in the urine of the 14 welders using only the MIG method was 64.5 ± 65.3 μg/L (range, 9.6–229.4 μg/L) compared with 35.1 ± 40.1 μg/L (range, 7.0–191.9 μg/L) for the 39 welders using only the MMA method. Confounding factors for increased urinary chromium include beer drinking, diabetes, occupational exposure to chromium, chromium supplementation, prostheses with chromium-containing alloys,[330,331] and exercise; however, these factors do not affect the concentration of chromium in erythrocytes.[332]

A study of welders exposed to chromium and nickel demonstrated a statistically significant increase in the rate of DNA single-strand breakage and the sister chromatid exchange frequencies when compared with unexposed controls.[333] However, there was no significant correlation between these measures and the results of the urine chromium or nickel concentrations. Almost all of the urine samples for the biological monitoring of these workers were below the current Biological Exposure Indices recommended by the American Conference of Governmental and Industrial Hygienists.

Blood

The concentrations of chromium in the erythrocyte may be a selective indicator of exposure to hexavalent chromium because Cr^{6+} is preferentially deposited in the red blood cell for its lifetime (110 days), whereas plasma chromium concentrations return to baseline

TABLE 9.4. Guidelines and regulations for metallic chromium and chromium compounds.

Exposure Level	Value
	US EPA
MCL	
Drinking water	100 µg Cr/L
RfD	
Food/water	3 µg Cr^{6+}/kg/day
	1,500 µg Cr^{3+}/kg/day (insoluble Cr^{3+})
	US FDA
Recommended dietary allowance (RDA)	35 µg Cr/day (adults 19–50 years)
Bottled drinking water	100 µg Cr/L
Food	120 µg/day (total Cr)
	WHO
Air	
4×10^{-2} lifetime risk	1 µg Cr^{6+}/m^3
Drinking water	50 µg total Cr/L
	OSHA
PEL–TWA (8-hour)[a]	5 µg Cr^{6+}/m^3 (action level: 2.5 µg/m^3)[b]
	500 µg Cr/m^3 (Cr^{2+}/Cr^{3+})
	1,000 µg Cr/m^3 (Cr^0/insoluble salts)
	NIOSH
REL–TWA (10-hour)	0.2 µg Cr^{6+}/m^3 (chromic acid/hexavalent salts)
	500 µg Cr/m^3 (Cr^0/Cr^{2+}/Cr^{3+})
IDLH	15,000 µg Cr^{6+}/m^3
	250,000 µg Cr/m^3 (Cr^0/Cr^{2+})
	25,000 µg Cr^{3+}/m^3
	ACGIH
TLV–TWA (8-hour)	
	500 µg Cr/m^3 (Cr^0/Cr^{2+}/insoluble Cr compounds)
	3 µg Cr^{3+}/m^3 [b,c]
	0.2 µg Cr^{6+}/m^3 (Cr^{6+} compounds)[c,d]
TLV–STEL	0.5 µg Cr^{6+}/m^3 (Cr^{6+} compounds) [c,d]
BEI[e]	
Urine	0.7 µg Cr/L (total urinary Cr)[f]

concentrations within days following cessation of an acute exposure to hexavalent chromium.[334] Although Cr^{3+} does not easily penetrate the erythrocyte, Cr^{6+} is reduced in the erythrocyte to Cr^{3+}. In a study of 103 stainless steel welders using both the manual metal arc and the metal inert gas methods, the median total chromium concentration in erythrocytes was 0.60 μg/L compared with 9.00 μg/L in plasma.[329] The median airborne total chromium exposure for the former was 4 μg/m^3 compared with 10 μg/m^3 for metal inert gas welders. As a result of the differential absorption of chromium species by erythrocytes, measurements of total chromium in serum (or plasma) and whole blood help distinguish between exposure to different chromium species. Following exposure to trivalent chromium, increased serum or plasma chromium concentrations relative to erythrocytes suggest trivalent chromium exposure, whereas elevated total chromium in erythrocytes compared with plasma or serum suggests hexavalent chromium exposure. In a study of 22 workers exposed primarily to airborne chromium with a range of 0.008–0.212 mg Cr^{6+}/m^3 and 0.010–0.10 mg Cr^{3+}/m^3, the total chromium concentration in blood versus nonexposed controls was as follows: serum, 2.2 μg/L vs. 1.1 μg/L; erythrocytes, 8.9 μg/L vs. 1.0 μg/L; and whole blood, 6.9 μg/L vs. 1.4 μg/L.[136] The total chromium concentration in the blood of 15 basic chromium sulfate workers exposed primarily to trivalent chromium (0.046–1.689 mg/m^3) and small amounts of hexavalent chromium (0.002–0.023 mg/m^3) were as follows: serum, 3.1 μg/L; erythrocytes, 1.4 μg/L; and whole blood, 1.8 μg/L.

Insufficient data are available presently to correlate the development of lung cancer with the ratio of plasma and erythrocyte chromium concentrations. Substantial differences in the ability of individuals to reduce chromium in plasma complicate the interpretation of chromium concentrations in erythrocytes.[2] Individuals reducing Cr^{6+} quickly have relatively high urinary chromium concentrations and relatively low blood chromium concentrations compared with slow reducers.

Medical Monitoring

Medical surveillance of workers exposed to hexavalent chromium involves a pre-placement and annual physical examination that includes the following: 1) comprehensive work and smoking history; 2) potential conditions that would be exacerbated by exposure to chromium (skin and pulmonary sensitization, skin or mucous membrane diseases, kidney disease); and 3) evidence of dermatitis, mucous membrane irritation, or chrome ulcers. OSHA (http://www.osha.gov/Publications/OSHA-3373-hexavalent-chromium.pdf) requires initial examinations for all workers as well as annual examinations for any worker exposed to Cr^{6+} air concentrations exceeding the action level. At termination, a medical evaluation is required unless the worker had an evaluation within 6 months of the end of employment. Routine laboratory tests include baseline urinalysis, chest X-rays, and kidney function tests. Although annual chest X-rays are recommended after the age of 40, a study of chromate workers did not detect a significant improvement in 5-year survival of workers in the screening program.[335] Air monitoring activity is not required by US OSHA where initial monitoring indicates that the 8-hour TWA is below the action level (2.5 μg Cr^{6+}/m^3), whereas exposures between the action level and PEL (5 μg/m^3) require monitoring every 6 months. Above the PEL, OSHA required air monitoring every 3 months.

TREATMENT

First Aid

Treatment is supportive. Dilution is the preferred first aid measure for the ingestion of hexavalent chromium compounds because of their corrosive properties. Dermal exposure to chromic acid requires careful decontamination with copious amounts of saline. Systemic toxicity may result from relatively small burns (1%) even after decontamination. Chromic acid produces severe injury to the cornea characterized by infiltration, vascularization, and opacification. Following instillation of chromic acid in the eye, the eye should immediately be irrigated copiously with saline for at least 15–20 minutes or until the pH normalizes in the conjunctival sac. Subsequently, the eye should be evaluated by slit lamp examination to determine the extent of injury.

Gut Decontamination

Patients ingesting large doses of hexavalent chromium usually vomit profusely. Syrup of ipecac is contraindicated for hexavalent compounds because of their strong oxidizing properties. If the patient presents within 1–2 hours of ingestion, the careful insertion of a soft tube is appropriate in order to aspirate and lavage the stomach. Insufficient data are available to recommend the use of lavage with magnesium hydroxide. Although ascorbic acid reduces the more soluble chromium compounds (hexavalent) to the relatively poorly soluble ones (trivalent) *in vitro*,[336] there are no data on the effectiveness of ascorbic acid to reduce the absorption

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. of hexavalent chromium when administered following lavage. Activated charcoal probably does not bind chromates well.

Antidotes

There are no currently available antidotes to remove hexavalent chromium and prevent the formation of reactive oxygen species. The efficacy of BAL, EDTA, DMPS, hemodialysis, and exchange transfusion for hexavalent chromium toxicity is unproven. *N*-acetylcysteine (NAC) is a potential antioxidant based on animal studies,[337] but human data are inadequate to evaluate the effectiveness of this regimen.

Enhancement of Elimination

Exchange transfusion and hemodialysis may reduce serum chromium concentrations,[338] but existing clinical data do not confirm the efficacy of these measures. A double-volume exchange transfusion removed only 3.77 mg Cr (i.e., 1.56 mg from plasma, 2.21 mg from erythrocytes) from a child following the ingestion of an estimated 1 g ammonium dichromate, whereas 3 hours of hemodialysis in this child removed only 0.17 mg chromium.[174] Hemodialysis is primarily a supportive modality rather than a method to enhance elimination; 5 hours of hemodialysis removed ~5 mg chromium from a 31-year-old man with an initial serum chromium concentration of 1.6 mg/L a few hours after accidental ingestion of potassium dichromate.[339] After the intentional ingestion of an estimated 22.5 g potassium dichromate by a 48-year-old man, 9 hours of hemodialysis removed only 3.3 mg chromium; this value represented ~0.16% of the estimated ingested Cr^{6+} dose.[180] Studies in dogs indicate that charcoal hemoperfusion removes only 1% of the estimated dose of hexavalent chromium following an acute dichromate poisoning.[340] Peritoneal dialysis does not effectively remove chromium from the blood. After 19 peritoneal dialysis runs, the clearance of chromium from the blood was estimated at ~24 mg/day in a 14-year-old child, who died after ingesting potassium chromate despite a reduction in the total serum chromium from 580 to 30 mg/dL.[177]

Supplemental Care

General

Renal failure generally occurs within 1–2 days of exposure; patients hospitalized for serious ingestions of chromates should be monitored for the development of renal failure. In general, the evaluation of a patient exposed to large oral doses of hexavalent chromium should include a urinalysis and CBC as well as laboratory assessment of liver and kidney function. Following exposure to high ambient air concentrations of hexavalent chromium, the evaluation should include a chest X-ray (pulmonary edema, infiltrates) and pulmonary function tests. Testing the urine for low-molecular-weight proteins (β_2 microglobulin, retinol binding protein) helps detect subtle changes in renal proximal tubule function in subjects exposed to low chromium concentrations, but the significance of any elevations of these biomarkers as predictors of chronic renal dysfunction remains unclear. Clinical availability of these tests in the United States is generally limited to specialty laboratories.

Supportive care also includes the correction of any fluid or electrolyte imbalance. Urine alkalinization may be necessary to help prevent renal injury due to massive hemolysis. Endoscopy may be necessary to evaluate the extent of esophageal and gastric burns. Liver transplantation is an option when severe hepatocellular necrosis results from the ingestion of potassium dichromate.[308]

Ascorbic Acid

There are no clinical studies to support the use of ascorbic acid after the ingestion of hexavalent chromium compounds or determine the potential complications (e.g., oxaluria) of this therapy. The intravenous administration of large doses (3 g ascorbic acid over 30–60 minutes) has been recommended for the reduction of chromate-induced renal toxicity based on uncontrolled, *in vitro* studies that suggest the reduction of hexavalent chromium to the less toxic trivalent form by ascorbic acid.[341] Subsequent animal studies indicated that large parenteral doses (0.5–5 g/kg) of ascorbic acid prevented renal toxicity *only* when administered within 1–2 hours following the administration of chromate.[342,343] In these studies, the delayed administration of ascorbic acid was associated either with no effect or with increased nephrotoxicity. A 24-month-old child recovered from the ingestion of up to 50 mL 10% sodium dichromate (serum chromium 0.21 mg/L 1 hour after ingestion) without the development of renal or hepatic toxicity.[338] Supportive care included the daily administration of ascorbic acid (1 g via nasogastric tube) as well as peritoneal dialysis and British Anti-Lewisite (BAL) therapy. A 49-year-old worker received burns to over 40% of his body from contact with hot chromic acid and 25% sulfuric acid.[344] Despite the use of 5 g ascorbic

acid per day beginning on the day of injury, the patient developed anuria on the second day and died on the sixth day.

Skin

The topical application of 1% aluminum acetate wet dressings is an anecdotal treatment for chrome ulcers along with topical ascorbic acid. An animal study demonstrated that the application of 10% ascorbic acid *within 30 minutes* of the initiation of chrome ulcers significantly reduced the healing times of these ulcers.[345] This nonblinded study did not use statistical analysis to compare treatment times with controls. There are also case reports that associate the use of a 10% ascorbic acid as a preventive cream with the resolution of chromate-induced dermatitis over a period of several months,[346,347,348] but there are no clinical studies that compare the healing rate of chromate-induced dermatitis with controls (i.e., no ascorbic acid). The early excision of burns secondary to hot chromic acid may be considered to prevent systemic poisoning because the extent of tissue deposition is difficult to assess depending on clinical judgment.[349]

Chapter 10

COBALT

HISTORY

The use of cobalt as a blue coloring agent for pottery, jewelry, and glass began in Egypt and Persia around 2,000 BC; currently, cobalt is an important constituent of blue glaze in Danish porcelain.[1,2] Leonardo Da Vinci was one of the first artists to use the bright blue pigment of cobalt in oil paints. Although blue pigments in Ming dynasty pottery and Venetian glass from the 15th century contained cobalt, copper comprised most of the blue pigment in earlier times. The Swedish chemist, George Brandt, first isolated cobalt in the 18th century; T.O. Bergman identified cobalt as an element in 1780.[3] The use of cobalt in industrial applications began in the 20th century. In the 1920s, the discovery that cobalt bound tungsten carbide into a hard substance began the use of this "hard metal" in a variety of important industrial applications (e.g., high-speed drills, cutting tools). Cobalt was a constituent of the first permanent magnetic alloy (alnico) developed during the 1930s. The use of cobalt has increased rapidly since World War II, reaching peak production in the mid-1980s. The development of rare-earth cobalt magnets that possess important power and size advantages contributed to the miniaturization of electrical and electronic equipment in the 1980s.

Cobalt is an essential element in humans necessary for the formation of vitamin B_{12} (hydroxocobalamin); this vitamin catalyzes reactions involving methionine synthesis, purine and folate metabolism, and formation of succinyl-CoA from methylmalonic acid. Excessive administration of this trace element may cause goiter and reduced thyroid activity. The medicinal use of a cobalt/iron formulation (Roncovite®) for the treatment of anemia in the 1940s was associated with blockage of iodine uptake by the thyroid gland.[4] Serious pulmonary complications from exposure to the dust from hard metals were first recognized in Germany during World War II.[5,6] In the industrial setting, cobalt is a common constituent of heat-resistant alloys and cobalt-containing hard metals. Chronic cobalt dust exposure from diamond polishing has been associated with "hard-metal pneumoconiosis" in industrial workers.[7] The acute form of this disease resembles a hypersensitivity reaction with malaise, cough, and wheezing; the chronic form can progress to pulmonary fibrosis and cor pulmonale.

In 1966, a syndrome characterized by pericardial effusion, elevated hemoglobin concentrations, and congestive heart failure occurred in heavy beer drinkers in Quebec City, Canada.[8] Similar cases were not reported in other parts of Canada where the cobalt concentration in beer was about 10 times lower. The following year, epidemics of "beer drinkers' cardiomyopathy" appeared in Omaha, Nebraska[9] and in Minneapolis, Minnesota.[10] Some Belgian breweries also added cobalt chloride to beer between 1959 and 1967, resulting in the occurrence of cardiomyopathies in heavy drinkers.[11] These cardiomyopathies occurred when local breweries added cobaltous chloride or nitrate as a method to reduce the effect of soap residues from electric dishwashers on the formation of foam. The fact that most of the cases developed in heavy drinkers ingesting cobalt doses substantially below doses previously used for refractory anemia suggests the occurrence of other factors necessary to develop cobalt-induced cardiomyopathy.[12] Suspected cofactors include inadequate protein

and vitamin (thiamine) intake, zinc depletion, and alcohol-induced heart damage.[13] Several case studies have associated exposure to cobalt dust with the development of cardiomyopathy, but the frequent lack of an etiology in cases of cardiomyopathy limits conclusions about causation.[14]

PHYSICOCHEMICAL PROPERTIES

Cobalt is a relatively rare (i.e., 33rd most abundant) metal that is a gray, ductile, brittle, magnetic element. This relatively unreactive metal does not oxidize in dry or moist air at normal environmental temperatures. The two common valence states are divalent cobaltous (Co^{2+}) and trivalent cobaltic (Co^{3+}). The trivalent forms are strong oxidizing agents. Table 10.1 lists the identifying information and physical properties of metallic cobalt and cobaltous salts. These properties are similar to the physical properties of iron and nickel; cobalt and nickel may substitute for ionic iron or zinc in various biomolecules, resulting in alteration of iron and oxygen homeostasis. Cobaltic oxide (CAS RN: 1308-04-9) is a black-gray trivalent salt that is water-insoluble. Other poorly soluble cobalt compounds include hydroxides, other oxides, sulfides, and some organic cobalt compounds (carbonate, cobaltous oxalate, propionate, stearate, naphthenate, 2-ethyl-hexanoate); inorganic chloride, nitrate, and sulfate salts of cobalt are usually water-soluble. Cobaltous acetate is also water-soluble.

Cobalt is stable in normal atmospheric oxygen, whereas heating produces mixed oxides at temperatures of <900°C and divalent cobaltous oxide above 900°C.[16] When heated, cobalt also combines with carbon, phosphorus, and sulfur, but not with hydrogen or nitrogen. Cobalt is the only element capable of increasing the saturation magnetization of iron; thus, cobalt is an important constituent of permanent magnets. Trivalent cobalt is thermodynamically unstable at typical redox conditions including the pH of the human body. The water solubility of cobalt compounds is pH dependent with the mobility of cobalt greater in acidic than alkaline conditions. Acidic conditions increase divalent cobalt concentrations, whereas alkaline conditions favor the formation of poorly soluble cobalt carbonate complexes.[17] ^{59}Co is the only stable cobalt isotope.

EXPOSURE

Commercial Processes

Mining and production

Cobalt exists in nature primarily as arsenides, oxides, and sulfides. The abundance of cobalt in the earth's crust is similar to the presence of silver; important mineral ores containing substantial amounts of cobalt include cobaltite (CoAsS) in high-temperature hydrothermal deposits and contact metamorphic rocks (Canada, Norway, Australia), erythrite [$Co_3(AsO_4)_2$] Co- and As-bearing sulfide assemblages (Canada, Morocco),

TABLE 10.1. Identifying information and physical properties of metallic cobalt and cobaltous compounds. (Based on Alessio et al.).[15]

Physical Characteristic	Cobalt	Cobaltous Acetate	Cobaltous Carbonate	Cobaltous Chloride	Cobaltous Hydroxide	Cobaltous Oxide	Cobaltous Sulfate
Molecular formula	Co	$Co(C_2H_4O_2)_2$	$CoCO_3$	$CoCl_2$	$Co(OH)_2$	CoO	$CoSO_4$
Synonym	Metallic cobalt	Cobalt diacetate		Cobalt dichloride	Cobalt dihydroxide	Cobalt monoxide	Cobalt sulfate

and smaltite ($CoAs_2$) in Canada and Morocco.[18] The new Idaho Cobalt Project is scheduled to produce >1,500 tons of high-purity cobalt metal annually near Salmon, Idaho. Cobalt is commonly found with copper, iron, lead, nickel, and silver ores in concentrations of <1%; most current cobalt production is a by-product of copper or nickel production.[19] The first stage in the recovery of cobalt from ores is the physical separation of cobalt from other metals either by froth flotation (sulfide ores) or by gravity (arsenide ores). Roasting or acid leaching is necessary to concentrate cobalt in the ores. Refined cobalt is available primarily as broken or cut cathodes.

Hard Metals

Hard metal results from the sintering (compacting) of powdered tungsten carbide with cobalt and some other agents to form a diamond-like, polycrystalline material (sintered carbides). These cemented carbides possess important physical properties, including heat resistance, hardness, and extreme strength, making them suitable for cutting tools and wear-resistant machine parts. This powdered metallurgic process forms hard metal using cobalt as a binder. The cemented carbides primarily contain tungsten carbide (80–95%) and cobalt (5–20%). Occasionally, small amounts (<5%) of nickel and other metals are added to the cobalt. The tungsten powder frequently consists of smaller amounts of titanium, tantalum, and vanadium oxides. The heating of fine particles of tungsten with carbon produces tungsten carbide. The resulting compound is mixed with powered cobalt and small amounts of other metals (chromium, nickel, niobium, molybdenum, titanium, tantalum) based on the desired properties of the final product. The powder is poured into steel or rubber frames, pressed into appropriate shapes, and attached to the backing material. Pre-sintering of this material produces a chalk-like material that is shaped into the final configuration. The final mixture is heated to 1,550°C; the hardness of the resulting material is similar to the hardness of diamonds. The aerosol created from the cutting and polishing of hard metal bathed in coolants and lubricants contains respirable particles of dissolved or ionized cobalt. Analysis of air in a hard metal tool production plant revealed that the highest exposure (range, up to 0.032 mg Co/m^3) occurred in the powder preparation, rubber press, and shaping areas.[20]

Uses

Categories of cobalt alloys include the following: high-temperature, corrosion-resistant superalloys (aluminum, chromium, nickel, tantalum, titanium, tungsten, zirconium) for gas turbines in aircraft engines, magnetic alloys (aluminum, copper, nickel, titanium), high-strength steels, electro-deposited alloys, and alloys with special properties. Technically, hard metals are not cobalt alloys because the cobalt acts as a binding agent for the metal carbides. Superalloys combine high-temperature mechanical properties with a resistance to creep and oxidize at these high temperatures. The base of these superalloys may be cobalt, nickel, or iron, and applications of these alloys include the production of jet engines and magnetic materials. In 1987, the approximate end-use of cobalt in the United States was as follows: superalloys, 41%; drier in paint, 13%; magnetic alloy, 11%; cutting and wear-resistant alloys, 8%; catalyst, 7%; ground coat or frit for porcelain enameling of steel fixtures and kitchen appliances, 5%; and pigment manufacture, 4%.[21] Increasing cobalt uses include high-capacity rechargeable batteries, recycling electronic waste, magnets, and clean energy applications (clean coal, gas-to-liquid and oil desulfurization, solar panels, wind and gas turbines, fuel cells).

Most of the production of cobalt involves the metallic form. For example, heat-resisting steels contain 25–65% cobalt and Vitallium® alloys in prostheses that comprise ~65% cobalt along with chromium, nickel, and molybdenum. The powder metallurgy sector uses cobalt as a binding agent for tungsten carbide. Typically, the hard metals in grinders and cutting tools contain 6–9% cobalt with an upper limit of ~30% cobalt. Electro-deposited cobalt alloys (iron, nickel, platinum, phosphorus) have magnetic properties that are important in computer applications and the recording industry.

Cobalt is a major constituent of cobalt (>34%)-chromium (>19%) metal alloy used in the manufacture of surgical devices, particularly joint replacements.[22] Particles (i.e., typically <50 nm) of bulk metal alloy and corrosion products may appear in cells and synovial fluids surrounding the joint replacements.[23] By the end of the first decade of the 21st century, an estimated 400,000 hip arthroplasties were performed annually in the United States with metal-on-metal (MoM) implants accounting for ~35% of the prostheses; however, that percentage has subsequently declined rapidly worldwide.[24] Other metals (nickel, molybdenum, tungsten) may be added to this alloy to improve its physical characteristics. Stainless steel implants contain little cobalt.

With the exception of mixed divalent and trivalent oxides, the most important cobalt-containing chemicals in the industry are divalent cobaltous salts. Some diamond polishers work with polishing disks composed of a half-hard steel frame (98% iron) and a polishing surface consisting of 10–20% microdiamonds cemented into

ultrafine cobalt metal powder. Less common uses of cobalt include catalysts (cobalt molybdate oxide, cobalt sulfides, cobalt carbonyl) in the chemical and oil refining industry, drying agents in paints (cobalt naphthenate), electroplating, radiology (^{60}Co), and an additive in fertilizers and animal feed. The latter use involves the addition of small amounts of cobalt to prevent cobalt deficiency in sheep and cattle. Fluomine is a cobaltous chelate (bis(3-fluorosalicylaldehyde) ethylenediimine cobalt] used as part of the oxygen recovery system in high-altitude aircraft.[25] Table 10.2 lists the industrial applications of a variety of cobalt compounds. Cobalt nanoparticles are relatively common in the electronics, medical (e.g., diagnostic testing, therapy), and textile industries.

Sources

For the general population, diet is the main source of cobalt exposure. The cobalt concentration in drinking water is low (<5 μg/L). In the occupational setting, cobalt exposure occurs primarily during the production of cobalt powders. In other industries (e.g., hard metal industry), cobalt exposure involves other compounds that modulate the effect of cobalt; tungsten carbide exposure increases the retention of cobalt in the lungs.[26]

Air

Sources of cobalt in the air are both natural (erosion, volcanic eruptions, forest fires, seawater spray) and anthropogenic (fossil fuel burning, engine emissions, sewage sludge, phosphate fertilizers, processing of cobalt-containing alloys).[21] The cobalt concentration in ambient air depends on the dispersion of particles into the soil by the wind.[16] Typically, the mean cobalt concentration in air is small (~1–2 ng/m^3) in urban areas and somewhat lower in remote areas.[21,27] Cobalt concentrations in ambient air may exceed 10 ng/m^3 near point sources with cobalt concentrations ranging up to 600 ng/m^3 near industrial sources in heavily industrialized areas.[21,28]

Soil

Cobalt is a relatively rare trace element with an average concentration in the earth's crust of 25 mg/kg. Basic and ultrabasic rocks contain cobalt concentrations of ~100 ppm, whereas mantle-type rocks (basalt) contain 40–50 ppm and acidic rocks (granite) contain 1–10 ppm.[3] Soils that contain <0.5–3 mg Co/kg have insufficient cobalt to meet the nutritional needs of grazing animals; therefore, these soils are considered cobalt-deficient. Examples of soils frequently deficient in cobalt include those composed of sand, sandstone, limestone, some types of acidic rocks (e.g., granite), and shale. Cobalt is a frequent addition to fertilizers (commercial, compost, manure, sewage sludge) used on agricultural soils; however, the soil is not a significant route of exposure for the general population. Co concentrations in the soil range from 1–40 mg/kg with an average in the United States of 7.2 mg/kg.[21,29] Cobalt-containing minerals typically exist in relatively small quantities in commercial ores (e.g., arsenides, oxides, sulfides). An important source of cobalt in the United States is smaltite ($CoAs_2$, 25% cobalt).

Water

Cobalt is detected rarely in drinking water with cobalt concentrations ranging from 0.1–5 μg/L when detectable; median Co concentrations in US drinking water are <2 μg/L.[30] Trace amounts of cobalt occur in rivers, lakes, and groundwater.[3] Coastal seawater generally contains more cobalt compared with open ocean waters as a result of the transport of cobalt dissolved with natural organic substances in river waters. Average concentrations in open ocean waters are ~0.3 μg/L. Mining activities and industrial use do not significantly affect the natural transport of cobalt in water because most of the cobalt resides in the sediment.

Diet

The diet accounts for a majority of the cobalt intake with relatively small contributions from drinking water and air. The average daily cobalt intake from the diet is highly variable, ranging from 5–45 μg/day; fish and vegetables contain relatively high Co concentrations.[31] The estimated average daily cobalt intake in samples from the Canadian population was 11 μg (range 4–15 μg).[32] In an evaluation of Canadian foods, the Co concentration was low in most foods with the highest concentration in waffles (76 ng/g), corn cereal (74 ng/g), and potato chips (70 ng/g). The estimated average daily cobalt intake in a standard French diet was 29 μg [33] compared with ~40 μg in an Australian study.[34] In the latter study, the mean cobalt intake in lacto-ovo vegetarians and vegans consuming normal amounts of potatoes was ~20 μg. The cobalt uptake by plants is species-dependent. Green leafy vegetables (broccoli, spinach), seafood, and fresh cereals are the richest sources of cobalt (0.2–0.6 μg Co/g dry weight), but meat is also an important source of cobalt for the general population, depending on the dietary preferences.[16,35] Animal livers also contain high

TABLE 10.2. Commercial uses of cobalt compounds. (IARC).[16]

Cobalt Compound	Formula	Uses
Acetate(III)	$Co(C_2H_2O_2)_3$	Catalyst
Acetate(II)	$Co(C_2H_2O_2)_2{\cdot}4H_2O$	Driers for lacquers and varnishes, invisible inks, catalysts, pigment for oil-cloth, mineral supplement, anodizer, stabilizer for malt beverages
Acetylacetonate	$Co(C_5H_7O_2)_3$	Vapor plating of cobalt
Aluminate	$CoAl_2O_4$	Pigment, catalysts, grain refining
Ammonium sulfate	$CoSO_4(NH_4)_2SO_4{\cdot}6H_2O$	Catalysts, plating solutions
Arsenate	$Co_3\ (AsO_4)_2{\cdot}8H_2O$	Pigment for paint, glass and porcelain
Bromide	$CoBr_2$	Catalyst, hydrometers
Carbonate	$CoCO_3$	Pigment, ceramics, feed supplements, catalyst
Carbonate (basic)	$2CoCO_3{\cdot}Co(OH)_2{\cdot}H_2O$	Chemicals
Carbonyl	$Co_2(CO)_8$	Catalyst
Chloride	$CoCl_2{\cdot}6H_2O$	Chemicals, sympathetic inks, hydrometers, plating baths, metal refining, pigment, catalyst
Chromate	$CoCrO_4$	Pigment
Citrate	$Co_3(C_6H_5O_7)_2{\cdot}2H_2O$	Therapeutic agents, vitamin preparations
Dicobalt manganese tetroxide	$MnCO_2O_4$	Catalyst
Dicobalt nickel tetroxide	$NiCO_2O_4$	Catalyst, anode
Dilanthanum tetroxide	La_2CoO_4	Catalyst, anode
2-Ethylhexanoate	$Co(C_8H_{15}O_2)_2$	Paint and varnish drier
Ferrate	$CoFe_2O_4$	Catalyst, pigment
Fluoride(II)	CoF_2	Fluorinating agent
Fluoride(III)	CoF_3	Fluorinating agent
Fluoride	$CoF_2{\cdot}4H_2O$	Catalyst
Fluorosilicate	$CoSiF_6{\cdot}6H_2O$	Ceramics
Formate	$Co(CHO_2)_2$-$2H_2O$	Catalyst
Hydroxide	$Co(OH)_2$	Paints, chemicals, catalysts, printing inks
Iodide	CoI_2	Moisture indicator
Lanthanum trioxide	$LaCoO_3$	Electrode
Linoleate	$Co(C_{18}H_{31}O_2)_2$	Paint and varnish drier
Lithium oxide	$LiCoO_2$	Battery electrode
Manganate	$CoMn_2O_4$	Catalyst; electro-catalyst
Naphthenate	$Co(C_{11}H_{10}O_2)_2$	Catalyst, paint and varnish drier
Nitrate	$Co(NO_3)_2{\cdot}6H_2O$	Pigments, chemicals, ceramics, feed supplements, catalyst
Oleate	$Co(C_{18}H_{33}O_2)_2$	Paint and varnish drier
Oxalate	CoC_2O_4	Catalysts, cobalt powders
Oxide(II)	CoO	Chemicals, catalysts, pigments
Oxide(II, III)	Co_3O_4	Enamels, semiconductors
Oxides	Mixed metal	Pigments
Phosphate	$Co_3(PO_4)_2{\cdot}8H_2O$	Glazes, enamels, pigments, steel pretreatment
Potassium nitrite	$K_3Co(NO_2)_6{\cdot}1.5H_2O$	Pigment
Resinate	$Co(C_{44}H_{62}O_4)_2$	Paint and varnish drier, catalyst
Sodium oxide	$NaCoO_2$	Battery electrode
Stearate	$Co(C_{18}H_{35}O_2)_2$	Paint and varnish drier, tire cord adhesives
Succinate	$Co(C_4H_4O_4){\cdot}4H_2O$	Therapeutic agents, vitamin preparations
Sulfamate	$Co(NH_2SO_3){\cdot}3H_2O$	Plating baths
Sulfate	$CoSO_4{\cdot}xH_2O$	Chemicals, ceramics, pigments
Sulfide	CoS	Catalysts
Tricobalt tetralanthanum decaoxide	$La_4Co_3O_{10}$	Catalyst
Tungstate	$CoWO_4$	Drier for paints and varnishes

concentrations of cobalt. Dairy products, refined cereals, and sugar contain the least cobalt (0.1–0.3 μg Co/g dry weight).

Lifestyle

Tobacco contains <0.3–2.3 mg Co/kg dry weight;[36] ~0.5% of the cobalt in cigarettes appears in the mainstream smoke.[37] The exact bioavailability of cobalt in tobacco is unknown. The contribution of beer to the current total cobalt intake is relatively small, even for heavy beer drinkers. In a Spanish study, the cobalt concentration in beer ranged from 0.16–0.56 μg/L (median, 0.39 μg/L).[38]

ENVIRONMENTAL FATE

Air

Cobalt compounds are nonvolatile; therefore, cobalt enters the ambient air in particulate form with a typical mass median diameter of 2.6 μm (range, <2–12 μm).[39] Cobalt from anthropogenic sources probably exists primarily as oxides with the exception of mining and ore processing facilities (arsenides, sulfides).[40] The fate of cobalt in the atmosphere depends on the size and density of the particles as well as the type of speciation. From sources of combustion, cobalt exists primarily as an oxide, whereas cobalt arsenide and cobalt sulfide complexes occur near extraction processes.

Water

Wet and dry deposition deposits cobalt on surface waters and soil. Sediment is the primary repository for cobalt in contaminated water. Precipitation and adsorption to suspended particles account for >98% of the cobalt present in freshwaters, whereas the remainder exists in the dissolved state. Acidic pH (hydrogen ions compete with metal binding sites), excess chloride anions, and chelating agents enhance the mobility of cobalt from sediment to water. Most of the cobalt released into water reaches the coastal zones of the oceans through transport as suspended matter in rivers. In the deep sea, cobalt precipitates iron and manganese oxides and crystalline sediments (e.g., aluminosilicate, goethite); similar to manganese and aluminum profiles, removal of cobalt involves the interaction of cobalt with MnO and the formation of nodules.[21] Cobalt also precipitates as carbonate or hydroxide in water. Cobalt strongly binds to humic substances naturally present in aquatic environments depending on pH, the metal-to-humic substance ratio, and the nature of the humic material. Cobalt mobility decreases as pH increases (i.e., pH >7), as a result of the formation of insoluble hydroxides or carbonates.

Soil

In most soils, cobalt exhibits lower mobility than cadmium, but higher than that of lead, tin, copper, nickel, and zinc.[41] At higher soil pH, the formation of hydroxide and carbonate complexes with cobalt limits cobalt mobility in soil. The translocation of cobalt from roots to the parts of the plant above ground is limited in most soils by limited Co mobility depending on pH, the concentration of organic matter (e.g., humus), and Fe/MnO_2 concentrations. Consequently, most terrestrial plant species do not accumulate cobalt with the exception of a few hyper-accumulators (Asteraceae, Cyperaceae, Lamiaceae, Scrophulariaceae families; *Alyssum corsicum*, *Berkheya coddii*); plants (e.g., barley, oats, wheat) grown in high-cobalt-containing soils do not translocate much cobalt from the soil.[18] In Saskatchewan where surface soil cobalt concentrations ranged from 3.7–16.4 mg/kg, 10 samples of durum wheat grain contained cobalt concentrations ranging from 0.01–0.02 mg/kg.[42] Significantly higher cobalt concentrations may occur in ryegrass foliage, oats, or barley grown in highly acidic soil (pH 3.3–5).[43] The relatively low cobalt concentrations in fish reflect the strong binding of cobalt to particles and sediment. Little biomagnification of cobalt occurs in animals, whereas the bioaccumulation factor for freshwater fish and marine fish ranges from 40–1,000 and 100–4,000, respectively.[21]

DOSE EFFECT

Acute Toxicity

A 19-month-old male died ~6 hours after the estimated ingestion of ~30 mL of a cobalt chloride solution.[44] The mother induced vomiting several times and then brought the child to the emergency, where he developed altered mental status and cyanosis after gastric lavage. The autopsy did not report any abnormalities in the respiratory tract. A 14-year-old girl presented to the emergency department ~12 hours after the ingestion of an estimated elemental cobalt dose of 96 mg from a chemistry set.[45] Although she vomited spontaneously several times before admission, she remained asymptomatic in the emergency department with stable vital signs and no evidence of hepatorenal dysfunction. She recovered without sequelae after receiving supportive care and three doses of $CaNa_2EDTA$. A 6-year-old boy

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. drank a solution containing an estimated 2.5 g cobalt chloride; he developed abdominal pain and vomiting prior to admission; he remained stable in the emergency department with a normal physical examination.[46] He was released 48 hours after admission without sequelae.

Chronic Toxicity

The most common adverse effect associated with cobalt chloride use in patients with anemia during the 1950s was gastrointestinal irritation. Nausea and vomiting were occasional with daily cobalt chloride doses of 100 mg and common with doses of 300–500 mg.[47,48] Hematological and thyroid changes are sensitive endpoints of cobalt toxicity.

Hematological

Roncovite® was a cobalt-iron medication previously used to treat refractory anemia. The erythrocyte count increased by 16–20% in six healthy volunteers receiving 1 mg Co/kg; within 9–15 days after cessation of therapy, the erythrocyte count returned to baseline.[49] In a study of 23 infants aged 1–24 months receiving an aqueous solution of 40 mg $CoCl_2$ (9.9 mg elemental cobalt) and 75 mg ferrous sulfate for iron deficiency anemia, mild nausea, vomiting, and anorexia developed in three subjects.[50] A significant increase in eosinophils (i.e., >6%) occurred in 16 of 23 subjects. The daily administration of this preparation at doses of 50–100 mg cobalt chloride (18.5–37 mg Co/day) was tolerated for long periods of time without significant toxicity. Cobalt chloride without iron supplementation does not prevent the decrease in the hematocrit and hemoglobin concentration typically associated with pregnancy. The ingestion of 75–100 mg cobalt chloride (~0.53 mg Co/kg) daily by 20 pregnant women was associated with a slight decrease in the hemoglobin concentration; no other effects were reported.[51]

Thyroid

In a study of four patients receiving 150 mg cobalt chloride (37.5 mg elemental cobalt) daily for over 10 days, 2 of the subjects had depressed 24-hour thyroid^{131} I uptake.[52] The most common complaint was nausea and vomiting. There were no reported blood cobalt concentrations. The oral administration of 3–4 mg cobalt chloride/kg body weight to children with sickle cell resulted in goitrogenic effects that resolved after cessation of therapy.[53]

Cardiovascular

The estimated daily intake of beer drinkers developing cardiomyopathy was 6–8 mg Co as the chloride or sulfate salt;[54] this dose is relatively small and substantially less than patients treated with cobalt salts for refractory anemia. A 5-year follow-up cohort study of 24 Belgian patients with beer drinkers' cardiomyopathy indicated that the progression of this disease required reduced protein intake and a poor diet, suggesting that factors other than cobalt are necessary for the expression of the disease.[55] The mean daily beer consumption at the time of initial evaluation was ~18 beers. The cobalt salt added to this beer was cobalt chloride in typical doses of 0.5–1.5 ppm with a range up to 5.5 ppm; however, the development of the cardiomyopathy was not dose-related as some brands were not associated with cardiomyopathies despite high cobalt concentrations.

Pulmonary

The risk of pulmonary fibrosis in hard metal workers increases when the cobalt concentration in the air exceeds 100 μg/m^3.[56]

Neurological

Several case reports associate neurological symptoms (hearing loss, visual deficits, tinnitus) with cobalt exposure; however, a causal relationship between these symptoms and specific cobalt concentrations is not well established. Evidence of peripheral neuropathy including eighth-nerve dysfunction as measured by the Weber and Rinne tests was not demonstrated in four anephric patients on hemodialysis receiving 50 mg $CoCl_2$ daily for 12 weeks.[57] Slight high-tone deafness developed in one patient after an additional 40 weeks of therapy. The mean serum cobalt concentration in six anephric patients ranged from 340–1,490 μg/L during therapy, with concentrations declining within several months of cessation of treatment as measured by atomic absorption spectrometry. Transient hearing loss as measured by elevated thresholds on audiometry developed in 3 of 14 dialysis patients receiving consecutive 4-week courses of 25 mg and 50 mg $CoCl_2$.[58] The audiograms returned to baseline values within 1 month in two patients (the third was lost to follow-up). The serum cobalt concentrations at the end of the study ranged from 220–600 μg/L with 1 outlier at 2,100 μg/L. Animal studies suggest the possibility of cochlear damage following the infusion of high Co concentrations. In a study of rabbits receiving daily intravenous infusions of cobalt chloride (1,354 μg over 42 days and 2,708 μg

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

over 53 days), histological examination revealed signs of degeneration of the organ of Corti with loss of sensory hair cells (outer hair cells > inner hair cells), reduction in the size of the spiral ganglia, and alterations of the ganglion cells (i.e., shrinking eosinophilic cytoplasm).[59] No pathological abnormalities were detected in vestibular structures.

TOXICOKINETICS

Absorption

Ingestion

The mechanism of the gastrointestinal absorption of cobalt is similar to that of iron with iron deficiency causing an increase in gastrointestinal cobalt absorption ranging from 18–44% in controls compared with 31–71% in iron-deficient subjects.[60] Other factors affecting cobalt bioavailability following ingestion include water solubility of the cobalt compound (soluble ≫ insoluble), the amount of co-ingested material, interindividual variation, and possibly sex (i.e., up to ~2-fold higher in women compared with men depending on iron status).[61] Studies of volunteers ingesting $^{60}CoCl_2$ suggested that the absorption of cobalt from the gastrointestinal tract depends on the dose and timing of the last meal. Absorption ranged from 1–5% ($n = 5$) for a dose of <1 μg ^{60}Co ingested between normal meals compared with 20–28% ($n = 3$) for 1,200 μg ^{60}Co administered between normal meals.[62] In a 70-day study of a worker accidentally swallowing $^{60}CoCl_2$, the estimated uptake of ^{60}Co from the gastrointestinal tract was ~4–5%.[63]

Volunteer studies indicate that low iron stores increase the absorption based on increased cobalt concentrations in subjects with low serum ferritin concentrations. In a study of 448 pregnant Norwegian women, the mean whole blood cobalt concentration in 257 women with low iron stores (serum ferritin <12 μg/L) was 0.61 ± 0.16 μg/L compared with 0.42 ± 0.10 μg/L ($P < 0.001$) in 191 women with adequate iron stores.[64] The average whole blood cobalt concentration in women on oral contraceptives was ~20% lower than nonusers; multiple regression models did not detect any correlation between iron stores and the use of oral contraceptives. The absorption of cobalt in the small intestine probably involves the same transport mechanism (divalent metal transporter 1) as iron; however, the exact role of the common transporter in cobalt absorption is not well defined.[65]

Inhalation

Variables affecting pulmonary absorption of cobalt compounds include water solubility, particle size, and breathing pattern. Inhaled cobalt particles deposit in upper and lower airways depending on particle diameter; mucociliary action removes particles of >2 μm impacting in the upper airways with subsequent ingestion or expectoration. Smaller particles enter the lower airways. In a study of cobalt oxide particles, the fractional deposition of particles with a geometric mean of 0.8 μm was ~50% compared with ~75% for particles with a mean geometric diameter of 1.7 μm.[66] At least ½ of these particles remain in the lung for 6 months.[67] Although limited data are available in humans, animal studies suggest that substantial uptake of cobalt occurs through the lungs. A study in hamsters demonstrated that the lungs absorb ~30% of an inhaled aerosolized dose of the poorly soluble cobalt oxide.[68] Generally, the amount of cobalt in the lungs is low in patients with hard metal pneumoconiosis.[69]

Dermal

Experimental studies suggest that some absorption of cobalt may occur following emersion of the hand in cobalt solution for 1 hour based on elevated urinary Co excretion compared with baseline (24 hours prior to exposure).[70] The mean permeation flux of cobalt in a Franz diffusion cell was 0.0123 ± 0.0054 μg/cm^2/hour with a lag time of 1.55 ± 0.71 hours (permeation coefficient, 0.00037 cm/hour).[71] *In vitro* studies using donor skin and simulated sweat suggest some systemic absorption of cobalt may occur following application to abraded skin by up to 400-fold.[72] *In vitro* studies with diffusion cell systems (Franz cells) suggest Co nanoparticles can penetrate the human skin.[73]

Distribution

Absorbed inorganic cobalt is distributed to the kidney, liver, heart, and spleen with lower concentrations occurring in bone, brain, hair, and the lymphatic system.[62] Divalent cobalt salts bind to albumin in the blood with a relatively small free fraction (<8–12%) based on the intravenous administration of ^{55}Co in two healthy volunteers [74] and $^{60}CoCl_2$ in rabbits.[75] Multiple observations in a 57-year-old woman with very high blood cobalt concentrations from corroded hip prostheses suggested reduced cobalt binding to albumin (whole blood 549 μg/L; plasma 260 μg/L) and increased free cobalt ions;[76] the whole blood/plasma ratio returned to ~1 after replacement of the corroded hip implant. The clinical

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

significance of changes to cobalt-albumin binding and other factors (oxidative stress, genetic polymorphism) to individual hypersensitivity to cobalt toxicity remains unclear. An observational study of 37 patients with MoM hip prostheses attending the Rizzoli Orthopedic Institute's Orthopedic Traumatology and Prosthetic Surgery and Revisions of Hip and Knee Implants clinic found no correlation between whole blood, serum, or urine Co concentrations and serum total albumin or ischemia-modified albumin.[77] Although the serum total albumin concentrations were within the reference range, most patients had serum ischemia-modified albumin concentrations above the upper limits of the reference range. Genetic screening for *known* proalbumin and albumin variants was negative for all patients; none of the patients complained of symptoms consistent with cobalt toxicity.

No specific organ accumulates cobalt with the exception of distribution of insoluble cobalt salts (e.g., cobalt oxides) to the lower airways after inhalation of insoluble cobalt particles (e.g., 45% for 0.8 μm particles and 56% for 1.7 μm particles after 180 days).[67] The highest concentrations of cobalt in normal subjects occur in the liver (median, 30 μg Co/kg with a range 6–151 μg Co/kg) and lesser amounts in the kidney, adipose tissue, and heart.[16] Following the intravenous administration of cobalt, the liver accumulates about 20% of the administered dose of radioactive cobalt chloride.[62] Divalent cobalt salts (Co^{2+}) cross the red cell membrane slowly via Ca-dependent pathways; this uptake is practically irreversible as the Ca-pump does not extrude cobalt from the cell as a result of cobalt binding to the globin moiety of hemoglobin.[78] In the cytosol, Co^{2+} also binds to the globulin moiety of hemoglobin with little free cobalt (1%) remaining in the cytosol. The binding is initially reversible; however, the cobalt is more tightly bound with time. Unlike lead and cadmium, significant accumulation of cobalt does not occur in the body with age; the body lacks long-term storage sites for cobalt.[19] Most cobalt in the body resides in the vitamin B_{12} organometallic complex.

Elimination

Cobalt excretion occurs rapidly with the majority of the administered dose eliminated within a few days after exposure ceases. Cobalt elimination is triphasic with the vast majority of the absorbed cobalt dose excreted renally; biliary excretion is small (i.e., <10%) based on volunteer studies receiving radiolabeled Co.[62] Iron deficiency anemia increases the renal excretion of cobalt. In a study of 17 volunteers with normal iron stores, the mean renal excretion of radiolabeled $CoCl_2$ in urine samples collected during the first 24 hours after ingestion was 18% of the administered dose (range, 9–23%).[79] The mean urinary excretion of cobalt in 10 subjects with iron deficiency anemia was 31% of the administered dose (range, 23–42%).

In a whole-body retention study of eight volunteers receiving intravenous chloride salts of ^{57}Co and ^{58}Co, the short-term biological half-time was 0.71 ± 0.03 day compared with 32 ± 8.5 days for the intermediate component and 80–720 days for the long-term component (n = 2).[80] Following accidental inhalation of insoluble radioactive cobalt (^{60}Co), most of the absorbed dose (i.e., 80–90%) has a biological half-life of several days, but a small portion of this dose has a half-life of years.[81] In a study of 12 hard metal workers exposed to cobalt during stone cutting diamond wheel production, the urinary excretion of cobalt was multiphasic with a rapid first phase ($t_{1/2}$ = ~44 hours), a second phase of slower elimination ($t_{1/2}$ = 10 days), and a prolonged terminal phase (years).[82] The first phase of urinary elimination was faster (i.e., ~20 hours) in four control subjects with occupational exposure to cobalt. In an 11-year follow-up study of five workers following the accidental inhalation of the insoluble metal and oxide forms of ^{60}Co, the estimated clearance half-time for systemic cobalt was ~7 years.[83] Little accumulation of cobalt occurs in other organs.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Prior to the development of recombinant human erythropoietin and related analogs, cobalt salts were stimulants for the production of erythropoietin in patients with anemias of chronic disease (e.g., renal failure, malignancy). Cobalt induces hypoxia-like responses mediated by hypoxia-inducible factor-1α (HIF-α) and the upregulation of associated proteins including atrial natriuretic peptide. The primary physiological stimulus for erythropoietin production is hypoxia; the administration of cobalt salts (Co^{2+}) mimics the effect of hypoxia on erythropoietin-producing cells in the kidney and liver by stabilizing hypoxia inducible factor-1α (HIF-α) and preventing the docking of von Hippel–Lindau tumor suppressor protein. *In vitro* studies suggest that cobalt salts induce erythropoietin transcription by inhibiting the degradation of the transcriptional activator hypoxia-inducible factors, a family of proteins that regulate the cellular response to oxygen deficit.[84,85]

Mechanism of Toxicity

Classic cobalt toxicity primarily involves increased hemoglobin production (polycythemia), metabolic acidosis (disruption of Krebs cycle, inhibition of pyruvate conversion to acetyl CoA), hypothyroidism (TSH stimulation from blockade of iodine uptake), and cardiomyopathy (impaired myocardial contractility).

Hard metal disease

Hard metal lung disease is a pathological process of the pulmonary parenchyma that ranges from intense alveolitis to end-stage pulmonary fibrosis. This disease is called hard metal lung disease because it rarely, if ever, occurs following exposure to cobalt or tungsten carbide alone.[87] Hard metal contains tungsten and cobalt with small amounts of titanium, tantalum, and vanadium oxides. Because tungsten is relatively inert and the inhalation of cobalt in animal studies produces pulmonary lesions, some authors believe the respiratory effects of exposure to dust from hard metal result from cobalt.[87,88] However, the lesions in animals are not identical to the pathological changes in humans with hard metal lung disease; additionally, the dose of cobalt required to produce the lesions in animal studies is much higher compared with occupational exposure to cobalt. Epidemiological data indicate that interstitial lung disease occurs only among hard metal and diamond workers where exposure involves both cobalt dust and other components (e.g., diamond, iron, silica, titanium, tungsten).[89] A cross-sectional study of workers exposed only to cobalt suggests that exposure to other dust (e.g., tungsten, titanium, iron, silica, diamond) in the hard metal process is necessary to produce the clinical picture of pulmonary fibrosis.[90]

The low incidence of fibrosing alveolitis in cobalt-exposed workers along with similarities to extrinsic allergic alveolitis (positive lymphocyte transformation test, reduced helper/suppressor T cell ratios)[91] suggest that hypersensitivity is the etiology of these effects rather than direct toxicity.[88] A study of Italian workers with hard metal lung disease suggested a genetic predisposition (residue Glu-69 of the HLA-DP β-chain) to the development of hard metal disease.[92] However, specific precipitins have not been demonstrated in exposed workers or patients with hard metal diseases.

The exact cause of these effects remains to be determined as alternate mechanisms include the formation of reactive oxygen species from electrons migrating from cobalt to the tungsten carbide surface.[93] Several histological features of fibrosing alveolitis argue against delayed-hypersensitivity as an etiology. For example, epithelioid cell granulomas and lymphocytic infiltration typically are absent in cobalt-induced fibrosing alveolitis, whereas unusual multinucleated giant cells commonly are present. An alternative hypothesis is the non-immunological activation of macrophages and macrophage-derived mediators (interleukin-1, leukotrienes, prostaglandins) by cobalt that generates toxic oxygen radicals.

Hard metal asthma

Cobalt is a known allergen that produces contact dermatitis [94] as well as asthma in workers exposed to cobalt alone (e.g., cobalt powder, cobalt salts)[95] or cobalt in association with other metals (e.g., hard metal dust) or irritant gases.[96] The etiology of this disease probably is a Type I allergic reaction based on the demonstration of specific IgE antibodies against a complex of cobalt and albumin in workers with hard metal asthma.[97] Cobalt is considered the primary causal agent, although specific IgE antibodies to nickel may be present and may contribute to the etiology of hard metal asthma in some individuals.[98] Both environmental factors and individual susceptibility contribute to the development of hard metal asthma. An epidemiological study of hard metal workers demonstrated that age and atopy were risk factors for hard metal asthma.[99] Multilogistic analysis of the data indicated that the development of hard metal asthma was not dose-related because exposure to cobalt concentrations of $<50\ \mu g/m^3$ was a significant risk factor, but exposure to higher cobalt concentrations was not.

Contact Dermatitis

Cobalt, chromium, and nickel are important skin sensitizers; simultaneous reactivity to these metals occurs frequently. Animal studies indicate that simultaneous reactivity to cobalt and nickel results from multiple sensitizations rather than cross-reactivity.[100,101] *In vivo* studies indicate that cobalt, chromium, and nickel leach from hard metal alloys after sustained contact with sweat; the release of cobalt is sufficient to cause allergic contact dermatitis in cobalt-sensitized patients.[102] The release of cobalt ions and patch test reactivity do not directly correlate to the Co concentration in the alloy. *In vitro* tests suggest that cobalt is released in sufficient quantities from some inexpensive earrings to cause contact dermatitis.[103]

Beer drinkers' cardiomyopathy

This syndrome developed in a small fraction of the beer-drinking population exposed to cobalt during the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

1960s.[55] The etiology of beer drinkers' cardiomyopathy is probably multifactorial because of the inability to replicate the cardiomyopathy in animal models and the absence of similar cardiovascular effects at similar cobalt sulfate doses in other Co exposures. Potential cofactors in this cardiomyopathy include alcoholism, hypothyroidism, thiamine deficiency, genetic susceptibility, and/or a low-protein diet. The cobalt concentration in the beer averaged 1.1–1.2 ppm.[104] Beer drinkers' cardiomyopathy shares many clinical features of hypothyroidism including fatigue, anorexia, pericardial effusions, dilated cardiomyopathy, and elevated hepatic enzymes.[105] The estimated cobalt dose (0.04–0.14 mg/kg/day) in these patients was substantially below Co doses typically associated with adverse effects; the estimated cobalt dose (0.6–1 mg/kg/day) in pregnant women and renal failure patients treated with cobalt chloride for 90 days did not produce evidence of cardiac abnormalities.[10,51] Despite the development of cobalt-induced hypothyroidism and goiter for >40 years from cobalt chloride doses at substantially higher concentrations than the estimated dose in beer drinkers' cardiomyopathy, very little published medical evidence supports a causal relationship with cobalt and cardiomyopathies in these patients.[106]

The mechanism of cardiotoxicity in these beer drinkers is unclear. A suggested mechanism of action is cobalt-induced depression of oxygen uptake in the myocardial mitochondria.[107] This action may result from inhibition of the sulfhydryl groups of α-lipoic acid in the citric acid cycle and the subsequent inhibition of the oxidation of α-ketoglutarate and pyruvate to succinyl CoA and acetyl CoA, respectively. Because cobalt has a high affinity for sulfhydryl (SH) groups, the protective effect of proteins and amino acids probably results from the sequestration of free cobalt in the cell. Other proposed mechanisms of toxicity include the following: 1) cobalt-induced damage to the transmembrane transport system resulting in increased intracellular calcium concentrations[108] and 2) chronic inhibition of sympathetic tone.[109]

Carcinogenesis

Although data are lacking in humans, *in vitro* and *in vivo* experimental studies suggest that cobaltous ions (Co^{2+}) exert potential genotoxic properties. Several potentially carcinogenic mechanisms including the inhibition of DNA repair mechanisms by soluble cobalt(Cr^{2+}) cations (cobalt chloride, cobalt sulfate) and the damage to DNA bases by the production of hydroxyl radicals (i.e., oxidative stress) from interactions with cobalt particles, particularly hard metal particles.[110,111]

Cobalt salts are only weakly genotoxic in bacterial systems. Direct implantation of cobalt-chromium alloy and cobalt salts produced tumors (primarily rhabdomyosarcomas) in rats, but not in mice.[2] In an experiment in rats, the intratracheal instillation of cobalt oxide produced a slight excess of benign and malignant lung tumors.[112]

Pathological Changes

Hard metal lung disease

An interstitial lung disease that ranges from focal peribronchiolar inflammation to diffuse interstitial fibrosis and honeycombing develops after prolonged exposure to high dust concentrations from tungsten carbide-based hard metals that contain cobalt or from cobalt in association with other metals or dust (diamond polishers). Diamond polisher's lung (i.e., cobalt lung) is the name given to the interstitial disease that occurs in diamond polishers using a high-speed polishing disk consisting of a diamond-cobalt surface without tungsten carbide.[113,114] These polishing discs contain 10–20% microdiamonds cemented with cobalt metal powder (80–90%). Depending on the disc type, other components (carbon, iron, manganese, nickel, silicon, sulfur) may be present.

The two histological patterns of hard metal lung disease are the following: 1) an acute or subacute desquamative pneumonitis, and 2) a more latent fibrotic form characterized by progressive interstitial fibrosis. Histological features of the acute or subacute desquamative pneumonitis primarily involve intra-alveolar desquamation of large vacuolated mononuclear cells and limited interstitial fibrosis. The pulmonary changes are relatively uniform. The filling of alveoli with macrophages is significant enough to resemble desquamative interstitial pneumonitis. The presence of unusual, multinucleated giant cells on lung biopsy or bronchoalveolar lavage is a distinctive giant cell interstitial pneumonia,[115] but not invariable feature of hard metal lung disease.[116] Giant cells become less prominent as fibrosis and honeycombing develop. Electron microscopy indicates that these giant cells are both pneumocytes and macrophages.[117] Some evidence associates susceptibility to cobalt-related interstitial lung disease with the *HLA-DPB1* allele (i.e., glutamate substitution at position 69), similar to hypersusceptibility associated with the same allele in chronic beryllium disease.[118] The absence of epithelioid granulomas helps differentiate hypersensitivity pneumonitis from hard metal lung disease.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

The more chronic form is characterized by diffuse mural pulmonary fibrosis with few intra-alveolar cells. Peribronchial and perivascular fibrosis may be present. The extent of fibrosis depends on the duration of the inflammatory process, but substantial variation in the amount of inflammation and fibrosis occurs in different areas of the lung. Hard metal particles in the lung frequently contain high concentrations of tungsten and tantalum, but the concentration of cobalt is usually, but not always, low because cobalt dissolves rapidly in the lung.[119] Transmission electron microscopy detects cobalt in pulmonary particles more effectively than scanning electron microscopy.[113]

Beer drinkers' cardiomyopathy

Postmortem histological changes in patients dying of beer drinkers' cardiomyopathy involve myocardial fiber degeneration, increased vacuolation, and interstitial edema without histological evidence of acute inflammation.[120] Typically, the pericardium contains fluid but not inflammatory exudate. The heart is enlarged, dilated, and flabby; the chambers may contain mural thrombi.[10] Electron microscopy demonstrates extensive intracellular changes involving glycogen, lipid, mitochondria, and myofibrils. The mitochondria are swollen with alterations in the cristae. Myofibrils, Z lines, and A bands demonstrate little detail after staining.

The histological changes associated with beer drinkers' cardiomyopathy are not unique; these changes also occur in patients with ischemia. Myofibrillar loss and atrophy are more prominent in cobalt-induced cardiomyopathy compared with idiopathic forms of cardiomyopathy.[121] In animal experiments, cobalt-induced cardiomyopathy is similar to alcoholic cardiomyopathy with vacuolation and loss of myofibrils along with randomly scattered areas of coagulation necrosis.[109,122] Postmortem examination of thyroid glands from 14 of these patients demonstrated no gross abnormalities; however, histological examination demonstrated distortion of the follicles with depletion of colloid and atypical hyperplasia.[123] There were no clinical features of goiter or hypothyroidism reported in these patients.

The mean concentration of cobalt in the cardiac tissue from postmortem examination of eight patients with fatal beer drinkers' cardiomyopathy was $0.48 \pm 0.24\,\mu g/g$ wet cardiac tissue (range, 0.027–0.77 μg/g weight) as measured by neutron activation analysis.[124] This value was ~10 times higher ($P < 0.005$) than controls (non-alcoholics). The myocardial cobalt concentration in a patient dying 3 months after stopping cobalt chloride treatment was 1.65 μg/g wet weight compared with ≤0.06 μg/g wet weight in control samples (dialysis patients without cobalt therapy and subjects without renal dysfunction).[125] Concentrations of cobalt in normal cardiac tissue range from 0.05–0.4 μg/g dry weight tissue.[14]

Metallic hip prostheses

All materials used for hip implant wear. For metal-on-plastic (MoP), wear produces particle debris in the tens of microns range (i.e., >0.1 μm, primarily polythene) that causes aseptic osteolysis and prosthesis failure, complicating the use of traditional metal-on-polyethylene hip prostheses. These particles are usually seen in surrounding tissue by light microscopy. Subsequently, the second generation of metal-on-metal (MoM) hip prostheses was introduced to reduce wear (i.e., ~100 times) and increase the size of the femoral component; wear of these prostheses produces wear particles primarily in the nanometer range (<100 nm) with relatively larger surface area/volume that is susceptible to corrosion and ion release.[126] The amount of cobalt ions generated from wear and electrochemical corrosion depends on a complex interaction of implant and patient factors. Systemic toxicity potentially results from the transport of soluble cobalt ions and wear particles generated in the periarticular space through the lymphatic and vascular systems to remote sites. Cobalt also mimics hypoxia by interfering with the sensing of oxygen deficiency and stabilization of transcriptional activator hypoxia-inducible factor (HIF), resulting in stimulation of erythropoietin production and upregulation of the response to hypoxia.[127]

The typical alloy composition (ASTM F75) is 60% cobalt, 30% chromium (trivalent), and 7% molybdenum. Particulate wear and corrosion debris also occur following implantation of these prostheses including The following: 1) free metallic ions; 2) inorganic metal (Cr^{3+}, Co^{2+}, Ni^{2+}, Fe^{3+}, Ti^{4+}) salts or oxides (Cr^{3+}, Co^{2+}, Ni^{2+}, Fe^{3+}, Ti^{4+}); 3) metal–protein complexes; and/or 4) organic storage forms (e.g., hemosiderin).[128] Metal-on-metal (MoM) hip replacement involves the use of a stemmed (femoral) component. In younger patients, hip resurfacing is often preferred to conventional MoM hip replacement; the former refers to the capping or resurfacing of the femoral head rather than removal.

Following implantation of cobalt-chromium alloy inside the synovial fluid, a passive oxide layer forms over the implant; *in vitro* studies suggest the composition of this spontaneously-formed biolayer includes ~90% trivalent chromium (oxide, hydroxide, phosphate) with ~5% cobalt (oxide, hydroxide, phosphate) and no detectable hexavalent chromium.[129,130] Factors affecting

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. the physiochemical characteristics of MoM wear debris include implant position, implant type, cycle number, loading vectors, fluid chemistry, wear process, and extraction techniques.[131,132] Compared with polyethylene wear particles (>100 nm), the wear particles from MoM hip prostheses are much more numerous (i.e., ~13,000-fold), much smaller (average, 40 nm; range, 30–80 nm), and undetected by light microscopy.[133] In a study of metal wear particles from 13 patients undergoing revision of MoM total hip replacements with cobalt–chromium–molybdenum bearing couples, most wear particles were <50 nm (range, 6–834 nm).[134] The common type of corrosion involves crevice corrosion at tight junctions and pitting corrosion from acidic conditions.

For the typical metallic femoral component of the total hip prosthesis, the estimated rate of total alloy release is 11–22 mg/year (0.15–0.3 μg/cm^2/day); however, excess wear may increase these rates 10-fold.[135,136] Volumetric wear rate is relatively low for well-functioning MoM hip implants (<5 mm^3/10^6 cycles or year), whereas malpositioned implants produce much higher volumetric wear rates (i.e., up to 100 mm^3/10^6 cycles or year) with larger debris particles (up to 1 μm) and higher cobalt content.[132] Both particle size and chemistry contribute to subsequent tissue reactions. Under suboptimal conditions resulting from the absence of the tribolayers (i.e., the fine-grained layer that incorporates the organic material in the joint fluid with the bulk material in the implant), larger wear particles may form (100–500 nm) with the highest concentration of wear particles in the superficial zone of the peri-implant tissue membrane.[137] These conditions develop during abnormal loading (e.g., edge loading, sliding wear conditions) of the implant. The larger particles usually contain more cobalt than chromium as a result of the greater solubility of cobalt; *in vitro* studies suggest that cobalt nanoparticles are more toxic to macrophages than chromium nanoparticles at similar intracellular concentrations.[138] The form of chromium in hip prostheses at neutral pH is predominately trivalent based on analysis of implant debris from hip capsules obtained during MoM hip explantation. Oxidation of the trivalent chromium to the hexavalent form in the body is unlikely physiologically.[139] The majority of nanoparticles from wear debris that enter the systemic circulation probably are chromium rather than cobalt because of the relatively high solubility of cobalt; hence, the primary form of cobalt in the circulation is ionic rather than metallic.[140]

Pathological studies have not detected clinically significant amounts of hexavalent chromium with most chromium existing as trivalent chromium phosphate.[141] Scanning transmission electron microscopic examination of wear debris from a patient undergoing hip resurfacing arthroplasty (DePuy Articular Surface replacement made from ASTM F75 alloy) demonstrated the following two types of wear debris: 1) a diffuse phase containing primarily trivalent chromium with trace amounts of divalent cobalt, and 2) dense core-shell particles containing metallic cobalt, chromium, and molybdenum surrounded by trivalent chromium.[142] The small amounts of cobalt in the majority of debris suggest cobalt particles undergo rapid corrosion in the tissues. In areas of high chromium concentrations from tissue in another study, cobalt (i.e., mixture of metallic Co and divalent Co) and molybdenum oxide were present;[143] hexavalent chromium was not detected in the debris. Macrophages and giant cells phagocytize the wear debris; in the acidic environment of lysosomes, corrosion of the metallic fragments occurs. Corrosion products include metal oxides (CoO, Cr_2O_3, TiO_2) and hydroxides [$Cr(OH)_3$], whereas chromium phosphates ($CrPO_4$) form in extra-synovial environments and metal phosphates [$Co_3(PO_4)_2$, $CrPO_4$] deposit in other extra-synovial sites. The shape, morphology, and physical properties (e.g., agglomeration, surface area) influence the cellular uptake and toxicity of the nanoparticles. Postmortem examinations of patients with revised MoM hip arthroplasties indicate a majority of the livers and spleens in these cases had macrophages with submicron metal particles; however, these macrophages formed focal aggregates without obvious toxicity.[144]

Pathological characteristics of pseudotumors include neo-synovial proliferation with or without fluid and/or tissue necrosis; they typically occur in soft tissues and less often in bone. The formation of pseudotumors is probably a persistent cytotoxic and/or hypersensitivity response to wear debris including cobalt and chromium nanoparticles and microparticles;[145] however, the biological pathway of pseudotumor formation remains unclear and variable (i.e., unpredictable) between patients. The process of pseudotumor formation is neither infectious nor malignant. The extent of tissue destruction seen during revision surgery does not correlate directly (i.e., not dose-related) to the volumetric wear rate suggesting other factors contribute to pseudotumor formation.[146] Proposed mechanisms of toxicity include the following: 1) cytotoxic reaction from macrophage-induced necrosis; 2) cell-mediated, T-cell-mediated, Type IV hypersensitivity reaction (ALVAL); or 3) some combination of these two reactions depending on individual sensitivity.[147] ALVAL is the lymphocyte-dominated immunological response in periprosthetic tissues that correlates the cellular reaction with the presence of wear debris; the ALVAL score is typically higher in low-wear than high-wear

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

components suggesting the lymphocyte reaction results from subtoxic corrosion.[148] The distinguishing features of ALVAL in patients with MoM include variable, often extensive surface necrosis, metallic debris-laden macrophages, and loss of architecture; however, these pathological findings also occur in other inflammatory arthropathies.[149] Although up to ½ of the patients with MoM hip implants develop lymphocyte reactivity (i.e., positive lymphocyte transformation test) to Co and Cr within 1–4 years after implant, symptoms in these patients are not related to the metal reactivity.[150] Some patients with MoM hip arthroplasties develop pseudotumors without evidence of hypersensitivity to metals (i.e., negative lymphocyte transformation test).[151] Macrophages and T cells produce cytokines (IL-1β, IL-2, IL-6, TNF-α, IFN, RANKL) and/or upregulation of costimulatory molecules (CD80, CD86, ICAM-1) that initiate an aseptic inflammatory response and tissue destruction (pseudotumor). *In vitro* studies suggest that ionic metal implant debris induces this monocyte/macrophage response more than metallic particles.[152] The presence of robust lymphocytic infiltration in periprosthetic tissue suggests a hypersensitivity reaction.

Postmortem Examination

The autopsy of a 19-month-old child dying ~6 hours after the ingestion of cobalt chloride revealed few specific findings.[44] The stomach mucosa was congested with a thin layer of coagulative necrosis involving the inner 1/3 of the stomach mucosa. The esophageal mucosa demonstrated a few small bullae. Microscopic examination of the brain revealed only edema. The postmortem examination did not report any abnormalities of the respiratory tract (the mother induced vomiting several times, and gastric lavage was performed in the emergency department). A 17-year-old adolescent with renal failure requiring hemodialysis developed a fatal biventricular heart failure after receiving 50 mg cobaltous chloride daily for the preceding 8 months.[153] Analysis of cardiac tissue by neutron activation analysis demonstrated cobalt concentration of 8.9 μg/g dry tissue compared with 0.2 μg/g dry tissue in two patients with renal dysfunction.[154] The case report did not include antemortem or postmortem blood cobalt concentrations.

CLINICAL RESPONSE

The classic presentation of cobalt toxicity involves polycythemia, metabolic acidosis, thyroid hyperplasia, and cardiomyopathy.[155]

Adverse Medical Effects

Past therapeutic use

In the 1950s and 1960s, cobalt chloride was a treatment for refractory anemia (sickle cell disease, renal failure) as well as nephritis and infections. A variety of adverse effects were associated with the use of cobaltous chloride for these conditions including polycythemia and hypothyroidism in a child with lipid nephrosis,[156] congestive heart failure, goiter with dry skin, thin hair, and anorexia,[157] myxedema in a child with goiter and congestive heart failure,[158] hearing/visual impairment, and polyneuropathy. Hypothyroidism, thyroid hyperplasia, and goiter are recognized side effects of the use of cobaltous chloride to treat anemia.[159] Rare case reports associated the use of cobalt chloride with tinnitus (50–150 mg daily),[160] vertigo, transient hearing loss in 3 of 14 dialysis patients receiving consecutive 4-week courses of 25 mg and 50 mg $CoCl_2$,[58] optic atrophy,[161] reduced vibratory sense,[162] and unsteady gait. These case reports involved patients with serious chronic diseases (e.g., chronic renal failure, sickle cell disease, blood dyscrasias); additionally, biomarkers of cobalt exposure were not included in the reports. Consequently, the contribution of cobalt to the development of these neurological effects is unclear.

Metallic Prostheses

A total hip arthroplasty (THA) consists of the following: 1) a femoral head attached to a stem inserted into the femur (metal or ceramic), and 2) a cup anchored in the pelvis (metal, ceramic, or polyethylene). In MoM implants, both surfaces are metal with cobalt-chromium-molybdenum alloy being the predominant metal alloy, whereas other types of implants use polyethylene on metal or metal-on-ceramic surfaces. An MoM-resurfacing hip prosthesis consists of a femoral head capped with a metal covering. The bearing surfaces of hip prostheses contain cobalt and chromium, ceramic, polyethylene, or stainless steel, whereas the nonmoving parts include titanium alloys with small amounts of aluminum and vanadium, cobalt and chromium with trace nickel and molybdenum, or stainless steel. Total knee replacement implants consist of the following: 1) a metallic femoral component attached to the distal femur; 2) a plastic articulating layer; and 3) a tibial component that binds the articulating layer to the proximal tibia. In contrast to MoM total hip prostheses, the design of total knee implants avoids direct metal-to-metal contact.

Friction between bearing surfaces and corrosion of nonmoving parts produce elevated local and systemic metal concentrations, typically <7 μg/L. Very rare case reports associate systemic cobalt toxicity with hip arthroplasties compared with >1 million total hip implants performed worldwide to date. These case reports typically involve fractured ceramic hip prostheses and excessive wear of metal-on-metal hip arthroplasties. A 2014 review of the English medical literature identified 26 papers describing 18 individual cases of systemic toxicity associated with hip prostheses involving 10 cases of the replacement of fractured ceramic prostheses with metal surfaces and 8 cases of MoM hip implants with excessive wear.[163] The authors proposed the following criteria for assessing patients with hip implants and elevated blood cobalt/chromium concentrations:

(1) History – The patient has an MoM or fractured ceramic-containing prosthesis replaced by a metal component for local pain and symptoms consistent with systemic cobalt toxicity (cardiac, neurological, and thyroid effects). Other explanations for these symptoms are less likely than cobalt toxicity.
(2) Clinical findings – Local abnormalities (corrosion, metallosis) are documented by pathological or imaging studies along with objective evidence of cardiac, neurological, and thyroidal changes consistent with cobalt toxicity. Other explanations for these changes are less likely than cobalt toxicity.
(3) Temporal relationships – Clinical features develop months to years after substantially increasing blood cobalt concentrations.
(4) Blood cobalt concentrations – Blood cobalt concentrations in symptomatic patients are substantially higher than in patients with well-functioning prostheses.
(5) Response to removal and debridement of worn prosthesis – Blood cobalt concentrations decrease after the removal of the prosthesis usually along with improving clinical symptoms.

Using these criteria, the authors attributed 10 of the 18 identified cases to systemic cobalt toxicity; all the attributed cases had very elevated blood cobalt concentrations (i.e., >250 μg/L). A 2016 review of the English medical literature also identified 18 cases of systemic cobalt toxicity associated with hip arthroplasties; MoM articulations accounted for 10 cases.[164] In a retrospective case series of 31 patients referred to outpatient toxicology clinics for evaluation of MoM THA, the median peak cobalt and chromium concentrations were 10 μg/L (IQR = 3.8–32.8 μg/L) and 6.9 μg (IQR = 3.7–18.7 μg/L), respectively. Two patients diagnosed with systemic cobalt toxicity were a 56-year-old man 7 years post-bilateral MoM THA with extreme lethargy and hip pain (peak serum cobalt = 164.8 μg/L, peak serum chromium 100.2 μg/L) and a 60-year-old man 16 years post-right sided MoM THA with optic neuropathy, peripheral axonal neuropathy, polycythemia, and hypothyroidism (peak serum cobalt = 1,096 μg/L).[165] Polycythemia and hepatorenal dysfunction do not usually occur following cobalt exposure except in symptomatic patients with multisystemic diseases and highly elevated serum cobalt concentrations.[166]

Local tissue reactions

The deposition of cobalt-chromium wear particles from wear and corrosion around the MoM hip prostheses may produce inflammatory and necrotic changes, resulting in soft tissue and bone lesions that contribute to loosening of the implant and implant failure. Adverse reactions to metal debris include the following histological changes: 1) metallosis (macroscopic staining of periprosthetic soft tissues); 2) aseptic lymphocytic vasculitis-associated lesions (ALVALs); 3) and 4) pseudotumors (cystic, solid, or mixed peri prosthetic soft tissue mass).[167] The umbrella term, adverse reactions to metal debris (ARMD), refers to large sterile hip effusions, and/or tissue metallosis/necrosis ranging from small pseudocysts to large soft tissue masses (pseudotumors) that ultimately lead to osteolysis and painful joint failures. ARMD also refers to secondary inflammatory cellular reactions and host immune reactions.[168] The cause–effect relationship between hypersensitivity and implant failure remains uncertain. Although the prevalence of hypersensitivity is substantially higher in patients with implant failures than well-functioning arthroplasties, many patients with positive tests have good clinical outcomes.[169]

Symptomatic pseudotumors with ALVAL, extensive tissue necrosis, bone loss around the hip implant, and loosening/failure of the prosthesis requiring revision develop in a relatively small number of total hip replacements (i.e., <5%);[170,171] however, thin-walled cystic lesions on MRI also occur in asymptomatic hip implant patients.[172] The clinical course of pseudotumors is difficult to predict (i.e., expansion, contraction, unchanged).[173] In a study of 1,419 metal-on-metal hip resurfacings implanted by a British orthopedic service in 1,224 patients, 1.8% of the patients had a revision for pseudotumor.[174] Solid pseudotumors almost exclusively occur with resurfacing procedures, particularly with

acetabular malposition in women under 40 years of age.[175] Case reports associate pseudotumor formation with lower extremity edema (vascular compression)[176] and impairment of the femoral or lateral cutaneous nerve.[177]

Cardiovascular System

Several case reports attribute serious cardiac abnormalities (i.e., impaired diastolic function, dilated cardiomyopathy, pericardial effusion) with excess wear/corrosion of hip prostheses and extremely high blood cobalt concentrations (≫200–300 μg/L), often with comorbidities (e.g., alcoholism, renal dysfunction, diabetes).[178] An otherwise healthy 46-year-old man sustained a fracture of the polyethylene-ceramic sandwich acetabular liner of the left total hip replacement.[166,179] Within 6 months of revision surgery with metal-on-polyethylene (MoP) bearing, he developed severe fatigue, anorexia, weight loss, hypothyroidism, and left hip pain. One year after surgery, he complained of worsening fatigue and dyspnea despite thyroid replacement. He developed left ventricular failure (LV ejection fraction <10%), pericardial effusion, and cardiogenic shock. Despite 2 weeks of chelation therapy, he developed multisystem failure and died. His peak whole blood cobalt and chromium concentrations during this hospitalization were 6,532 μg/L and 23.6 μg/L, respectively. There was severe wear (secondary to embedded ceramic particles) on his implanted Co–Cr alloy femoral head with an estimated 23.3 g loss of mass from the implant. A 60-year-old woman with a history of MoP replacement for a fractured ceramic-on-ceramic right total hip arthroplasty developed right hip pain, dyspnea, increased hearing loss, metallic taste, and weight loss.[180] A whole blood cobalt concentration following the reduction of dislocation of her right hip was 817 μg/L. Prior to succimer initiation and prosthesis removal, she developed hypotension and cardiorespiratory failure. Autopsy demonstrated extensive metallic effusion surrounding the right hip prosthesis.

Moderately reduced systolic left ventricular function, hypothyroidism, headache, muscle loss, peripheral paresthesias, and hearing loss developed in a 55-year-old man after the replacement of fractured ceramic head.[181] On revision, he had severe metallosis from retained ceramic debris; his serum cobalt concentration at revision was 625 μg/L. His symptoms resolved 6 months after the last revision. A 59-year-old woman developed biventricular cardiac failure requiring cardiac transplant and hypothyroidism several years after receiving bilateral MoM ASR™ hip prostheses; cough, exertional dyspnea, and pedal edema began while vacationing in Denmark.[182] There was no documented fever, rash, or new arthralgias. The complete blood count was normal. Deterioration of cardiac function continued posttransplant; 8 months after the transplant, imaging of the hip demonstrated metallosis and the serum cobalt concentration was 399 μg/L. Resection of the hip implants resulted in improved cardiac function and rapid reduction in the serum cobalt concentration. A 55-year-old man developed progressive heart failure, hypothyroidism, fever, and increasing visual loss and deafness after replacing a MoP prosthesis for a fractured ceramic hip implant.[183] Imaging demonstrated myositis ossificans-like changes and blood cobalt concentrations of 885 μg/L. Improvement in cardiac function occurred after removal of the MoP prosthesis and reduction in the blood cobalt concentration (85 μg/L).

Other case reports provide less convincing evidence of an association between cobalt-induced cardiac changes and hip prostheses as a result of preexisting illnesses, renal dysfunction, and nutritional deficiencies. A case report documented normalization of LV systolic function and improvement of cardiomyopathy in a 75-year-old farmer after removal of his MoM hip prosthesis and reduction of his plasma cobalt concentration (pre-op, 13.6 μg/L; 1-month post-op, 4.5 μg/L).[184] Multiple cardiac risk factors including Type 2 diabetes mellitus, single-vessel moderate coronary artery disease, Class I obesity, mild renal impairment, and hypercholesterolemia suggested alternate explanations for his cardiac disease. A 49-year-old man complained of exertional dyspnea 1 year after implant when his serum cobalt concentration was 23 μg/L.[185,186] Six months later, echocardiography indicated diastolic dysfunction; he reported symptomatic improvement 7 months after revision; however, there was no echocardiographic confirmation.

In a retrospective review of 39 patients consulting medical toxicologists about the toxicological effects of hip implants, none of the patients were diagnosed with cobalt-related heart disease.[187] The maximum whole blood cobalt concentration was 254 μg/L. In a cross-sectional study of 35 pairs of asymptomatic patients with metal-on-metal hip resurfacing MoMHR and conventional hip replacement matched for age, sex, and time since surgery (mean = 8 years), transthoracic echocardiography demonstrated a 7.7% reduction in the mean ejection fraction and a 6% increase in left ventricular end-diastolic diameter in the MoM group.[188] These differences did not result in any function impairment. Although the authors recommended monitoring of cardiovascular function, they did not ascribe the cardiovascular effects to cobalt toxicity. The mean whole blood cobalt concentrations were 1.75 μg/L (range,

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

1.11–6.11 μg/L) and 0.38 μg/L (range, 0.33–0.55 μg/L), respectively.

Central nervous system

Toxicological data associating cobalt exposure with central nervous system effects in patients with failing hip prostheses primarily involve rare case reports of impaired vision (bilateral optic atrophy and retinopathy), sensorineural hearing loss (bilateral nerve deafness), and peripheral neuropathy (primarily sensory and mixed sensorimotor) without a clear pathophysiological mechanism; frequently, these cases lack sufficient details to exclude comorbidities as causal factors.[189] A longitudinal analysis of the Medicare database 2005–2012 identified 29,483 MoM total hip arthroplasties and 23,587 age- and gender-matched MoP total hip arthroplasties; these groups were also matched in the prevalence of 26 of 30 Elixhauser-measure comorbidities.[190] Using ICD ninth revision procedure codes, the study compared new diagnoses of six neurological side effects (paresthesias, peripheral neuropathy, sensorineural hearing loss, tinnitus, vertigo, visual impairment) over 5 years. The new diagnoses of neurological side effects in the hip replacement were not statistically different than the control group.

Case reports associate substantially elevated cobalt and chromium concentrations with optic atrophy,[191] tinnitus, hearing and visual loss,[192,193] sensorimotor neuropathy (severe metallosis with ceramic debris),[181] and retinopathy with impaired visual acuity and color loss.[194] An 18-month follow-up of the latter case demonstrated improved visual acuity and color vision after hip revision, but electroretinogram abnormalities persisted with the development of optic nerve dysfunction; concurrent blood cobalt and chromium concentrations remained elevated (27.26 μg/L and 31.36 μg/L, respectively) after revision.[195] This 65-year-old man had multiple comorbidities including diabetes, hypertension, hypercholesterolemia, pulmonary embolism, atrial fibrillation, obesity, and cataracts. Other case reports associated additional neurological effects (cognitive decline, poor coordination) with elevated blood cobalt/chromium in hip implant patients;[185,186] however, the lack of data on the toxicokinetics of cobalt with specific types of cobalt biological binders, exposure to multiple metals, confounding illness (stroke, anxiety, depression age), absence of objective data, and the small number of patients affected compared with the number exposed limit conclusions regarding the causal role of cobalt in the development of the latter central nervous system effects. In a retrospective review of 39 patients consulting medical toxicologists about the toxicological effects of hip implants, 1 patient had a demyelinating peripheral neuropathy; her symptoms improved significantly with revision surgery and the decrease in her whole blood cobalt concentration from 254 μg/L to 10 μg/L (serum).[187] Two other patients had symptoms suggestive of demyelinating neuropathy. Nine patients sought consultation for fatigue; tinnitus was a frequent (n = 10) associated complaint, but the primary complaint was in only one patient. Two of the three patients with complaints of hearing loss also had tinnitus.

Thyroid Dysfunction

Large cobalt chloride doses (5–10 mg/day) may cause transient thyroid dysfunction based on the use of this compound to treat anemia in the 1950s.[196] A few case reports of patients with multisystem illnesses associated very high plasma cobalt concentrations (e.g., >400–4,000 μg/L) with malfunctioning hip implants;[179] however, the thyroid dysfunction and goiter in surviving patients typically resolve within several weeks after hip revision.[194]

Acute Toxicity

Pediatric case reports associate cobalt toxicity with exposure to cobalt chloride in chemistry sets.[197] These case reports document gastrointestinal irritation (nausea, vomiting, abdominal pain, erosion of the gastric mucosa). A 19-month-old child died after the ingestion of cobalt chloride; however, the cause of death was unclear.[44] This case report did not include serum cobalt concentrations.

Environmental Exposure

A Quebec case series of 48 alcoholics, mostly malnourished patients (46 M, 2 F) associated the development of cardiomyopathy (beer drinkers' cardiomyopathy) with very high consumption of beer containing relatively large cobalt concentrations (i.e., ~1 ppm as a foam-stabilizing agent) compared with other beers.[8] A majority of these patients drank >12 pints/day for ≥10 years. The clinical presentation included nausea, vomiting, diarrhea, abdominal pain, occasional hematemesis, and progressive heart failure characterized by hypotension, cough, chest pain, pericardial effusion, and progressive dyspnea.[198] These patients also demonstrated peculiar cyanosis limited to the face and trunk along with increased deposition of melanin on skin biopsy.[12] Twenty of the 48 patients died with many of the deaths occurring within 24 hours of the onset of cardiogenic shock. Cofactors (mineral

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and protein deficiencies, alcoholic cardiomyopathy) probably were involved in the development of beer-drinkers' cardiomyopathy because of the low dose of cobalt consumed by these patients and the rare occurrence of cardiomyopathy in subjects drinking cobalt sulfate-containing beer.

Occupational Exposure

Hard metal lung disease

Hard metal lung disease (AKA, giant cell interstitial pneumonia, cobalt lung, tungsten carbide pneumoconiosis, hard metal pneumoconiosis) is a rare giant cell interstitial pulmonary disease that occurs following chronic hard metal dust exposure (e.g., grinder, sharpener). The main pulmonary effects involve the following: 1) reversible airway obstruction; 2) subacute fibrosing alveolitis with intra-alveolar desquamation that includes interstitial, multinucleated giant cells; and 3) chronic, diffuse interstitial pulmonary fibrosis.[199] Although cobalt exposure alone causes occupational asthma, the development of the interstitial fibrosis associated with the hard metal lung disease usually requires exposure to other hard metals (e.g., diamond, iron, silica, titanium, or tungsten).[90] Clinically, this rare disease resembles hypersensitivity pneumonitis with a variable clinical course ranging from a subacute presentation to occasionally rapid progression to pulmonary fibrosis; the correlation between disease occurrence and length of occupational exposure is poor.[200] Pulmonary changes occur in workers using high-speed diamond-cobalt grinding tools with exposure to cobalt-diamond dust rather than hard metal (i.e., tungsten carbide) dust. These polishing disks possess a cutting surface consisting of microdiamonds cemented into a fine cobalt mesh and placed over a frame of half-hard steel that contains mostly iron. The epithet cobalt lung is an older term given to the pulmonary changes in these workers because of the absence of suspected effects from other metals present in the hard metal; however, the hard metal lung disease is a more accurate term because of the necessity for the presence of other metals or diamond dust for the expression of the disease. In addition, exposure to cobalt-containing particles may produce inflammation of the upper respiratory tract, either through direct inflammation or an immunological reaction.

The manifestations of interstitial lung disease following exposure to hard metal dust probably result from a continuous process. This disease process varies from acute alveolitis to chronic pulmonary fibrosis depending on the individual's susceptibility and the duration/severity of the exposure. The abrupt development of fever, anorexia, cough, and dyspnea with exertion indicates the presence of alveolitis, which typically begins months to several years after the initial hard metal dust exposure. Chronic forms of hard metal lung disease or bronchitis usually require prolonged exposure to dust composed of multiple metals. Typically, evidence of interstitial lung disease appears after 10–12 years of exposure to hard metal dust;[201] however, the appearance of symptoms or signs may be shorter (2–7 years) depending on the intensity of exposure.[118] Symptoms may improve following removal from the workplace, but symptoms may recur following reexposure. Repeat episodes of alveolitis may produce interstitial fibrosis.

The most common early symptoms of interstitial fibrosis involve exertional dyspnea and dry cough with the occasional production of scant, mucoid sputum. The fibrotic form of this disease is more progressive and insidious than the alveolar form. Tachypnea at rest, weight loss, and clubbing are late manifestations of pulmonary fibrosis. Inspiratory rales may occur either as a result of active alveolitis or diffuse pulmonary fibrosis. As the extent of pulmonary fibrosis progresses, pulmonary hypertension and cor pulmonale supervenes. Individuals with increased susceptibility may develop interstitial lung disease at lower concentrations and shorter durations of exposure compared with the general population of workers.[202] Pulmonary abnormalities usually improve considerably upon removal of the worker from exposure to hard metal dust;[203,204] continued exposure to high concentrations of hard metal may produce a rapid progression of the pulmonary fibrosis [114] and death.[205]

The presence of interstitial fibrosis in populations of active diamond polishers and tungsten carbide production workers is relatively rare (<1%). A cross-sectional study of tungsten carbide production workers with prolonged exposure to high concentrations of hard metal dust resulting in cobalt concentrations above current occupational standards revealed a 3.8% prevalence of interstitial infiltrates and a 5% prevalence of obstructive defects in nonsmoking workers.[206] The differential diagnosis of hard metal lung disease includes pneumoconioses, hypersensitivity pneumonitis, sarcoidosis, and other granulomatous lung diseases, interstitial pneumonia, and drug-induced lung disease.

Hypersensitivity

Asthma

Occupational asthma characterized by wheezing, coughing, and dyspnea occurs in hard metal workers with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

cobalt-specific IgE-albumin complexes[98] and a positive bronchoprovocation test with cobalt chloride.[207] Occupational asthma is more frequent than interstitial lung disease; occasionally, the two diseases may coexist.[199] These tests demonstrate early, late, and dual reactions to cobalt inhalation. A retrospective study of occupational asthma in a Finnish cobalt production plant reported 22 cases, who were diagnosed an average of 7.4 years after the onset of symptoms. Bronchial challenge tests demonstrated the following types of reactions: immediate, 16%; delayed, 61%, and dual, 19%.[97] One in 14 patients retested for bronchial hyperreactivity improved, whereas half the patient's reactivity remained unchanged on retesting. In contrast to hard metal lung disease, exposure to only cobalt is sufficient to produce asthma.[87] Clinically, asthmatic symptoms usually appear about 4–6 hours after exposure; often, the symptoms worsen in the early evening.[208] Characteristic improvement occurs on the weekend and holidays; however, the presence of late reactions to inhaled cobalt indicates that asthma symptoms may appear up to 48 hours after exposure.

The prevalence of occupational asthma in hard metal workers depends on the population studied (i.e., healthy worker effect) as well as the intensity of exposure. A cross-sectional study of hard metal workers revealed a prevalence of 5.6% for asthma in active workers.[209] The presence of concurrent sensitivity to nickel indicates that nickel may contribute to the development of hard metal asthma.[210] Although there is no evidence that workers with cobalt-induced occupational asthma develop interstitial fibrosis, rarely workers with asthma may develop hypersensitivity pneumonitis.

Dermatitis

Cobalt is one of the three most common metallic sources of occupational contact dermatitis along with nickel and chromium.[211] A meta-analysis of all publications between 1966–2000 using standardized patch testing demonstrated the presence of cobalt hypersensitivity in 4.8% of the patients.[212] Men and women have similar rates of cobalt hypersensitivity with the highest prevalence rates in hairdressers, barbers, building contractors, retail cashiers, machine operators, and domestic cleaners.[213] Products associated with this dermatitis include metal alloys, catalysts, electroplating materials, dyeing agents, and potter/glass colorants. In the occupational setting, cobalt-induced contact dermatitis characterized by erythematous papules occurs commonly on the hands of workers in the hard metal industries, cleaning industries, and textile and leatherwork. The prevalence of hand eczema and irritant reactions in a group of 776 workers in a hard metal factory was ~10% and 15%, respectively.[214] The majority of these rashes begin within the first year of employment. Risk factors for the development of severe eczema include prior nickel sensitization and irritative dermatitis.[95] In a study of 853 hard metal workers, 25% of the nickel-sensitive individuals developed cobalt allergies compared with 5% of the total population tested.[215] Almost all (88%) of the nickel-sensitive individuals were women who developed nickel sensitivity from the use of ear piercings.

Sensitization to these metals results from co-exposure to these metals rather than cross-reactivity among these metals.[216] The incidence of contact dermatitis from chromium, cobalt, and nickel in a group of 1,782 workers exposed to cement, waste fly ash, and asbestos cement was 8.6%, 3.1%, and 1.1%, respectively.[217] The diagnosis was based on definitely positive patch tests for these metals. This diagnosis of cobalt sensitivity is complicated by the fact that nickel contamination of cobalt patch tests may produce false-positive skin tests for cobalt in patients who are highly sensitive to nickel.[218]

Cardiovascular System

Several case reports associate the abrupt development of cardiomyopathy in workers with cobalt exposure based on elevated cobalt concentrations in tissues or blood and no other discernable cause;[14,154,219] however, the lack of exposure data, the absence of a unique marker of cobalt cardiomyopathy, the presence of coexisting illness (e.g., polycythemia),[154] and incomplete epidemiological data supporting a causal connection limit definite conclusions about causal relationships between cobalt exposure and clinically significant heart disease.[220] A Finnish study of 203 cobalt production workers did not detect any clinically significant cardiovascular disease in the exposed workers; however, echocardiography suggested altered left ventricular relaxation and early filling in the exposed workers.[221] In a Belgian study of 256 cobalt production workers, no evidence of dilated cardiomyopathy was detected in the workers as evaluated by echocardiogram and electrocardiogram.[222] The median urinary cobalt concentration was ~4 μg/g creatinine with a median cumulative estimated exposure of 100 μg/g creatinine; the interquartile range was 2.0–8.0 μg/g creatinine with a maximum value of 426 μg/g creatinine. There was no dose-effect suggesting a relationship between incipient dilated cardiomyopathy and cobalt exposure. Recent cobalt exposure was associated with a reduction in the left ventricular internal cavity. The exposure of most of these workers was below current workplace standards (e.g., 15 μg/g creatinine).

Central nervous system

Although a few case reports associate transient hearing and/or visual impairment with the use of cobalt chloride to stimulate erythropoiesis in chronically sick patients,[160,161] there are few data associating occupational cobalt exposure with impairment of the central nervous system. A 48-year-old smoker presented 4 months after leaving a job involving exposure to high concentrations of raw cobalt powder.[223] He had a 7-month history of progressive bilateral deafness, tinnitus, occasional vertigo, and optic atrophy; his whole blood cobalt concentration was 234 μg/L, and he had elevated CSF protein with oligoclonal IgG banding. Following cessation of cobalt exposure, his bilateral optic atrophy and nerve deafness improved over the next 7 months.

Reproductive Abnormalities

Humans

There are few data on the human reproductive effects of cobalt exposure; existing evidence does not associate cobalt exposure with teratogenesis based on case reports. A woman diagnosed with severe pulmonary fibrosis secondary to the hard metal lung disease before her pregnancy delivered a healthy full-term infant.[224] A 34-year-old woman with a Co concentration of 103 μg/L before her pregnancy delivered a healthy infant with hypospadias at 41 weeks; the maternal blood Co at delivery was 51 μg/L.[225] Blood chromium concentrations were also elevated. The infant was breastfed and developed normally; the infant's blood Co concentrations at 3 weeks and 9 weeks were 20 μg/L and 10 μg/L, respectively. A 41-year-old woman with a metal-on-metal hip implant developed a recurrent pseudotumor and elevated cobalt/chromium concentrations during her pregnancy.[226] The maternal whole blood cobalt concentration at delivery of a healthy full-term infant was 143 μg/L; the cobalt concentration in cord blood was 75 μg/L (52% of maternal blood), indicating that cobalt diffused across the placental barrier. No adverse maternal or neonatal effects were observed 14 months after birth. In a case series of 10 pregnant women with MoM hip arthroplasties, the maternal whole blood cobalt concentration at delivery was 1.39 ± 0.36 μg/L compared with 0.839 ± 0.26 μg/L in cord blood; however, the difference was not statistically significant ($P > 0.05$).[227] In a case study of three women with metallic hip implants during their pregnancy, no abnormalities were detected in the infants at birth.[228] A clinical study of 78 pregnant women receiving 60–100 mg cobalt chloride daily for pregnancy-related anemia detected no adverse effects in the mother or neonate.[51,229] The women received cobalt for a minimum of 3 months and a maximum of 6 months; the number of women receiving cobalt in the first trimester was not reported. Twenty of these patients received cobalt alone, whereas the other women received cobalt chloride and ferrous sulfate.

Animals

In bacterial systems, cobaltous salts are not mutagenic, but studies in mammalian cultures indicate that cobaltous salts inhibit DNA repair and thus may enhance the genotoxicity of other mutagenic agents.[230] Cobaltous chloride induced a low frequency of cleft palate in mice.[231] No fetotoxic or teratogenic effects occurred in rats gavaged with daily doses of 100 mg cobaltous chloride/kg body weight.[232]

Carcinogenesis

The genotoxicity and carcinogenicity of cobalt compounds depend on the type of cobalt compound. The US National Toxicology Program (NTP) lists cobalt-tungsten carbide powders and hard metals as reasonably anticipated to be human carcinogens based on limited evidence of carcinogenicity in human studies and supporting evidence in *in vitro* studies. Although epidemiological data are limited to a few independent populations, the basis for the NTP classification includes the following: 1) a consistent excess lung cancer mortality among cobalt–tungsten carbide hard-metal manufacturing workers, and 2) higher risks among workers with higher exposure levels after adjustment for tobacco smoking. The NTP also lists cobalt and cobalt compounds that release cobalt ions *in vivo* as reasonably anticipated to be human carcinogens based on sufficient evidence from studies in experimental animals and supporting plausible mechanisms (e.g., genotoxicity, oxidative damage from the generation of reactive oxygen species, stabilization of hypoxia-inducible factor resulting in enhanced cancer cell survival in oxygen-deficient environments, inhibition of DNA repair).[233] These experimental data include the development of tumors in the following: 1) two rodent species at several different tissue sites, and 2) experimental animals exposed to metallic cobalt or cobalt compounds via several different exposure routes. The evidence from human studies was inadequate to evaluate the association between cancer and exposure to cobalt and cobalt compounds that release cobalt ions *in vivo* including a lack of sufficient evidence to quantitate the cancer risk in patients with cobalt alloy-containing joint implants.

The IARC classifies cobalt metal with tungsten carbide as probably carcinogenic to humans (Group 2A) based on limited evidence in humans for the carcinogenicity of cobalt metal with tungsten carbide and sufficient evidence in experimental animals for the carcinogenicity of cobalt metal powder.[234] Cobalt metal, cobalt sulfate, and other soluble divalent cobalt salts without tungsten carbide are listed as possibly carcinogenic to humans (Group 2B) based on inadequate evidence in humans for the carcinogenicity of cobalt metal without tungsten carbide, limited evidence in experimental animals for the carcinogenicity of metal alloys containing cobalt, and sufficient evidence in experimental animals for the carcinogenicity of cobalt sulfate. *In vitro* studies suggest the carcinogenic potential of insoluble Co compounds (e.g., metallic Co) is less than that of soluble Co compounds (e.g., cobalt sulfate).[235,236] A 2-year whole-body inhalation study in rats and mice exposed to cobalt sulfate and insoluble metallic cobalt produced inflammation of the respiratory tract (hyperplasia, squamous metaplasia) and an increased incidence of alveolar/bronchiolar carcinoma, primarily at exposure levels of >10 times the current occupational exposure limits (100 $\mu g/m^3$).[111] The occurrence of pancreatic neoplasms in male rats and leukemias in female rats suggested these substances may be multisite rodent carcinogens at the airborne concentrations tested. In 1999, the IARC listed implanted foreign bodies of metallic chromium or titanium and cobalt-based, chromium-based, and titanium-based alloys as not classifiable as to their carcinogenicity to humans (Group 3).[237] Epidemiology studies of hip implants and cancer at that time were inconsistent with inadequate control of confounders and short follow-up periods compared with latency times for solid tumors.

Occupational Exposure

A cohort study of all hard metal-producing (i.e., cobalt and tungsten carbide) plants in France detected ~30% excess in lung cancer mortality SMR = 1.3, 95% CI: 1.00–1.66, 63 deaths when comparing 7,459 French hard-metal workers with national death rates.[238] A nested case-control study from this study comparing lung cancer risks in workers exposed to cobalt–tungsten carbide with minimally or unexposed workers demonstrated higher risks in the exposed workers (OR = 1.93, 95% CI: 1.03–3.62, 35 cases) based on a job-exposure matrix (0–7). The risk of lung cancer increased significantly with duration of exposure ($P = 0.03$) and cumulative dose (unweighted, $P = 0.01$); however, the increased risk with exposure level ($P = 0.08$) and cumulative dose (frequency weighted, $P = 0.08$) was not statistically significant. Adjustment for smoking and the presence of suspected carcinogens did not alter the odds ratios. In a mortality study of workers at the largest French hard metal production facilities included in the previous French study, the lung cancer risk was increased by ~2-fold for the duration of exposure to hard metal dust before sintering, after adjustment for smoking and known or suspected carcinogens.[239] The SMR for hard metal production workers was 2.42 (95% CI: 1.10–4.59) based on nine deaths. Although exposure misclassification probably would reduce the likelihood of detecting a true effect, these studies are limited by the lack of quantitative exposure assessment and potential confounding (e.g., other carcinogenic metals).

Analysis of data from an international study of 32,354 hard metal production workers from 3 companies and 17 manufacturing sites in 5 countries (Austria, 1970–2014; Germany, 1975–2012; Sweden, 1952–2012; United Kingdom, 1980–2014; United States, 1952–2012) was not consistent with the earlier French and Swedish studies.[240] Although the SMR for bronchus, trachea, and lung cancer in the pooled cohort using regional rates was statistically significant (1.20, 95% CI: 1.09–1.31; $n = 459$), the SMR for workers with >5 years of employment was 1.02 (95% CI: 0.88–1.17) after using regional comparisons and adjusting for age, calendar time, race, and sex. The study found no evidence of an exposure-response relationship for lung cancer or evidence that duration or average intensity of cumulative exposure to individual metals (cobalt, nickel, tungsten) increased the lung cancer mortality risk based on a job-exposure matrix composed of eight job classes.[241]

Some of these studies suggest the possibility of excess risk of other cancers (e.g., leukemia, esophagus, pleura);[242] however, there is no clear association of these cancers with hard metal workers because of the lack of clear dose-response relationships or statistically significant differences between exposed and unexposed workers.

Epidemiological evidence of cancer in humans is stronger following exposure to cobalt with cobalt-tungsten carbide than cobalt without tungsten carbide. A cohort mortality study of 1,143 French workers exposed to cobalt during the production of cobalt at an electrochemical plant revealed an excess of lung cancer.[243] The small number of lung cancer cases (4) and the lack of control of confounding variables (smoking, arsenic, nickel) prevent the establishment of a definite causal relationship between exposure to cobalt and the development of lung cancer. A follow-up study of this cohort of cobalt production workers for an additional 7 years revealed no excess mortality (SMR = 0.85, 95%

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. CI: 0.18–2.50, 3 deaths) from lung cancer.[244] A retrospective cohort study of 874 women exposed to cobalt in 2 Danish porcelain factories did not demonstrate a significantly increased relative risk of developing lung cancer (RR = 1.2, 95% CI: 0.4–3.8, $n = 8$ cases).[245] Direct measurements of cobalt concentrations were not available.

Metallic Prostheses

Case reports of sarcomas at the site of hip implants and the induction of carcinomas in animal models by cobalt and chromium wear particles raised concern about the carcinogenic potential of MoM prostheses;[246,247] however, there is no clear epidemiological relationship between implanted cobalt material and specific cancer based on follow-up of total hip or knee arthroplasties ranging from 6 months to 17 years (mean = 7.5 years).[248] Initial data from population-based studies using standardized mortality rates,[249] United Kingdom National Joint Registry data,[250] and standardized incidence ratios,[251] do not suggest an increased incidence of cancer or cancer mortality in patients with total hip arthroplasties containing cobalt. Although local metal concentrations in some patients with unstable hip replacements are substantially higher than normal values, the occurrence of adjacent tumors (e.g., sarcomas) remains rare.[252] The risk of these tumors is not significantly elevated in patients with MoM hip implants when compared with standardized rates.[253] Biochemical studies of patients with loose or worn prostheses indicate some increased chromosomal aberrations and clonal expansion of lymphocytes may develop within 10 years of these implants, but no cellular transformation indicative of cancer occur.[254]

Limitations of existing epidemiological data on hip implants and cancer include insufficient follow-up period, lack of dose-response information, and the presence of confounding comorbidities (e.g., bone infarctions, hereditary bone dysplasia, osteomyelitis, rheumatoid arthritis). Although these epidemiological studies have not detected an increased risk of cancer in patients with MoM total hip arthroplasties, the follow-up periods are relatively short compared with the latency periods for solid tumors.[255] In a Finnish population-based study of 10,728 patients with metal-on-metal total hip arthroplasty and a non-metal-on-metal cohort (conventional metal-on-polyethylene, ceramic-on-polyethylene, ceramic-on-ceramic total hip arthroplasty) of 18,235 patients, there was no association of MoM hip arthroplasty with an increased overall risk of cancer during a mean follow-up of 4 years.[251] The standardized incidence ratio of the MoM cohort was 0.95 (95% CI: 0.85–1.04). A UK observational study of 40,576 patients with MoM hip replacements and 248,995 with alternative bearing surfaces detected no statistically significant increased incidence of all cancers, malignant melanoma, hematological cancer, prostate cancer, or renal tract cancer in the study population compared with the general UK population or patients with alternate bearing surfaces.[256] The mean follow-up period was 3 years with 23% of the cohort followed for 5–8 years.

DIAGNOSTIC TESTING

SI Conversion Units

1 μg/L = 0.017 μmol/L = 16.97 nmol/L
1 nmol/L = 0.059 μg/L
1 nmol/mmol creatinine ≈ 0.59 μg/g creatinine
1 ppm = 2.4 mg/m^3

Analytical Methods

Techniques used to analyze cobalt concentrations in samples include atomic fluorescence spectrometry, voltammetry, liquid chromatography, gas chromatography, neutron activation analysis,[257] and flameless atomic absorption spectrophotometry.[258] Although neutron activation analysis demonstrates good sensitivity and specificity, the procedure is costly and time-consuming. Graphite furnace (electrothermal or flameless) atomic absorption spectrophotometry (GF/AAA) was previously a common method to determine cobalt concentrations in serum and urine as a result of low detection limits (i.e., ~1 μg/L) and ease of use;[259,260] the LOD with Zeeman or deuterium background correction in urine samples is ~0.1 μg/L with an analytical precision of 13%.[261] In this method, the sample is heated to 2,000 °C in the graphite furnace to form an atomic vapor; the atoms cross a light beam that is specific to the element. Absorption of energy during ionization of the element reduces the intensity of the beam in proportion to the concentrations of the element.

Inductively coupled plasma/mass spectrometry (high-resolution or collision/reaction cell quadrupole ICP/MS) has the advantage of lower sensitivity than GF/AAS and the ability to process multiple elements simultaneously.[262] In this method, the sample is nebulized in a changer containing argon and high temperatures to dissociate and atomize the elements; a collection of electrostatic discs extracts the positively charged ions and transports them to a quadrupole mass filter that selects the ions based on mass and charge. The

LOD for cobalt measured in urine samples by inductively coupled plasma/mass spectrometry is ~0.01 μg/L; however, the presence of polyatomic interferences from $^{42}Ca^{2+}$ and $^{43}Ca^{2+}$ isotopes occurs at very low cobalt concentrations.[261] Results from different laboratories using ICP/MS may vary significantly. In a study of 2 laboratories receiving 45 duplicate whole blood samples for cobalt analysis using ICP/MS, the mean difference between the results was 0.52 ± 1.35 μg/L ($P = 0.012$).[263] Differential pulse cathodic stripping voltammetry is an alternate method for the determination of cobalt in blood and urine with LODs of 0.8 μg/L and 0.2 μg/L, respectively.[264] The most commonly used method for quantification of cobalt in environmental samples is GF/AAS (LOD = 0.02–0.5 μg/L).[265,266] Gamma-ray spectrometry allows the determination of radioisotopes of cobalt in environmental samples.[267]

Sample preparation (e.g., wet ashing) and/or pre-concentration may be necessary for the determination of cobalt in environmental samples. Wet extraction with dilute nitric acid is most suitable for analyzing cobalt in dust samples. The use of filtered and unfiltered samples allows the quantification of soluble and insoluble cobalt. Similar to biological samples, the use of polyethylene containers and acidification of the solution to the appropriate pH reduce cobalt loss. Trace element-certified collection tubes are the best method to store biological media for analysis; preferably, the collection tubes have no additives, heparin, or EDTA with the first draw used for another routine testing. Cobalt contamination in blood samples may occur from the use of disposable syringes or technical-grade anticoagulants.[21]

Biomarkers

A progressive reduction in the reported range of cobalt concentrations in the general population resulted from the improvement in analytical methods.[16] Significant exposure to cobalt occurs primarily in occupational settings because cobalt concentrations in the environment are usually low.

Blood

Most cobalt in the blood occurs in the serum with a relatively small amount in the erythrocytes. Substantial variability occurs in serum, plasma, and whole blood cobalt concentrations in the same sample; consequently, the values for the different types of blood samples are not interchangeable. The serum is usually preferred to plasma because the use of serum avoids the potential complications of using anticoagulants (e.g., red cell lysis during prolonged storage). In general, the cobalt concentrations in plasma and serum are higher than those in erythrocytes as a result of rate-limited uptake of cobalt into the erythrocyte. In a study of 246 concurrent specimens from patients with metal-on-metal (MoM) hip replacements analyzed by high-resolution/inductively coupled/plasma mass spectrometry, the mean difference between serum and whole blood cobalt concentrations was 0.84 μg/L with relatively greater variation at lower concentrations; the difference was statistically significant ($P < 0.0001$).[268] Regression analysis estimated a serum/whole blood cobalt ratio of ~1.4, but excessive interindividual variation and substantial variation with different Co concentrations (i.e., ±65%) limit the usefulness of this conversion factor. In a study of 29 patients with normal functioning unilateral hip prostheses (54-mm femoral Birmingham Hip, Smith & Nephew, London, UK) followed 5–29 months after implantation, most of the cobalt appeared in the serum and plasma fractions with lower cobalt concentrations in erythrocytes.[269] The mean cobalt serum/whole blood ratio was ~1.2 with serum containing about ~5 times higher cobalt concentration than erythrocytes with median cobalt concentration of ~1 μg/L. In 34 paired samples of whole blood and serum from patients with high carbon content Cr–Co alloy in their hip implants, the mean serum/whole blood ratio was 1.37 (range, 0.72–1.80) with the mean serum Co concentration ~2 times higher than erythrocytes.[270] The plasma and whole blood cobalt concentrations were similar in a study of 202 patients with MoM hip prostheses; the median whole blood cobalt concentration was 2.71 μg/L with a range of 0.18–145.73 μg/L compared with 2.31 μg/L with a range of 1.00–158.65 μg/L for plasma.[271]

General Population

The average serum and whole blood cobalt concentrations in the general population without occupational cobalt exposure is ~0.2–0.5 μg/L. In a study of urban adolescents in Sweden, the cobalt concentration in whole blood and serum averaged 0.31 μg/L (range, <0.2–0.9 μg/L) and 0.48 μg/L (range, <0.2–1.1 μg/L), respectively.[272] In a Swedish study of 25 volunteers without occupational exposure to cobalt, the mean whole blood cobalt concentration was 0.50 μg/L (range, 0.10–1.20 μg/L); there was no difference in the whole blood Co concentration between smokers and nonsmokers.[273] In a study of trace metals in a representative sample of 441 urban, suburban, and rural northern Italian residents, the mean whole blood cobalt concentration was 0.39 μg/L with a range of 0.01–0.91 μg/L compared with 0.21 ± 0.008 μg/L (range, 0.008–0.4 μg/L)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in serum as measured by atomic absorption spectroscopy and neutron activation analysis.[274] The mean whole blood cobalt concentration in 110 healthy urban residents in Rome was 0.12 ± 0.08 μg/L with a 95% CI 0.03–0.25 μg/L as measured by sector field/inductively coupled plasma/mass spectrometry.[275] The corresponding mean serum concentration was 0.19 ± 0.11 μg/L with a 95% CI 0.06–0.42 μg/L.

Therapeutic Use

In a study of four volunteers ingesting a liquid supplement containing 400 μg cobalt daily for 15–16 days, the whole blood cobalt concentrations at the end of the study were 1.8, 2.6, 4.7, and 5.1 μg/L (mean = 3.6 μg/L) as measured by inductively coupled plasma/mass spectrometry.[276] No adverse effects were reported. In a follow-up study of five women and five men receiving 1 mg Co in the form of liquid $CoCl_2$, the mean whole blood cobalt in men was 20 μg/L (range, 12–33 μg/L) compared with 53 μg/L (range, 6–117 μg/L) in women.[277] The mean serum Co concentrations were 25 μg/L (range, 15–46 μg/L) and 71 μg/L (range, 9–149 μg/L), respectively, in men and women. There were no clinically significant changes in biochemical or hematological tests; the T_4, TSH, hemoglobin, creatinine, and liver enzymes remained within normal ranges. The administration of 500 μg soluble $CoCl_2$ to 12 male volunteers produced a mean whole blood cobalt concentration of 2.0 ± 1.6 μg/L (90% range, 0.5–3.0 μg/L) at the end of the 10-day study compared with 7.55 ± 7.48 μg/L (90% range, 1.12–10.77 μg/L) in 11 female volunteers.[62] For 12 men receiving the 500 μg insoluble CoO, the mean whole blood Co concentrations were 0.20 ± 0.18 (90% range, 0.10–0.30) compared with 0.67 ± 0.3 μg/L (90% range, 0.20–1.01 μg/L) in 11 female volunteers. Fourteen hemodialysis patients received 25 mg cobaltous chloride daily for 4 weeks, then 50 mg daily for 4 weeks.[59] At the end of the clinical trial, the pre-dialysis serum cobalt concentrations ranged from 220–2,100 μg/L as measured by atomic absorption spectrometry. Three of the patients developed transient hearing loss detected by audiometry; there was no deafness, tinnitus, or hypothyroidism (i.e., baseline TSH concentration unchanged). Elevated whole blood cobalt concentrations may persist in hemodialysis patients treated with cobalt chloride. In a series of seven dialysis patients treated 13–20 months earlier with cobalt chloride, the whole blood cobalt concentration ranged from 3.1–138 μg/L (median, 6.7 μg/L) as measured by neutron activation analysis.[126] The median whole cobalt concentration in seven dialysis patients without cobalt treatment was 1.4 μg/L with a range of 0.9–3.9 μg/L.

Acute Toxicity

A 6-year-old boy drank a solution containing an estimated 2.5 g cobalt chloride; he developed abdominal pain and vomiting, but he was released 48 hours after admission without sequelae.[46] His serum cobalt concentration ~7 hours after ingestion was 426.6 μg/L (whole blood, 237.2 μg/L; method not reported). Two weeks later, the serum cobalt concentration decreased to 12.7 μg/L (whole blood, 8.9 μg/L). Approximately 4 weeks after the ingestion, the serum and whole blood cobalt concentrations remained ~5-fold above the upper reference range at ~5 μg/L. A 14-year-old girl presented to the emergency department ~12 hours after the ingestion of cobalt chloride from a chemistry set; she had vomited spontaneously several times before admission. Her serum cobalt concentration on admission was 77.9 μg/L as measured by atomic absorption spectrometry.[45] Her vital signs remained stable and asymptomatic; she recovered without sequelae after receiving supportive care and three doses of $CaNa_2EDTA$.

Metallic Prostheses

A variety of factors influence the metallic ion concentrations in patients with prostheses including implant material/design, position of implant, diameter of the bearings, and implant type. No single biomarker is specific for the development of adverse local tissue reactions following metal-on-metal (MoM) total hip arthroplasty; similarly, the blood cobalt/chromium ratio does not correlate closely with adverse effects.[278] The cobalt and chromium (but not molybdenum) concentrations in blood samples from patients with long-term MoM total hip prostheses substantially exceed values for the general population; however, correlating these values to the prevalence of adverse effects in patients with hip prostheses is a complex process including the determination of the existence of a threshold.[279] Some patients with high initial serum cobalt concentrations (e.g., 49 μg/L) during the running-in period may remain asymptomatic, and their serum cobalt concentrations return to more normal concentrations (e.g., 1.6 μg/L) after several years.[280] Postoperative cobalt concentrations usually stabilize over 6 months after a period of variability. An observational, non-randomized cross-sectional study analyzed intraoperative plasma, synovial, and CSF samples from 461 patients undergoing primary (controls) or revision hip/knee arthroplasty.[281] The cobalt concentration was quantifiable (>0.3 μg/L) in 42% of controls (range, 0.30–6.79 μg/L, $n = 106$), 76% of well-functioning implants (range, 0.30–27.67 μg/L, $n = 107$), and 98.5% of hip revisions (0.34–32.21 μg/L, $n = 64$). The reported CSF cobalt concentrations

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

were <1% of the synovial fluid adjacent to the joint replacements and <15% of plasma.

Total plasma or serum cobalt concentrations probably reflect both metallic cobalt wear nanoparticles along with free and protein-bound soluble cobalt ions, whereas erythrocyte cobalt reflects the free ionized cobalt (e.g., Co^{2+}) entering the erythrocytes during the lifespan of the red blood cells. Current data suggests that serum cobalt and chromium concentrations are useful biomarkers of excessive wear, localized tissue effects, and potential failure of hip implants when correlated to imaging (plain radiographs, metal artifact reduction sequence MRI, ultrasound) and clinical symptoms (localized pain, grinding sensation with activity, clicking with ambulation).[282]

Metal Concentrations Cobalt toxicity in patients with hip prostheses is a clinical diagnosis based on a constellation of clinical features including hip pain; there are no pathognomonic signs/symptoms of cobalt toxicity. The blood cobalt values must be interpreted in relation to the clinical presentation as the blood cobalt concentration alone is not pathognomonic of cobalt toxicity. Most patients have well-functioning joint implants with serum cobalt concentrations in the range of 2–3 μg/L; however, electrochemical corrosion and wear occur in all metallic joint replacements, resulting in the release of chemically active metallic ions and oxidative stresses on the prosthetic joint. The extent of elevated blood cobalt concentrations depends on a variety of factors including wear and alignment, corrosion, alloy composition, type of implant, renal function, analyticic method, type of sample (serum, whole blood), and femoral head size.[283] Although blood cobalt concentrations are usually elevated in the presence of adverse local tissue reactions (pseudotumors, necrosis, inflammation) and most of these patients demonstrate excessive wear on their implants, the high degree of variability of blood cobalt concentrations between these patients limits determination of a dose-response between wear, blood cobalt concentrations, and local tissue reactions.[284] In a study of 156 consecutive patients with a unilateral ASR XL total hip replacement and plasma cobalt concentration of >5 μg/L, the plasma cobalt concentration correlated to the presence of periprosthetic lucency on radiographs and pseudotumor on magnetic resonance imaging ($P < 0.05$), but not to the patients' symptoms.[285] All patients with high blood cobalt concentrations and high wear do not develop adverse reactions;[286] blood cobalt concentrations may be very elevated (e.g., >300 μg/L) in the absence of systemic toxicity.

In patients with well-functioning hip implants, an initial rise in metallic ion concentrations occurs during the first 1–2 years (i.e., "running-in" or "bedding-in" phase), followed by a steady-state phase with much-reduced wear rates and some reduction in blood cobalt concentrations.[175,287] In a 10-year prospective follow-up study of 10 patients with well-functioning metal-on-polyethylene total hip replacements, the mean serum cobalt concentration was ~3 times higher than baseline as measured by high-resolution sector field/inductively coupled/plasma mass spectrometry.[288] An analysis of 43 studies representing 16 different MoM implants with at least a mean follow-up of 1 year demonstrated average (mean or median) total cobalt concentrations in whole blood of 0.7–3.4 μg/L compared with 0.3–7.5 μg/L in serum.[289] This study did not detect any clear difference in chromium concentrations between the different implants; exclusion criteria included single case reports and bilateral implants.

Studies of patients with MoM implants undergoing revision of hip arthroplasties mostly for malposition of the hip replacement indicate that serum cobalt concentrations are an order of magnitude above reference values in these patients, whereas the elevation of serum chromium concentrations is significantly less. Most blood cobalt concentrations in patients with well-functioning MoM hip prostheses are 1–10 μg/L. After substantial increases (e.g., up to 1–7 Co μg/L) during the running-in period during the first 6–12 months after implant,[280] the cobalt concentration stabilizes without evidence of continuing accumulation as long as the implant remains well-aligned without excessive wear.[290] In a 5-year prospective study of 50 patients with Metasul® MoM total hip arthroplasty (Zimmer Biomet Warsaw, IN), the median serum cobalt concentration at 1 year was 1 μg/L compared with 0.7 μg/L at 5 years.[291] The highest serum cobalt concentration in 10 patients with a minimum of 5-year follow-up after metal-on-metal total hip replacement was 7.93 μg/L (median, 1.55 μg/L)[292] compared with 50.1 μg/L (median, 0.75 μg/L) in 22 patients followed a minimum of 10 years as measured by atomic absorption spectrometry.[293] The patient with maximum serum cobalt concentration of 50.1 μg/L had groin pain and an osteolytic lesion behind the acetabular component; she underwent implant head and liner exchange with the serum cobalt decreasing to 0.8 μg/L 5 months postoperatively.

The blood cobalt concentrations are typically lower in patients undergoing knee or ceramic-on-ceramic hip replacements than with MoM hip implants having similar length of the implant and wear. In a study of 41 patients with cemented unconstrained unilateral total knee arthroplasty without patellar resurfacing

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

implanted a median of 66 months prior to analysis, the median serum cobalt and chromium concentrations were 3.28 μg/L (maximum <8 μg/L) and 0.92 μg/L (maximum ~9 μg/L), respectively.[294] The implants had no evidence of excessive wear or osteolysis. The serum cobalt concentrations in the study group were ~10-fold higher than the control group. By comparison, the mean serum cobalt concentration in 28 patients followed for an average of 27 months (range, 16–49 months) after unilateral ceramic-on-ceramic (Co–Cr stem, short Ti modular-neck) total hip replacement was 1.21 μg/L (range, 0.8–2.0 μg/L).[295] All hip replacements were well-functioning.

The concentration of these metals in joint fluid is 1–2 orders of magnitude above serum concentrations. In a study of 26 patients undergoing revisions of hip replacement, the median serum cobalt and chromium concentrations were 5.8 μg/L and 13.2 μg/L, respectively.[296] The median ratio of joint fluid/serum concentration for cobalt was 36.5 (range, 8.3–699.1) and for chromium was 47.4 (range, 10.5–394.4). In this study, serum cobalt concentrations exceeding 19 μg/L (and serum chromium concentrations >17 μg/L) suggested the presence of metallosis. The serum cobalt concentration was below the limit of detection (0.3 μg/L) in all 50 patients with ceramic-on-polyethylene articulations. In this series, a patient with end-stage renal disease had a serum cobalt concentration of 119.2 μg/L compared with a mean serum Co concentration of 12.5 μg/L (range, <0.1–51.6 μg/L) in five patients with renal failure and no evidence of excessive wear or osteolysis.[297]

In a study of 132 patients with MoM implants followed for a mean of 7 years (range, 5–11 years), the median whole blood Co concentration remained relatively stable 4–5 years after implant near 2 μg/L (range up to ~4 μg/L).[298] Long-term studies (i.e., up to 36 years) indicate that these elevated values persist throughout implantation with the whole blood cobalt concentration becoming grossly elevated when excessive wear and osteolysis of the loosened implant occurs.[299,300] The whole blood cobalt concentration in 15 patients implanted with the Metasul® MoM prosthesis with a mean of 2.8 years (range, 2–4 years) prior to analysis, the mean cobalt concentration was 4.1 ± 1.5 μg/L (range, 1.3–6.3 μg/L) compared with 0.3 ± 0.1 μg/L in individuals with similar ages and without implants, as measured by electrothermal/atomic absorption spectrometry with Zeeman background correction.[301] The whole blood chromium concentration was similar between the two groups.

Clinical Correlation Clinical data correlating cobalt concentrations in the blood primarily involve case reports; therefore, the relationship between the prevalence of adverse effects in patients with MoM implants and elevated serum cobalt concentrations is not well-defined. Furthermore, existing serum cobalt data do not correlate closely with patient complaints because symptoms vary significantly between individuals. The UK Medicines and Healthcare Products and Regulatory Authority recommended whole blood cobalt and chromium concentrations of 7 μg/L as a value of concern for the potential development of local reactions and excessive wear from MoM hip prostheses;[302] this cutoff has moderate sensitivity and specificity. Blood ion concentrations alone are not the sole indirect screening test for the surveillance of symptomatic patients with MoM prostheses; reducing the cutoff increases sensitivity while decreasing specificity. In a retrospective review of 209 symptomatic patients with unilateral MoM hip arthroplasties, the median plasma cobalt concentration was 4.2 μg/L (range, 0.4–335.4 μg/L).[303] Using metal artifact reduction sequence MRI scans as the gold standard, the cutoff of 7 μg/L had a sensitivity of 57% (positive predictive value, 52%) and specificity of 65% (negative predictive value, 69%). Although the plasma cobalt concentration helps discriminate well-functioning from failed hip replacements, the plasma cobalt concentration does not reliably predict periarticular soft-tissue damage at the time of revision surgery. In a pair-matched, case-control study of 88 cases with a pre-revision, unexplained failed unilateral MoM hip implant and 88 matched controls with well-functioning unilateral MoM hip replacements, the sensitivity of a 7 μg/L cutoff for detecting a preoperative, unexplained failed MoM hip replacement was 52% with a specificity of 89%.[304] Lowering the cutoff to 5 μg/L increased the sensitivity to 63% while lowering the specificity to 86%.

Many patients with elevated serum cobalt concentrations and excessive wear of hip MoM implants have no or minimal (myalgias, fatigue) symptoms. In a retrospective review of 39 patients consulting medical toxicologists about the toxicological effects of hip implants, 11 patients had elevated cobalt and chromium concentrations without complaints; the maximum serum cobalt concentrations in this group were 132 μg/L.[187] The serum concentrations of these metals do not correlate well with systemic symptoms including neurological effects. The contribution of cobalt to these symptoms remains unclear because of the lack of symptoms in other arthroplasty patients with similar cobalt concentrations; however, cobalt toxicity is unlikely to occur in patients with well-functioning hip prostheses and low blood cobalt concentrations (<4 μg/L).[305]

Classic features of severe cobalt toxicity include hypothyroidism, polycythemia, cardiomyopathy, hearing/visual impairment, and polymyopathy. Rare case reports associate cardiac (e.g., dyspnea, heart failure) and neurological symptoms (e.g., myalgias, weakness, fatigue, metallic taste, cognitive decline) with dramatically elevated serum cobalt and chromium concentrations in patients with MoM total hip arthroplasty and periprosthetic inflammation.[184,306] These case reports typically occur following the revision of fractured ceramic prostheses with metal implants and the development of extremely high blood cobalt concentrations (i.e., >250–300 μg/L). Revision with MoP implants usually does not result in significantly elevated blood cobalt concentrations unless complicated by the retention of ceramic fragments and excessive wear. Rarely, corrosion of the modular head-neck junction of the MoP results in local pain and modestly elevated cobalt concentrations. In a series of 10 patients with adverse local reactions to the MoP prostheses, the mean serum cobalt concentration was 9.55 ± 12.73 μg/L (range, 1.60–42.45 μg/L).[307]

The serum cobalt concentrations in patients with hip arthroplasties and classic cobalt toxicity typically are very elevated (i.e., >250–300 μg/L).[179,181] A Czech case described the development of weight loss, distal paresthesias, hyporeflexia, gait disturbances, pericardial effusion, left ventricular hypertrophy, and subclinical hypothyroidism 20 months after replacing a fractured ceramic-on-ceramic hip prosthesis with a metal-on-metal prosthesis.[308] At that time, his serum cobalt and chromium concentrations were 506 μg/L and 14.3 μg/L, respectively. With the exception of the hearing impairment, the symptoms improved during chelation therapy despite persistently high serum cobalt and chromium concentrations (i.e., 40-fold above reference values). The improvement in symptoms occurred before the replacement of the metal prosthesis with a ceramic endoprosthesis 21 months after chelation began. Retained ceramic fragments were found during the revision. Severe cobalt toxicity also occurred following excessive wear from retained ceramic fragments in a patient with a metal-on-polyethylene implant. An otherwise healthy 46-year-old man developed severe wear on a metal-on-polyethylene hip implant as a result of retained fragments from a fracture of the polyethylene-ceramic sandwich acetabular liner of his left total hip replacement; he subsequently developed hypothyroidism, pericardial effusion, and fatal cardiomyopathy despite 2 weeks of chelation therapy.[166,179] His peak whole blood cobalt and chromium concentrations during his hospitalization were 6,532 μg/L and 23.6 μg/L, respectively.

Alternate explanations (e.g., diabetes, advanced age, recent stroke, morbid obesity) potentially account for some of the symptoms (e.g., cognitive decline) in case reports of elevated blood cobalt concentrations and systemic complaints. In a case report of a 73-year-old woman with a history of MoM implant 5 years previously, her declining cognitive function and memory loss occurred with a blood cobalt concentration of 24 μg/L.[306] Her age, depression, and a stroke 7 months prior to evaluation are alternate causes of her cognitive decline. A 49-year-old flight surgeon developed neuropsychiatric symptoms (mood swings, anxiety, irritability, loss of libido, depression, tinnitus, hearing loss, tremor).[185,186] His serum cobalt concentration 36 months after MoM hip arthroplasty was 122 μg/L. Subsequently, visual flashes and diastolic dysfunction occurred within 6 months before explantation; progressive improvement in mood, neurological symptoms, and cognition followed post-explantation, but fatigue and subtle visual field deficits persisted for 2 years after explantation. A review of systemic toxicity related to metal hip prostheses indicated the systemic features of this case report were unlikely to be associated with cobalt toxicity.[163]

Hard Metal lung Disease

This disease is not usually associated with any specific blood abnormalities; however, high serum immunoglobulins or autoantibodies occasionally may develop concurrently. *Ex vivo* lymphocyte transformation tests and patch testing for delayed hypersensitivity do not reliably diagnose cobalt-associated lung disease.

Urine

General Population

In a Swedish study of 25 volunteers without occupational cobalt exposure, the mean urine cobalt concentration was 0.41 μg/L (range, 0.10–2.24 μg/L).[273] The concentration of cobalt in urine was higher in smokers (mean = 0.6 μg Co/L) than nonsmokers (mean = 0.3 μg Co/L). In the US National Health and Nutrition Examination Survey NHANES III) study, the upper 95th percentile cobalt concentration was 8.3 μg/L urine as measured by inductively coupled argon plasma mass spectrometry.[309] In the 2009–2010 NHANES IV involving a representative sample of 2,848 individuals aged 6 years and older, the upper 95% was 1.40 μg/dL with a geometric mean Co concentration of 0.37 μg/L (95% CI: 0.341–0.398 μg/L).[310] The estimated upper 95% of Co in urine samples from 189 adult male and female Danish subjects was 1.38 μg/L (23 nmol/L) and 1.86 μg/L (31 nmol/L), respectively.[311]

Toxicity

Toxic cobalt concentrations in the urine are not well defined. The urinary Co excretion increases rapidly during the first 24 hours after exposure to large amounts of cobalt followed by a slower phase. A 33-year-old metal refinery worker sustained 40% burns from a hot, acidic mixture of nickel and cobalt salts.[312] The patient received a 5-day course of ethylene-diaminetetra-acetic acid (EDTA) beginning 24 hours after the injury; the urine cobalt concentration at the end of the first chelation was 175 µg/L. No obvious signs or symptoms of cobalt toxicity developed.

Abnormalities

Hard metal lung disease

Hard metal lung disease demonstrates the same radiographical and physiological features as other forms of interstitial lung disease except for small multiple nodules in the middle and lower lung zones that may appear initially on the chest X-ray.[199] Diffuse reticulonodular opacities or ground-glass infiltrates usually occur, particularly in the lower lung fields. In a case series of 23 patients with a pathological pattern of hard metal pneumoconiosis, the most common radiographic findings were ground-glass opacities (93%) and small pulmonary nodules (64%).[313,314] Histological features of giant cell interstitial pneumonia appeared in 17 of 20 (85%) surgical biopsies. Although giant cell interstitial pneumonia occurs in other diseases (hypersensitivity pneumonitis, usual interstitial pneumonia, sarcoidosis, nonspecific interstitial pneumonia), the presence of cannibalistic, multinucleated giant cells with a history of hard metal exposure and consistent imaging studies is characteristic of hard metal lung disease.[315] Fibrosis and honeycombing develop in advanced stages of the disease. Abnormalities on high-resolution CT scans of patients with hard metal lung disease include patchy lobular ground-glass opacities, reticulation, consolidation, centrilobular nodularity, and, in advanced disease, honeycombing.[316] Magnetic resonance imaging may reveal residual parenchymal activity before the presence of an abnormal chest X-ray.[317] Abnormalities on bronchoalveolar lavage (BAL) and transbronchial biopsy demonstrate diverse changes related to inflammation including multinucleated giant cells, fibrosis, excessive mast cells and eosinophils, and increased T cells with abnormal helper/suppressor ratios.[318] Although the presence of multinucleated giant cells is pathognomonic for hard metal lung disease, the absence of these cells in BAL does not exclude the diagnosis of hard metal lung disease.

The pulmonary changes associated with hard metal lung disease are not pathognomonic because these common abnormalities occur with other diseases including restrictive impairment, decreased diffusing capacity, resting hypoxemia, and oxygen desaturation with exercise; obstructive changes also may occur. Additionally, evidence of a restrictive impairment on pulmonary function tests may precede changes on the chest X-ray. A reduction in PaO_2 may also occur during exercise.

Neuropsychological testing of retired workers with hard metal lung disease suggests deficits may occur in encoding (allocation of attentional resources, short-term verbal memory) rather than retrieval (long-term memory) when compared with solvent and asbestos workers.[319] The presence of multiple confounders, potential selection bias, and the lack of exposure data limit conclusions regarding the effect of cobalt exposure on these neuropsychological parameters.

Hard metal asthma

Broncho-provocation tests with cobaltous chloride are the gold standard for determining the presence of hard metal asthma.[99] Positive reactions to bronchoprovocation challenges include early, late, and dual reactions. Patch and intradermal skin tests do not discriminate patients with hard metal asthma from controls in the general population.

Beer drinkers' cardiomyopathy

Hemodynamic studies of patients with beer drinkers' cardiomyopathy demonstrated low cardiac output, reduced myocardial compliance, and normal peripheral vascular resistance.[12] Elevated systolic pressure occurred in the right ventricle as a result of increased pulmonary resistance and increased left end-diastolic pressure. Although the patients frequently had sinus tachycardia, dysrhythmias were uncommon. The electrocardiograms demonstrated low voltage in the QRS segment and broad-peaked P waves with right axis deviation in the limb leads along with some nonspecific ST-T wave changes, whereas intraventricular conduction defects were rare. During the acute stages of illness, the serum bilirubin and hepatic aminotransferases were strikingly elevated along with the prothrombin time, suggesting concurrent liver disease.

Metallic hip prostheses

Elevated blood cobalt and chromium concentrations have not been associated with markers of renal dysfunction. In a cross-section study of 31 patients receiving

MoM implants 10 years earlier, median serum creatinine concentrations, creatinine clearance, and markers of tubular (retinol-binding protein, β_2-microglobulin), glomerular function (albumin), and microtissue damage (Brush Border antigen, *N*-acetyl-β-D-glucosaminidase) were similar to controls.[320] There was no dose-effect relationship between metallic ions and renal markers. In a retrospective Mayo Clinic review of 59 blood samples with serum cobalt concentration of >4.0 ng/mL, statistical analysis indicated no correlation between serum cobalt concentrations and erythrocyte counts.[321] The median serum cobalt concentration was 8.0 ng/mL with a maximum of 108 ng/mL. Almost all these samples were drawn from patients scheduled for total hip arthroplasty revisions.

HEALTH SURVEILLANCE

Risk Assessment

The US EPA has not published a chronic oral reference concentration (RfC) or a reference dose (RfD) for cobalt; however, with the last update in 2000, the EPA is currently evaluating this metal. Based on the development of decreased iodine uptake in a 10-week, multiple-dose study in children at 0.9 mg/kg/day,[322] a calculated chronic oral RfD of 30 μg/kg/day based on uncertainty factors of 10 for human variability and 3 for database adequacy.[323] The European Food Safety Authority guidance value for cobalt in food supplements is 600 μg daily,[324] whereas the United Kingdom Expert Group on Vitamins and Minerals recommends an upper limit of 1,400 μg daily to prevent adverse effects.[325]

The ATSDR MRL (minimal risk level) chronic-duration inhalation exposure is 0.1 μg Co/m^3 based on a NOAEL of 5.3 μg Co/m^3 for decreased respiratory function (FEV_1, FVC) in a cross-sectional study of 194 diamond polishing workers.[326] The MRL for intermediate-duration oral exposure is 10 μg/kg-day based on a LOAEL of 1 mg/kg-day for the development of polycythemia in human volunteers ingesting cobalt chloride.[49]

Environmental Monitoring

Typical ambient air cobalt concentrations in occupational settings vary widely; prior to the mid-1980s, these concentrations ranged from 10–1,700 μg/m^3.[19] The current US OSHA PEL–TWA is 50 μg Co/m^3 for cobalt metal dust and fumes compared with the ACGIH recommendation for the TLV–TWA of 20 μg Co/m^3. The TLV–TWA for cobalt carbonyl and cobalt hydrocarbonyl (C_4CoO_4) is 100 μg Co/m^3. The US NIOSH established an IDLH value of 20,000 μg Co/m^3. Although exposure to cobalt dust exceeding current workplace standards may cause restrictive or obstructive (asthma) disease, exposure to cobalt dust within current guidelines does not usually produce a significant reduction in pulmonary function. In a retrospective follow-up study of 582 Swedish hard metal workers, the age-related decline in FEV_1 was within the expected range of 20–30 mL/year in healthy nonsmoking adults.[327] The exposure to cobalt was below 50 μg/m^3 with the exception of the powder production unit 8 years before the study. A preliminary cross-sectional study of active workers, who volunteered for the study in a plant producing diamond-cobalt tools, demonstrated a moderate restrictive defect in the workers exposed >5 years to cobalt concentrations exceeding 50 μg Co/m^3.[328] Data associating cobalt exposure with obstructive lung disease are less convincing. A statistically significant reduction in FEV_1 occurred in hard metal workers exposed to an average concentration of 126 μg Co/m^3, suggesting that this concentration of cobalt exposure can produce chronic obstructive disease.[329] A cross-sectional study of 46 female Danish porcelain workers associated exposure to cobalt blue dyes with small airway obstruction ($\downarrow MEF_{50}$, $\downarrow MEF_{25}$), when compared with values during a plant shutdown.[220] However, there was no clear dose-response with intensity or duration of exposure. The post-shutdown pulmonary function tests obtained a median of 29 days after the shutdown also demonstrated a statistically significant increase in PEF and FEV_1 during cobalt exposure. These changes were not responsive to salbutamol. Table 10.3 lists regulatory and recommended limits for cobalt exposure.

Biological Monitoring

The exact concentration of cobalt in the urine and serum at which the risk of adverse effects is negligible is not well defined. Biological monitoring of cobalt provides objective data for the evaluation of changes in workplace practices and personal hygiene based on the amount of cobalt absorbed by workers.

Urine

The kidneys initially eliminate cobalt rapidly, but the urinary cobalt concentration gradually rises during the workweek as a result of a slower secondary elimination phase. In high-exposure groups, other routes of

TABLE 10.3. Guideline and regulatory limits for exposures to metallic cobalt and inorganic cobalt compounds.

Exposure Limit	Value
	OSHA
PEL–TWA[a]	100 μg Co/m^3 (metal, dust, fumes)
PEL-ceiling	None
PEL-acceptable maximum concentration (30-minute maximum during 8-hour shift)	None
	NIOSH
REL–TWA (10-hour)	50 μg Co/m^3 (metal, dust, fumes)
REL–STEL (15-minute)	None
IDLH (30 minute)	20,000 μg/m^3
	ACGIH
TLV–TWA (8-hour)	20 μg/m^3 (Co and Co salts as Co)
REL–STEL (15-minute)	None
BEI	Blood: 1 μg/mL[b] Urine: 15 μg/mL[b]
	US FDA
Bottled water allowable limit	None
	US EPA
RfC (chronic inhalation exposure)	None
RfD (chronic oral exposure)	0.3 μg Co/kg-day (Provisional)
EPA carcinogenic unit risk (oral, daily)	4.3/(mg/kg)
EPA carcinogenic unit risk (inhalation, daily)	2.4×10^{-3}/(mg/kg)[c]
MCL	None
	ATSDR
Oral intermediate (15–364 days)	10 μg/kg/day
Inhalation chronic (≥365 days)	0.1 μg/m^3

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; BEI = biological exposure indices; IDLH = immediately dangerous to life and health; MCL = maximum contaminate level; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; RfC = reference concentration; RfD = reference dose; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average; US EPA = US Environmental Protection Agency; US FDA = US Food and Drug Administration.

exposure (gastrointestinal, dermal) to cobalt reduce the correlation of urinary cobalt to cobalt concentration in the air.[330,331] After cessation of exposure to high cobalt doses in the work environment, the reduction of urine cobalt concentrations to values present in the general population may require weeks to months.[332] The use of multivitamins containing vitamin B_{12} may substantially increase the urinary cobalt concentration. Limited data suggest that a substantial portion of the total cobalt in urine is organic Co. Analysis of urine from five controls without occupational Co exposure demonstrated an inorganic/organic cobalt ratio of 1.3 compared with mean ratios of 2.05–2.8 in four groups of four hard metal workers with varying occupational Co exposures.[333] The analytical technique involved Chelex 100 resin chromatography with neutron activation analysis.

The correlation of urine cobalt concentration to the ambient air concentration of cobalt is variable depending on the solubility of the cobalt compound. Total urine cobalt concentration is a better measure of exposure to soluble cobalt compounds (metal, salts, hard metals) than insoluble cobalt compounds (e.g., cobalt oxides).[334] At low ambient air cobalt concentrations (<100 μg/m^3), the correlation between ambient air cobalt concentrations and urinary or blood cobalt concentrations is relatively good.[335] Studies of hard metal workers indicate that urine cobalt concentrations correlate to airborne Co concentrations. Based on the regression equations from these studies, end-of-shift, mid-week urinary cobalt concentrations of 7–15 μg/L occurred following exposure to airborne Co concentration of 20 μg/m^3, whereas airborne cobalt concentrations of 100 μg/m^3 correlated to an upper 95% cobalt concentration of 59–78 μg/L in end-of-shift, mid-week urine samples.[336] The use of dust respirators by 25 of the hard metal workers reduced the urine cobalt concentration by ~85%. Exposure of 26 hard metal manufacturing workers to a TLV–TWA of 100 mg Co/m^3 resulted in an average, end-of-week urine Co concentration of ~60 μg/L.[337] Smoking and alcohol consumption did not significantly affect the urine concentration of cobalt.[71]

A study of 122 cobalt refinery workers and 10 cemented tungsten carbide production workers exposed to the maximum PEL–TWA (50 μg Co/m^3) suggests ~32 μg Co/g creatinine post-shift Monday urine correlates to a soluble cobalt exposure at the maximum PEL–TWA.[334] The types of exposure were as follows: metallic cobalt, 35; cobalt salts, 2; and cobalt oxides, 15. In a review of data on workers exposed to soluble cobalt salts, the average urine cobalt concentration in post-shift-end-of-the-week samples following exposure to cobalt TWA airborne concentrations of 20 μg/m^3

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

and 50 μg/m^3 were 18 μg Co/g creatinine and 32 μg Co/g creatinine, respectively.[338]

The ACGIH recommends a BEI of 15 μg Co/L urine at the end of shift at the end of the workweek. Workers sensitized to cobalt may react to concentrations of cobalt much lower than non-sensitized workers. A cross-sectional study of 249 Belgian cobalt production workers did not detect any abnormal thyroid (serum TSH, free T_3, or T_4) or red cell parameters; the median urine cobalt concentration during the end of the fourth or fifth workday was 39 μg/g creatinine with a range up to 204.3 μg/g creatinine.[339]

Blood

Studies of hard metal workers suggest some correlation between blood cobalt concentrations and airborne Co concentrations. Based on the regression equations from these studies, airborne cobalt concentrations of 100 μg/m^3 correlate to an estimated upper 95% limit of whole blood cobalt concentrations of 5.7–7.9 μg/L.[336] The use of dust respirators by 25 of the hard metal workers reduced the whole blood cobalt concentrations by ~60%. A study of 40 cobalt foundry workers suggested that cobalt exposure to 50 μg/m^3 was associated with a mean serum concentration of ~2.5 μg Co/L.[340] The study did not report the solubility of the cobalt salts. A cross-sectional study of 249 Belgian cobalt production workers did not detect any abnormal thyroid (serum TSH, free T_3, or T_4) or red cell parameters; the median blood cobalt concentration during the workday was 1 μg/L with a range up to 32 μg/L.[339]

Medical Screening

The preplacement examination should focus on the evaluation of the respiratory tract (interstitial disease, asthma), skin, blood (polycythemia), and thyroid (thyromegaly). Laboratory examination should include chest X-ray and complete pulmonary function tests. Table 10.4 lists guidelines for the surveillance of hard metal workers. The specific guidelines necessary to monitor workers depend on the amount of exposure to dust from hard metals. Workers should be observed for the development of skin sensitization, hypersensitivity pneumonitis, and occupational asthma. Such workers should be referred to appropriate specialists for allergy testing. The development of interstitial lung disease (e.g., progressive reduction in pulmonary diffusion) in a worker exposed to cobalt indicates the need to terminate the exposure.

TABLE 10.4. Suggested guidelines for health surveillance of hard metal workers. (Adapted from Sabbioni et al.).[318]

Guideline	Examination
Pre-exposure clinical assessment	History/physical examination
	Clinical Lab: (CBC with differential, renal function)
	Lung function: spirometry, carbon monoxide diffusing capacity
	Methacholine challenge, if indicated
	Electrocardiogram
	Chest X-ray
	Urine cobalt concentrations (spot sample)
	Symptom questionnaire
Periodic assessment	History/physical examination (yearly)
	Lung function tests (yearly)
	Chest X-ray (every 3 years)
	Urine cobalt concentration (post-shift, end-week sample every 6 months)
	Symptom questionnaire (yearly)
Symptom questionnaire	Within the last year, have you had the following persistent symptoms:
	Nonproductive cough (during/after work)
	Sudden shortness of breath (during/after work)
	Shortness of breath with exercise
	Repeated episodes of mild fever or night sweats
	Unintentional weight loss
	Fatigue
	Skin rash
	Do you relate any of these symptoms to the workplace

TREATMENT

Treatment is primarily supportive. Cobalt chloride is a gastrointestinal irritant; most significant ingestions produce vomiting, and decontamination measures are usually unnecessary.

Chelation

Acute Toxicity

Clinical data on the efficacy of specific chelation agents are inadequate to determine guidelines for the use of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

these agents in acute cobalt intoxication.[341] Although the administration of $CaNa_2EDTA$ or NAC has reduced blood cobalt concentrations in single case reports, the use of these chelators depends on a careful analysis of risk, benefit, and the expected clinical course. A 14-year-old adolescent presented to the emergency department 12 hours after ingesting cobalt chloride and vomiting several times. Her serum cobalt concentration at admission was 7.8 μg/L.[45] After three intravenous doses of 1 g $CaNa_2EDTA$ during the next 10 hours, her serum cobalt concentrations decreased to 0.7 μg/L. She remained asymptomatic with stable vital signs. The case report included no clearance data. An experimental study of seven patients on chronic bimonthly EDTA chelation therapy and nine patients recently receiving EDTA chelation therapy reported no increased urinary cobalt excretion within the first 4 days after an infusion containing 89 μg Co.[342] Methodological flaws in the design of this study (e.g., no controls, lack of reporting on statistical analysis/kidney function/limits of quantitation, self-collection of urine samples) prevent determination of the influence of EDTA chelation of renal Co excretion.

Rat experiments suggest five daily chelation doses increase cobalt excretion following the administration of *N*-acetylcysteine (↑urine/fecal), EDTA (↑fecal), diethylenetriaminepentaacetic acid (↑urine, DTPA), and DMSA (↑fecal).[343] However, few human data confirm the clinical efficacy of these chelation agents. In a study of cobalt chloride intoxication in Sprague-Dawley rats, *N*-acetylcysteine administered immediately after the oral administration of an LD_{50} dose of cobalt chloride did not reduce mortality in the rats compared with controls (no antidote).[344] There are inadequate data to suggest any other regimen than standard doses of these chelating agents.

Hip Prostheses

There is no consensus on the treatment of elevated blood cobalt concentrations in patients with cobalt-containing hip prostheses including the use of chelation.[345] The UK Medicines and Healthcare Products and Regulatory Authority recommends a whole blood concentration of 7 μg/L as the level of concern for potential local reactions to metal-on-metal (MoM) cobalt-containing hip prostheses.[302] Actions recommended for patients above this value include whole blood cobalt analysis every 3 months and consideration for revision if the whole blood cobalt concentrations continue to rise. The US FDA does not recommend actions at a specific cobalt concentration in blood. The decision to replace the MoM prosthesis depends on clinical judgment based on symptoms, clinical course, cobalt concentrations, imaging (metal artifact reduction sequence magnetic resonance imaging, ultrasound), and orthopedic consultation.[346]

Asymptomatic Patients

Elevated blood cobalt concentrations in asymptomatic patients should be evaluated to exclude contamination and the ingestion of cobalt-containing compounds (supplements, medications). The specimens should be collected in metal-free collection tubes, analyzed by laboratories with substantial experience with metals, and serial analyses performed using the same laboratory and collection methods. Two asymptomatic patients with total hip replacements and elevated blood cobalt concentrations (i.e., 16.06 μg/L, 20.24 μg/L) received 100 mg *N*-acetylcysteine/kg/day for 10 days without complications.[347] The blood cobalt concentrations decreased by 86 and 45% from pre-chelation concentrations; however, the blood cobalt concentration rebounded in the latter patient and both patients were chelated after the cobalt concentrations were significantly declining from peak concentrations. The report did not document clearance rates.

Symptomatic Patients

Symptomatic patients with elevated blood cobalt concentrations should be referred to their orthopedist for evaluation of excessive wear with orthogonal plain-film radiographs of the hip; ultrasound and metal artifact reduction sequence MRI are indicated if the orthopedist suspects a malfunctioning hip prosthesis. Clinical laboratory examination in symptomatic patients includes complete blood count with differential, C-reactive protein, erythrocyte sedimentation rate, serum creatinine, blood urea, serum electrolytes, liver enzymes, total bilirubin, serum albumin, pro-time, and thyroid-stimulating hormone.

As in acute cobalt intoxication, there are inadequate data to recommend a specific chelator and when to administer the chelating agent to patients with hip prostheses and elevated blood cobalt concentrations. The decision to use chelation (NAC, $CaNa_2EDTA$, DMPS) depends on clinical judgment and a careful evaluation of the risks, benefits, the severity of symptoms, and the expected clinical course.

A 58-year-old woman developed visual loss, hearing impairment, generalized weakness, and sensory loss after replacement of her broken ceramic–ceramic coupling with a Co–Cr head.[348] She received weekly EDTA chelation during the 2 months before replacement of the hip prosthesis. Some rebound in plasma and whole blood Co concentrations occurred between chelations.

The plasma cobalt concentration decreased from ~280 to ~100 μg/L during this time, whereas the whole blood cobalt concentration decreased from ~600 μg/L to slightly <200 μg/L. The case report did not discuss the clinical course of the neurological symptoms or provide pharmacokinetic data to determine the amount of cobalt removed by EDTA chelation. Other case reports suggest the potential use of *N*-acetylcysteine[349,350] and DMPS;[308] however, results are variable and difficult to compare with the natural course of blood and urinary cobalt concentrations post-explantation, particularly when the blood and urinary cobalt concentrations remain extremely high despite chelation therapy. The definitive treatment for symptomatic patients with high blood cobalt concentrations is a revision of the hip prosthesis.

Supportive Care

Management of hard metal lung disease is also supportive following removal from exposure. Although several case reports document improvement following steroid therapy,[199] there is no proven pharmacological treatment for hard metal lung disease. Improvement in patients with hard metal lung disease occurred following the administration of corticosteroids (40–60 mg prednisone daily)[199] and cyclophosphamide (25 mg twice daily),[224] but these case reports do not confirm the effectiveness of these agents. Several patients with hard metal lung disease received lung transplants;[205] however, one patient developed recurrent lung disease in the transplanted lung.[351]

Chapter 11

COPPER

HISTORY

The cold working of native copper existed during the 9–7th millennia BC in western Iran and Anatolia.[1] Smelting became common by 3,500 BC with the production of relatively pure copper from oxidized low arsenic-containing copper ores. Although copper sulfide-containing minerals contain naturally high arsenic concentrations, the roasting process releases most arsenic into the air. Even though there are only marginal differences between tin bronzes and arsenical copper, tin bronzes dominated the commercial trade throughout the European and Middle Eastern world within 300–400 years. The reappearance of arsenic-copper artifacts occurred primarily during periods of trade disruption.[2] Presumably, the preference for tin bronzes (copper/tin ratio, 9:1) reflected the prominence of chronic arsenic toxicity and the subsequent ease in establishing a causal relationship between signs of arsenic toxicity and exposure to arsenic during the smelting of copper. Near the time of Christ, Assyrian, Egyptian, and Hindu alchemists prescribed copper compounds for a variety of human aliments.[3] In the past, copper sulfate was an anthelmintic agent, an astringent, and an emetic. Currently, rare cases of copper toxicity result from the use of "spiritual green water" for religious purposes.[4] In a Spanish study of human bones from different historical epochs, the peak copper concentrations occurred in bones from the Byzantine Period, whereas the copper concentrations in bones from the Neolithic Period and present-day samples were similar.[5]

Copper contamination of food and beverages may cause an acute gastrointestinal illness. Potential sources of copper poisoning include copper or brass vessels and rarely drinking water.[6] In India, copper is a popular suicidal agent. Discontinuation of the medicinal use of copper as an emetic resulted from case reports associating copper toxicity (hemolysis, acute hemorrhagic necrosis of the small bowel, hepatorenal failure) with the use of copper sulfate as an emetic.[7]

PHYSIOCHEMICAL PROPERTIES

Copper is a member of the third transition series (chromium, iron, cobalt, manganese, nickel, zinc) that occupies a position between nickel and zinc in Group 11 (Group Ib) of the periodic table; copper is a noble metal similar to gold and silver. There are two stable copper isotopes, ^{63}Cu and ^{65}Cu with natural abundances of 69.2% and 30.8%, respectively. Radioactive isotopes include ^{64}Cu and ^{67}Cu, but these isotopes have very short half-lives (12.7 hours and 61.9 hours, respectively). Useful physical properties of copper for industrial applications include appearance, alloying ability, low corrosion, malleability, and high thermal and electrical conductivity. Copper does not dissolve in acidic environments unless an oxidizing agent is present; the formation of a green layer of copper carbonate over the metal limits further oxidation. Copper sulfate forms bright blue crystals that contain five molecules of water (bluestone). Table 11.1 lists the identifying information and the physical properties of copper and copper sulfate.

TABLE 11.1. Identifying factors and physical properties of copper and copper sulfate.

	Copper	Copper Sulfate
Synonyms	Metallic copper	Copper sulfate; blue, Salzburg, or Roman vitriol; blue copperas
Chemical formula	Cu	$CuSO_4$
Molecular weight (g/mol)	63.546	159.61
Valence	0	+2
CAS RN	7440-50-8	7758-98-7
Color	Reddish	Blue
Physical state	Solid	Solid (crystals)
Odor	Odorless	Odorless
Boiling point (°C)	2567	650 (decomposes to CuO)
Melting point (°C)	1083.4	>200 (decomposes slightly)
Density (g/mL)	8.92	3.603 2.284 (pentahydrate)
Water solubility (g/dL)	Insoluble	320 (20°C)

Abbreviation: CAS RN = Chemical Abstracts Service Registry Number.

In the environment, copper usually occurs in the cupric (Cu^{2+}) state as well as in the 0, +1, +2, and rarely +3 valence states.[8] Cuprous ions (Cu^{+}) oxidize rapidly in aqueous solutions to cupric (Cu^{2+}) compounds and disassociate to metallic copper (Cu^{0}). Only insoluble cuprous compounds (e.g., CuCl) are stable in water. Divalent cupric oxide (Cu^{0}) is also insoluble in water; however, many other cupric compounds are soluble in water. Dissolution of these compounds in water frequently causes a blue or green discoloration of the water. The taste threshold of copper in water ranges ~1–5 mg/L; a slight blue-green color appears in the water when copper concentrations exceed 5 mg/L.[9]

Copper binds to metallothionein in the cuprous (Cu^{+}) state; cupric ions (Cu^{2+}) require reduction to cuprous ions prior to transport on metallothionein. Metallic copper is sparingly soluble in water, salt, and mildly acidic solutions, but strong acids (nitric, sulfuric) and basic solutions (ammonium hydroxide) dissolve this metal easily. Acidification of water increases the amount of copper leached from copper piping.[10] Copper sulfate is a strong oxidizing agent with an acidic pH (i.e., ~4) in concentrated solutions. Copper ions can oxidize hemoglobin to methemoglobin. Cupric ions bind easily to oxygen in organic ligands; organic compounds complex almost all copper present in the environment.[11] Cu^{3+} is a strong oxidizing agent that is not important industrially or environmentally.[12] Copper comprises about 40% of the mass of copper sulfate. Copper naphthenate is poorly water soluble, but highly lipophilic with moderately low volatility.

EXPOSURE

Production Process

The most important copper ores are chalcocite (Cu_2S), chalcopyrite ($CuFeS_2$), and malachite [$CuCO_3 \cdot Cu(OH)_2$]. Copper content of ore deposits ranges from 0.5–5% Cu by weight, whereas igneous and crystalline rock typically contain 0.01% and 0.0055% Cu by weight, respectively.[8] Other copper ores include azurite and bornite. Following the mining of the ore, the material is concentrated by crushing and flotation. Leaching of the remaining ore occurs followed by extraction of the remaining copper with ion exchange or solvent extraction. The smelting of chalcopyrite produces metallic copper via a two-stage process: 1) slag-forming stage – formation of iron oxides by oxidation of FeS and the subsequent combination of iron oxides with silica flux to form a slag and 2) copper-producing stage – oxidation of CuS_2 to form SO_2 and Cu^{0}. Copper sulfate is a by-product of copper production during the leaching of the ore with sulfuric acid. Metallic copper is the basis for most industrially important copper compounds; most copper metal is recycled.

Uses

Commercial

The primary use of copper is as a metal or as an alloy (brass, bronze, gun metal, Monel metal). Most metallic copper appears in electrical applications in construction, machinery, transportation, and ordnance, accounting for ~25% of Cu production. Agricultural uses (fungicides, algicides, nutritional supplements) account for the majority of copper sulfate production. Copper naphthenate is a constituent of fungicides and wood preservatives. Industrial uses include azo dye manufacturing, engraving, lithography, petroleum refining, water treatment, metal finishing, wood preservatives, and mineral froth flotation. Copper is a catalyst in the chemical industry and an important constituent of white gold and the newer nickel-tin and palladium alloys used for imitation jewelry.[13]

Medical

Dental applications of copper-based alloys (aluminum, cobalt, manganese, nickel, zinc) include the fabrication of dental bridges and crowns.[14] The addition of small amounts of platinum or palladium to high-copper amalgams reduces tarnish and increases durability.[15]

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Corrosion products of the copper amalgam following exposure to saliva include copper oxides, chloride oxides or hydroxides, chlorides, and sulfides.[16] These high-copper amalgams are less susceptible to corrosion compared with low-copper amalgams.

Copper is a constituent of intrauterine contraceptive devices; the release of copper from these devices is necessary for their contraceptive effects.[17] These devices contain about 100–150 mg Cu, which is approximately equivalent to the average total body burden of copper. The wearing of copper bracelets is a folk remedy for arthritis; currently, data do not support the efficacy of this remedy.[18,19,20] Spiritual water (green water) is an African cathartic used in rituals; the ingestion of this solution may cause hemolysis, renal failure, and death.[4] Samples of spiritual water contained copper concentrations of ~13 g/L.[21]

Copper oxide nanoparticles possess physical properties capable of improving energy conservation by enhancing fluid viscosities and increasing thermal conductivity. Industrial applications include use in high-temperature superconductors, batteries, gas sensors, solar energy converters, catalytic reactions, and lubrication.[22] Potential biomedical uses for copper nanoparticles include applications as antimicrobials, biocides, and nanocomposite coatings; however, evidence of injury to the liver, kidney, and spleen in rodents following ingestion of these nanoparticles and formation of reactive oxygen species in cell lines have limited their use.[23,24]

Sources

Copper is the third most prevalent trace element in animals and plants behind iron and zinc. However, acute copper toxicity is uncommon with the development of acute copper toxicity usually resulting from the contamination of food, water, or other beverages. Chronic copper toxicity (Wilson's disease, Indian Childhood Cirrhosis, idiopathic copper toxicosis) apparently results from a combination of genetic susceptibility and high copper intake. Experimental data suggest that these infants received a mean of 900 μg Cu/kg/day when their milk was boiled in brass vessels.[25] However, these diseases may develop in breast-fed infants without obvious sources of high copper intake.[26]

Air

Average copper concentrations in the atmosphere range ~5–50 ng Cu/m^3 in rural areas and ~30–200 ng Cu/m^3 in urban areas, depending on proximity to point sources (incinerators, power plants, smelters) of copper emissions.[12] A study of the air in several US industrial cities demonstrated fine (<1–2.5 μm) and coarse (2.5–10 μm) copper concentrations ranging <0.1–1,610 ng/m^3 and <0.1–224 ng/m^3, respectively.[27] Emission of copper into the air represents only a small fraction (i.e., ~0.4%) of the copper released into the environment; [28] these emissions result from both natural (windblown dust, volcanoes, forest fires, sea spray) and anthropogenic (nonferrous metal production, copper smelters, iron and steel production, municipal incinerators) sources.[29] In general, combustion processes produce copper in the form of fine particles (<1 μm) of oxides and elemental copper, whereas copper released from particulate matter (windblown dust) exists primarily as large particles (<10 μm) of copper compounds (carbonate, oxide, sulfate).[30] Airborne sampling at a distance of 13 km from a copper smelter in Chile demonstrated average copper concentrations for fine (<2.5 μm) and coarse (2.5–15 μm) copper particles of 66 ng/m^3 and 131 ng/m^3, respectively.[31] During the suspension of operations during a strike, the mean copper concentrations were 22 ng/m^3 and 50 ng/m^3, respectively.

Soil

The natural concentration in soil is ~6–80 ppm Cu (median ~25–30 ppm) by dry weight with higher concentrations near point sources.[8] Copper in tailings from copper mines and mills usually exists in the form of insoluble sulfides and silicates. Most of this copper is incorporated into mineral lattices; therefore, this copper is biologically inert. Accumulation of copper in soil may result from the application of copper-containing fertilizers or fungicides. An analysis of copper in US agricultural soil ranged from 0.3–495 mg/kg with the highest samples reflecting the use of copper fungicides and fertilizers.[32]

Water

The copper concentration in aqueous solutions depends on several factors including pH, the presence of competing cations, concentrations of compounds that complex organic and inorganic copper substances, and concentration of anions in insoluble cupric salts. The most important determinates of copper concentrations in drinking water from copper pipes are pH, the age of the system, and the standing time prior to water collection.[33] The presence of insoluble organic and inorganic copper compounds reduces the bioavailability of copper in drinking water. The median copper concentration in natural

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

water is ~4–10 μg/L with most of copper tightly bound to organic matter and not readily exchangeable.[12] Cuprous (Cu^+) ions are unstable in aqueous solutions unless the cuprous ion is present as an insoluble salt (e.g., Cu_2S, CuCN, CuF, CuCl). Most ionizable copper in aqueous solutions exists in divalent form.[34]

The average copper concentration in a study of runoff from 19 cities in the United States ranged from 1–100 μg/L with a geometric mean of 18.7 μg/L.[35] The majority of copper in water results from the natural run-off of copper from soil.[12] Municipal treatment facilities remove ~80% of the total copper in pre-treatment water; the copper concentration in effluent is usually <100 μg/L.[36] Dissolved and total copper concentrations in the water from 11 tributaries feeding Lake Michigan ranged 0.2–2.0 μg/L and 0.4–5.5 μg/L, respectively.[37] The acidity of the water affects the concentrations of copper leaching from point sources. In water discharged from a mine with large sulfide deposits, the copper concentration was below detection limits at pH >5.[38] Dissolved copper concentrations ranged from 0.12–13.5 μg/L at pH 3–4; the copper concentration at pH 2.4 was 190 μg/L. Sediment is an important reservoir for copper.

Diet

Food is the major source of copper for the general population; however, copper in drinking water may contribute significantly to the daily copper intake depending on the composition of the distribution lines and natural sources. The estimated mean daily intake of copper in the US population is <2 mg[39,40] compared with 0.8–1.8 mg with the estimated upper 90 percentile ranging from 1.1–2.2 mg in European populations.[33] A study of 11 healthy adult men demonstrated that the ingestion of slightly less than 0.8 mg Cu daily was sufficient to maintain copper balance during the 42 days of the study.[41] The copper concentrations in food and beverages vary widely depending on the type of processing (i.e., use of copper vessels), growing conditions (soil, use of copper-containing chemicals), and the food product. Copper concentrations in food range from 0.2–44 ppm by wet weight.[9] Foods relatively high in copper content include cereals, mushrooms, dried fruits, legumes, whole-cereal-grain products, peanut butter, nuts, organ meats (liver), and shellfish (crustaceans, oysters). Copper concentrations in freshwater typically are low compared with seawater, where fish and shellfish harvested from the ocean floor contain higher copper concentrations than fish inhabiting shallow waters.[42] In a study of eight species of freshwater fish collected in the US National Contaminant Biomonitoring Program in 1978–1979, the copper concentration in whole fish ranged 0.25–38.75 ppm by wet weight with an average of 0.68–0.86 ppm by wet weight.[43] Meat and dairy products generally contain low copper concentrations; however, boiling milk in a copper vessel results in the binding of copper to the main milk protein (casein).[25] The acidic environment of the stomach liberates copper from the casein; this process allows the rapid absorption of copper present in milk. The acute ingestion of liquid containing concentrations >30 ppm Cu produces gastrointestinal irritation (nausea, vomiting, abdominal pain).[44]

Copper in drinking water is a relatively minor source of copper for the general population.[33] At an average concentration (0.13 mg Cu/L drinking water), drinking water contributes about 6–13% of the average daily intake of copper.[39] Copper from pipes in the water distribution system may contribute up to 1 mg Cu daily to copper intake depending on the acidity of the water, softness of the water, and the extent of copper pipes and brass faucets. The biological significance of this amount of copper depends on its bioavailability. A mail survey suggested that copper-contaminated water caused a gastrointestinal illness among residents of recently remodeled homes in an area where the water supplies were naturally corrosive.[45] However, there was no clear dose-response relationship between the copper concentration in "first draw" tap water and the presence of gastrointestinal symptoms. Water left overnight in these fixtures may contain up to 60 mg Cu/L.

Lifestyle

Alcoholic beverages typically contain low copper concentrations, and the contribution of alcoholic beverages to the total copper intake is minor.[33] A rare case reports associated copper toxicity mimicking Wilson's disease (fulminant hepatic failure, encephalopathy, rhabdomyolysis) with the chronic ingestion of multiple nutritional, weight-loss, and performance-enhancing supplements by a 32-year-old bodybuilder.[46]

Medical Use

The rate of copper loss from copper-containing intrauterine devices (IUDs) depends on the time in the body as well as the weight and surface area of the IUD.[47] Oxidation of the copper and the deposit of calcium limit the amount of copper released from the IUD. During the first month following insertion, mean doses of copper released from IUDs with a surface area of 100–400 mm^2 ranged from 26–74 μg/day.[48] Over the course of 10 years, the loss of copper from a Copper T averages ~8 μg/day for IUDs covered with calcareous deposits and 23 μg/day for devices without visible coating.[49]

ENVIRONMENTAL FATE

Air

In the air, copper exists as particulate matter or a complex of copper and particulate matter. The fate of copper released into the atmosphere depends on particle size, wind velocity, and source characteristics. Dry disposition, rain, snow, and gravitational settling remove copper from the air. Generally, gravitational settling governs the dispersion of large particles (>5 μm), whereas dry and wet deposition remove smaller particles. Combustion produces sub-micron particles containing copper oxides that may remain in the troposphere for up to 30 days, traveling far from the source of the particles.[12]

Soil

Copper deposited in soil adsorbs strongly to clay minerals, iron and manganese oxides, and organic material. Copper usually remains in the upper few centimeters of soil. Factors that influence the fate of copper in the soil include soil composition (clay, silt, sand), distribution of organic matter, pH, oxidation-reduction potential, presence of bases in the soil, and cation exchange capacity.[8] The binding of copper to ligands in the soil is stronger than that of other metals; therefore, the movement of copper in soil is less influenced by pH compared with other metals.[50] Sandy soils with low pH possess the greatest potential for leaching copper.[51]

Water

The fate and bioavailability of copper in water depend on a variety of factors including pH, oxidation-reduction potentials, oxygen concentrations, bioaccumulation, adsorption to water contaminants (clays, metal oxides, particulate organic matter), and the presence of complexing agents (inorganic and organic ligands). The physiochemical form of copper influences these processes, particularly speciation.[8] Soluble cuprous ions are unstable in water; these ions form cupric compounds and metallic copper complexes, whereas insoluble cuprous compounds (cyanides, fluorides, sulfides) are stable in water. The divalent state (cupric) is the most common valence of copper in water; this ion commonly forms complexes with ammonia, chloride, carbonate, and hydroxide ions. The following species predominate at the following pH: cupric ion below 6; $CuCO_3$, between 6–9.3; and aqueous $[Cu(CO_3)_2]^{2-}$, ion between 9.3–10.7.[52] Copper also forms stable complexes with organic ligands (e.g., humic acids). Near the surface of sea water, almost all (i.e., up to 98%) copper appears in the form of complexes with organic compounds.[53] Sediment is an important reservoir for copper with relatively clean sediment containing <50 ppm Cu and polluted sediment containing several thousand ppm Cu.[12] Iron oxides and humic substances most frequently bind copper in sediment, and such tightly bound copper exerts little biological effects.

Bioaccumulation refers to the net uptake of copper by microorganisms, plants, or animals from sediment, soil, and water in their environment, as well as from their diet. The bioaccumulation of copper from the environment depends on the species of copper and the variety of factors listed above that affect the physiochemical form of copper.[54] The bioaccumulation of copper varies widely between different organisms and between various organs within an organism.[55] High copper concentrations may develop in certain animals and terrestrial plants that are exposed to copper with high bioavailability. However, many organisms are capable of regulating their body burden with copper. Bioconcentration within aquatic organisms refers specifically to the uptake from water. The bioconcentration factor (10–100) of copper in fish is low, but filter feeders (e.g., molluscs) possess high factors (i.e., up to 30,000).

Biomagnification of copper implies that the copper concentration increases in animals at progressively higher levels in the food chain. To date, there is no evidence of biomagnification of copper in the food chain.[56] A study of bottom-feeding fish (white suckers, brown bullheads) from two acidic New York lakes that received elevated loads of copper did not detect elevated copper concentrations in muscle tissues from these fish.[57] The average copper concentration in their muscles was 0.85 and 1.2 ppm. The ratio of copper in the food to the copper concentration in tissue (i.e., the biomagnification ratio) was <1. Similarly, evidence of bioaccumulation was not apparent in a study of fish from copper-contaminated lakes in Canada[58] or in a study of rabbits grazing on land contaminated with sewage sludge from a copper mine.[59]

DOSE EFFECT

Acute Toxicity

Humans

The adult emetic dose of copper sulfate is 0.25–0.5 g copper sulfate, expressed as Cu. Toxic copper concentrations may occur after the ingestion of doses exceeding 1 g Cu.[7] The ingestion of beverages or foods containing ≥25 mg Cu/L has been associated with acute

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

gastroenteritis.[60,61] An 18-month-old child developed hemolytic anemia (Hgb = 5.6 gm/dL) and renal tubular damage (hematuria, glycosuria, proteinuria with a normal serum creatinine level) after the estimated ingestion of 3 g cupric sulfate (~120 mg elemental Cu/kg).[62] Copper sulfate is ~40% Cu by weight. Massive hemolysis and renal dysfunction developed in an adult ingesting an estimated dose of 175 g copper sulfate (70 g Cu).[63] Transient hepatic dysfunction and rhabdomyolysis occurred in an adult after ingesting an estimated 250 g copper sulfate despite chelation.[64]

Animal

In animals, the maximum tolerated dose is ~250 mg Cu/kg/day.[65] Copper ingestion exceeding this dose produces extensive hepatic centrilobular necrosis. The toxicity of copper is dependent on the animal species and the type of copper compound. Sheep are the most sensitive species,[66] whereas mice are more resistant to the toxic effects of cupric sulfate compared with rats.[67] Dogs are more susceptible to copper overload compared with humans as a result of differences in copper metabolism.[68]

Chronic Toxicity

Adults tolerate daily Cu doses of 8–10 mg for up to 12 weeks without significant toxicity including normal serum hepatic aminotransferases and biomarkers of oxidative stress.[69,70] The estimated absorption of 7.7 mg Cu after an explosion of copper azide causing multiple lacerations did not produce evidence of copper toxicity in a 55-year-old chemist.[71] The peak serum copper concentration 4 days after the explosion was 1.23 mg/L. The chronic consumption of drinking water containing excessive copper concentrations based on an early morning sample demonstrating 7.8 mg Cu/L was associated with the development of acute gastrointestinal symptoms (nausea, vomiting, abdominal pain) that resolved after cessation of drinking the contaminated water.[6]

TOXICOKINETICS

Absorption

Ingestion

The absorption of copper from the intestines depends on a number of factors including the following: 1) chemical form of copper (e.g., acetate, gluconate, and sulfate salts of copper are more easily absorbed than copper oxides);[8] 2) dietary components (fiber, fats, organic acids); 3) interaction with other metals, particularly zinc and cadmium; 4) pH; and 5) inversely proportional to the amount of copper in the stomach.[72,73] Metabolic studies suggest that copper retention is small (0.06 mg/day) following copper intake of 1.6 mg daily, whereas the retention increased (0.67 mg/day) following copper ingestion of 7.1 mg daily.[74] These values are based on evaluation of nine men on a metabolic research unit. The gastrointestinal tract absorbs ~60% of an ingested dose of ^{64}Cu as the acetate salt, but interindividual variation was large (15–97%).[75] The absorption of copper from the diet was ~65–70% of the dietary intake (~1 mg Cu/day) as measured by flame atomic absorption spectrophotometry.[76]

Animal studies indicate that most absorption of copper from the diet occurs in the small intestine where metallothionein compounds bind most Cu in the cytosol of the mucosal cells.[72] Metallothionein compounds are small, cysteine-rich proteins that store divalent metal ions (e.g., Cu^{2+}, Zn^{2+}, Cd^{2+}, Mn^{2+}). Elevated zinc concentrations enhance the formation of intestinal metallothionein, which blocks copper absorption by the formation of complexes with copper in the intestinal cells.[77] This mechanism and the potential re-distribution of copper in the liver account for the use of zinc in the treatment of Wilson's disease.[78] The amount of copper stored in the body does not affect the absorption of copper; a clinically significant reduction in copper absorption does not occur following the ingestion of zinc concentrations (<15 mg/day) near the Recommended Dietary Allowance.[79] Animal studies suggest that high dietary levels of ascorbic acid may reduce the amount of copper absorbed from the diet.[80] Metallic copper is insoluble; therefore, the absorption of metallic copper from the gastrointestinal tract is probably small. The absorption of copper from the ingestion of 275 US coins (174 pennies) was sufficient to cause fatal copper poisoning.[81]

Inhalation

Little data are available on the absorption of copper from the lungs. The occurrence of metal fume fever during the volatilization of copper metal indicates that the lung absorbs some copper, but the incidence of copper-induced metal fume fever is low because of the high temperatures required to volatilize copper.[82]

Dermal

Little data are available on the dermal absorption of copper compounds; however, case reports indicate that

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. copper sulfate[83] and copper azide[71] can be absorbed through damaged skin after prolonged exposure.

Distribution

The body tightly controls copper homeostasis through a complex system of chaperone proteins and copper transporters. Following copper absorption from the stomach and duodenum, albumin and amino acids loosely bind copper during transport in portal blood. The liver releases copper attached mostly to ceruloplasmin. This α_2-globulin binds ~95% of the serum copper, whereas the remainder forms complexes with albumin and certain amino acids (e.g., histidine) in the serum.[84] The copper-albumin complex represents the toxicologically active ("free") portion of the serum copper.[85] Membrane-bound proteins (copper transporters) mediate the cellular uptake and export of copper. Within the cells, copper binds to cytoplasmic transport proteins (copper chaperones) that deliver the copper to specific cytoplasmic compartments and target proteins. Consequently, very little unbound ionic copper exists in man except in the stomach. In acute poisoning, excess copper binds to albumin rather than ceruloplasmin. The liver is the major site of deposition of copper following a large ingestion with most of the copper bound to metallothionein.

The estimated total body burden of copper is ~70 mg with ~1/3 of this amount in the liver and brain.[86] Under normal conditions, the highest copper concentrations occur in the bile, liver, brain, heart, and kidneys. However, ~50% of the total body burden of copper resides in bone and muscle because of their large mass.[87] The mean copper concentration in 35 postmortem sternum samples was 0.59 μg/g wet weight with a range of 0.18–5.17 μg/g wet weight.[88] In samples of ribs from autopsies of 19 individuals, the copper concentration was 5.1 ± 2.6 μg/g dry weight.[89] The copper content in normal adult livers ranges from ~18–45 mg/g dry weight. The liver releases large quantities of copper in the blood at concentrations exceeding 50 mg/g dry weight when liver necrosis occurs.[81] This release of large amounts of copper by the liver causes the rapid accumulation of copper in erythrocytes, resulting in the subsequent production of oxidative damage to the red blood cell. The average total body burden of copper in men ranges from ~50–120 mg.[90]

Elimination

Figure 11.1 outlines the elimination of copper from the human body. Biliary excretion is the major route of elimination for copper; animal studies indicate that little resorption of biliary copper occurs.[42,92] In volunteer studies, urinary excretion of copper accounts only for ~3% of copper absorbed from normal diets.[85] The biological half-life of copper in the blood after the ingestion of 0.29 mg ^{67}Cu ranged from 13–33 days as measured by flame atomic absorption spectrophotometry.[76]

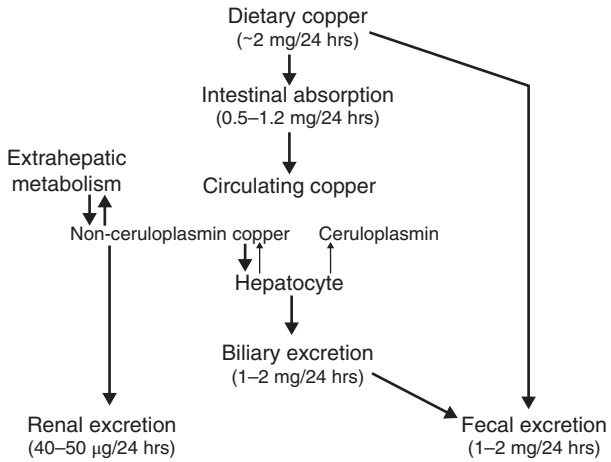

FIGURE 11.1. Elimination of copper from the human body. (Data from Schilsky).[91]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Copper is an essential trace metal for all biological organisms from bacteria to mammalian species, where copper content ranges from parts per billion (ppb) to parts per million (ppm).[93,94] In humans, copper catalyzes processes in heme synthesis and iron absorption. After iron and zinc, copper is the third-most abundant trace element in the body. The liver is the main organ responsible for copper homeostasis with uptake of copper into the hepatocytes via copper transporter 1. Redox reactions involving copper occur in the synthesis of melanin, cross-linking of collagen, and mitochondrial respiration. A class of proteins called copper chaperones facilitates the intracellular transport of copper to copper-dependent enzymes. The copper chaperone, ATOX1 delivers copper to ATP7B (Wilson's disease protein). ATP7B facilitates the transport of copper into the trans-Golgi and holo-ceruloplasmin as well as into vesicles for export of copper into bile under conditions of copper excess. Copper is a cofactor in the redox function of a variety of cellular enzymes involved in growth and development as a result of the

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

property of copper to be an electron donor or acceptor. Copper-dependent enzymes include Cu/Zn superoxide dismutase, ceruloplasmin, amine oxidase, cytochrome-c oxidase, dopamine-β-hydroxylase, tyrosinase, lysyl oxidase, peptidyl-β-amidase, *S*-adenosylhomocysteine hydrolase, and protein-lysine-6-oxidase. These enzymes regulate numerous cellular functions including oxidative phosphorylation, electron transport in the mitochondria, bioactivation of peptide hormones, melanin production, cross-linking of collagen and elastin, formation and maintenance of myelin, detoxification of free radicals, iron transport, blood clotting, and biosynthesis of catecholamines as displayed in Table 11.2.[95] Clinical manifestations of copper deficiency occur primarily in low-birth-weight infants and young children on diets with inadequate copper content; these patients have hypochromic anemia unresponsive to iron and boney abnormalities (osteoporosis, impaired/abnormal bone growth, pathological fractures) similar to scurvy.[12] Other clinical features of copper deficiency include cardiac dysfunction, increased low-density lipoprotein and decreased high-density lipoprotein cholesterol, decreased methionine and leucine enkephalins, decreased erythrocyte copper-zinc superoxide dismutase, decreased glucose clearance, and posterior cord syndrome.[96]

TABLE 11.2. Copper-containing enzymes and their functions. (Adapted from Stern).[93]

Enzyme	Function
Amine oxidases	Group of enzymes oxidizing primary amines (e.g., tyramine, histidine)
Ceruloplasmin (ferroxidase I)	Multi-copper oxidase in plasma, essential for iron transport and copper transport
Cytochrome c oxidase	Terminal oxidase enzyme in mitochondria respiratory chain, involved in electron transport
Dopamine β-hydroxylase	Involved in catecholamine metabolism, catalyzes conversion of dopamine to norepinephrine
Hephaestin	Multi-copper ferroxidase, involved in iron transport across intestinal mucosa into portal circulation
Lysyl oxidase	Cross-linking of collagen and elastin
Peptidylglycine *n*-amidating monooxygenase (PAM)	Multifunctional enzyme involved in maturation and modification of key neuropeptides (e.g., neurotransmitters, neuroendocrine peptides)
Superoxide dismutase (Cu, Zn)	Intracellular and extracellular enzyme involved in defense against reactive oxygen species (e.g., destruction of superoxide radicals)
Tyrosinase	Enzyme-catalyzing melanin and other pigment production

Mechanism of Toxicity

Under conditions of excess copper, redox cycling potentially generates unbound ionic copper, hydroxyl radicals, and oxidative damage along with the displacement of other essential metal cofactors from metalloenzymes.[97] These reactions are similar to the production of oxidative stress and cellular damage (DNA, lipid, protein) from the generation of hydroxyl radicals by the effect of Fe^{2+} on H_2O_2 (Fenton and Haber–Weiss reactions). The copper excess inhibits sulfhydryl groups on enzymes (glucose-6-phosphatase, glutathione reductase), which protect cells from damage by scavenging free radicals. Inhibition of glucose-6-phosphatase leads to hemolysis by the oxidation of the sulfhydryl groups in hemoglobin; increased cellular permeability also results from the inhibition of the Na^+/K^+ ATPase pump. Although copper toxicity is usually associated with the initiation of oxidative damage from free copper-induced reactive oxygen species, other cellular events may contribute to toxicity including alteration of cellular processes (e.g., gene expression, neuronal Cu-protein interactions, hepatic Cu distribution, ceramide release following activation of acidic sphingomyelinase, α-synuclein aggregation).[98] Case reports associate hemolysis and methemoglobinemia with the increased generation of reactive oxygen species.[99]

During acute copper poisoning, erosion of the epithelial lining of the gastrointestinal tract occurs along with centrilobular necrosis of the liver and acute tubular necrosis in the kidney. Copper causes direct damage to the proximal renal tubules, and acute tubular necrosis occurs following copper poisoning in the absence of hypotension or severe hemolysis.[100] Detoxification mechanisms for copper include reduction of copper uptake, enhancement of copper excretion, and sequestration of copper in the body. In mammals, sequestration by copper-binding metallothionein proteins and export via copper-translocating ATPases contribute to copper detoxification.[101] Metallothionein is a cysteine-rich, low-molecular-weight protein that binds to copper and provides some protection against copper toxicity. In acute copper toxicity, formation of metallothionein occurs early in the liver and kidney.[102]

Pathological Changes

Copper Poisoning

Cupric sulfate is a gastrointestinal irritant that causes erosion of the lining of the gastrointestinal tract, a striking blue-green discoloration of the mucosa, and hepatorenal failure.[103] Histological changes in acute

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. copper poisoning are nonspecific. Glycogen accumulates in the nucleus and cytoplasm, resulting in fatty degeneration of the liver.[62] Hepatocellular necrosis is the predominant pathological change in the liver following copper toxicity. Copper may also accumulate in periportal hepatocytes following chronic cholestasis drug therapy (e.g., chlorpromazine).[104] Severe chronic copper poisoning has been associated with fatty metamorphosis and portal fibrosis with intralobular extension.[81] The primary changes in the kidney involve necrosis of the tubular epithelium, edema of the medulla, and occasionally the appearance of eosinophilic casts.[102] Histological changes associated with copper toxicity and intravascular hemolysis include anisocytosis, echinocytosis, poikilocytosis, pyknocytosis, intracellular precipitation of hemoglobin, microspherocytosis, and basophilic stippling.[105]

Wilson's Disease

Ceruloplasmin is a copper-containing glycoprotein synthesized primarily in the liver; the main function of this glycoprotein is a ferroxidase for the mobilization of tissue iron. Ceruloplasmin binds ~90% of serum copper. Wilson's disease is a rare autosomal recessive, inherited metabolic disease of copper metabolism that results from alterations in the gene designated *ATP7B* on chromosome 13.[106] *ATP7B* encodes a transmembrane copper-dependent ATPase located intracellularly; the ATP7B protein transports copper into the trans-Golgi network prior to incorporation into ceruloplasmin and into vesicles that merge with bile canaliculus, resulting in biliary copper excretion. A rare genetic abnormality in *ATP7B* produces chronic copper toxicity by causing a defect in a copper-transporting, adenosine triphosphatase. Low ceruloplasmin concentrations allow the accumulation of large amounts of copper first in the liver and then in the brain and other organs. Normally, the liver excretes most excess copper in the bile with very little urinary copper excretion. The incorporation of copper into the six binding domains of ceruloplasmin and the excretion of copper in the bile require the action of Wilson Cu-ATPase (ATP7B). The *ATP7B* gene resides in the trans-Golgi network of hepatocytes and contains a transduction domain (ATP hydrolysis to cation transport), a cation channel, and a phosphorylation domain, in addition to the six copper-binding domains. The accumulation of copper in the liver, brain, and other organs results from the inability of the liver to excrete copper in the bile, resulting in a progressive neurological and hepatic degenerative disorder. Low plasma ceruloplasmin concentrations and increased urinary excretion of copper characterize Wilson's disease.

Pathological changes in Wilson's disease involve cellular injury, apoptosis, and fibrosis that rarely present before age 6 years and progress to advanced stages of the disease.[107] Early changes of Wilson disease include microsteatosis, macrosteatosis, and glycogenated nuclei, along with diffuse cytoplasmic copper accumulation that is detectable only with special immunohistochemical stains for copper. Ultrastructural abnormalities include enlargement and separation of the mitochondrial inner and outer membranes, increased density and granularity of the matrix, widening of the intercristal spaces, and the presence of large vacuoles. These ultrastructural changes are characteristic of Wilson's disease in the absence of cholestasis; these changes are usually present only during the early stages of fatty infiltration.[108] Wilson's disease progresses to an intermediate stage characterized by mononuclear infiltrates, periportal inflammation, lobular necrosis, and bridging fibrosis similar to autoimmune hepatitis.[109] Mallory bodies may be present in areas of cirrhosis. Nonspecific mitochondrial abnormalities produce dense copper-containing lysosomes; however, the absence of histochemical evidence of copper excess does not exclude the diagnosis of Wilson's disease. The intermediate changes of Wilson's disease invariably progress to a micronodular or a mixed macronodular–micronodular cirrhosis in untreated patients.[91] Later, neuronal cell death occurs in the basal ganglia, cerebellum, and spinal cord.[110] Kayser–Fleischer rings are the only clinical sign unique to Wilson's disease.

Menkes Disease

Menkes disease is an X-linked disorder of copper deficiency that results from the intracellular entrapment of copper in the intestinal wall. This rare disease (1/200,000 live births) affects mostly boys and includes the following three clinically distinct copper deficiency disorders: 1) Menkes disease 2) occipital horn syndrome and 3) mild Menkes disease. Male children with Menkes disease are profoundly deficient in copper; these patients rarely live beyond the age of 3–4 years as a result of rapid central nervous system degeneration.[111] Clinical features of this disease (also known as kinky hair disease) include 1) impaired synthesis of collagen and elastin from reduced lysyl oxidase activity 2) coarse, kinky hypopigmented hair secondary to tyrosinase deficiency and poor cross-linking of keratin; 3) diffuse brain atrophy; and 4) severe mental retardation. These patients have loose skin, pathological fractures, and aortic aneurysms. The Menkes disease gene (*ATP7A*) encodes the copper-transporting P-type ATPase (Menkes disease protein).[112] This enzyme regulates the extrusion

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

of copper from the cell and the transport of copper from the cytosol to copper-dependent enzymes. The relative copper deficiency associated with the inherited alteration of this gene causes mental retardation, poor temperature control, severe developmental delays, anemia, spontaneous fractures, poor bone development, and disruption of connective tissue.[113]

Indian Childhood Cirrhosis

This disease affects children living primarily in rural India who are between the ages of 6 months and 5 years. Until the 1970s, Indian Childhood Cirrhosis was a common cause of death in children in India, but now this disease is rare.[114] The reduction in the incidence of this disease was associated with a reduction in the use of brass vessels to store food and milk.[115] The disease produces elevated copper concentrations without the reduction in ceruloplasmin concentrations that accompanies Wilson's disease.[116] Typical histological changes in Indian Childhood Cirrhosis include marked degenerative ballooning of the hepatocytes, diffuse Mallory bodies, predominant neutrophilic infiltrate in acini, and a severe micronodular (pericellular) fibrosis.[117] The presence of coarse dark-brown orcein staining and intralobular pericellular fibrosis distinguishes Indian Childhood Cirrhosis from Wilson's disease.[118] The absence of steatosis and appearance of cholestasis late in the course of the disease characterize Indian Childhood Cirrhosis.

These changes probably result from the massive accumulation of copper in hepatic nuclei along with a reduction in catalase activity.[119] Unlike the treatment of Wilson's disease, lifelong treatment with D-penicillamine is unnecessary and chelation with D-penicillamine may be stopped after recovery from Indian Childhood Cirrhosis.[120] The most plausible explanation of the etiology of this disease is the excessive ingestion of copper. Indian Childhood Cirrhosis probably is a specific form of copper-associated childhood cirrhosis, which requires high concentrations of copper in the environment for full expression.[115] This disease may also represent an inherited metabolic disorder because of reports of similar cases outside the geographical area of India.[121,122,123] Rare case reports associate liver pathology (idiopathic copper toxicosis) similar to the hepatic changes reported in Indian Childhood Cirrhosis with infants residing outside India (non-Indian Childhood Cirrhosis).[124,125]

Postmortem Examination

In a postmortem examination of a 58-year-old psychiatric patient dying after the massive ingestion of US coins, extensive disruption of the liver architecture was present with ballooning degeneration, infiltration of polymorphonuclear leukocytes around necrotic cells, Mallory hyalin, and portal fibrosis with intralobular extension.[81] All hepatocytes contained cytoplasmic granules that stained positive for copper (Timm's silver sulfate, rhodamine stain), whereas the bile duct epithelium contained no copper granules. The proximal and distal convoluted renal tubules also contained copper granules. Examination of other organs was unremarkable. Postmortem examination of the liver of a 46-year-old intellectually disabled male, who died after chronically ingesting >700 copper coins, revealed extensive portal fibrosis and portal tract-central vein bridging without cirrhosis.[126] Extensive deposition of granular golden-brown pigment (copper-associated protein) appeared throughout the hepatic parenchyma. Additional findings included patchy lymphocytic infiltration, proliferation of bile ductules, and intracanalicular bile plugs. Following ingestion of copper sulfate, blue staining of the upper lips, gums, and mucous lining of the esophagus may occur.[127]

CLINICAL RESPONSE

Acute Toxicity

The clinical features of copper toxicity depend on the specific copper salt. Copper sulfate is a gastrointestinal irritant that potentially may cause gastrointestinal ulceration, liver or renal dysfunction, intravascular hemolysis, and coma.[128] Case reports of the intentional ingestion of copper sulfate document lethargy, coma, rhabdomyolysis, hemolysis, refractory hypotension, and multi-organ failure.[129] In a retrospective case series of 35 patients presenting to a tertiary care hospital with severe copper sulfate toxicity, vomiting was the most common symptom (85%), followed by diarrhea (46%), epigastric pain (43%), and melena (31%).[130] Major complications included hemolysis (69%), renal failure (51%), acute hepatitis (46%), and upper gastrointestinal bleeding (40%) with hepatic failure accounting for a majority of the deaths. Sepsis may complicate ulceration of the gastrointestinal tract.

Hepatic injury usually develops within several days after massive copper sulfate ingestion with resolution within 1 week unless hepatic failure complicates the clinical course.[64] Hemolysis typically occurs ~12–24 hours after ingestion. A 11-year-old girl died several hours after the accidental ingestion of a saturated solution of copper sulfate despite immediate transfer to medical care; her postmortem blood copper concentration of

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

66 mg/L confirmed a large copper sulfate overdose.[131] A 62-year-old man with underlying myocardial disease developed hemorrhagic gastroenteritis, hemolytic anemia, and refractory hypotension after the surreptitious ingestion of copper sulfate; he died on hospital day 2 from cardiovascular failure despite intensive care.[132] Following the subcutaneous injection of copper glycinate, a 41-year-old woman developed nausea, vomiting, renal failure, and hemolytic anemia requiring multiple transfusions.[133] Despite venovenous hemodiafiltration and fresh frozen plasma, hepatic dysfunction with coagulopathy and respiratory failure with bibasilar pneumonia occurred. She survived with intensive care and intubation.

Gastrointestinal Tract

Copper sulfate is a gastric irritant that produces a metallic taste, nausea, vomiting, epigastric burning, and hematemesis beginning soon after ingestion. Nausea, vomiting, diarrhea, hematemesis, and melena also occur following subcutaneous and intravenous administration of copper sulfate.[134] Severe gastrointestinal irritation may cause perforated pyloric ulcers and diffuse bleeding from the duodenal mucosa.[135] A 2-year-old boy developed hemolytic anemia, renal failure, arrhythmias, and central nervous system depression after the occurrence of *Escherichia coli* septicemia secondary to the penetration of the intestinal wall by the bacteria.[136] The greenish-blue vomitus may discolor contaminated skin. Diarrhea is less common with melena or hematemesis occurring primarily in severe cases.[128] The liver is the initial site of copper deposition; severe acute copper toxicity may cause jaundice and centrilobular necrosis of the liver along with hemolytic anemia, hemoglobinuria, and acute renal failure.[133] In patients with chronic renal failure patients receiving excess intravenous copper from dialysis through copper tubing, an acute necrotizing hemorrhagic pancreatitis developed.[137]

Skin

The increased adsorption of copper by hair shafts causes a green hue, particularly in damaged portions of the hair. Additional changes include the loss of the cuticle and the presence of scattered micropits.[138] Corrosion of copper rings and glasses by sweat may cause greenish discoloration of the skin along with localized irritation as a result of a primary irritant reaction.[139,140] Allergic reactions to copper intrauterine devices and metallic copper are uncommon.[141] Sensitization to copper usually occurs from the leaching of copper-containing material in corrosive environments (e.g., dental amalgams, intrauterine devices).[142] Typically, these exposures produce delayed (Type IV) allergic contact dermatitis or systemic contact dermatitis. Rarely, case reports associate an allergic contact dermatitis with copper-containing jewelry[143] and urticaria with the use of a copper intrauterine device.[144] There are inadequate data in the medical literature to associate dermal exposure to copper with systemic toxicity,[93] except following the application of copper-containing liquids to yellow phosphorus burn areas.[145]

Kidney

Anuria or oliguria may develop following acute copper sulfate intoxication, but renal dysfunction is usually mild. Damage to the proximal renal tubules results from the direct effect of copper sulfate, hypotension, and/or hemoglobinuria released from massive hemolysis. Rarely, myoglobinuria is a complication of acute copper poisoning. A 37-year-old Nigerian man developed hemolysis and renal failure requiring hemodialysis after the ingestion of spiritual (green) water containing ~13 mg Cu/L as a home remedy for mid-epigastric pain.[21]

Environmental Exposure

There are few data on copper toxicity associated with environmental copper exposure. A case report temporally associated intermittent vomiting and abdominal pain with drinking water from a copper line; the symptoms resolved after the family ceased using drinking water from the copper line.[6] Although water samples contained copper concentrations exceeding 1.0 mg/L, the report lacked a thorough medical evaluation of the family and an extensive evaluation of comparison families in the area drinking water from the same main line. The median blood copper concentration of the family was below the median concentration of one other neighborhood family. A case report associated the ingestion of royal jelly (honey bee extract) and large doses of copper supplements (30–60 mg copper daily for 3 years in mineral supplements plus zinc and selenium) with the development of cirrhosis and liver failure, resulting in an orthotropic liver transplant.[146] The patient had Kayser–Fleischer rings and elevated copper concentrations in the explanted liver; however, the serum copper and ceruloplasmin were within normal values at presentation. A 20-month-old Australian child developed liver failure that required liver transplantation; histological examination demonstrated findings consistent with Indian Childhood Cirrhosis; the explanted liver

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

had a 10-fold increase in copper content.[117] The authors attributed the source of excess copper to copper conduits used to transport the child's milk; these authors suggested the term copper-associated liver disease in childhood for similar cases occurring outside India.

Occupational Exposure

Although copper may act as an irritant to the respiratory and gastrointestinal tracts, there are no well-designed epidemiological studies of workers exposed primarily to copper that demonstrate chronic toxicity including fibrotic interstitial lung disease.[147] Case reports associate occupational exposure to copper dust with mucosal irritation of the mouth, eyes, and nose along with perforation of the nasal septum following heavy exposure.[148,149] In a case report of 26 workers cutting brass pipes with electric cutting torches, metal fume fever (fever, chills, myalgias, headache, malaise, dry throat) was attributed to the inhalation of copper fumes from copper-welding operations;[150] however, only 5 of 12 workers tested had elevated urinary copper concentrations. Inadequate documentation of copper exposure, atypical complaints, and the lack of consistent symptoms from specific work practices limit conclusions regarding the association between copper dust and metal fume fever.[151] The high temperature required to produce copper fumes relative to the temperature of copper in most industrial applications also limits the pulmonary effects of copper dust.

Vineyard sprayer's lung is an occupational disease associated with the use of Bordeaux mixture (~1–2% copper sulfate in hydrated lime) by European vineyard workers.[152] The abnormalities resemble silicosis with early micronodular changes that progress to massive pulmonary fibrosis and respiratory failure. Lung biopsies typically demonstrate three histological stages including alveoli filled with macrophages, granulomas in the alveolar septa, and fibro-hyaline nodules similar to silicotic nodules in areas previously containing granulomas.[153] The granulomas, desquamated macrophages, and fibrohyaline scars usually contain copper. Case series suggest that lung cancer occurs commonly in vine growers diagnosed with vineyard sprayer's disease, but the cause of these tumors remains unclear as a result of the presence of multiple confounding factors (arsenic, smoking) and selection bias.[154]

Wilson's Disease

This rare genetic disorder of copper metabolism causes progressive hepatic and neurological damage that usually manifests during the second or third decade of life; late-onset Wilson's disease (i.e., >40 years of age) is unusual.[108] There are over 300 different mutations distributed across the *ATP7B* gene, resulting in complex genotypes and a wide range of symptoms varying from asymptomatic patients to end-stage liver disease with cirrhosis, portal hypertension, and acute liver failure.[108] Acute liver failure occurs in ~12% of patients with Wilson's disease, predominately in young females.[155] Clinical manifestations include cognitive impairment, behavioral changes (emotional lability, depression, insomnia, loss of concentration), motor abnormalities (dysarthria, tremor, dysphagia, ataxia, difficulty writing), Coombs-negative hemolytic anemia, renal tubular dysfunction (uricosuria, hypercalciuria), renal stones, and fulminant hepatic failure with encephalopathy.[156,157] The liver is the primary organ affected by copper excess; hepatic disease usually occurs before the appearance of extra-hepatic signs and symptoms with the exception of elderly patients, who often present with neurological and psychiatric features. Symptomatic patients, particularly those with neurologic manifestations, often present with Kayser–Fleischer rings (i.e., peripheral golden-brown corneal deposits of copper within Descent's membrane); other ophthalmic findings include sunflower cataracts, night blindness, optic neuritis, pallor of the optic disk, and exotropic strabismus. The ophthalmic changes are usually reversible with medical treatment or liver transplantation. The classification of neurological abnormalities in Wilson's disease includes 1) Parkinson-like akinetic-rigid syndrome, 2) multiple sclerosis-like degeneration dominated by tremor, 3) ataxia, and 4) dystonia.[108] Depression, anxiety, and psychosis may also occur. In the absence of lifelong chelation with D-penicillamine or trientine, progressive anatomical and physiological changes develop, primarily in the liver and brain.[158] The diagnosis of Wilson's disease is based on the presence of a typical history and physical examination including slit lamp evaluation along with elevated copper concentrations in the urine and serum. There is no one definitive test for the diagnosis of Wilson's disease.

Reproductive Abnormalities

Copper is an essential metal that is not a recognized animal or human teratogen. Data on the reproductive effects of copper exposure are limited. Analysis of questionnaires from a group of workers exposed to 111–434 mg/m^3 copper dust during grinding and sieving operations revealed complaints of sexual impotence in 16% of the sample; the lack of a control group and multiple confounding factors limit conclusions regarding causation.[159]

Carcinogenicity

Neither the International Agency for Research on Cancer nor the US Toxicology Program lists metallic copper or copper compounds as suspected human or animal carcinogens. Epidemiological studies have not established a positive correlation between copper exposure and an increased incidence of cancer. The increased incidence of lung cancer in workers in copper refineries probably results from contamination of copper ore with arsenic or co-exposure to nickel sulfate. Preliminary studies suggest that squamous and small cell lung cancers predominate in pulmonary tumors from copper smelter workers,[160] whereas adenocarcinomas are more common in lung cancer patients without occupational exposure to carcinogens. In a Finnish study of 1,388 workers employed for at least 3 months at a copper/nickel smelter and nickel refinery, the elevated risks of nasal and lung cancer were limited to the nickel refinery and attributed to insoluble nickel compounds rather than copper exposure.[161] A Chinese mortality study of 7,088 copper miners detected increased mortality from lung cancer (SMR = 147, 95% CI: 112–189, $P < 0.01$);[162] however, lack of control of confounding (arsenic, radon, smoking) limits conclusions regarding causation. In a case-control study of four rural Arizona towns near copper smelters, there was little evidence of a positive association between copper smelter emissions and lung cancer incidence based on historical estimates (i.e., interviews and diffusion modeling) of residential exposures.[163]

DIAGNOSTIC TESTING

SI Conversion Units

1 mmol = 63.54 mg
1 mg = 15.74 μmol

Analytic Methods

The most common methods used to determine copper levels in biological or environmental samples are atomic absorption spectrometry (flame or graphite) and inductively coupled plasma/atomic emission spectrometry. The later technique is highly sensitive. These methods determine total copper concentrations. Depending on sample preparation procedures, the detection limits of graphite furnace/atomic absorption spectrometry are about 1 μg/L water compared with 10–20 μg/L water for the less sensitive flame atomic absorption spectrophotometry.[8,164] The major problems with these methods are contamination from impurities in the environment and loss of copper during sample preparation.[12] For laboratories without atomic absorption spectrophotometers, rapid colorimetric assays are available with detection ranges near 0.1 mg Cu/L.[165] Electrochemical and equilibration techniques are available to determine the species of copper present in environmental[166] and biological samples.[167]

Biomarkers

Blood

The whole blood/serum Cu ratio is typically slightly <1; in a study of healthy Italians, the mean whole blood/serum Cu ratio was 0.86.[168] Whole blood copper concentrations may substantially exceed serum copper concentrations during the first few days after intravenous copper exposure.[137]

General Population

The upper range of serum copper concentrations in the general population is ~1.5–1.6 mg/L as measured by ICP/MS.[169] The median serum copper concentration of 122 Czechoslovakian volunteers was ~1.06 mg/L with a range of 0.7–1.53 mg/L.[170] A Spanish study of 15 healthy adults demonstrated a mean serum copper concentration of 0.86 mg (14.4 μmol/L).[171] In a sample of 36 healthy adults[172] and 372 Swedish adolescents,[173] the mean whole blood and serum concentrations were similar (i.e., ~1 mg/L). In a French study of 106 volunteers, the median whole blood copper concentration was 0.937 mg/L (95th percentile, 1.51 mg/L) compared with 0.952 mg/L (95th percentile, 1.66 mg/L) in plasma as measured by ICP/MS.[174] Serum copper concentrations do not significantly increase with age. In a study of 66 Greek children (mean, 7.53 ± 3.31 years; range, 3–14 years) and their parents, the mean serum copper concentrations were 1.67 ± 0.35 mg/L and 1.47 ± 0.33 mg/L, respectively ($P < 0.001$) as measured by flame atomic absorption spectrometry.[175] Renal failure does not significantly increase plasma copper concentrations based on comparisons of healthy adults and hemodialysis patients.[176] The use of oral contraceptives is associated with a moderate, asymptomatic increase in the plasma and whole blood copper concentrations above normal ranges, but erythrocyte copper concentrations usually remain within the normal reference range.[177,178] The increase probably reflects estrogen-associated increased ceruloplasmin production. Serum copper concentrations return to normal values within 2 months of cessation of oral contraceptive use.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Wilson's Disease

Almost 95% of patients with Wilson's disease have reduced serum concentrations of oxidase-active ceruloplasmin (<20 mg/dL).[179] Reduced concentrations of serum ceruloplasmin alone are not diagnostic of Wilson's disease because ~20% of heterozygotes have decreased ceruloplasmin concentrations. Other conditions with low concentrations of ceruloplasmin include protein-losing enteropathies and nephropathies, as well as defective production of ceruloplasmin peptide. Healthy infants <6 months of age frequently have low serum ceruloplasmin concentrations. A variety of conditions are associated with elevated serum copper concentrations beside Wilson's disease including iron deficiency anemia, leukemia, lymphoma, biliary cirrhosis, hemochromatosis, thyroid disease, pregnancy, infection, and collagen vascular diseases. The use of the penicillamine challenge test for the diagnosis of Wilson's disease remains controversial, in part because penicillamine increases urinary copper secretion in patients without Wilson's disease.[180,181]

Toxicity

The correlation between clinical outcome and blood copper concentrations is limited, in part because of the complexity of copper kinetics and few data comparing whole blood, serum, and unbound copper during copper intoxication. Although serum ceruloplasmin concentrations increase during the first 3 days after acute copper toxicity as a result of increased hepatic synthesis,[182] severity of copper toxicity does not correlate to plasma ceruloplasmin concentrations. Unbound or free copper accumulates rapidly following saturation of metallothionein binding sites, resulting in the rapid intracellular accumulation of free copper and the generation of reactive oxygen species along with liver necrosis. In this situation, serum copper concentrations are low despite serious toxicity. As a result of rapid uptake by the liver and erythrocytes, serum copper concentrations increase rapidly within a few hours after ingestion and then decline rapidly over the next 24–48 hours, typically returning to normal values within 1 week.[135] Although serum ceruloplasmin concentrations increase during acute copper toxicity as a result of increased hepatic synthesis, severity of copper toxicity does not correlate to plasma ceruloplasmin concentrations.[182]

In an Indian case series of 10 patients sent to a referral hospital with renal failure, the mean serum copper was 1.98 mg/L (range, 1.2–3.9 mg/L). The report did not document the time between ingestion and blood sampling, but the time to referral of almost all patients was substantially delayed (3–8 days).[183] Four patients died. On admission to the hospital ~1 hour after ingesting a solution of copper sulfate, the serum from an 18-month-old child contained 16.5 mg Cu/L; within 24 hours, the serum copper decreased to 2.3 mg/L.[62] He developed hemolytic anemia and renal tubular dysfunction but no hepatorenal failure, and he survived without sequelae. A 42-year-old man developed jaundice, 100-fold elevation of his serum transaminases, and rhabdomyolysis after the intentional ingestion of copper sulfate; he survived without sequelae.[64] His serum copper concentration the day after ingestion was 14.2 mg/L.

In an Indian case series of copper sulfate intoxication in 48 adult patients presenting during the 1960s, the mean whole blood copper concentration in patients with mild gastrointestinal symptoms was 2.87 ± 1.27 mg/L compared with 7.98 ± 3.96 mg/L in patients with hepatorenal dysfunction and/or shock as measured by spectrophotometric methods;[184] mean serum copper concentrations were similar between the two groups.[128] The case report did not document the time between ingestion and blood sampling. An Indian case series of four cases of fatal acute copper intoxication documented whole blood copper concentrations ranging from 2.12–2.83 mg/L within 24 hours after ingestion.[185] This study from the 1970s did not report the analytic method. A 55-year-old chemist remained asymptomatic after sustaining multiple lacerations following an explosion involving copper azide.[71] His peak serum copper concentration 4 days after the explosion was 1.23 mg/L.

Postmortem

The rapid uptake of copper by erythrocytes and the prolonged course of acute copper sulfate toxicity prior to death complicate the interpretation of most copper concentrations in postmortem blood. An 11-year-old female died 2 hours after accidentally ingesting an estimated one mouthful of a saturated solution of copper sulfate; her postmortem blood sample contained 66 mg Cu/L.[127] The antemortem copper concentrations in whole blood and serum samples drawn 1 hour after ingestion were 16 mg/L and 25 mg/L, respectively. A 30-year-old woman became comatose and died 48 hours after receiving a concoction of copper sulfate and other substances by an *inyanga* (traditional African herbalist); the autopsy demonstrated aspiration pneumonia and centrilobular congestions of the liver.[186] The copper concentration in her postmortem blood was 42 mg/L.

Urine

Copper concentrations in urine samples are usually relatively low because copper elimination occurs primarily via the bile. In studies of the general population, urine

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

copper concentrations range up to 0.05 mg/L.[187] In a French study of 100 healthy volunteers, the median urine copper concentration was 0.007 mg/L with an upper 95% CI of 0.012 mg/L as measured by ICP/MS.[188] The mean urine copper concentration in convenience sample of 507 urban and rural Italian residents without occupational copper exposure was 0.023 ± 007 mg/L with a range of 0.004–0.05 mg/L.[189] The urine copper concentration in patients with symptomatic Wilson's disease usually exceeds 0.1 mg/24-hour urine collection;[190] however, increased copper excretion also occurs from other causes of severe liver disease. One day after ingestion of copper sulfate, the copper concentration in a 2-hour urine sample was 0.5 mg/L; the peak urine concentration of 3 mg/L occurred 11 days after ingestion.[62]

Hair

Limited data are available on copper concentrations in hair. A study of 41 adults undergoing minor surgical procedures demonstrated mean copper concentration of 17.7 ppm (range, 9.5–33.1 ppm) in the proximal 2–3 cm of occipital scalp hair samples and 11.9 ppm (range, 7.2–19.9 ppm) in pubic hair as measured by flameless atomic absorption spectrometry (LOD, 0.6 ppm).[191] In a study of menstruating Polish women, the mean copper concentration in the proximal 1 cm of occipital scalp hair from 28 women aged 19–30 years was 25.8 ± 19.4 ppm (range, 7.6–67.7 ppm) compared with 12.9 ± 5.43 ppm (range, 7.12–17.9 ppm) in 25 women aged 31–40 years.[192] The mean copper concentration in hair from 24 menstruating women aged 41–50 years was intermediate between the former two groups. A study of 39 children aged 1–12 years living in and around a large Australian port city demonstrated copper concentrations in proximal neck hair samples ($n = 22$) from 7–415 ppm with a median of 56.27 ppm; first morning void urine copper concentrations in 37 samples were <0.085 mg/L with a median of 0.012 mg/L.[193] Examination of house dust and drinking water did not suggest the presence of significant copper contamination in their home environment. In a German study of proximal scalp hair samples from 474 preschool children, the geometric mean copper concentration was 10.6 ppm with a range of 5.4–20.7 ppm.[194] Stepwise regression analysis did not detect any significant association between hair copper concentrations and a variety of factors (e.g., place of residence, season, sex, age, hair color). Analysis of metal concentrations in hair of children with autism including copper, cadmium, lithium, mercury, and selenium indicates that these metals are not associated with autism.[195]

Abnormalities

Overdose

Abnormalities resulting from severe copper sulfate poisoning include intravascular hemolysis (anemia, increased plasma hemoglobin, reticulocytosis, hemoglobinuria, hyperbilirubinemia, crenated and fragmented erythrocytes, Heinz body formation), acute proximal renal tubular dysfunction (aminoaciduria, hypercalciuria, phosphaturia, proteinuria, uricosuria), hematuria, elevated serum hepatic transaminases/total bilirubin, oliguria, rhabdomyolysis, and methemoglobinemia.[196,197] Serum hepatic aminotransferase concentrations peak within 3 days of ingestion and resolve by 1 week. A retrospective Indian study of 35 patients with copper sulfate poisoning suggested that elevation of peak serum alanine aminotransferase (ALT) concentrations substantially increases the risk of mortality.[130] All patients dying in this series had peak serum ALT concentrations exceeding 55 IU/L. Massive hemolysis may complicate the analysis of hepatorenal function, blood compatibility, and arterial blood gases.[198] Copper salts, but not metallic copper, are radiolucent.

Wilson's Disease

In Wilson's disease, the free fraction of copper in the plasma is elevated along with subsequent increased urinary copper excretion. Severe liver disease from other causes also produces similar increases; however, the extent of these changes is much more severe in Wilson's disease. Laboratory testing typically demonstrates persistently elevated serum hepatic transaminases with disease progression characterized by reduced albumin, elevated international normalized albumin, elevated international normalized, ratio, hyperbilirubinemia (mostly indirect), and marked Coombs-negative hemolytic anemia.[199] CT imaging demonstrates hypodense nonenhancing foci in the thalami and basal ganglia with dilation of the frontal horns secondary to brainstem and caudate atrophy. MR imaging typically displays increased bilateral, symmetric T2-weighted images in the deep gray areas, commonly in the globus pallidus and putamen.[200] Other abnormalities in these patients include scattered high-signal-intensity foci in white matter and scattered hypo-intensities in the pons, midbrain thalami, and lentiform nucleus.

Serum ceruloplasmin concentrations <0.2 g/L are consistent with Wilson's disease with concentrations <0.14 g/L demonstrating 100% positive predictive values;[201] however, low ceruloplasmin is not specific for Wilson's disease. Although ~95% of patients with

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Wilson's disease will have low serum ceruloplasmin concentrations, other causes of low serum ceruloplasmin concentrations include malnutrition, malabsorption, and cachexia. Low serum ceruloplasmin concentrations also occur in Menkes disease; this protein is an acute-phase reactant that decreases in acute liver failure. Diagnostic criteria for Wilson's disease include 1) the presence of Kayser–Fleischer rings (granular, golden-green corneal copper deposits within Descemet membrane) and low ceruloplasmin, 2) low serum ceruloplasmin and hepatic copper concentrations >75 μg/g dry weight with appropriate histology, and 3) evidence of two mutations of *ATP7B*.[202] In acute hepatic failure, the presence of serum alkaline phosphatase/total bilirubin ratio <4 and serum aspartate aminotransferase/alanine aminotransferase ratio >2.2 is highly suggestive of Wilson's disease.[203] Kayser–Fleischer rings almost always occur in patients with psychiatric or neurological complications of Wilson's disease, whereas only 40–66% of patients with the hepatic form have this sign. These deposits are uncommon in young, asymptomatic patients with the disease.[180] The normal copper content of the liver is <55 μg/g dry weight, whereas hepatic copper concentrations in homozygous Wilson's disease is typically >250 μg/g dry weight; however, values <250 μg/g dry weight do not exclude the possibility of Wilson's disease, particularly in the presence of severe hepatic fibrosis.[108] Urine copper concentrations may exceed 100 μg/24 hours in acute liver failure secondary to Wilson's disease and >40 μg/24 hours; however, asymptomatic patients with this disease may not have elevated urinary copper concentrations.[204]

HEALTH SURVEILLANCE

Risk Assessment

The acute-duration oral minimal risk level (MRL) for copper is 10 μg/kg/day based on the lack of adverse effects (NOAEL) in women ingesting 27.2 μg/kg/day in drinking water for 2 weeks; the uncertainty factor for human variability was 3.[205] Gastrointestinal distress developed in women ingesting drinking water containing 73.1 μg Cu/kg/day. An intermediate-duration oral MRL for copper is 10 μg/kg/day based on the lack of adverse effects (NOAEL) in volunteers ingesting 42 μg/kg/day in drinking water for 2 months; the uncertainty factor was 3.[206] Gastrointestinal effects (i.e., nausea) occurred in volunteers ingesting 91 μg Cu/kg/day in drinking water for 2 months.

Health-based guidelines for copper in drinking water in many countries range from 1–2 mg/L. The World Health Organization guideline for copper in drinking water is 2 mg/L.[52] Blue-green discoloration of laundry and plumbing fixtures occurs at copper concentrations of 1 mg/L, whereas a bitter taste develops in water at copper concentrations of 1–5 mg/L. The US EPA maximum contaminant level (MCL) is 1.3 mg Cu/L based on taste and, to a lesser extent, on limited toxicity data. This drinking water regulation was calculated by Equation 11.1

$$\begin{aligned}\text{MCL} &= \text{LOAEL} \div \text{Safety factor} \\ &\quad \times \text{Daily water consumption.} \\ &= 5.3\ \text{mg} \div 2 \times 2\ \text{L/day} = 1.3\ \text{mg/L/day}\end{aligned} \qquad \text{(Equation 11.1)}$$

where:

lowest-observable-adverse-effect level (LOAEL) = 5.3 mg
Safety factor = 2
Daily water consumption (adult) = 2 L/day

The LOAEL was based on a reconstruction of an incident in 1957 when a group of nurses developed acute gastrointestinal symptoms after ingesting alcoholic beverages from a copper cocktail shaker.[207] The actual amount of copper ingested during the incident was not measured. The estimated amount ingested by these nurses ranged from 5.3–32 mg Cu. Although the data are incomplete, not all nurses became ill; hence, the 5.3 mg dose may represent a NOAEL rather than a LOAEL.[208] Such a change would reduce the safety factor used to calculate the health-based guidelines. Sidhu et al. proposed a reduction in the drinking water standard to 0.3 mg Cu/L as a means to increase the uncertainty factor to account for the sensitivity of children under the age of 10 to copper toxicity. However, currently there are little data to support such a revision.[209] A prospective study of healthy infants aged 3–12 months measured changes in serum concentrations of copper, ceruloplasmin, bilirubin, transaminases, γ-glutamyl transferase, superoxide dismutase, and erythrocyte metallothionein.[210] There were no adverse effects and no statistical differences detected between the group receiving drinking water with 2 mg Cu/L and the control group (<0.1 mg Cu/L). The development of liver disease has not been associated with water supplies that contain concentrations >2 mg Cu/L.[26] A study of 60 women volunteers demonstrated a statistically significant increase ($P < 0.01$) in the incidence of nausea, vomiting, and abdominal pain in the women ingesting drinking water over 2 weeks that contained ≥3 mg Cu/L.[205] The serum copper, ceruloplasmin, and liver enzymes of these women did not change significantly

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

from baseline concentrations. A mortality study of Massachusetts residents consuming drinking water with concentrations ranging up to 8.8 mg Cu/L in 1969–1991 did not detect any excess deaths from liver disease.[211] In a Swedish cohort study of 430 children, 43 developed diarrhea and 95 developed vomiting; the mean intake of copper for all children was estimated from the analysis of drinking water.[212] The median copper concentration of the mean drinking water values for the children was 0.61 mg/L (10–90th percentile, 0.04–1.57 mg/L). Comparison of the children with and without gastrointestinal illness indicated no association between copper intake or maximal drinking water copper concentrations and gastrointestinal illness.

Environmental Monitoring

The ACGIH recommends a TLV–TWA for workers exposed to copper fumes of 0.2 mg Cu/m^3 and copper dusts and mists of 1 mg Cu/m^3. Table 11.3 lists the guidelines and regulations formulated for copper exposure.

TABLE 11.3. Copper regulations and guidelines.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	0.1 mg/m^3 (fumes as Cu)
	1 mg/m^3 (dusts/mists as Cu)
NIOSH	
REL–TWA (10-hour)	0.1 mg/m^3 (fumes as Cu)
	1 mg/m^3 (dusts/mists as Cu)
IDLH	100 mg/m^3
ACGIH	
TLV–TWA (8-hour)	0.2 mg/m^3 (fumes as Cu)
	1 mg/m^3 (dusts/mists as Cu)
US FDA	
Bottled water allowable limit	1.0 µg/L
US EPA	
Action level	1.3 mg/L
MCLG	1.3 mg/L
ATSDR	
MRL (oral, acute ≤14 days)	0.01 mg/kg/day
MRL (oral, intermediate >15 days)	0.01 mg/kg/day

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; ATSDR = Agency for Toxic Substances and Disease Registry; EPA = (US) Environmental Protection Agency; FDA = (US) Food and Drug Administration; IDLH = immediately dangerous to life and health; MCLG = maximum contaminate level goal; MRL = minimal risk level; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; TLV = threshold limit value; TWA = time–weighted average.

Workers with potentially increased susceptibility to copper exposure include the following diseases: Wilson's disease, glucose-6-phosphate dehydrogenase deficiency, and possibly liver disease.[12] The preemployment physical examination should concentrate on detecting the following diseases: liver disease, kidney dysfunction, anemia, and the other preexisting diseases listed above.

Biological Monitoring

Copper concentrations in the blood reflect recent exposure; whole blood copper concentrations average 1.2 mg/L (range, 0.8–1.6 mg/L) in workers without copper exposure;[189] however, there are insufficient data to establish biological exposure limits for workers exposed to copper.

TREATMENT

Overdose

Gastrointestinal Decontamination

The induction of emesis or gastric lavage is usually unnecessary following acute copper sulfate ingestions because of persistent vomiting. Copper sulfate is a corrosive that should be treated with early dilution with a glass of water rather than emetics as reexposure of the esophagus to this corrosive substance could worsen gastrointestinal irritation. There are no *in vitro* or *in vivo* data on the efficacy of activated charcoal following an acute ingestion of copper sulfate.

Enhancement of Elimination

Copper is not effectively removed by hemodialysis. Analysis of copper concentrations in serum and dialysate before and after hemodialysis on day 1 and day 3 of hospitalization following the intravenous and subcutaneous injection of copper sulfate did not demonstrate significant differences before and after hemodialysis.[134] The removal of copper by peritoneal dialysis is small, even with the use of salt-poor albumin. Following the ingestion of saturated copper sulfate crystals by a 2-year-old boy, albumin-enriched peritoneal dialysis removed 9.1 mg Cu over 60 hours compared with 0.7 mg Cu over 40 hours of peritoneal dialysis without albumin.[136] Case reports suggest therapeutic plasma exchanges (plasmapheresis) may be effective adjunctive therapy for acute copper overload during acute Wilson's disease while initiating preparations for liver transplantation;[213] however, the amount of copper eliminated by plasmapheresis was not documented and serum copper concentrations remained unchanged.

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

Chelation

Chelating agents are often recommended for severe poisoning, but little pharmacokinetic data on humans exist to guide their use or support their efficacy.

BAL and $CaNa_2EDTA$

Either intravenous $CaNa_2EDTA$ or intramuscular BAL are the agents most frequently recommended for severe copper sulfate ingestions;[196] however, availability of these chelating agents is limited, and there is no consensus on the most effective chelating agent.[135] Typically, the duration of chelation is based on reduction of serum copper concentrations to normal or resolution of clinical symptoms (i.e., usually ~5–7 days).

D-Penicillamine

D-Penicillamine may be administered orally, if tolerated, to non-penicillin-allergic patients. A 42-year-old man intentionally ingested ~250 g copper sulfate (serum copper ~24 hours after ingestion = 1,423 μg/dL); he received 4 gm/kg dimercaprol intramuscularly and oral D-penicillamine within several hours of ingestion.[64] Despite developing rhabdomyolysis (CPK 5,620 IU/L), liver dysfunction (bilirubin = 7.0 mg/dL), and hemolysis, he recovered; however, the efficacy of these chelating agents following the ingestion of large doses of copper sulfate was not well documented.[214]

Pharmacokinetics Good absorption of D-penicillamine occurs in the gastrointestinal tract (40–70%); some ingestants (antacids, iron, food) may reduce the efficiency of D-penicillamine absorption.[215] Gastric mucosal injury and subsequent GI distress may limit the oral administration of D-penicillamine. Peak D-penicillamine concentrations appear within several hours following ingestion. Elimination of D-penicillamine is rapid (elimination half-life ~3 hours), almost exclusively by excretion of metabolites into the bile.

Dosage D-Penicillamine is available in 125 mg and 250 mg capsules that may be sprinkled on a more palatable vehicle; the daily adult dose is 1,000–1,500 mg in four divided doses. Limited pediatric experience suggests a dose of 20 mg/kg twice daily up to a maximum of 1,000 mg. Side effects are reduced by beginning with $1/4^{th}$ of the full daily dose and increasing to the full dose over 3–4 weeks. D-Penicillamine is administered orally in four divided doses 2 hours before meals, usually for 4–12 weeks, depending on the occurrence of adverse reactions. The use of D-penicillamine is contraindicated in the presence of penicillin allergy. Complete blood counts and urinalyses should be obtained on days 1, day 14, day 28, and monthly thereafter. If the absolute neutrophil count falls to <1,500 neutrophils/μL, the blood count should be repeated at least daily and D-penicillamine therapy stopped, if the blood count falls below 1,200 neutrophils/μL.[216]

Adverse Effects Side effects resemble penicillin hypersensitivity and appear immune-related rather than dose-related. Adverse reactions occur in up to 33% of patients given D-penicillamine for lead poisoning;[217] these reactions include rash, transient leukopenia and thrombocytopenia, anorexia, eosinophilia, proteinuria, fever, hyporeflexia, and rarely autoimmune hemolytic anemia, Stevens-Johnson syndrome, and nephrotoxicity.[218] Nausea, vomiting, and abdominal pain occur at high D-penicillamine doses; the onset of these symptoms is usually dose-related. The eosinophilia occurs in ~20% of children given D-penicillamine for lead poisoning; often resolution appears spontaneously.[217] Proteinuria and microscopic hematuria may respond to a reduction in dosage or resolve spontaneously.[218] Follow complete blood count with differential counts and urinalysis weekly during therapy. The use of D-penicillamine is questionable during pregnancy because this chelator crosses the placental barrier and is a potential teratogen.

DMSA/DMPS

Although experimental studies in rodents suggest that DMSA and 2,3-dimercaptopropane-1-sulfonate (DMPS) are effective chelating agents for copper and reducing serum copper concentrations,[219,220] human data are inadequate to determine efficacy. A 33-year-old woman intentionally ingested an unknown amount of copper sulfate; she developed gastritis, methemoglobinemia, severe hemolysis, and hepatorenal failure.[221] She survived with supportive care and the intravenous administration of DMPS within ~8 hours after poisoning. The serum copper concentration was within normal limits after admission; serial copper concentrations and copper elimination were not reported.

Supportive Care

Serious complications of copper sulfate ingestions include ulceration and perforation of the gastrointestinal tract with resulting sepsis, rhabdomyolysis, hepatorenal failure, methemoglobinemia, intravascular hemolysis, and subsequent anemia. These complications typically appear within the first few days after ingestion; patients should be monitored for the development of these complications with serial CBC, serum chemistries (electrolytes, creatinine, hepatic transaminases, haptoglobin, creatine phosphokinase), and methemoglobin

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

as indicated in the clinical course. Hypotension may result from fluid loss, hemolysis, or sepsis.

Treatment of copper sulfate ingestion is primarily supportive. Endoscopy may be necessary to evaluate the severity of gastrointestinal injury following copper sulfate ingestion in symptomatic patients (hematemesis, gastrointestinal pain). Similar to other corrosive ingestions, endoscopy should be performed within 24–48 hours to minimize adverse effects. Methemoglobinemia usually does not require treatment with methylene blue unless the patient is symptomatic with methemoglobin concentrations above 25–30%; patients with anemia or cardiopulmonary disease may develop symptoms below these concentrations. Patients should be evaluated for the presence of preexisting glucose-6-phosphate dehydrogenase (G6PD) or NADPH-dependent methemoglobin reductase deficiencies. Patients with rhabdomyolysis or hemolysis should be adequately hydrated and observed for the development of renal dysfunction.

Wilson's Disease

FDA-approved drugs for the treatment of Wilson's disease include D-penicillamine, trientine, and zinc acetate. The initial treatment for symptomatic neurological, psychiatric, and liver diseases is chelation with D-penicillamine (initial daily adult dose, 1–1.5 g orally in 2–4 divided doses 1 hour before or 2 hours after meals).[91] Neurological symptoms may initially worsen during the first few weeks to months of chelation therapy, requiring reduction in the chelation dose.[222] Symptoms usually resolve, but neurological deterioration or adverse reactions (fever, rash, lymphadenopathy, neutropenia, thrombocytopenia, proteinuria, aphthous stomatitis) may require the use of other therapies (e.g., trientine). Penicillamine may affect pyridoxine metabolism; vitamin B_6 supplementation (50 mg weekly) should be given to susceptible patients (children, pregnant women, malnourished patients). Trientine is an acceptable alternative to penicillamine for the initial treatment of Wilson's disease.[108] The initial adult dose is 1,200–1,800 mg divided in two to three doses with daily maintenance therapy of 900–1,200 mg and similar restrictions on food as penicillamine. Pancytopenia may occur, but hypersensitivity reactions and renal dysfunction do not usually occur. Tetrathiomolybdate (up to 2 mg/kg orally in divided doses) is an investigational drug, which avidly chelates copper in sheep. Data on humans are limited with relatively few adverse reactions.[223,224] Zinc induces intestinal metallothionein; thus, reduces copper absorption by binding copper within the duodenal enterocytes. A negative copper balance results from the shedding of copper during normal cell turnover. The daily adult dose of elemental zinc is 150 mg; food interferes with the absorption of zinc; dyspepsia may interfere with compliance.

Dietary therapy alone is not effective treatment for Wilson's disease, but foods with high copper concentrations (shellfish, nuts, liver, mushrooms, chocolate) should be avoided. Zinc acetate (50 mg tid) is effective maintenance therapy with relatively minor adverse effects; the US FDA approved the use of this agent in Wilson's disease in 1997.[225] Zinc induces the formation of intestinal metallothionein, which blocks the absorption of copper by inhibiting the transfer of copper from the intestinal mucosa to the blood.[226] The use of hemodialysis in patients with fulminant Wilson's disease (hemolysis, renal failure) was associated with increased clearance of copper, but the serum copper concentrations increased and clinical deterioration occurred.[227] Liver transplantation is an option for patients who are unresponsive to medical therapy. The molecular adsorbent recirculating system (MARS) is an investigational method of treatment in Wilson's disease patients with little data to guide us in acute copper toxicity.

Chapter 12

GERMANIUM

HISTORY

Germanium is a rare element that always occurs naturally in combination with other elements. In 1886, Clemens Winkler isolated germanium in Germany, naming the element after his native country.[1] Widespread use of germanium did not begin until World War II with the application of germanium in electronics and the initial development of semiconductors. The ability of germanium to convert alternating current into direct current is a desirable physical property to use in simple radio signal detectors as well as in sophisticated semiconductor devices in computers. William Shockley created the first transistor in 1948 based on this metalloid. Germanium tetrahydride is a doping agent for solid-state electronic components; silicon–germanium alloys appeared in the mid-1950s. The use of germanium in diodes, rectifiers, and transistors continued until the early 1970s when high-purity silicon began replacing germanium as a semiconductor.

The use of germanium compounds in the early 20th century as anti-tuberculosis agents and erythrocyte-stimulating drug was ineffective. Uncontrolled animal and human studies suggest that germanium compounds possess analgesic,[2] antihypertensive,[3] erythropoietic,[4] immune modulating,[5,6] and tumor-inhibiting properties.[7,8] Germanium compounds generally produce low toxicity. Although animal studies of germanium compounds in the 1950s demonstrated adverse neurological effects (nystagmus, tremors, seizures),[9] germanium compounds became popular diet supplements in the 1970s for Japanese people with chronic diseases and in the mid-1980s in the United Kingdom. A clinical study using organic germanium compounds (spirogermanium) in the 1980s revealed neurological dysfunction (e.g., ataxia, dizziness) associated with the intravenous administration of these compounds.[10] Case reports also appeared at the same time associating the use of inorganic germanium supplements with the development of acute tubulointerstitial nephritis that progressed to renal failure and permanent renal damage.[11] In the United States, the US Food and Drug Administration (US FDA) does not list germanium as a substance generally recognized as safe (GRAS) to ingest; however, germanium supplements are available over the internet. Suppliers in Europe market germanium compounds as nonprescription drugs for the treatment of AIDS and metastatic cancer.

PHYSICOCHEMICAL PROPERTIES

Germanium (atomic mass, 72.61 g/mol; CAS RN: 7440-56-4) is a member of Group 14 (Group IVa) of the periodic table along with carbon, lead, tin, and silicon. The five natural germanium isotopes are ^{70}Ge (20.55%), ^{72}Ge (27.37%), ^{73}Ge (7.67%), ^{74}Ge (36.74%), and ^{76}Ge (7.67%). Similar to other members of this group, germanium possesses both metallic and nonmetallic properties. This grayish-white, brittle, lustrous metalloid melts at ~972°C. Germanium conducts heat and electricity intermediate between nonmetals and metals similar to other metalloids (antimony, arsenic, astatine, boron, germanium, polonium, silicon, tellurium).[12]

The semiconducting capacity of germanium is similar to the physical properties of silicon; these properties resulted in the widespread use of germanium in the initial development of electronics. Crystalline germanium is a true semiconductor ("n" or "p" type), but in industrial applications, germanium frequently exists as an alloy with antimony, arsenic, gallium, or indium.[13] A unique property of germanium is the ability to pass electricity only in one direction. The high transparency of germanium to infrared light coupled with its high index of refraction is a desirable property for specialized optical instruments. Germanium can act either as a donor or as a receiver in the formation of chemical bonds, but the valence of germanium is usually +2 to +4. The quadrivalent form of germanium is the most common. Germanium tetrahydride (germane, CAS RN: 7782-65-2, MW: 76.63 g/mol) is a colorless gas that is insoluble in water and is reasonably stable at temperatures below 130°C.

EXPOSURE

Production Processes

Germanium never occurs in its pure metallic state. The most common germanium commercial ores are argyrodite (Ag_8GeS_6, 5–7% Ge) and germanite ($7CuSFeSGeS_2$, 8.7% Ge); however, production of Ge primarily involves the recovery of residues from the metallurgical treatment of zinc or copper–lead–zinc ores. Zinc–cadmium and copper–lead–zinc sulfide ores are readily available sources of germanium. Germanium is present in small quantities in many types of coal.

Uses

The use of germanium in the semiconductor industry has decreased with the improvement in the technology of silicon semiconductors. The major use of metallic germanium now is in the production of infrared sensing, infrared optics, γ-ray spectroscopy detectors, and identification systems.[14] Less common applications involve catalysts, metallurgy, and phosphors. Germanium tetrahydride is a doping agent for electronics, whereas germanium tetrachloride is an intermediate in the production of germanium dioxide and organic germanium compounds. Although a number of medicinal uses of germanium compounds have been proposed (e.g., arthritis, cancer, osteoporosis),[15] the efficacy of these compounds remains unproven.[16]

Sources

Environment

Ge is a relatively common metal in the Earth's crust with similar to those of lead and zinc. Soils contain an average Ge concentration of ~1.5–7 mg Ge/kg. The amount of germanium in air varies widely (0.01–1,700 ng Ge/m^3), depending on the presence of point sources (e.g., coal-burning plants).[17] Similar to other metalloids, Ge generally forms oxides in the environment. Combustion of coal releases substantial amounts of germanium into the air; flue gas and coal ash may contain up to 280 mg Ge/kg.[14] Soil germanium concentrations range from 0.6–1.0 ppm. In a study of waters in and around Tampa Bay, Florida, germanium concentrations in seawater averaged ~79 ng/L compared with 16 ng/L (maximum, 600 μg/L) in fresh water as measured by hydride generation/atomic emission spectrometry.[17] The study found little methyl germanium in the environment.

Diet

Despite relatively low Ge concentrations in food, the diet is the main source of Ge for the general population. Dietary studies from the 1960s and 1970s estimated the average adult ingested ~1.5 mg germanium daily with a range of 0.4–3.5 mg Ge.[18,19] In the 2006 UK Total Diet Study, the estimated mean daily Ge intake for adults was 0.001–0.018 mg/kg (upper 97.5%: 0.002–0.033 mg/kg) as measured by inductively coupled plasma/high resolution/mass spectrometry (LOD, 0.0003–0.002 mg/kg).[20] The primary sources of germanium in this diet were offal and meat products. The latter estimated daily intake values are substantially less than earlier estimates using older analytical methods (e.g., atomic absorption spectometry). Germanium occurs in most food sources. A spectrophotometric study of food sources revealed the highest Ge concentrations (>2 mg/kg wet weight) of germanium existed in raw clams, fish, tomato juice, and canned baked beans.[18] Cereals (e.g., barley, oats), garlic, ginseng, tomato juice, and seafood also contain relatively high Ge concentrations.

ENVIRONMENTAL FATE

The geochemical behavior of germanium in fresh water and seawater is similar to that of silicon. The weathering of continental rocks releases germanium into rivers, which transport this metal to the oceans. Siliceous organisms absorb germanium and deposit the germanium in biogenic opal.[21] Methylated germanium species

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

are highly stable in ocean waters. The estimated residence time of monomethyl and dimethyl germanium in oceans is hundreds of thousands of years compared with thousands of years for inorganic germanium.[22] Unlike all other metals, the concentrations of methylated germanium species in the ocean are much higher than inorganic species. The most important environmental form of germanium in aqueous solution is germanic acid (H_4GeO_4).[12] The high first and second dissociation constants (pH 9 and 11.5) are too high to affect germanic acid under normal environmental conditions. Although polymeric forms of Ge exist, these species are probably unstable in the environment.

DOSE EFFECT

Acute Toxicity

There are few data on the effects of large, single ingestions of germanium. Generally, the acute toxicity of germanium compounds is low. Germanium tetrahydride is a moderately toxic gas that causes hemolytic anemia similar to arsine gas based on German data from the 1920s.[23] Animal studies suggest a 1-hour germanium tetrahydride exposure to 100 ppm may cause hemolytic anemia and exposures exceeding 185 ppm may cause death.[24]

Chronic Toxicity

Some suggested therapeutic doses of daily germanium supplements include the following: germanium dioxide, spirogermanium, 120 mg (22 mg Ge); carboxyethylgermanium sesquioxide, 150–500 mg (Ge-132, 32–107 mg Ge); and germanium lactate-citrate, 250 mg (45 mg Ge). There are inadequate data to determine a safe or effective dose. Estimating toxic doses based on data from case reports is limited by the lack of analytical confirmation, poor labeling, confounding illnesses, and reporting bias. In a review of 31 case reports of germanium toxicity (as dioxide, carboxyethylgermanium sesquioxide, germanium lactate-citrate, unspecified forms), the total Ge dose varied from 15–>300 g over a duration of 2–36 months.[25] This review estimated the LOAEL for these cases as 1–4 mg/kg/day. Cumulative germanium dioxide doses of 30 g (~21 g Ge)[26] over 2 months and ~110 g germanium lactate-citrate (~76 g Ge)[27] over 8 months were associated with the development of chronic tubulointerstitial nephritis. The latter case was associated with severe necrotizing pancreatitis, localized peritonitis with negative blood cultures, elevated serum CK, lactic acidosis, and intractable hypotension in a patient with breast cancer on tamoxifen. She ingested nine times the supplier's recommended dose. A case series of five patents ingesting a cumulative dose of 27–250 g GeO_2 (19–174 g Ge) developed tubulointerstitial nephritis that progressed slowly and improved (but did not resolve) 10–40 months after cessation.[28] The ingestion of ~80 g inorganic Ge over 6 years (36 mg daily) as a dietary supplement by a 63-year-old woman was associated with the development of anorexia, nausea, vomiting, peripheral neuropathy (difficulty in writing, gait disturbance), and mild renal dysfunction.[29] The neuropathy and renal dysfunction did not improve after cessation of germanium supplements; she later died after developing pneumonia and sepsis. The lack of improvement following cessation of Ge use limits conclusions regarding causation.

TOXICOKINETICS

Very few human data are available on germanium kinetics. In a study of eight different healthy adult volunteers receiving liquid oral preparations containing organic Ge (Ge-132) in doses of 1 g/m^2 BSA, 2.5 g/m^2 BSA, or 4 g/m^2 BSA, the mean C_{max} was 5.3 ± 2.2 mg/L, 13 ± 5 mg/L, and 18 ± 8 mg/L, respectively.[30] The T_{max} (time to C_{max}) ranged from 0.7–2.0 hours. The terminal elimination half-life based on a two-compartment model was 5–6 hours. Renal elimination accounted for <11% of the administered dose. In a study of seven workers exposed to metallic germanium ($n = 3$) and germanium oxide ($n = 4$), the urinary elimination half-life of germanium averaged ~13 hours with a range of 8–13 hours.[31]

In animals, the lung and gastrointestinal tract absorb inorganic and organic germanium compounds rapidly with absorption almost complete within several hours. These studies indicate that germanium compounds are fairly evenly distributed throughout the body with the highest concentrations occurring in the kidney, liver, spleen, and, to a lesser extent, in bone.[32] Plasma and erythrocyte Ge concentrations are similar. Elimination of germanium occurs primarily by excretion in the urine with most of the dose eliminated within 4–7 days.[9] In these animal studies, the body does not accumulate germanium; the biological half-life is ~1.5 days.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

The role of germanium in the body is unclear; there are inadequate data to determine if germanium is an

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. essential trace element. Similarly, the mechanism of toxicity is unknown, but other heavy metals (cadmium, copper, lead) produce similar kidney damage.

Kidney

The kidney is the most sensitive organ to the effects of the chronic ingestion of inorganic germanium; the classical pathological abnormalities associated with renal damage include interstitial changes (focal interstitial infiltrates) and vacuolar degeneration of the tubular epithelium with relative sparing of the glomeruli.[33] In a fatal germanium intoxication, electron microscopy of the renal tissue demonstrated mild mesangial proliferation with foamy cell transformation of the glomerular epithelium.[11] Permanent sequelae may occur. The chronic ingestion of a high dose of germanium lactate citrate by a patient with stage II HIV infection produced focal distal tubular atrophy and slight interstitial fibrosis on renal biopsy 20 months after discontinuation of germanium supplements.[34] In animal studies, the administration of inorganic germanium induces degenerative changes in the epithelium of the proximal and distal convoluted tubules; however, markers of proximal tubular dysfunction (*N*-acetyl-β-D-glucosaminidase) are usually normal.[28]

Liver/Muscle

Histological features of germanium toxicity other than renal pathology include marked liver steatosis and vacuolar degeneration of skeletal muscle and myocardium.[35] In animal models, long-term administration of germanium dioxide produces a myopathy characterized by the formation of ragged-red fibers.[36] The associated decrease in cytochrome *c* oxidase activity and the accumulation of high electron-dense material in the mitochondria suggest mitochondrial dysfunction is an important mechanism in the development of germanium-induced myopathy.

CLINICAL RESPONSE

Adverse Medicinal Effects

Case reports associated chronic ingestion of inorganic (germanium dioxide, germanium lactate-citrate) and organic (carboxyethylgermanium sesquioxide, spirogermanium) germanium compounds as diet supplements with the insidious onset of renal failure, primarily involving the renal tubules and interstitial tissue with little glomerular damage.[37] Some of these patients had neurological (hyperesthesias, paresthesias, hyporeflexia, hypotonia) and myopathic (muscle weakness) symptoms as well as chronic illnesses (diabetes mellitus, malnutrition, unexplained weight loss).[38] The cessation of germanium therapy stops the progression of the renal disease, but renal dysfunction may persist.[39] Transient neurological dysfunction (ataxia, dizziness, nystagmus, paresthesias, vertigo) and interstitial pneumonia occurred in Phase I and Phase II clinical trials of an azaspiran organic germanium compound (2-aza-8-germanspiro[4,5] decane-2-propamine-8,8-diethyl-*N*,*N*-dimethyl dichloride, spirogermanium) used for the treatment of advanced stages of cancer.[8,40,41,42] These clinical trials did not report adverse renal effects. Case reports also associate the chronic ingestion of inorganic Ge as a dietary supplement with the development of gait disturbances and sensory ataxia, resulting in difficulty with fine motor movements (writing), paresthesias, and weakness.[29,43] Germanium tetrachloride is a strong irritant of the skin, mucous membranes, and upper respiratory tract as a result of the hydrolysis of this compound to HCl.[44] Germanium tetrahydride is probably a hemolytic agent with toxic properties similar to arsine and stibine based on guinea pig studies;[45] however, there are few human data to determine the toxicity of this gas.

Carcinogenesis

Germanium exposure has not been associated with a significantly increased risk of reproductive abnormalities, mutagenic activity, or increased prevalence of cancer.[46] Neither the International Agency on Cancer nor the US National Toxicology Program list Ge as a suspected carcinogen. Although there are limited data, germanium compounds do not demonstrate significant mutagenic activity; however, under certain conditions, the administration of Ge compounds may inhibit the mutagenic activity of other substances.[47] Studies of patients with cancer suggest that organic germanium compounds possess some anti-tumor activity.[34,48] Examination of these properties has not progressed beyond Phase II clinical trials.

DIAGNOSTIC TESTING

Analytical Methods

Techniques for analyzing total Ge in biological samples include graphite furnace/atomic absorption spectrometry (GFAAS), various applications of inductively coupled plasma/mass spectrometry (ICP/MS), and microwave-induced plasma/mass spectrometry (MP/MS). In standard solutions of Ge, the LOD for GFAAS and MP/MS were 3 μg/L and 0.05 μg/L, respectively.[49] The use of high-performance liquid chromatography with quadrupole/ICP/MS allows speciation of organic and inorganic germanium.[50]

Biomarkers

In a study of 100 healthy French volunteers, the median plasma germanium concentration was 5.06 μg/L with a 95% CI of 3.70–6.17 μg/L as measured by ICP/MS (LLOQ, 0.09 μg/L).[51] The median whole blood Ge concentration in this group was 16 μg/L (95% CI: 10.8–19.5 μg/L) with an LLOQ of 0.17 μg/L. The urine germanium concentration in the general population is often below the limits of detection (<0.25 μg Ge/L).[31] In this French study, the median urine Ge concentration was 2.0 μg/L (95% CI: 1.17–3.37 μg/L) with an LLOQ of 0.08 μg/L.

Abnormalities

Proteinuria and hematuria are uncommon in patients with germanium-induced renal disease because the disease process primarily involves the interstitial renal parenchyma and tubules. Additionally, markers of proximal renal function are frequently normal and the physiological dysfunction involves the distal tubules (i.e., defect in concentrating ability).[28] Consequently, laboratory studies demonstrate disturbances in water and electrolyte balance. Animal studies demonstrate myopathies following the chronic ingestion of germanium compounds.[36] Therefore, the elevation of serum creatinine phosphokinase and hyperuricemia theoretically may occur in germanium toxicity, although no human data are available to confirm animal studies. Other abnormalities reported in association with the chronic ingestion of germanium compounds include elevated liver serum hepatic aminotransferases and lactic acidosis.[27] Evidence of hemolysis (anemia, hemoglobinuria, free plasma hemoglobin) may occur following exposure to germanium tetrahydride.

HEALTH SURVEILLANCE

The ACGIH recommends an 8-hour TLV–TWA for germanium tetrahydride of 0.2 ppm (0.6 mg/m^3) with no TLV–STEL.[24] The United Kingdom has a 10-minute STEL of 0.6 ppm germanium tetrahydride. The US OSHA PEL is the same as the ACGIH-recommended standards. There are few data on the use of urine germanium concentration to monitor occupational exposures to germanium. Exposure to inorganic germanium compounds (e.g., GeO_2) in occupational settings typically is greater (i.e., 7–10-fold) than exposure to metallic Ge. Using a hydride generation-based method coupled with flow-injection graphite furnace atomic absorption spectrometry (limit of detection, 0.25 μg Ge/L urine), germanium was not detectable in urine samples from Belgian control male subjects without occupational Ge exposure.[31] The urine samples of workers exposed to metallic Ge had a mean Ge concentration of 3.4 μg/g creatinine compared with 23.4 μg/g creatinine for workers exposed to inorganic germanium. In a cross-sectional study of 75 workers exposed to airborne inorganic Ge concentrations ranging from 0.03–300 μg/m^3, the exposed workers had a slightly higher urinary concentration of high-molecular-weight proteins (albumin, transferrin) when compared with 79 matched referents.[52] Although this finding suggests the presence of subclinical glomerular changes, the lack of a relationship between these changes and the intensity of exposure does not support a causal association. Renal and tubular function as measured by serum creatinine and low-molecular-weight proteins (retinol binding protein, *N*-acetyl-β-D-glucosaminidase, β_2- and α_1-microglobulin) were similar between the two groups. Because of the relatively rapid urinary elimination of germanium, post-shift urine specimens are the preferable samples for monitoring inorganic germanium exposure in the occupational setting.

TREATMENT

Because there are few human data on the treatment of germanium toxicity, treatment is primarily supportive. Theoretically, the treatment of an exposure to germanium tetrahydride would be similar to the treatment of arsine poisoning (see "Arsenic" chapter).

Chapter 13

GOLD

HISTORY

Gold has been a precious metal since antiquity. The Chinese, Egyptians, and Greeks admired the luster and corrosion resistance of this metal, especially as a constituent of jewelry and adornments. Some alchemists during the Dark Ages considered gold a panacea for all diseases and an elixir for eternal youth. In the 16th century, Paracelsus considered the combination of mercury and gold the "elixir of life."[1] Following Robert Koch's 1890 report that gold cyanide inhibited the tubercle bacilli *in vitro* but not *in vivo* (guinea pigs), gold monovalent salts (sanocrysin, sodium aurothiosulfate) were administered as nonspecific antiseptics for various infections including bacterial endocarditis, gonococcal arthritis, lupus vulgaris, rheumatic fever, and syphilis.[2] In 1927, Lande introduced the parenteral use of the gold thio salt, aurothioglucose (Solganal-B-Oleosum), for rheumatoid conditions believing these conditions resulted from nonspecific, low-grade infections (e.g., tubercle bacilli).[3] Also believing in an infectious etiology, Jacques Forrestier and later TA Kean promoted the use of gold for the management of rheumatoid arthritis during the 1930s.[4,5] Gold therapy (also known as chrysotherapy) flourished during 1925–1935 as the period became known as the Gold Decade in tuberculosis treatment; however, the recognition of serious adverse effects and questionable efficacy limited the overall use of gold therapy by the end of the 1930s.[6] During this period, bluish discoloration of the skin (chrysiasis) became a recognized complication of parental chrysotherapy. In 1945, Thomas Fraser reported that parenteral sodium aurothiomalate (Myocrisin® or Myocrisin®) was effective for the treatment of rheumatoid arthritis in the first controlled clinical trial based on clinical improvement in 82% of the Myocrisin® patients and 45% of the controls.[7] However, 75% developed mostly mild toxic reactions (headache, shivering, skin rash, oral lesions, albuminuria, reduced white blood cell count, colitis) when using the high gold doses associated with treating tuberculosis. In 1961, the Empire Rheumatism Council concluded multicenter trials that documented the efficacy of monovalent gold (aurothioglucose, gold sodium thiomalate).[8] The oral gold phosphine compound, auranofin, was approved for the treatment of rheumatoid arthritis in 1985; however, this drug is rarely used now because subsequent clinical studies reported injectable gold drugs are more effective than auranofin.[9] Despite the introduction of therapeutic drugs for rheumatoid arthritis with fewer adverse effects and greater overall efficacy, chrysotherapy remains an option for patients with poor responses to other antiarthritic drugs. Currently, gold nanoparticles (i.e., engineered nanoparticles with all three dimensions < 100 nm) are constituents of automobile parts, beverages, cosmetics, food packaging, lubricants, toothpaste, and medical diagnostics.[10,11]

PHYSIOCHEMICAL PROPERTIES

Gold is a soft, malleable, lustrous yellow, water insoluble, and corrosion-resistant member of Group 11 (Group Ib) in the periodic table with several oxidation states (1−, 0, 1+, 2+, 3+, 5+). This tasteless and odorless metal does not oxidize in air. Metallic gold (0) is relatively inert, resulting in low toxicity and

immunogenicity. This metal shares similar electronic configuration as other transition metals (e.g., copper, silver). Although gold has at least 70 isotopes, only ^{197}Au is stable. The high chemical affinity of mercury for gold results in the common formation of mercury–gold amalgams.

Gold nanoparticles possess unique optical and physiochemical properties useful in biological and pharmaceutical fields (e.g., drug delivery, imaging, phototherapy), particularly the property of surface plasmon resonance. The absorption and scattering of light in response to the resonance of gold electrons produce localized heating and color changes. As a result of coherent oscillations by conduction-band electrons *plasmons* during irradiation with light, gold nanoparticles appear in different colors (e.g., red, blue) depending on the wavelength and size/shape of the nanoparticles.

Therapeutic use of gold involves the use of complex, monovalent gold. Parenteral monovalent gold compounds include gold sodium thiomalate, gold thioglucose, and gold sodium thiosulfate. Auranofin (triethylphosphine gold) is a lipid-soluble oral gold preparation that differs structurally from parenteral compounds by the presence of gold–phosphine and gold–thiol bonds. The gold content of auranofin is ~29% w/w, whereas the injectable formulations contain ~50% gold w/w. Figure 13.1 displays the chemical structures of three gold preparations previously used to treat rheumatoid arthritis, including auranofin.

EXPOSURE

Uses

The uses of this rare metal include components of jewelry and medical devices (prostheses, acupuncture needles), chrysotherapy (soluble gold salts) for rheumatoid arthritis, and restorative dentistry (prosthetic alloys containing copper, silver, and platinum).[13] The ductility, high malleability, and ease of conduction of heat and electricity favor industrial uses in telecommunication (semiconductors, integrated circuits, cable termination) and electrical contacts as well as an antiglare agent in space helmets to protect astronauts from intense solar radiation.[14] Newer uses of this metal involve the production of gold nanoparticles to deliver drug and gene therapy, noninvasive whole-body imaging, and hyperthermic cancer therapy. Properties useful for biomedical applications include the high biocompatibility of bulk gold, easy surface functionalization with amine and thiol compounds, narrow size control during synthesis, and good chemical stability.[15]

Production Processes

Gold exists naturally in its elemental state typically in pyrites, quartz, or gold telluride ores. Pure metallic gold is reddish-yellow; however, the presence of other metals (e.g., copper, nickel, palladium, platinum, silver, tellurium) in ores or alloys produces multiple colors from silver-white to orange and red/purple. White gold is a gold-based alloy containing nickel, palladium, platinum, silver, and zinc that produce the white color. Extraction and purification of gold involve the following: 1) amalgamation with mercury and 2) MacArthur-Forrest Process (cyanide), flotation procedures (telluride ores), Miller Process (chlorination), and Wohlwill Process (electrolytic).[14] Adverse effects associated with these processes usually result from by-products or contaminants (e.g., arsenic, free cyanide, mercury vapor, radon, silica dust) rather than gold.

Sources

The earth's crust contains an average of ~5 ppb Au (5 μg/kg) dry weight. A review of gold concentrations in the environment reported maximum gold concentrations of 0.001 ppb (0.001 μg/L) in rainwater and 0.0015 ppb in seawater.[16] Fallout from atmospheric dust accounts for most of the gold in ocean surface waters. Commercial ventures mining gold from the ocean have been unsuccessful; during the 1920s, German

scientists failed to recover sufficient gold from seawater to help reduce the German debt from World War I.[17] Comparisons of gold concentrations in preconcentrated samples from various sites are complicated by the use of various analytical techniques with different limits of quantitation. Gold is detectable in vegetable and animal sources, including food. In a cross-sectional study of 84 German children aged 14–83 months, the median *weekly* dietary gold intake was 1.1 μg with an upper 95% of 4.9 μg as measured by sector-field inductively coupled plasma mass spectrometry.[18] The weekly arithmetic mean was 2.07 ± 4.33 μg with a maximum weekly Au intake of 35 μg.

DOSE EFFECT

The usual dosage schedule for parenteral gold involves weekly injections of 1, 5, or 10 mg, followed by 50 mg each week up to a total dose of 1 g Au. The typical oral dose of auranofin (triethylphosphine gold) for rheumatoid arthritis is 6 mg daily for 6 months and 9 mg daily for an additional 3 months if initial therapy was ineffective. In dose-establishment studies, the efficacy of 2, 3, and 6 mg auranofin is similar.[19] Although higher doses are more frequently associated with more rapid clinical improvement, more frequent or severe lower gastrointestinal complaints occur at higher doses. Most overdoses of parenteral compounds involve the iatrogenic administration of 10 times the daily dose. Patients have tolerated 500 mg aurothioglucose without significant toxicity or deterioration in their disease.[20] There are no data in humans on the fatal dose of gold.

TOXICOKINETICS

Absorption

The pharmacokinetics of gold depends on the oxidation state and the route of exposure. In general, absorption of elemental gold from the gastrointestinal tract is low.[18] The absorption of auranofin following ingestion is relatively low (i.e., ~25%) compared with the parenteral route.[21] A 50-mg intramuscular injection of gold sodium thiomalate produces peak serum gold concentrations of 6–8 mg/L within 2 hours.[22] These values decline over 7 days to the range of 3 mg/L. Oral daily doses of auranofin of 2–9 mg produce serum Au concentrations of 0.3–1 mg/L; these values do not vary significantly during the day while on chronic therapy.[23]

Distribution

Gold distributes widely throughout the body with the highest concentrations occurring in the liver, kidneys, adrenals, and spleen during therapeutic use. In the blood, gold is ~80–90% protein-bound, primarily to metallothionein,[24] albumin,[25] and γ-globulin.[26,27] Parenteral gold preparations produce higher gold concentrations in the tissues compared with the oral gold preparation, auranofin. Gold concentrates in red blood cells, particularly in smokers,[28] whereas little accumulation of gold occurs in the hair, nails, or skin.

Elimination

Following intramuscular administration of gold sodium thiomalate (Myochrysine®), excretion accounts for ~40% of the dose within the first week as measured by neutron activation analysis. During this period, ~70% appeared in the urine and ~30% in the feces.[29] The initial elimination half-life of gold in the blood after parenteral gold therapy is ~6 days compared with a half-life of 17–26 days after daily oral administration of 6 mg auranofin.[30] However, the body retains parenteral gold (sodium thiomalate) longer than auranofin. After 250 days, ~25% of a parenteral dose of gold remains in the body compared with 1% of an auranofin 180 days after administration.[31]

Maternal–Fetal Kinetics

Gold crosses the placenta and diffuses into fetal tissue. Umbilical blood and maternal blood contain similar concentrations of gold after the maternal administration of sodium aurothiomalate throughout pregnancy.[32]

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Although a few plants accumulate gold while growing in gold-rich soils, living organisms do not use metallic gold in chemical processes reflecting the stability and rarity of elemental gold. The mechanism of action for the anti-inflammatory effects on the joints of rheumatoid arthritis patients remains unclear. *In vitro* studies suggest gold has an affinity for thiol-containing proteins, selenoproteins, cysteine proteases, mitochondrial isoforms, and transcription factors.[12] Potentially, the difference in binding accounts for the difference in toxicity between the two main types of gold compounds. Gold compounds also inhibit mononuclear function as well as pinocytosis and phagocytosis *in vitro*. Pathological changes associated with gold therapy include acute

tubular necrosis, tubular degeneration, and immune complex glomerulonephritis; proximal tubular epithelial cells may contain gold inclusions (aurosomes) on pathological examination.[33]

CLINICAL PRESENTATION

Adverse Medicinal Effects

Adverse reactions develop in approximately one-third of patients undergoing treatment with gold salts for rheumatoid arthritis, primarily dermatological (dermatitis, pruritus, stomatitis), and gastrointestinal (diarrhea).[21] Bluish-gray discoloration of the skin (chrysiasis) has been a recognized complication of gold therapy since the late 1920s. In a case series of five patients receiving 4–10 g elemental gold parentally as an aurothiopolypeptide over many years, skin biopsies demonstrated crystalline, amorphous, and spherical auriferous deposits in the upper dermis.[34] Most adverse reactions are mild (anemia, thrombocytopenia), but life-threatening complications may involve kidney failure, agranulocytosis, or aplastic anemia depending on the type of gold compound and dose.[35] Proteinuria develops more commonly in patients receiving parenteral therapy than other types of exposure or other second-line drugs for rheumatoid arthritis;[9] the proteinuria usually resolves within 1–3 years after cessation of therapy.[36] Some of these patients progress to nephrotic syndrome and reversible renal failure.[37] Rarely, an enterocolitis characterized by profuse diarrhea and vomiting along with abdominal pain, fever, and eosinophilia develops, typically during parenteral gold therapy.[38] Pulmonary complications (bronchiolitis, fibrosis) are also rare. Case reports associate the development of diffuse pulmonary infiltrates and a restrictive ventilatory defect with gold therapy.[39,40] Studies in animals suggest high gold concentrations may produce acute renal failure.[41]

Acute Toxicity

Most overdoses to date involve the inadvertent administration of 500 mg gold salt as an intramuscular injection (10 times the therapeutic dose). Typically, these patients remain asymptomatic; occasionally, mild elevations in serum hepatic aminotransferase concentrations[42] and thrombocytopenia[43] develop. Rarely, case reports associate cardiac dysthymias with gold toxicity. Three hours after the intramuscular injection of 500 mg of aurothiomalate, a 32-year-old patient developed ventricular tachycardia along with weakness, palpitations, and dizziness.[44] The dysrhythmia resolved within a few hours of treatment with lidocaine and BAL.

Environmental Exposure

Eczema of the head and neck is the most common hypersensitivity reaction to gold, particularly gold-containing body-piercing jewelry containing other metal sensitizers (white gold);[45] however, hypersensitivity to pure gold is very rare.[46] A 24-year-old woman developed a contact hypersensitivity reaction to her 18-carat gold wedding ring.[47] Patch testing with pure gold leaf was negative. Patch testing with 0.2% gold chloride was positive at 72 hours, whereas the response with 0.02% gold chloride was equivocal.

Occupational Exposure

Gold is a rare skin allergen that may produce allergic contact dermatitis or pigmented papular eruption. A 32-year-old man developed discrete dark-brown macular pigmentation 30 minutes after direct contact with gold trichloride crystals; he subsequently developed pigmented papules at the contact site.[48] Patch tests and intradermal injections with gold salts confirmed hypersensitivity to gold. In a cross-sectional study of 1,197 active South African gold miners, 139 (12%) had evidence of reactive airways as defined by >10% increase in FEV_1 following inhalation of salbutamol.[49] A history of wheezing in these miners did not predict the presence of reactive airway disease. Of the 272 miners (i.e., 23% of the cohort) with a history of wheezing, only 40 miners had objective evidence of reactive airways as defined above. The study detected no correlation between the duration of mining and airway reactivity with the authors concluding that the evidence did not support an association between gold exposure and airway reactivity. Silicosis was prevalent in the gold miners; a subsequent study reported that emphysema accounted for the pulmonary changes in this cohort.[50]

Reproductive Abnormalities

Gold compounds demonstrate dose-related teratogenic effects in rabbits and rats;[51] however, gold doses in these experiments far exceed currently recommended doses. Limited human data on the use of gold therapy do not suggest an increased risk of reproductive abnormalities.[52] A follow-up study of six offspring of mothers who received parenteral gold from the second to ninth week of gestation did not detect any congenital abnormalities.[53]

Carcinogenesis

The International Agency for Research on Cancer and the US National Toxicology Program do not recognize gold or gold compounds as potential human carcinogens. A mortality study of 13,603 Canadian gold miners revealed an increased risk of cancer (SMR = 129, 95% CI: 115–145) in gold miners with >5 years of gold mining experience before 1945.[54] The minimum latency period between initial employment in the gold mine and the discovery of cancer was 15 years. Lung cancer mortality was not increased in workers employed after 1945. A follow-up study of these gold miners demonstrated a number of respirable carcinogens in the mines including radon, arsenic, and asbestos.[55]

DIAGNOSTIC TESTING

Analytical Methods

Typical analytical procedures for the determination of picogram ranges (μg/L) involve pretreatment (e.g., dry ashing, microwave-assisted decomposition, wet digestion) followed by separation from interferents/complex matrices and multielement instrumental techniques.[56] Sensitive, reliable analytical techniques for quantitation of gold in environmental samples include inductively coupled plasma/mass spectrometry and inductively coupled plasma/optical emission Spectrometry.[57] Electrothermal atomic spectrometry (graphite furnace/atomic absorption spectrometry) and neutron activation analysis provided low limits of detection. High-performance liquid chromatography/inductively coupled plasma/mass spectrometry can identify oxidation state and gold complexation in aqueous environments with detection limits in the range of 0.05–0.30 μg/L.[58]

Biomarkers

The weekly administration of 50 mg of soluble salt produces steady-state serum gold concentrations of 4–8 mg/L by the eighth week; however, adverse reactions were not correlated to serum gold concentrations. The peak serum gold concentration after an injection of 500 mg gold aurothiomalate was 50 mg/L.[43] In the cross-sectional German Environmental Survey of 1,080 inhabitants aged 18–69 years, the geometric mean urine gold concentrations were 45.5 ng/L with an upper 95% of 239 ng/L and a maximum of 2,120 ng/L.[59] The number of bridges, crowns, and dental inlays strongly influenced the urinary gold concentration.

TREATMENT

Treatment is primarily supportive. Individual case reports document the use of steroids (pneumonitis),[60] peritoneal dialysis,[61,62] and BAL chelation;[63] however, few clinical data are available to confirm efficacy or guide treatment. The reports of the successful use of dimercaprol,[64] penicillamine,[65] and *N*-acetylcysteine[66] as chelating agents for gold toxicity are largely anecdotal without good clearance data. Technically, anti-rheumatoid arthritis drugs are monovalent gold compounds that do not contain the four atoms in a square-planar four-coordinate necessary for the formation of a chelate ring; trivalent gold compounds are able to form chelate rings.[67] A study in mice receiving 3 mol antidote/mol gold intraperitoneally 20 minutes after the intraperitoneal administration of monovalent gold indicated that survival was greater in the mice administered 2-dimercaptosuccinic acid (DMSA) or sodium 2,3-dimercpatopropane-1-sulfonate (DMPS) than *D*-penicillamine or *N*-acetyl-L-cysteine.[68] There are inadequate human data on DMSA or DMPS to determine the efficacy of these agents for gold intoxication. A patient who received two 500-mg gold aurothioglucose injections within 1 week remained asymptomatic without chelation therapy.[42] Consequently, the decision to use chelation therapy (e.g., BAL) for gold toxicity depends on clinical judgment, the degree of expected toxicity, and the adequacy of treatment alternatives.

Chapter 14

INDIUM

HISTORY

In 1863, Theodore Richter and Ferdinand Reich isolated indium from zinc ores using spectroscopy. The name indium derives from the indigo flame created by the ignition of indium. Until the early 1990s, indium production was small with uses limited to dental alloys, nuclear reactor rods, and semiconductor research. The development of transparent conductive coatings for liquid crystal displays and plasma televisions with fine, poorly water-soluble indium compounds (indium oxide, indium hydroxide, indium tin oxide) substantially increased the exposure of workers to indium compounds. In 2001, a worker exposed to indium dust during the polishing of indium tin oxide targets died after developing bilateral pneumothoraces from interstitial pulmonary disease.[1] Subsequently, several cases of pulmonary alveolar proteoses, interstitial fibrosis, and emphysema ("indium lung") have been associated with occupational exposure to indium compounds in Japan, the United States, and China.

PHYSIOCHEMICAL PROPERTIES

Indium is a rare, soft, ductile, silvery-white nonferrous metal in Group 13 (Group IIIa) of the periodic table with boron, aluminum, gallium, and thallium; indium phosphide is a black cubic crystalline powder. As a malleable and ductile metal, indium easily forms alloys, particularly low-melting-point alloys. Indium tin oxide is a sintered ceramic material consisting of 90% trivalent, water-insoluble indium oxide (In_2O_3, CAS RN: 1312-43-2) and 10% tin oxide (SnO_2). In aqueous solutions, only the trivalent form of indium is stable. The most common indium salts are trivalent; monovalent and divalent indium salts also exist. Table 14.1 lists the identifying information and physical properties of indium and indium phosphide.

TABLE 14.1. Physical and chemical characteristics of indium and indium phosphide.

Physical Characteristic	Indium	Indium Phosphide
CAS RN	7440-74-6	22398-80-7
Molecular formula	In	InP
Molecular weight (g/mol)	114.82	145.79
Melting point/boiling point (°C)	156.6/2080	1062
Density (g/mL)	7.31	4.81
Water solubility (25 °C)	Insoluble	Low

Abbreviations: CAS RN = Chemical Abstracts Service Registry Number.

EXPOSURE

Uses

The use of indium is limited by the low rate of recovering indium as a by-product of zinc and lead–zinc smelting; trace amounts of indium exist in sphalerite (ZnS). Occupational exposure to indium occurs primarily in the microelectronics industries. The leading end use of indium is the production of indium tin oxide for electronics. Thin-film coatings of indium tin oxide are

used primarily for their electrical conduction properties as transparent conductive films on a variety of flat-panel devices (e.g., liquid crystal displays, light-emitting diodes, plasma display panels). Optoelectronics (e.g., photovoltaic, light-emitting diodes) uses a variety of indium compounds besides indium tin oxide, including indium phosphide, indium arsenide, indium sulfide, copper indium diselenide, and copper indium gallium diselenide. Indium phosphide is an excellent semiconductor with high operating efficiency and power; the relatively high refractive indices of indium phosphide and ternary (InGaAs) and quaternary (InGaAsP) derivatives allow sharp, small bends for the fabrication of very small devices. Indium phosphide is used for the production of nanowires and quantum dots.[2,3] Other uses of indium include semiconductors, electrical components, low-melting point solders and alloys (fuses, temperature indicators, infrared detectors, high-speed transistors, high-efficiency photovoltaic devices), and medical research (indium radioisotopes). Medical uses of organoiridium complexes include electrodes for stimulation, brachytherapy in gynecological oncology, catalysts, and anticancer agents.[4]

Production Processes

Zinc ores are the most common sources of commercial indium including christophite (FeS:ZnS) and sphalerite (ZnS). Methods to recover indium from the acid leachate of crude zinc liquors during zinc smelting include precipitation as a phosphate or on metallic zinc rods. The primary source of indium is a by-product of smelting zinc ores and, to a lesser extent, sulfide ores of copper, tin, iron, and lead. Indium combines with phosphorus under controlled conditions (high temperature, pressure) to form indium phosphide; alternately, the thermal decomposition of trialkyl indium and phosphine gas (PH_3) produces indium phosphide. This compound does not occur naturally. Disposal and recycling of component materials in liquid crystal displays may result in exposure to indium compounds.

Sources

Air

Ambient air concentrations of indium are very low. In a study of ambient air in the relatively unpolluted Lake District of the United Kingdom, the average indium concentration in air samples collected during the calendar year was ~0.3 ng/m^3 as measured by neutron activation analysis.[5] This value was similar to analyses of indium in ambient air samples collected at six other UK nonurban sites. The mean indium concentration in high-volume air particulate filters collected in downtown Kellogg, Idaho, during a calendar year was 5.79 ng/m^3 (range, 0.06–43.3 ng/m^3).[6] This town is located in the Kellogg Valley near a lead smelter that began operations in 1916.

Soil

Indium is a rare element with soil concentrations typically of <0.01 ppm. In a study of soil samples near an Idaho lead smelter, the mean indium concentration was ~2 ppm as measured by neutron activation analysis.[6]

Water

In a Taiwanese study of 30 groundwater samples from an industrial district containing a large industrial park with semiconductor manufacturers, the mean indium concentration was 9.25 μg/L (range, 0.95–20.05 μg/L) compared with 0.01 μg/L (range, <0.005–0.05 μg/L) in a distant district (control).[7] The samples were collected from well water 10 m below the surface and analyzed by inductively coupled/mass spectrometry. The mean indium concentration in 229 dissolved river water samples from a summary of 4 Japanese studies was 1.9 ± 4.4 ng/L compared with 9.1 ± 35.5 ng/L in 179 particulate samples from the same area, as measured by ICP/MS.[8] For 25 dissolved and particulate lake water samples, the mean indium concentrations were 1.4 ± 1.8 ng/L and 4.8 ± 14.8 ng/L, respectively. The mean indium concentrations in 38 dissolved and 24 particulate water samples from coastal seawater were 3.0 ± 6.4 ng/L and 2.4 ± 1.5 ng/L, respectively. There are few data on the environmental exposure of the general population to indium.

Food

The estimated average daily intake of indium is minimal (i.e., <10 μg/kg body weight) as a result of the poor oral absorption of indium and the low indium concentration in most foods.[9] Beef and ham typically have the highest indium concentrations (<0.01 ppm), although shellfish and fish living near point sources may contain indium concentrations exceeding these concentrations. The estimated body burden is ~50 ppm.

DOSE EFFECT

There are inadequate data to determine dose-effect responses in humans. Pulmonary exposure of rodents

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

to indium compounds produces inflammation in the lungs. Intratracheal instillation of 24 mg/kg copper indium diselenide produced pulmonary inflammation within 72 hours characterized by an influx of macrophages, lymphocytes, and polymorphonuclear leukocytes.[10] Some systemic absorption of indium occurred.

TOXICOKINETICS

Tracer studies indicate that indium is poorly absorbed (<2%) through the gastrointestinal tract when administered as the $^{113m}InCl_2$ or ^{113m}In DTPA (diethylene triamine penta acetic acid) complex.[11,12] *In vitro* studies indicate that trivalent indium binds to transferrin in the blood.[13] Rodent studies suggest that most indium is distributed to kidneys, liver, and spleen.[14] In these studies, the kidney excretes ~50% of the indium chloride with an initial elimination half-life of ~2 days followed by a slower elimination half-life of ~2 months.[15,16] An observational study of 465 current and 127 former indium workers suggested the dissolution and clearance of indium from the body are slow.[17] The mean serum indium concentrations were similar in the two groups (8.4 μg/L and 9.6 μg/L, respectively), despite time following cessation of indium exposure of 58.3 months (95% CI: 2–201 months) for the latter group; however, estimates of cumulative exposure parameters for former workers were not reported. In a follow-up study of retired indium workers, the estimated indium biological half-life was ~8 years based on serial serum indium concentrations drawn after retirement.[18] For indium colloidal hydrated indium oxide, the feces account for a majority of the elimination with <10% of the dose eliminated in the urine during the first month. The biological half-lives of indium chloride and indium oxide were similar.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Indium is a rare metal with no known physiological role in humans. Occupational exposure to indium compounds is associated with pulmonary inflammation and interstitial disease in some of the exposed workers. In a case series of 10 workers diagnosed with indium lung, a granular, eosinophilic intraalveolar exudate consistent with alveolar proteinosis was present in all but one worker.[19] Other histological changes included cholesterol clefts (acicular spaces resulting from the dissolution of cholesterol esters during histological processing), granulomas associated with the cholesterol clefts, fibrosis, and occasionally honeycombing and emphysema. Occasional macrophages and lymphocytes occur in alveolar wall cellular infiltrates. Fibrotic foci may occur in areas without cholesterol clefts. The pathogenesis of these indium-associated changes remains unclear.

CLINICAL RESPONSE

Acute Toxicity

The medical literature contains little documentation of the acute effects of indium exposure.

Environmental Exposure

Indium is a rare metal with minimal exposure to the general population.

Occupational Exposure

There are few epidemiological data on the toxicity of indium compounds. Case reports of indium-exposed workers suggest that occupational exposure to indium compounds may cause pulmonary disease beginning as pulmonary alveolar proteinosis and progressing to interstitial lung disease ("indium lung") with fibrosis and emphysema.[20] Follow-up studies of indium workers suggest interstitial lesions regress partially with reduction in ambient air indium concentrations; however, emphysematous lesions continue to progress.[18] Two case reports from a Japanese factor associate wet surface grinding of indium tin oxide during production of liquid crystal displays with the development of pulmonary toxicity (subpleural emphysema, cholesterol granulomas).[1,21] Symptoms included dry cough, dyspnea, sputum production, weight loss, and exertional dyspnea. Both patients had elevated serum indium concentrations (51 μg/L, 290 μg/L) compared with controls; lung biopsies demonstrated the presence of submicron particles in the alveolar spaces, alveolar septum, and bronchiolar lumens that contained indium and tin based on X-ray energy spectrometry. One of these patients died after developing bilateral pneumothoraces. The exact etiology remains unclear as there was no exposure data on indium or tin concentrations in the workplace; other disease processes (e.g., lipoid pneumonia) may have contributed to the pulmonary effects. A cross-sectional study of 108 workers in this plant revealed 18 workers (83% smokers) with chronic cough and/or sputum production with the geometric mean indium concentrations in working areas of 0.01–0.05 mg/m^3 up to a

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

maximum of 0.36 mg/m^3 as measured by inductively coupled plasma/mass spectrometry (ICP/MS).[22,23] Four workers had clubbed fingers; however, none of the workers complained of exertional dyspnea or peripheral cyanosis. There was evidence of subclinical pulmonary disease (fine reticulonodular shadows, reduced diffusing capacity, DL_{CO}, and vital capacity, VC) in some of the workers; 79% of the workers were former or current workers. The DL_{CO} decreased with each quartile of serum indium concentrations, with the fourth quartile statistically significantly lower than the first quartile.

Two workers (hydrogen furnace operator, indium tin oxide department) developed pulmonary alveolar proteinosis while working at a US facility producing indium tin oxide.[24] Both workers had symptoms of impaired gas exchange including dyspnea on exertion. Lung biopsies demonstrated intraalveolar proteinaceous material and globules positive for periodic acid-Schiff (PAS) stain and the presence of indium in the lung material. One worker died of progressive pulmonary failure, whereas the other worker improved after treatment (albeit with some respiratory impairment). The latter worker had positive antibodies to granulocyte macrophage-colony stimulating factor. Pulmonary alveolar proteinosis is a rare, usually idiopathic disease that classically involves the alveoli rather than the interstitial infiltration and fibrosis seen in Japanese workers. Four months before developing pulmonary symptoms, the surviving worker had an undetectable plasma indium concentration following an acute ammonium hydroxide exposure.

A cross-sectional study of 93 Japanese workers in 2 indium tin oxide manufacturing and 2 recycling plants and 93 controls without indium exposure did not detect differences in spirometry, subjective symptoms, or the prevalence of interstitial or emphysematous changes on lung high-resolution computerized tomography between exposed and nonexposed workers.[25] About half the workers were exposed to airborne concentrations of indium tin oxide compared with 40% to indium trioxide and/or indium hydroxide dust and ~10% to metallic indium dust. The study did demonstrate an exposure-response relationship between serum indium concentrations and markers of lung inflammation (Krebs von den Lungen-6 or KL-6, surfactant protein-A or SP-A, SP-D); however, the clinical significance of these serum markers remains unclear.

Reproductive Abnormalities

There are few data in humans; animal studies suggest that the teratogenic potential of indium and indium compounds is relatively low.[26,27]

Carcinogenicity

There are few data on the carcinogenicity of elemental indium in humans that focus specifically on indium. Despite the limited human data, the IARC lists indium phosphide as probably carcinogenic to humans (Group 2A) based on extraordinarily high incidence of malignant pulmonary, hepatic, and adrenal (pheochromocytoma) neoplasms in rodents following inhalation exposure to indium phosphide.[28] One case of lung cancer was reported in a nonsmoking Japanese worker exposed to indium tin oxide;[29] however, the IARC lists these substances as a possible human carcinogen (Group 2B) based on sufficient evidence in animals (i.e., ↑ bronchioloalveolar carcinoma in rats, but not mice)[30] and inadequate data in humans.[31]

DIAGNOSTIC TESTING

Analytical Methods

Techniques for the determination of indium in biological samples include spectrophotometry, voltammetry, neutron activation analysis, electrothermal atomic absorption spectrometry,[32] graphite furnace atomic absorption spectrometry (GF/AAS), and inductively coupled plasma/mass spectrometry (ICP/MS). The latter technique has good sensitivity (LOD, 0.17 μg/g; LLOQ, 0.57 μg/g) with small sample sizes, minimal elemental interference, and capability for multi-elemental analysis.[33] The use of GF/AAS after precipitation of chitosan at pH 7–9 allows the determination of indium in water samples with a limit of detection (LOD) of 0.04 μg/L with a relative standard deviation of <5%.[34] Using flame atomic absorption spectrometry with slotted quartz tube or slotted quartz tube atom trap, the LOD was 3.63 ng/mL and 2.60 ng/mL, respectively.[35] The low indium concentration in environmental samples and the matrix effects of interfering species complicate indium analysis; consequently, a separation enrichment procedure is necessary prior to spectrometry. Techniques for preparation of samples containing indium include solvent extraction, coprecipitation, electrochemical methods, and solid-phase extraction with

various absorbants (e.g., Chromosorb 108 resin).[36] Current analytical methods typically measure total indium without speciation. The use of selective sequential extractions combined with inductively coupled plasma/mass spectrometry allows the determination of elemental indium, soluble trivalent salts, and insoluble trivalent salts.[37]

Biomarkers

Indium is not typically quantifiable in the blood of persons without occupational exposure to indium depending on the sensitivity of the analytical method.[38] In a study of occupational indium exposure, 19 of the 24 controls (management jobs in the same factory) had whole blood indium concentrations below the limit of detection (<0.7 ng/mL); 23 of the 24 controls had serum indium concentrations below the limit of detection (<0.4 ng/mL) as measured by graphite furnace atomic absorption spectrophotometry after wet digestion.[39] The single regression coefficient for whole blood and serum indium concentration was 0.94, suggesting that indium is relatively evenly distributed between serum and erythrocytes. However, the uptake of indium by erythrocytes is relatively small, resulting in the distribution of indium primarily in the plasma of partially hepatectomized rats.[40] There are inadequate data to quantitate the plasma/erythrocyte indium ratio.

Abnormalities

Indium lung disease is an interstitial illness characterized by pulmonary alveolar proteinosis that may progress to fibrosis with or without emphysema. Spirometric abnormalities include reduced diffusing capacity, FEV_1, and FVC. Additionally, biomarkers of interstitial lung disease (e.g., Krebs von den Lungen-6, surfactant protein-D) are typically elevated.[41]

HEALTH SURVEILLANCE

Environmental Monitoring

There are no established regulatory limits for exposure to indium phosphide. The ACGIH recommends a threshold limit value/time-weighted average (TLV–TWA) of 100 μg/m^3 for inhalation of indium. Table 14.2 lists regulatory and suggested guidelines for exposure to indium and indium compounds. In a study of a Japanese ingot production plant, the indium concentration in air varied between ~10–1,030 μg/m^3 with a mean of 190 μg/m^3 and a median of 55 μg/m^3.[38] There was substantial interindividual and intraindividual variation. The study did not detect a correlation between ambient air indium concentrations and the indium concentration in the blood or urine of the workers.

TABLE 14.2. Regulations and guidelines for exposure to indium and indium compounds.

Exposure Limit	Value
OSHA	
PEL–TWA (8-hour)	NE
PEL-Ceiling	None
PEL-Acceptable Maximum Concentration (30 minute maximum during 8-hour shift)	None
NIOSH	
REL–TWA (10-hour)	100 μg/m^3
REL–STEL (15-minute)	None
IDLH	None
ACGIH	
TLV–TWA (8-hour)	100 μg/m^3
Indium and indium compounds	100 μg/m^3 (as In)
Indium tin oxide	0.1 μg/m^3 (as In)
TLV–STEL (15-minute TWA)	None

Abbreviations: ACGIH = American Conference of Governmental Industrial Hygienists; IDLH = immediately dangerous to life and health; NE= not established; NIOSH = National Institute for Occupational Safety and Health; OSHA = Occupational Safety and Health Administration; PEL = permissible exposure limit; REL = recommended exposure limit; STEL = short-term exposure limit; TLV = threshold limit value; TWA = time-weighted average.

Biological Monitoring

Urine

The mean indium concentration in end-of-shift, end-of-work week urine samples from nine indium ingot production workers exposed primarily to In_2O_3 was 1.58 μg/L (1.54 μg/g creatinine) with a range in workweek samples of 0.13–8.68 μg/L (0.22–3.50 μg/g creatinine).[38] In a study of 72 production workers and 72 engineers exposed to unspecified indium compounds, the 2 exposed groups had mean inhalable air indium concentrations of 8.4 μg/m^3 (range, 0.34–101.26 μg/m^3) and 7.4 μg/m^3 (range, 0.25–100.27 μg/m^3), respectively, compared with a mean of 2.1 μg/m^3 (range, 0.14–18.00 μg/m^3) for 72 administrative workers as measured by ICP/MS.[42] The mean indium concentrations in spot end-of-shift urine samples were 7.0 ng/mL (range, 3.05–35.89 ng/mL), 5.9 ng/mL (range, 3.02–34.09 ng/mL), and 1.2 ng/mL (range, 0.05–7.27 ng/mL), respectively.

Measurements of inhalable gallium and arsenic in this study indicated that exposure to these two metals in this semiconductor plant was higher than indium.

Blood

Although plasma or serum indium concentrations are commonly used as biomarkers of indium exposure, limited data are available to determine the best biomarker. In a study of 87 current ITO facility workers with median duration of indium exposure of 1.9 years, current and cumulative exposures ranged from 0.4–108 μg/m^3 and 0.4–923 μg-year/m^3, respectively.[43] For participants with duration of indium exposure of <1.9 years, current ($r_s = 0.74$) and cumulative ($r_s = 0.72$) were similar; however, the correlation between indium exposure and health effects was better for cumulative indium exposure than the current plasma indium concentration. Cumulative indium exposure is correlated with dyspnea, ↓FEV_1, ↓FVC, and elevated biomarkers of interstitial lung disease (KL-6, SP-D). An observational study of an indium-tin oxide production facility with a medical surveillance program to prevent the occurrence of indium lung detected more spirometric changes (restriction, excessive decline in FEV_1, low TLC, low DL_{CO}) and abnormal chest X-rays in workers with serum indium concentrations exceeding 5 μg/L than workers with lower indium concentrations.[44] However, the difference between the two groups was not statistically significant ($P = 0.07$).

In a study of 93 workers in indium-tin oxide manufacturing and recycling plants, the geometric mean serum indium concentration was 8.25 ± 4.55 ng/mL (maximum, 116.9 ng/mL) in the exposed workers compared with 0.25 ± 2.64 ng/mL in 93 nonexposed workers.[25] For comparison, the geometric mean indium concentration in 107 workers exposed to water-insoluble, partially respirable particles of unspecified indium compounds was 4.09 ± 7.15 ng/mL (90th percentile: 42.7 ng/mL) in whole blood and 2.86 ± 8.81 ng/mL (90th percentile: 36.1 ng/mL) in serum.[39] The whole blood and serum indium concentrations were below the limit of detection in 34 and 37 workers, respectively. The mean whole blood indium concentration in 103 Taiwanese workers exposed to unspecified indium compounds was 0.22 ± 0.17 ng/mL compared with 0.14 ± 0.12 ng/mL in blood samples from unexposed controls (office workers), as measured by inductively coupled plasma/mass spectrometry after microwave dissolution.[45] There was no difference in the mean urine indium concentrations between the two groups. The mean plasma indium concentration in nine current indium ingot production workers in Friday post-shift blood samples was 5.59 μg/L with a workweek range of 0.32–12.61 μg/L (0.22–3.50 μg/g creatinine) compared with a mean of 0.71 μg/L and median of 0.17 μg/L in plasma samples from five retired workers.[38] These workers were exposed primarily to In_2O_3 along with $In(OH)_3$ and elemental indium. The persistence of indium in former workers limits the correlation of plasma or serum indium concentrations with current indium exposure.

The Japan Society for Occupational Health proposed a serum indium concentration of 3 ng/mL as a biological monitoring limit based on reducing pulmonary inflammation as defined by elevated serum KL-6 concentrations.[22] In a Korean study of 50 indium workers, workers with serum indium levels of ≥3 μg/L had longer exposure durations and a higher prevalence of HRCT-detected interstitial lung changes; the KL-6 and surfactant protein-D (SP-D) concentrations were significantly higher in the highest serum indium quartile than the lowest quartile.[46] In a cross-sectional study of 87 indium-tin oxide production and reclamation facility workers, the median duration of exposure was 2 years (range, 0.1–5.5 years); the median plasma indium concentration was 1.0 ng/mL (interquartile range, 0.2–2.3 ng/mL with maximum value, 37 ng/mL).[41] The majority of the workers (56%) were asymptomatic. Spirometric abnormalities (i.e., emphysema ($n = 4$), fibrosis ($n = 2$), alveolar proteinosis ($n = 0$)) were similar to the general population; however, statistically significant differences occurred in the subset with plasma indium concentrations of ≥1 ng/mL when compared with workers with plasma indium concentrations <1 ng/mL. These differences included dyspnea (but not chronic cough, wheezing, sputum production, or chest tightness), predicted FEV_1 and FVC (92% ± 2.6%), and increased serum inflammatory markers (Krebs von den Lugen-6, surfactant protein-D).

TREATMENT

Treatment is supportive. There are no human data to recommend specific antidotes or methods to enhance elimination of indium.

Chapter 15

IRON

HISTORY

Iron is an essential element for body function that has been used for many centuries in commercial processes. The production of steel is one of the cornerstones of the development of the industrialized world. For thousands of years, man used steel to build a variety of structures. In contrast to other cases of heavy metal poisoning involving the workplace and environment, most cases of iron toxicity result from the ingestion of iron-containing products by children. A dramatic increase in iron poisoning appeared during the middle of the 20th century. In the 1980s, ~5,000 cases of poisoning with iron preparations occurred annually in the United States, with the vast majority of these poisonings occurring in children of <6 years of age. Although the introduction of deferoxamine in the 1960s substantially reduced the mortality of patients hospitalized for iron poisoning, fatalities from iron ingestion remained a leading cause of death in young children ingesting adult iron medications.[1] Between 1983–1998, 44 reported pediatric deaths occurred in the United States from iron toxicity.[2] A US federal packaging regulation in 1997 required unit-dose packaging for all pharmaceutical products containing ≥30 mg elemental iron/dose. Pediatric deaths consequently decreased to <1/year. According to American Association of Poison Control Centers (AAPCC) data, exposure to iron salts accounts for <15% of the reported exposure to minerals and electrolytes (e.g., fluoride, calcium, potassium), whereas iron salts produce a majority of the moderate and major adverse outcomes following exposure to iron salts.[3] Among the electrolytes/minerals or vitamins with iron categories during 2013, the AAPCC reported no pediatric or adult fatalities from iron or iron salts.

Prolonged iron exposure from iron overload disorders increases intestinal iron absorption and causes hemochromatosis. This disease produces excessive iron deposition in tissues along with progressive fibrosis and organ failure (i.e., liver, heart, pancreas). During the mining and/or refining of iron ore, the protracted inhalation of iron or iron oxide dust may cause siderosis, particularly following heavy iron dust exposures in the 1940s and 1950s.[4] This condition describes the presence of stainable iron in lung tissue, but siderosis is usually benign and does not result in pulmonary dysfunction.

PHYSIOCHEMICAL PROPERTIES

Iron (CAS RN: 7439-89-6, atomic weight 55.85 g/mol) is a silver-white transition metal that is the primary constituent of the earth's molten core. The specific gravity of iron is 7.86. The magnetic properties of iron exceed similar properties of other metals; however, elemental iron loses its magnetic properties when heated to >770°C. The physical properties of iron change significantly with the addition of impurities (i.e., in ferroalloys) or temperature changes. The melting point of iron is 1,535°C, whereas the boiling point is 2,750°C. Fumes of iron oxide are red-brown in color. Iron pentacarbonyl (CAS RN: 13463-40-6) is a yellow, highly flammable, viscous, water-insoluble liquid that is a strong reducing agent. This compound forms in the presence of high partial pressures of carbon monoxide (e.g., steel cylinders containing carbon monoxide, steel pipes containing

illuminating gases). The vapor pressure of iron pentacarbonyl at 25°C is 35 torr. Reduced iron is a high-density, amorphous powder formed by the reduction of iron oxide. The oxidation of reduced iron is an exothermic reaction.

Iron combines with many compounds including carbonates, carbonyls, chlorides, disulfides, oxides, and sulfates. The most stable oxidation states of iron compounds are ferrous (2+) and ferric (3+). While ferrous chloride, ferrous sulfate, ferric chloride, ferric nitrate, and ferric sulfate are water-soluble, the water solubility of the following iron salts is limited: carbonates, fluorides, hydroxides, oxides, phosphates, and sulfides. The strong tendency of iron to combine with oxygen results in the formation of stable hydroxyl groups (chelates). In the body, iron compounds promote (catalyze) oxidation reactions for many important functions. Iron binds to carbon forming a variety of commercial ferroalloys including wrought iron (0.035% C), cast iron (2–4% C), and steel (~0.2–1.5% C). Mild steel contains ~0.25% carbon, whereas high-carbon steel contains carbon concentrations exceeding 0.6%.

EXPOSURE

Production Processes

Steel is the main refinery product for processing iron ore; besides iron, steel may contain other metals including chromium, manganese, molybdenum, or nickel to improve the characteristics of the steel. Most iron ores are oxides; the most common iron ores are the orange-red hematite (Fe_2O_3, 40–70% Fe) and silver-gray magnetite (Fe_3O_4, ~70% Fe) ores; taconite is a lower-grade magnetite ore (i.e., 25–30% Fe, silicates, quartz) found in North America (e.g., Minnesota, Labrador). Steelmaking consumes almost all of the mining of hematite ores. Less common iron ores include limonite ($Fe_2O_3 \cdot H_2O$) and siderite ($FeCO_3$). Occupational exposure to iron occurs primarily following the inhalation of iron oxide during mining, steel refining, or the use of iron products (arc welding, metal polishing). Limited data from the 1960s suggest that airborne iron oxide concentration in some steel manufacturing plants in those years may have averaged 20–30 mg/m^3 (i.e., substantially above current workplace standards) ranging up to 60–70 mg/m^3.[5] Depending on the specific processes used, iron and steel foundry workers may be exposed to a variety of air contaminants in addition to iron oxides including silica, metal dust, carbonyl sulfide, hydrogen sulfide, sulfur dioxide, phenols, benzene, formaldehyde, acrolein, aldehydes, nitrogen oxides, ammonia, aromatic amines, and diisocyanate.[6] The latter chemical is associated with occupational asthma in iron and steel foundry workers. Processing iron containing arsenic or phosphorus may liberate arsine or phosphine gases, respectively. The reduction of iron oxide by hydrogen produces reduced iron.

Uses

The vast majority of iron is used to construct arms, bridges, buildings, highways, railroads, ships, and vehicles. Steel is an iron product that contains up to 1.5–2% carbon. The tensile strength of steel increases with increasing carbon content; hence, mild steel is suitable for fabricating wire, pipes, and sheets, whereas tools and cutting instruments require high-carbon steel. Structural steel typically uses medium steels. The addition of silicon, tungsten, or manganese to ferroalloys increases the hardness of steel, whereas nickel and chromium improve resistance to corrosion (i.e., stainless steel).

Iron compounds (e.g., iron oxides) account for <1% of the total consumption of iron; these compounds appear in magnetic tapes, pigments, polishing compounds, and plastics. In Europe, iron pentacarbonyl is an antiknock agent in gasoline. Reduced iron is the main ingredient in instant hand warmers and disposable heating pads that produces heat when exposed to oxygen. Superparamagnetic iron oxide nanoparticles contain maghemite (γ-Fe_2O_3) and magnetite (Fe_3O_4); these nanomaterials are typically considered biocompatible with numerous biomedical applications including enhanced MRI contrast agents for early detection of metastatic lesions and receptor-specific targeted drug delivery to cancerous tissues.[7,8]

Pharmaceutical Formulations

Indications for the medical use of iron salts include primarily iron deficiency and mineral supplementation during pregnancy. The relative toxicity of iron depends on the amount of elemental iron ingested, which varies according to the type of iron salt involved. Many iron poisonings result from the ingestion of ferrous sulfate. The percentages of elemental iron contained within various ferrous salts are listed in Table 15.1.

In general, the ingestion of nonionic forms of iron (carbonyl, iron polysaccharide complex) produces less severe toxicity than ionic ferrous salts. Carbonyl iron contains uncharged submicroscopic spheres of elemental iron crystals that require solubilization to ionized iron in the stomach prior to absorption. Consequently, the toxicity of carbonyl iron does not correlate to ionic

TABLE 15.1. Elemental iron content in various iron salts.

Compound	Salt	Elemental Iron (%)
Ferrous sulfate	Anhydrous	36.8
	Crystalline	20.1
Ferrous chloride	Anhydrous	44.1
	Crystalline	28.1
Ferrous gluconate	Anhydrous	12.5
	Dihydrate	11.6
Ferrous fumarate		33.0
Ferric chloride	Anhydrous	34.3
	Hexahydrous	20.7
Ferric ammonium citrate		14.0–18.0

ferrous salts on a weight basis, despite the presence of 98% elemental iron in carbonyl iron products.[9] Similarly, iron polysaccharide complex contains 46% elemental iron by weight, but the effect of this product depends on the rate-limiting step of gastrointestinal absorption. Typically, chewable children's multivitamins contain up to 20 mg elemental iron/tablet compared with 50 mg elemental iron/tablet adult multivitamins and 100 mg elemental iron/tablet prenatal multivitamins. Table 15.2 lists the approximate elemental iron concentrations in representative iron products.

Sources

Environment

Iron is the fourth most abundant atomic element comprising ~5% of the earth's crust; iron-containing ores include hematite, magnetite, limonite, and siderate. The iron concentrations in freshwater and drinking water supplies vary widely with concentrations ranging from 0.01–1 mg/L,[10] whereas seawater contains much lower iron concentrations (<60 µg/L). Sampling of ambient air iron concentrations in the United States indicates that rural air contains 0.08–0.7 µg Fe/m_3 compared with 0.3–4.2 µg Fe/m^3 in air surrounding urban areas.[11] The average concentration of iron in the soil is ~5% (50 mg Fe/kg); some iron ores contain >50% Fe.

Diet

The average daily American diet contains about 15–40 mg Fe with approximately half of the iron in soluble form.[12,13] The concentration of iron is relatively high (30 mg Fe/kg) in beef, egg yolk, kidney, liver, and soybeans, whereas iron concentrations in grains, milk, and fruits are usually low (1–20 mg/kg).

TABLE 15.2. Elemental iron content of representative iron products. (Manoguerra et al.).[9]

Iron Product	Dosage Forms	Elemental Iron/Unit Dose
Ferrous sulfate		
	250 mg tablets	50 mg/tablet
	325 mg tablets	65 mg/tablet
	Timed-release tablets	65–105 mg/tablet
	Elixir 220 mg/5 mL	44 mg/5 mL
Ferrous gluconate		
	Drops (75 mg/0.6 mL)	9 mg/0.6 mL
	240 mg tablets	28 mg tablet
	300 mg tablets	36 mg/tablet
	325 mg tablets	40 mg/tablet
Ferrous fumarate		
	100 mg chewable tablets	33 mg/tablet
	Time-release tablets	50–110 mg/tablet
	200 mg tablets	65 mg/tablet
	325 mg tablets	107 mg/tablet
	350 mg tablets	115 mg/tablet
	Suspension (350 mg/5 mL)	33 mg/5 mL
Multivitamin hematinic products		
	Tablet or capsule	65–150 mg/tablet
Prenatal vitamins with iron		
	Tablet or capsule	9–106 mg/tablet
Adult multiple vitamin plus iron		
	Tablet or capsule	3–110 mg/tablet
Pediatric multiple vitamin plus iron		
	Chewable tablet	10–18 mg/tablet
	Drops	10 mg/mL
	Liquid	10 mg/5 mL
Carbonyl iron		
	Tablets and capsules	50–66 mg/tablet or capsule
	Liquid	15 mg/1.25 mL
Polysaccharide-iron complex		
	Tablets	50–150 mg/tablet
	Capsules	150 mg/capsule
	Elixir	100 mg/5 mL

The consumption of iron-rich staples combined with heavy iron contamination during the preparation process significantly increases the average daily iron intake in the diet of people in rural Ethiopia (i.e., 450 mg);[14] however, the clinical effects of high iron load is limited by the poor solubility of most iron forms. The local

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. brewing of kaffir (corn beer) in South Africa produces high iron concentrations (50–250 mg/L) in the beer as a result of the acidity and the presence of iron-binding ligands (e.g., fructose).[15] Consequently, beer-drinking Bantu men ingest an average of 50–100 mg Fe/day. The relatively high prevalence of hemosiderin deposits and liver cirrhosis probably results at least partly from genetic influences, apart from HLA-linked hemochromatosis.[16,17]

DOSE EFFECT

Acute Ingestion

Reduced iron is an amorphous powder that has low toxicity as a result of limited gastrointestinal absorption;[18] however, case reports suggest that mild gastrointestinal irritation and slight elevation of serum iron may occur after ingestion of the contents of disposable heating pads.[19] An accurate estimation of the number of iron tablets ingested depends on the reliability of the history. Consequently, the onset and severity of symptoms are a more reliable way to determine the seriousness of iron poisoning than an estimation of the iron dose. Early onset of gastrointestinal symptoms may limit the amount of iron absorption, reducing toxicity.[20] Children's multivitamins with iron do not usually contain sufficient iron amounts or bioavailability to produce serious iron intoxication.[21,22] Based on the quantity of iron tablets ingested, the following amounts of elemental iron indicate the severity of toxicity:

Minimal risk of toxicity: <10–20 mg of elemental iron ingested per kilogram (e.g., 3 tablets of ferrous sulfate in a 10-kg child = 3 × (0.20) (325 mg)/10 kg = 19.5 mg/kg) produces little risk of toxicity.

Toxic range: At 40 mg elemental iron/kg (7 ferrous sulfate tablets in a 10-kg child = 7 × (0.2) (325 mg)/10 kg = 45.5 mg/kg), the risk of iron toxicity is moderate and referral to a health care facility is recommended.[9] Pediatric or adult patients with severe or persistent symptoms and patients with stated or suspected self-harm should also be referred to a health care facility. The risk of iron toxicity becomes high as iron concentrations exceed 60 mg Fe/kg. At this level, referral to a physician is necessary and chelation may be required.[9,23]

Lethal range: 180–300 mg elemental iron/kg (30–45 tablets in a 10-kg child). Death has been associated with the ingestion of 2.7 g (542 mg elemental iron/kg) and survival after the ingestion of 19.5 g of ferrous sulfate (3,900 mg elemental iron/kg). Solutions of ferric chloride are corrosive (pH 1.0). Death occurred 4 hours after the ingestion of 200 mL ferric chloride (230 mg Fe/kg) in a patient with aspiration pneumonia and hypoxemia.[24]

Chronic Iron Overload

As a result of the limited ability to excrete excess iron, chronic overload occurs from enhanced absorption (e.g., hemochromatosis) or excessive exposure (e.g., multiple transfusions in aplastic anemia, myelodysplastic syndrome, thalassemia). Hemochromatosis is an autosomal-recessive disorder (i.e., mutation in homeostatic iron regulator (*HFE*) gene in chromosome 6) that results from the inability to down-regulate intestinal iron absorption in the presence of high iron loads.

TOXICOKINETICS

Absorption

Following typical iron doses, iron absorption is a capacity-regulated process that depends on several factors including the iron formulation, the presence of polyanionic iron-binding compounds (e.g., phosphates, phytic acid, tannins), rate of erythropoiesis, total body iron stores, and genetic status. The diet contains iron primarily in the ferric state (3+), but cell membranes essentially are impermeable to iron in this form.[25] Gastric secretions facilitate the conversion of ferric iron to the ferrous state (2+), as does the presence of ascorbic acid and other reducing agents. The presence of different types of food in the stomach has a variable effect on the bioavailability of iron.[26] Iron absorption occurs primarily in the duodenum and the proximal jejunum, where iron penetrates the mucosal barrier in the ferrous (2+) form. The absorption of iron by the cells of the mucosal lining of the gastrointestinal tract exhibits the following two phases: 1) the uptake of iron by the enterocyte from the gastrointestinal lumen, and 2) the active transfer of iron across the cell and into the circulation where iron attaches to the storage protein, ferritin.[27] Brush border membranes in the epithelial lining of the proximal intestines contain saturable iron receptors for inorganic iron and duodenal cytochrome B (DCYTB, iron-regulated ferric reductase). The latter enzyme promotes the formation of ferrous iron before being transported into the enterocyte by the apical transporter, DMT1/NRAMP2.[28] The basolateral transporter (ferroprotein1) transfers the ferrous ion from the enterocyte to the plasma; this process requires the ferroxidase activity of a ceruloplasmin-like molecule

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

(hephaestin).[29] Even after a massive ingestion of iron, first-order kinetics describes the absorption of iron with the intestines controlling the amount of iron absorbed.[30] Control of iron stores depends on variations in absorption because there is no specific mechanism for iron excretion.

The ingestion of large iron doses overwhelms the normal gastrointestinal regulatory mechanism, resulting in massive iron absorption.[31] Saturable transport systems probably are not involved in the absorption of high iron doses. There are few data regarding the amount of iron absorbed after a toxic dose, but the percentage of the absorbed dose is probably near 10%.[32] The absorption of nonchewable iron tablets is somewhat erratic and slow compared with chewable iron tablets, which reach peak concentrations 4.2–4.5 hours following the ingestion of 5–10 mg Fe/kg.[33] Peak serum iron concentrations occur ~4–6 hours after ingestion in pharmacokinetic studies.[34] At a given iron dose, the chewable tablets in multivitamin preparations tend to produce higher and earlier peak levels of iron than regular adult preparations. A fatal case of iron toxicity developed in a worker who fell into a vat of ferrous chloride as a result of iron absorption through aspiration, ingestion, and burned skin.[35]

Distribution

The average adult body contains about 3–4 g Fe; hemoglobin attaches ~70% in the ferrous state, whereas apoferritin binds ~25% of the iron in the ferric state as ferritin. Ferritin releases the iron in the plasma to a glycoprotein β-1-globulin, transferrin. This transporter tightly binds iron in the blood while transferring the iron to the blood-forming sites for incorporation into hemoglobin. Free iron is not typically present in the blood.

The body stores iron as ferritin (70%) and to a lesser extent as hemosiderin (30%).[34] The liver is the primary site for the storage of ferritin. In an acute iron overdose, plasma transferrin becomes saturated and free iron appears in the circulation. Greater than 99% of the iron present in whole blood appears in the erythrocyte bound to hemoglobin; therefore, the whole blood iron concentration is directly proportional to the hemoglobin concentration.

Elimination

No adequate mechanism for iron excretion exists. Consequently, the natural elimination of iron by the body is extremely limited with the loss occurring primarily by bleeding or desquamation of gastrointestinal mucosa. Adults lose up to 2 mg of iron daily. The half-life of transferrin in the blood is ~8 days compared with a plasma iron half-life of ~2–3 hours after therapeutic doses[36,37] and 4–6 hours after an overdose.[38]

Maternal–Fetal Kinetics

Transplacental transfer of iron is an active, saturable process; thus, the risk to the fetus is maternal toxicity rather than a direct effect of excessive maternal iron on the fetal tissues.

HISTOPATHOLOGY AND PATHOPHYSIOLOGY

Mechanism of Action

Iron is an essential biological catalyst involved with electron transport, oxygen transport, cell proliferation, and DNA synthesis.[39] Every cell in the body acquires iron in the heme and nonheme forms, except differentiated lens epithelium and mature red cells. Although iron is essential for growth and survival, specialized mechanisms and molecules are necessary for the transport and storage of iron in a soluble, nontoxic form that prevents the development of oxygen radicals and oxidative damage to cell structures. At pH 7.4 and normal oxygen tension, the relatively soluble ferrous ions easily oxidize to the ferric ion followed by hydrolysis to insoluble ferric hydroxides. The most common proteins involved with these protective functions are transferrin, transferrin receptor, and ferritin; however, a variety of proteins participate in iron metabolism and transport including ceruloplasmin, ferrochelatase, frataxin, heme oxygenase-1, hepcidin, hephaestin, lactoferrin, mitoferrin, sideroflexin 1, and STEAP3 metalloreductase.

Mechanism of Toxicity

The mechanism of iron toxicity involves a direct local corrosive effect on gastrointestinal mucosa and the physiological effects of free iron in tissues. The presence of free iron results in the formation of highly reactive hydroxyl radicals via the iron-catalyzed Haber–Weiss reaction using Fenton chemistry.[40] Although other transition metal ions can catalyze this reaction, the major mechanism for the formation of hydroxyl radicals from superoxide and hydrogen peroxide involves free iron.[41] A number of reactive species occur in biological systems beside hydroxyl radicals including other reactive oxygen species (peroxyl radical, superoxide anion, alkoxyl

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

radical). These reactive oxygen species contribute to various pathological conditions being prominent toxicological intermediates involved with oxidation stress. These processes produce depolymerization of polysaccharides, inactivation of enzymes, DNA damage (strand breaks, oxidative base modifications, DNA-protein cross-links), and initiation of lipid peroxidation, particularly in the mitochondrion.[42,43] Superoxide radical anion also reacts with nitric oxide to produce the strong oxidant, peroxynitrite.

In severe iron overdose, coagulative necrosis with platelet aggregation appears similar to the damage caused by corrosive agents. Major toxicity occurs when serum iron concentrations exceed the iron-binding capacity of transferrin. Free-circulating iron damages systemic blood vessels. The iron-induced release of the potent vasodilator, nitric oxide, and, possibly, the release of serotonin and histamine potentiate the vascular damage caused by free serum iron. Cellular damage from iron overload occurs in a wide range of tissues with a high rate of superoxide radical anion ($O_2^{\bullet -}$) formation, particularly the liver, heart, and pancreatic beta cells.

Gastrointestinal Tract

The corrosive effect of iron produces congestion, edema, hemorrhage, ulceration, coagulative necrosis, and infarction of the stomach and proximal intestine (i.e., hemorrhagic gastritis, peritonitis, perforation); however, there is a lack of correlation between the severity of intestinal damage and death. An empty stomach increases iron-induced gastrointestinal damage.[44] Pyloric obstruction and intestinal scarring are rare, late complications of an iron overdose. The ingestion of enteric-coated iron tablets results in damage to the more distal portions of the small intestine.[45] The mechanism of the erosion of the lining of the gastrointestinal tract includes direct corrosive effect, local ischemia secondary to the formation of thrombi, disruption of the cell membrane as a result of ATP depletion, and the formation of hydroxyl radicals. Masses of iron-containing granules accumulate in the capsular space and lumen of the renal tubules; however, tubular degeneration is rare.

Liver

Acute Toxicity

Circulating free iron initially accumulates in the Kupffer's cells and later in the mitochondrial crista of hepatic parenchymal cells when free iron exceeds the storage capacity of ferritin. Ferrous ions catalyze the lipid peroxidation of mitochondrial membranes, leading to the increased intra-mitochondrial accumulation of iron. The effects of excess iron on the liver are highly variable, ranging from no abnormalities to cloudy swelling of the hepatocytes, mitochondrial injury, portal iron disposition, fatty metamorphosis, and massive periportal necrosis.[46] Free iron inhibits the thrombin-induced conversion of fibrinogen to fibrin, and free iron also directly affects coagulation. Therefore, a coagulopathy potentially may appear before iron-induced liver dysfunction occurs.[47]

Chronic Toxicity

The liver is a major site of iron storage that is susceptible to damage from the chronic accumulation of iron, particularly from hemochromatosis. The major pathological effects of chronic iron overload include cirrhosis, porphyria cutanea tarda, and hepatocellular carcinoma.[48] Current data do not suggest that chronic iron overload occurs following exposure to iron compounds in the work environment.

Cardiovascular System

Direct myocardial injury (e.g., fatty degeneration of the myocardium) may occur in fatal cases of iron poisoning. Histopathological changes in hearts from fatal iron overdose cases include stainable iron in the myofibrils, contraction bands, myocytolysis, and frank necrosis.[49] In animal models of iron poisoning, depletion of intravascular volume is the single most important hemodynamic effect; however, other factors influence the development of hypotension because the maintenance of cardiac filling (pulmonary artery wedge pressure) does not prevent a reduction of cardiac output in this model.[50] Iron acts on the vascular system to increase venous pooling (increased capillary permeability) and to decrease cardiac output (reduced post-arteriolar and venous tone). Proposed etiologies for post-arteriolar dilation include a direct iron effect, ferritin release, and serotonin/histamine release.

Blood

The release of free iron inhibits the oxidative phosphorylation pathway. This interference with oxidative enzymes in the Krebs cycle along with the release of hydrogen from the conversion of ferric ion to the ferrous state and anaerobic metabolism may produce severe metabolic acidosis with hyperlactatemia.[51] Ferrous ions catalyze lipid peroxidation that can cause disruption of mitochondrial membranes and the Krebs cycle. Iron

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

also shunts electrons from the electron transport system by acting as an electron sink.[52] The result is impaired reconstitution of adenosine triphosphate (ATP), that produces metabolic acidosis.

CLINICAL RESPONSE

Acute Ingestion

Classically, severe iron toxicity presents in five distinct but sometimes overlapping phases and not necessarily related to the time since ingestion.[53,54] Symptoms in the first phase result primarily from the corrosive effects of iron on the gastrointestinal mucosa; the initial phase also may involve the early (<6 hours) onset of metabolic abnormalities (e.g., acidosis, hyperglycemia) following severe overdoses. Ferric chloride is a corrosive acid that produces nausea, vomiting, sore throat, abdominal pain, and oral ulcers.[55] In severe cases of exposure to ferric chloride, metabolic acidosis, hypotension, aspiration pneumonia, and respiratory failure develop. Maroon or reddish-colored, nonbloody stools may occur after the ingestion of cefdinir (third-generation cephalosporin) with iron or iron-containing products (e.g., infant formula).[56,57] The stools return to normal color after cessation of cefdinir with no recognized adverse effects.

Initial Period (Gastrointestinal Phase)

Irritation of the gastric mucosa (phase 1) characterizes the initial period during the first 1/2–2 hours and up to 6 hours postingestion; a severe hemorrhagic gastritis (i.e., protracted vomiting, hematemesis, diarrhea, hematochezia) may develop depending on the iron dose. Vomiting is the most sensitive indicator of iron ingestion with 94% sensitivity but only 25% specificity; however, the presence of vomiting does not necessarily indicate severe iron ingestion.[58] Diarrhea is a less sensitive, but more specific indicator, of iron ingestion. Most patients do not progress beyond this stage, and symptoms resolve within 6–8 hours.[20] The early appearance of central nervous system (lethargy, coma) or cardiovascular (pallor, tachycardia, hypotension) effects are the most reliable signs of a severe ingestion. The absence of symptoms in children within the first 6 hours after ingestion indicates that further sequelae are highly unlikely.[2,9]

Quiescent Period (Latent Phase)

Most patients appear well during phase 2, and the majority of patients will recover uneventfully. However, during this variable period (6–24 hours postingestion), a deceptive improvement and stabilization occur in severely poisoned patients that may result in the premature discharge of the patient from the health care facility. Alternating periods of lethargy may emerge during this stage. During severe overdoses, this quiescent period may be very brief and evidence of multi-organ failure develops quickly. Although gastrointestinal symptoms often resolve during this period, progressive cellular damage continues during serious intoxication with the development of metabolic acidosis.

Recurrent Period (Metabolic/Cardiovascular and Hepatic Phases)

Systemic symptoms (phase 3) that appear during this phase (12–48 hours postingestion) are life-threatening (hemodynamic instability, shock, coagulopathy) with multi-system organ failure. Vasomotor collapse, cyanosis, and pulmonary edema may develop as a result of myocardial depression. Intractable shock appeared in three cases of iron intoxication at 1 day, 2 days, and 5 days postingestion; the patients died in spite of aggressive fluid management and catecholamine infusions.[49] The etiology of shock in this phase is multifactorial and includes fluid and blood loss, metabolic acidosis, and primary cardiac dysfunction.

Acute hepatic failure (phase 4) occurs only in those patients with severe iron poisoning, usually within the first 24–48 hours.[59,60] Hepatic damage may progress to hepatic failure with hypoprothrombinemia, hypoglycemia, and the hepatorenal syndrome. Coagulopathy may occur without hepatic failure as a result of the inhibition of thrombin by free iron.[61] Complications include hematemesis, melena, and gastrointestinal perforation. Hepatorenal failure develops usually toward the end of this phase with coagulation defects and acute renal tubular necrosis.[62] Most authors consider hepatic necrosis a separate phase from the recurrent phase. Increasing lethargy, coma, and convulsions develop, depending on the severity of the overdose.

Late Period (Delayed Phase)

Gastric scarring, strictures, fistulas, and pyloric or jejunal obstruction may appear during phase 5 (4–6 weeks post-ingestion).[63] These obstructions develop in the area of initial damage to the gastrointestinal mucosa, causing abdominal pain.

Occupational Exposure

Iron Oxides

Exposure to iron (i.e., primarily iron oxides) occurs in iron mining, iron refining, and the welding or polishing of iron or steel. Concurrent exposure to other toxic substances (e.g., welding, diesel fumes, silica, radon) complicates the interpretation of the health effects of iron oxides on these workers. In a 17-year follow-up study of 167 miners (80 active workers, 58 retired) from the original cohort of 240 Swedish iron ore miners, the prevalence of chronic bronchitis was 9.6% with no excess chronic obstructive pulmonary disease based on a structured interview and pulmonary function testing.[64] Smoking, but not working in the mine, correlated to the prevalence of chronic bronchitis; spirometry values were similar between surface and underground workers. The study could not exclude selection bias (i.e., healthy worker effect).

The inhalation of iron oxide fumes for 6–10 years produces radiographic changes in the lungs characteristic of a benign pneumoconiosis (siderosis) that probably does not progress to pulmonary fibrosis.[65] In a study of 14 iron oxide production workers with total particulate exposures of 10–15 mg/m^3 for a mean of 10 years, chest radiographs demonstrated some nodular opacities; however, the pulmonary function tests did not demonstrate evidence of obstructive or restrictive disease.[66] The deposition of iron oxide in the lung (i.e., siderosis) usually causes little physical disability.[67] Studies of workers with siderosis generally demonstrate minimal or no clinical changes.[68] Siderosis occurs in arc welders, oxyacetylene cutters, and silver finishers as a result of the prolonged inhalation of ferric oxide fumes and dust, but hematite iron ore workers rarely develop siderosis unless they are exposed to arc welding fumes.[69] The prevalence of siderosis among iron workers (electric arc and powder-burning operations) exposed to levels exceeding 10 mg Fe/m^3 for periods of >5 years was 5–15%.[5] Pulmonary siderosis following occupational exposure is not associated with superficial siderosis of the central nervous system (hearing loss, cerebellar ataxia, myelopathy) secondary to the deposition of breakdown products of hemoglobin (hemosiderin) in the brainstem, cerebellum, and spinal cord.[70]

Iron Pentacarbonyl

There are limited human data on the clinical effects of iron pentacarbonyl. Based on animal studies,[71,72] the clinical effects of a single large exposure to iron pentacarbonyl vapors clinically resemble those of an exposure to nickel carbonyl with the exception that iron pentacarbonyl is a less potent toxin.[73] Clinical symptoms include the immediate onset of headache, vomiting, and lightheadedness followed in 12–36 hours by cough, cyanosis, dyspnea, and fever. Exposure to high concentrations of iron pentacarbonyl may cause pulmonary consolidation, degeneration of the central nervous system, and death within 4–11 days.[74] Short-term studies in animals do not indicate that iron carbonyl possesses significant fibrogenic properties after chronic exposure.[72]

Carcinogenicity

Iron Oxides

Neither the International Agency for Research on Cancer (IARC) nor the US National Toxicology Program lists iron oxide as a potential carcinogen. Most studies of iron foundry workers demonstrate an excess of lung cancer; however, potential carcinogens (silica, polycyclic aromatic hydrocarbons) contaminate the work environment in the foundries. A nested case-control study of lung cancer mortality from 1950–1989 in a cohort of 8147 foundry men did not detect an increased incidence of lung cancer, even among workers exposed to formaldehyde and silica.[75] Based on conditional logistic regression analyses, cigarette smoking was strongly associated with lung cancer mortality; however, there was no significant association between lung cancer mortality and work at any of the six major work areas of the foundry.

Underground hematite miners have ~10-fold increase in the risk of developing lung cancer compared with surface hematite workers, probably as a result of exposure to radon. A retrospective mortality study of workers in a hematite mine did not demonstrate an excess incidence of lung cancer in workers with low-grade exposure to radon, diesel exhaust, and silica and work rules prohibiting smoking underground.[76] The standardized mortality ratios based on standard US rates were similar between underground (SMR = 100) and above-ground (SMR = 88) miners. In a mortality study of 3,444 men employed for at least 3 months in Minnesota taconite mining operations from 1947–1958 and followed until 1983, the standardized mortality ratio for all deaths was 88 using rates for US Caucasian males.[77] There were 41 respiratory cancer deaths compared with 67 expected (SMR = 61, $P \leq 0.01$). The study did not demonstrate evidence of a significant exposure-response with 25 respiratory cancers (SMR = 57, $P \leq 0.01$) in workers employed at least 20 years. A 5-year follow-up study of this cohort updating deaths to 1988 did not detect a significant increase

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

in the SMR for respiratory cancer.[78] Studies of workers exposed to iron oxides are complicated by the presence of other potential carcinogens (e.g., soot, crystalline silica, asbestos). There is no conclusive evidence that the inhalation of iron oxide in mice, hamsters, or guinea pigs produces carcinogenic effects.[79]

Iron Dextran

Both the IARC and the US National Toxicology Program[80] list iron-dextran complex as a probable carcinogen based on sufficient evidence of carcinogenicity in animals. The repeated subcutaneous and intramuscular injection of iron dextran complex in rodents produces local sarcomas. The evidence for the carcinogenicity of iron-dextran complex in humans is inadequate. An uncontrolled study of 196 cases of sarcoma of the buttock revealed that 4 cases had received intramuscular injections of iron-dextran complex with an interval of at least 2 years occurring between the injection and the development of the sarcoma in 3 cases.[81] Selection bias limits the interpretation of this study regarding the issue of causation.

Reproductive Abnormalities

The risk of spontaneous abortion is low following an acute iron overdose in a pregnant woman, but some risk may exist. A study of 49 pregnancies involving iron poisoning did not reveal an excess incidence of malformations or premature births at follow-up 2 months postdelivery.[82] When treated with deferoxamine, the majority of the women ingesting large doses of iron in the second or third trimester ultimately deliver a normal infant. The primary risk to the fetus during maternal iron toxicity is metabolic acidosis and hypotension.

DIAGNOSTIC TESTING

SI Conversion Units

1 μmol/L = 5.5845 μg/dL
1 μg/dL = 0.1791 μmol/L

Analytical Methods

Iron

The colorimetric method using both liquid reagents and dry agents is the most common technique in clinical laboratories for the determination of small amounts of iron. Atomic absorption spectrometry (AAS) correlates well to colorimetric methods, but AAS is more specific than colorimetric techniques. For example, the administration of deferoxamine interferes with colorimetric methods of iron determination (i.e., falsely lowers the serum iron); however, this antidote does not interfere with assays that rely on atomic absorption spectrophotometry.[83] The addition of sodium hydrosulfite reduces the effect of deferoxamine on the colorimetric assays of iron.

Total Iron-Binding Capacity

The lack of sensitivity and specificity of the serum total iron-binding capacity (TIBC) seriously limits the usefulness of this laboratory test in the diagnosis and treatment of iron poisoning. The use of the TIBC is generally not recommended because of issues about the reliability of this test and the lack of clinical evidence that this test separates toxic from nontoxic, iron-exposed patients. Case reports document serious iron toxicity in infants with the TIBC exceeding the serum iron concentrations.[23] Most clinical laboratories use colorimetric methods to determine the TIBC. Experimental studies indicate that procedures measuring TIBC by the addition of excess iron followed by adsorption with alumina are not suitable for estimating TIBC. The homogeneous TIBC method is more reliable only when the serum iron is <500 μg/dL; however, this test yields falsely elevated results in the presence of free deferoxamine.[84] Consequently, unpredictable variability in test results complicates the interpretation of test results in patients with serious iron toxicity or in patients receiving deferoxamine. A study of six healthy volunteers receiving 20 mg elemental Fe/kg demonstrated that the serum TIBC level remained elevated for 6 hours postingestion compared with the TIBC level before ingestion, even though the serum iron level rose to 300 μg Fe/dL.[85] In this study, the TIBC after the iron ingestion increased to the upper limits of normal for the TIBC level. Occasionally, TIBC levels increase above the reference range and then return to normal as the serum iron level returns to normal. The temporary elevation of the TIBC during iron intoxication probably represents a laboratory aberration rather than a true increase.[86] Additionally, this study noted a substantial variation in the measurement of the TIBC as reflected in a mean coefficient of variation of 16% for a TIBC of 60 μmol/L (333 μg/dL). Deferoxamine contributes to the iron-binding capacity of the serum; therefore, the administration of deferoxamine falsely elevates the TIBC without interfering directly with the colorimetric assay.[87] The normal TIBC level in a healthy child is ~300–350 μg/dL.

Biomarkers

Theoretically, systemic iron toxicity occurs when free iron appears in the plasma (i.e., the serum iron concentrations exceed the total iron-binding capacity). The serum iron concentration is the most useful laboratory test for the diagnosis and management of acute iron poisoning. The TIBC level is not recommended because of the highly variable correlation of this test to iron toxicity. Gastrointestinal toxicity results from local corrosive effects of iron rather than the systemic effects of serum iron; therefore, gastrointestinal symptoms do not necessarily correlate to serum iron concentrations. Peak serum iron concentrations occur 2–4 hours after ingestion depending on the type of iron preparation; peak serum iron concentrations correlate best with potential toxicity. Serum iron concentrations drawn >6 hours postingestion may underestimate toxicity because of the binding of iron to ferritin and the distribution of iron into the tissues.

Indications

All symptomatic patients and those patients with a history of ingestion of >40 mg of elemental Fe/kg should have blood drawn for serum iron. Heparinized samples of whole blood should be drawn 3–5 hours postingestion. Because of rapid iron clearance, low serum iron concentrations after this period may underestimate the seriousness of iron poisoning. Fatal iron toxicity may occur in patients with normal serum iron concentrations 24 hours after ingestion as a result of the intracellular redistribution of iron 6–12 hours after ingestion.[88] Deferoxamine interferes with the analysis of the serum iron and the TIBC; therefore, blood samples should be drawn at least 4 hours after the last dose of deferoxamine to minimize this interference.[84]

Interpretation

Because of the variability of the TIBC and the interference of deferoxamine with the analytical procedure, the serum iron is the best laboratory measure of potential toxicity.[89] Fewer than 10% of patients with peak serum iron concentrations of <500 μg/dL will develop cardiovascular collapse or coma. Between 500–700 μg/dL, the percentage increases to 25% with the majority of patients developing hepatotoxicity. Above 700 μg/dL, ~50% of the patients have severe symptoms.[90] In a retrospective study of 77 patients with peak serum iron concentrations of >300 μg/dL *within* 12 hours of ingestion, 12 patients had hepatotoxicity (serum ALT or AST >150 U/L).[91] The nine patients with severe liver toxicity (serum ALT or AST >1,000 U/L) had peak serum iron concentrations of >1,000 μg/dL; clinically significant liver injury was unlikely in patients with peak serum iron concentrations of <700 μg/dL within 12 hours of ingestion. Case reports suggest that severe neurologic, hepatic, metabolic, or cardiovascular complications may not occur in the presence of high initial serum iron concentrations (2,260 and 6,798 μg/dL 1.5–2 hours postingestion) following prompt administration of deferoxamine.[92,93] Coma, radiopaque iron tablets in the gut, leukocytosis, and an elevated anion gap suggest serum iron concentrations of >500 μg Fe/dL.[94] The absence of any of these indicators suggests a serum iron level of <500 μg Fe/dL; however, the lack of these indicators does not exclude serum iron concentrations of >300 μg/dL or significant toxicity.[95] The clinical presentation is a more important determinate of appropriate therapy than either the serum iron concentrations or the history of ingestion. When inconsistencies occur between these measures of potential toxicity, the clinical presentation should be given preference over the history and laboratory values. Table 15.3 correlates the peak serum iron concentrations (i.e., 3-5 hours postingestion) with expected clinical effects.

Serum iron concentrations decline rapidly 12 hours postingestion; consequently, serum iron concentrations are not good biomarkers during the clinical course of iron poisoning. The presence of persistent metabolic acidosis during this interval indicates serious toxicity.

TABLE 15.3. Peak serum iron concentrations and expected clinical effects.

Peak Serum Iron (μg/dL)	Clinical Effect
0–150	Normal range.
150–350	Possible poisoning. Signs of gastrointestinal toxicity may appear, but systemic toxicity is unlikely.
350–500	Potentially serious toxicity. Chelation may be required depending on clinical features and history.
500–1,000	Definite serious toxicity. Chelation is necessary.
>1,000	Potentially fatal. Case reports document survival[63,96] and death[59] in severely poisoned infants with peak serum iron concentrations near 14,000–16,000 μg/dL.

Abnormalities

Abdominal X-Rays

The appearance of iron tablets on the abdominal radiograph depends on several variables, including time since ingestion, content of elemental iron, and type of formulation (e.g., vitamins with iron and sugar-coated candy tablets are not radiopaque). Ferrous sulfate tablets remain radiopaque longer than ferrous gluconate tablets because ferrous sulfate tablets contain higher elemental iron concentrations than ferrous gluconate. Negative abdominal radiographs do not exclude iron overdose, particularly >2 hours after ingestion;[97] however, the presence of iron tablets indicates the need for gut decontamination and whole bowel irrigation should be considered. Although chewable vitamins with iron are radiopaque, visualization of these tablets clinically is unlikely.[98] Within several hours of ingestion, the abdominal X-ray is a useful measure of the efficiency of any gastric emptying procedure except following minor ingestions.

Blood

Potential indicators of elevated serum iron concentrations include the white blood cell count and blood glucose concentration. A leukocytosis of > 15,000/mm^3 and hyperglycemia of >150 mg/dL correlated with elevated serum iron concentration (>300 μg/dL) in a retrospective study;[58] however, these tests are *not* sensitive predicators of severe iron intoxication. These values have poor negative predictive power for serious iron intoxication if there are <15,000 WBC/mm^3 or the serum glucose is <150 mg/dL. When serum iron concentrations are not immediately available, the presence of hyperglycemia and leukocytosis suggests serious iron intoxication. However, decisions for the management of iron overdose should be based on clinical history and physical examination rather than the presence of these values alone. Severe metabolic acidosis and hypoglycemia may develop as a result of hepatic and pancreatic damage.

Ancillary Tests

Supportive studies in patients with a potentially serious iron ingestion (i.e., serum iron concentrations > 350 μg/dL) include guaiac tests of the stool and gastric aspirate, serum hepatic aminotransferase levels, coagulation studies, complete blood count, hemoglobin, hematocrit, electrolytes, glucose, arterial blood gases, blood type, and antibody screen. Iron ingestion does not cause false-positive guaiac test results. Hepatic injury is unusual when peak serum Fe concentrations are < 500 μg/dL.

Rapid Screening Tests

Fischer developed a rapid *qualitative* method for determining the presence of iron using the chromogen 2,4,6-tripyridyl-*s*-triazine (TPTZ).[99] McGuigan et al. described a qualitative deferoxamine color test for gastric aspirate as an adjunctive screening method for iron within 2 hours of ingestion.[100] Two milligrams of gastric fluid and two drops of 30% H_2O_2 are placed in each of two plastic tubes. One-half milliliter of a deferoxamine solution (composed of one 500-mg ampule of deferoxamine and 4 mL of distilled water) is added to one tube. An immediate change of color (light orange to dark red) in that tube compared with the control indicates the presence of iron. Negative results from these tests >2 hours postingestion do not reliably exclude iron poisoning because of the possibility of absorption. This test does not distinguish between toxic and nontoxic ingestion.

HEALTH SURVEILLANCE

Table 15.4 lists guidelines and regulatory values for exposure to iron and iron compounds. The US OSHA PEL–TWA for iron oxide dust and fumes is 10 mg Fe/m^3 measured as total particulate, whereas the ACGIH recommends a TLV–TWA of 5 mg Fe/m^3 to minimize the potential for the occurrence of radiographic changes of siderosis after long-term exposure.[73] European regulations for the TWA–TLV range from 3.5 mg Fe/m^3 in Sweden to 6 mg Fe/m^3 in Germany. The 10-minute STEL in the United Kingdom is 10 mg Fe/m^3, but there is no US OSHA recommendation for a STEL. The US OSHA PEL–TWA for iron pentacarbonyl is 0.1 ppm (0.23 mg/m^3), while the TLV-STEL is 0.2 ppm (0.45 mg/m^3) measured as Fe.

TREATMENT

Decontamination

The American Association of Poison Control Centers (AAPCC) recommends evaluation of pediatric

patients at a health care facility when the estimated accidental ingestion exceeds 40 mg elemental Fe/kg; all intentional ingestions should be evaluated at a health care facility regardless of the estimated dose. The appropriate measures for decontamination of the gut following the ingestion of iron tablets are controversial. The ingestion of children's vitamins, carbonyl ions, or polysaccharide-iron complex formulations typically can be observed at home with follow-up. Any ingestion with persistent nausea or vomiting, altered consciousness, or gastrointestinal bleeding should be referred immediately to a medical facility. Acute ingestions without symptoms in the first 6 hours postingestion do not usually require referral or observation.

Emesis

Induced-emesis is usually unnecessary because early vomiting commonly occurs during iron toxicity. Syrup of ipecac should not be administered unless the benefits clearly outweigh the risks. The induction of emesis with syrup of ipecac is an option early in the course of iron poisoning if the history indicates a very large ingestion of iron presenting 1–2 hours after ingestion to the health care facility and there are a substantial number of iron tablets in the stomach on abdominal radiograph. A definite risk of aspiration within the expected duration of action contraindicates the use of syrup of ipecac. Abdominal X-rays should be repeated after decontamination measures to assess the effectiveness of these measures. The disappearance of iron tablets from the X-ray does not necessarily indicate that the decontamination measures were successful because of the natural tendency of the tablets to dissolve. The use of syrup of ipecac delays the use of whole bowel irrigation for at least several hours after the administration of syrup of ipecac.

Lavage

The use of gastric lavage is not routinely recommended. Mechanical removal by lavage may be difficult because of tablet size and cohesiveness; therefore, large bore (32–40 F) lavage tubes are necessary to remove iron tablets efficiently. The type of lavage fluid used to complex iron is controversial. Although there are theoretical advantages to the use of bicarbonate and deferoxamine in lavage solutions, there are insufficient data to conclude that either lavage solution is superior to saline. Consequently, the routine use of these solutions as decontamination measures is *not* recommended due to a lack of proven efficacy, unless the physician determines that specific conditions exist to indicate that these solutions will improve the clinical outcome. All patients with potentially serious iron ingestions should receive an abdominal X-ray. Decontamination procedures should be repeated if the upright abdominal film shows retained tablets in the stomach. Otherwise, whole bowel irrigation should be considered. Volunteer studies do not support the administration of magnesium hydroxide (Milk of Magnesia) as a measure to reduce iron absorption.[101]

Bicarbonate

A 1–4% sodium bicarbonate solution (add one 50 mEq ampule to 1 L D_5W/0.45% NaCl) complexes some of the free ferrous ion into the relatively insoluble ferrous carbonate form. The actual amount of ferrous carbonate formed has not been well studied *in vivo*; factors affecting the formation of ferrous carbonate include gastric pH, contact time, and relative concentrations. *In vitro* studies of the effect of lavage solutions of bicarbonate and phosphate indicate that these solutions retard the dissolution of the iron tablets,[102] but ~83–86% of the iron remains in the soluble form.[103] Furthermore, these insoluble complexes of iron appear labile and may dissociate into soluble complexes when the pH decreases in

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

the gastrointestinal tract.[104] Whether this solution significantly decreases iron absorption remains controversial; conventional antacids probably are an equally safe alternative to the administration of the standard solution of bicarbonate (1 mEq/kg).

Deferoxamine

The role of oral deferoxamine solution is limited, in part because of the lack of sufficient data to support the efficacy of this treatment.[105,106] This complex requires an alkaline solution; hence, bicarbonate must be added. A major problem is the large amount (and high cost) of deferoxamine required to complex the intestinal iron (100 mg deferoxamine complexes 8.5 mg iron). An animal study of oral deferoxamine revealed that the use of lavage solution of deferoxamine reduced the absorption of iron, but serum iron concentrations were not significantly decreased.[107] The methodology (colorimetric assay) used in this study did not reliably measure serum iron absorbed as ferrioxamine. In a group of seven adults administered 5 mg elemental iron/kg, the concurrent ingestion of equimolar doses (59 mg/kg) of buffered deferoxamine did not significantly alter the plasma iron concentrations over 8 hours when compared with the control (iron alone).[108] Large oral doses of deferoxamine may produce hypotension.[106] Additionally, volunteer studies do not support the oral administration of $CaNa_2EDTA$ as a method to reduce iron absorption following ingestion of iron.[109]

Bezoar Formation

Iron tablets may form concretions or adherent masses that are resistant to decontamination measures and endoscopic removal. Continued release of iron from large bezoars may produce delayed elevation of serum iron concentrations, gastrointestinal inflammation, hemorrhage, and scarring.[110] Endoscopy and gastrotomy are therapeutic modalities to reduce complications (e.g., perforations) when serum iron concentrations increase and the concretions fail to progress down the gastrointestinal tract.[111,112] Emergency gastrotomy should be considered only after endoscopy, and decontamination measures including whole bowel irrigation fail to remove the iron tablets.

Activated Charcoal

Animal studies do not support the use of activated charcoal to reduce the absorption of iron compounds (e.g., iron sulfate).[113] Activated charcoal binds relatively small amounts of iron; however, the iron-deferoxamine complex does adsorb onto charcoal with an affinity similar to that of salicylates.[114] A prospective, crossover, controlled volunteer study evaluated the effect of the simultaneous administration of 5 mg ferrous sulfate/kg and a slurry of 8 g DFO and 25 g of 20% (weight/volume) activated charcoal on the absorption of iron.[115] The area under the curve (AUC) and peak serum iron concentration in the DFO/activated charcoal limb was significantly different compared with the two control limbs. The clinical relevance of this study is unclear; there are no clinical trials to support the use of the combination of DFO and activated charcoal.

Whole Bowel Irrigation (WBI)

Whole bowel irrigation is the enteral decontamination method of choice for iron based on case reports; however, randomized clinical studies are not available to confirm efficacy. If the abdominal radiograph reveals iron tablets beyond the pylorus, neither emesis, activated charcoal, nor lavage will reduce the absorption of these tablets. Whole bowel irrigation with a polyethylene glycol electrolyte lavage solution (Colyte, GoLYTELY) is a safe and rapid method for the removal of iron tablets from the intestines that is preferable to the use of saline cathartics (sodium sulfate or magnesium sulfate).[116] Over 44 L of lavage fluid were administered to a 33-month-old child over 5 days without complications.[117] The major indication for WBI is massive iron ingestion in which the usual decontamination measures fail to remove iron tablets from the gastrointestinal tract (stomach and small bowel) in adults or children.[118] Further studies are necessary to define the use of WBI as a routine part of decontamination measures. Case reports indicate that iron bezoars may remain in the gut after prolonged WBI, despite the presence of a clear rectal effluent.[119]

The rate of fluid administration for WBI is 20–35 mL/kg/hour in infants, 0.5 L/hour in children, and 2 L/hour in adolescents and adults via a nasogastric or orogastric tube until the rectal effluent is clear. Oral administration of this solution is an alternative to the use of the nasogastric tube if the patient can tolerate oral fluids. Adverse effects associated with WBI include vomiting and, less often, abdominal pain.[120] Slowing the infusion and the use of IV metoclopramide help reduce the amount of vomiting associated with the use of WBI in the setting of an iron intoxication.[121] Contraindications to the use of WBI include hemorrhage, obstruction, and ileus. Ipecac should not be administered within several hours of the initiation of WBI.

Cation Exchange Resin

Studies in volunteers indicate that sodium polystyrene sulfonate does not reduce the absorption of iron when administered 45 minutes after the administration of a 10 mg/kg iron dose.[122]

Elimination Enhancement

Exchange Transfusion

Exchange transfusion offers the greatest potential for iron removal. In animal models, this procedure removes more iron than intravenous deferoxamine;[123] however, the clinical efficacy of such removal is uncertain because deferoxamine chelates only the important toxic component (i.e., *free* iron), whereas exchange transfusion removes both *free* and *bound* iron. The rapid cellular uptake of free iron limits the effectiveness of exchange transfusion; the use of exchange transfusion to remove the iron-deferoxamine complex is primarily useful in massive iron overdose when the patient continues to deteriorate despite high-dose deferoxamine.[63]

Hemodialysis

Hemodialysis removes the iron-deferoxamine complex, but this procedure does not increase the elimination of iron. Hence, its use is limited to patients with impaired renal function. Methods to enhance elimination probably do not alter clinical outcome as a result of the minimal removal of absorbed iron. Animal studies suggest that continuous arteriovenous hemofiltration (CAVH) is an alternative to hemodialysis for patients with renal failure following iron intoxication;[124] however, there are inadequate human data to recommend the routine use of CAVH to remove absorbed iron.

Antidotes

Mechanism of Action

Deferoxamine is the chelating agent of choice for acute iron poisoning;[125] this compound is a specific chelator in a 1:1 molar ratio of ferric iron that is produced by the bacteria *Streptomyces pilosus*. Ferrioxamine is the chelated iron-deferoxamine complex. Potential alternative chelating agents for iron based on preliminary studies include ethylenediamine-*N*,*N*′-bis(2-hydroxyphenylacetic acid[126] and calcium salts of diethylene triamine pentaacetic acid (DTPA);[127] however, inadequate clinical data are available to assess the effectiveness of these agents compared with or in addition to deferoxamine. Newer oral iron chelating agents are available in the United States for patients with chronic iron overload from conditions requiring multiple transfusions including deferasirox[128] and deferiprone.[129] The latter is a bidentate chelator that binds iron in a 3:1 ratio. Although studies of patients with thalassemia major indicate the administration of deferiprone is efficacious in reducing their iron load, risks include neutropenia, arthropathy, and rarely agranulocytosis.[130] Deferasirox is a tridentate molecule that binds iron in a 2:1 ratio. At low doses, adverse effects are mild and usually limited to transient skin rashes and gastrointestinal upset. At high chronic doses (>40 mg/kg/day), potential complications include hypophosphatemia (Fanconi-like syndrome), cataracts, and hepatorenal dysfunction.[131]

In vivo, 100 mg of deferoxamine binds ~9 mg of free circulating elemental iron. Additionally, deferoxamine removes iron to a limited extent from ferritin, hemosiderin, and transferrin; deferoxamine does not remove iron from hemoglobin.[132] Deferoxamine may operate on the labile iron pool in the intracellular portion of hepatocytes, where deferoxamine preferentially removes ferritin iron over hemosiderin iron.[133]

Increasing iron elimination is not necessarily the main mechanism involved with the reduction of iron toxicity.[20] Because the volume of distribution of the iron-deferoxamine (ferrioxamine) is relatively small, free iron is kept in the extracellular space. The binding of cytoplasmic free iron reduces the free iron-induced disruption of mitochondrial cell membranes and enzyme systems. The iron-deferoxamine complex (ferrioxamine) is highly stable at physiological pH.[106]

Pharmacokinetics

Deferoxamine is poorly absorbed from the gastrointestinal tract; therefore, this agent should be given parenterally for maximum effect. Although orally administered deferoxamine blocks the uptake of only a small amount of iron by the small intestine, parenteral deferoxamine inhibits the uptake of inorganic iron and transferrin-bound iron, perhaps by limiting the chelatable pool of iron in the epithelial cells of the small intestine.[134] Animal studies indicate that deferoxamine has a volume of distribution of about 60% of body weight corresponding to total body water.[135] The plasma elimination half-life of deferoxamine is short (i.e., <1 hour).[136] Steady-state concentrations occur after ~90 minutes of a constant deferoxamine infusion.[137] Renal clearance accounts for ~30% of the total body clearance of a pharmacological dose of deferoxamine, whereas the liver detoxifies the rest of the absorbed deferoxamine dose.[138] The kidney excretes the deferoxamine iron complex (ferrioxamine)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. unchanged. The volume of distribution of ferrioxamine is ~20% of body weight based on animal studies.[111]

Adverse Effects

Acute Administration

Cardiorespiratory Hypotension is the most serious side effect of an infusion of deferoxamine; the blood pressure usually returns to normal within 1 hour.[139] Doses of 45 mg/kg/hour produce hypotension that usually responds to a reduction in the infusion rates and increasing fluid administration. Vasopressors may be necessary. Typically, hypotension associated with a deferoxamine infusion occurs during a rapid infusion; however, there is no specific threshold infusion rate for the development of hypotension during a deferoxamine infusion. The infusion of 425 mg deferoxamine/kg intravenously over 24 hours (i.e., 16 g) to thalassemia patients and 50 mg deferoxamine/kg/hour to dialysis patients did not cause clinically significant complications.[140,141] Hypotension in a patient with iron poisoning on deferoxamine may occur when the infusion rate exceeds 20–45 mg deferoxamine/kg/hour and other causes of hypotension (inadequate filling pressure, vasodilation) have been excluded. The lower limit of deferoxamine-induced hypotension below this infusion rate remains a possibility.

Acute respiratory distress syndrome (ARDS) may develop in iron overdose patients receiving large deferoxamine doses for >1 day. Tenenbein et al. reported four fatal cases of ARDS in adults receiving deferoxamine infusions of 15 mg/kg/hour for 32–72 hours.[142] However, studies from the 1950s before the use of deferoxamine indicate that pulmonary toxicity similar to ARDS may develop in patients poisoned by iron.[143] Consequently, the contribution of deferoxamine to the development of ARDS remains unclear. Several case reports associate the use of deferoxamine with the development of *Yersinia enterocolitica* O:9 sepsis.[144,145] This organism displays low virulence in the absence of free iron because of the lack of yersiniabactin, the iron-binding siderophore of *Yersinia pestis* (plague). In the presence of free iron, *Y. enterocolitica* develops an invasive phenotype capable of causing sepsis.

Systemic Reactions Flushing, erythema, urticaria, and rare cases of anaphylactoid reactions may occur; although histamine release is a suspected etiology, pretreatment with diphenhydramine does not prevent these reactions.[105] Rapid desensitization protocols have been developed for sensitive patients with serious iron toxicity.[146] The initial dose is 0.015 mg deferoxamine over 30 minutes; if no symptoms develop, the dose increases by 10-fold during each 30-minute interval until achieving the maximum infusion rate. Other adverse effects of deferoxamine include abdominal discomfort, diarrhea, fever, leg cramps, and dysuria.

Ocular and Auditory The major risk factors for ototoxicity or ocular toxicity include dose and duration of deferoxamine therapy, low serum ferritin, and low iron stores. Almost all reported cases of ocular or ototoxicity involve the chronic administration of deferoxamine. A single case report associated short-term administration of deferoxamine with visual impairment.[147] Ocular toxicity is usually reversible.

Kidney Renal impairment limits the excretion of the deferoxamine-iron complex (ferrioxamine); therefore, deferoxamine should be used cautiously in patients with compromised renal function. Some case reports suggest acute kidney injury may occur following deferoxamine use in renal dialysis patients.[148] Hemodialysis may be necessary in cases requiring high deferoxamine doses. Preliminary animal studies suggest the development of high-molecular-weight derivatives of deferoxamine may reduce the toxicity associated with high-dose deferoxamine, allowing the use of higher doses of this chelator during massive iron overdose.[149]

Chronic Administration

A small number of patients treated with deferoxamine for chronic iron overload (e.g., thalassemia, Diamond-Blackfan syndrome) develop neurotoxicity (visual impairment, hearing loss). Risk factors for the development of neurological complications include the presence of renal failure, the maximum deferoxamine dose, low serum ferritin levels (<2,000 μg/L), and young age. Risk factors for ototoxicity may be somewhat different than ocular toxicity because ototoxicity may occur at low deferoxamine doses when the iron overload is minimal as defined by the serum ferritin.[150] Lens opacities usually improve with cessation of therapy; these opacities are rare following the subcutaneous administration of deferoxamine.[151]

Case reports of prolonged daily administration of large intravenous doses (125 mg deferoxamine/kg) associated night blindness and visual field defects that improved on withdrawal.[152] Reported ocular complications of long-term, high-dose deferoxamine therapy include reduced visual acuity and peripheral vision, retinal stippling, defective dark adaptation, abnormal visual evoked responses, thinning of the retinal vessels, cataracts, and dyschromatopsia.[153] Recovery from retinal pigmentary changes, optic atrophy, and

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

abnormal visual evoked responses may be incomplete.[154] Rheumatoid arthritis patients treated with deferoxamine doses as low as 15 g over a week have developed retinal damage.[155] Auditory abnormalities at doses up to 126 mg deferoxamine/kg/day involve bilateral, high-frequency sensorineural hearing loss.[156] The development of hypersensitivity pneumonitis (cough, dyspnea, pulmonary infiltrate, a restrictive defect on pulmonary function tests) appeared within 4–9 days of the initiation of a continuous deferoxamine infusion.[157]

Indications

Acute Overdose

The severity of symptoms and the serum iron concentrations determine appropriate therapy. Treatment of moderately to severely symptomatic patients (e.g., altered consciousness, metabolic acidosis, shock, hepatotoxicity) should begin as soon as possible because of the rapid distribution of iron from blood into tissue; confirmation with serum iron concentrations in these patients is not necessary to begin intravenous deferoxamine. Seriously symptomatic patients should be given IV deferoxamine regardless of the relationship of the serum TIBC to the serum iron concentrations. The interpretation of serum iron concentrations drawn during deferoxamine therapy should be discussed with laboratory personnel because deferoxamine interferes with colorimetric assays of iron, resulting in falsely low (25–50%) serum iron concentrations. The presence of a normal abdominal radiograph, a normal serum leukocyte count, and/or a normal serum glucose concentration does not obviate the need to administer deferoxamine unless confirmed by nontoxic serum iron concentrations and a benign clinical presentation.

Peak Serum Iron Levels <350 μg/dL The value of deferoxamine at this concentration is minimal, if any, because significant toxicity does not usually occur. The presence of significant symptoms of iron poisoning indicates the need to repeat the serum iron concentration and begin deferoxamine.

Peak Serum Iron Levels 350–500 μg/dL Any symptomatic patient (excluding nausea or vomiting) with serum iron concentrations in this range should receive deferoxamine. No clear, well-documented guidelines exist to decide which asymptomatic patients in this range will develop subsequent toxicity.[158] Some patients with self-limited, non-bloody vomiting and diarrhea and peak serum iron concentrations in this range within 3–5 hours after ingestion will not develop sequelae when deferoxamine treatment is withheld.[159] Hence, the use of deferoxamine in this range requires clinical judgment. The presence of persistent or worsening metabolic acidosis indicates serious toxicity and the need for immediate chelation.

Peak Serum Iron Levels >500 μg/dL Almost all patients should receive intravenous deferoxamine therapy promptly. Patients with serum iron levels exceeding 1,000 μg/dL almost always develop serious toxicity, whereas asymptomatic patients rarely present with serum iron concentrations of >500 μg/dL.

Significantly Symptomatic Patients All patients with altered mental status (after checking for hypoglycemia), hypotension, bleeding, or protracted vomiting that suggest severe poisoning should receive prompt intravenous deferoxamine therapy without waiting for the results of the serum iron concentration. The correlation between reported iron dose or clinical symptoms is less clear in mild to moderate iron toxicity. In a retrospective analysis of UK poison control data on mild to moderate iron intoxication in 475 adults/teenagers and 86 children ≤12 years of age, the reported iron dose and clinical symptoms did not correlate to 4–6-hour iron concentrations.[160] The total series of 1,839 single-agent iron ingestions reported to the UK National Poisons Information Service did not contain any patients developing organ failure or fatalities.

Pregnancy Pregnancy is not a contraindication to the use of deferoxamine; intravenous deferoxamine should be administered promptly based on the serum iron concentrations and the clinical presentation.[161,162] Limited human data and data from the ovine model of maternal iron poisoning do not indicate that deferoxamine crosses the placenta in the last trimester.[163] Deferoxamine has been administered to pregnant women without adverse effects to the developing child;[164] conversely, a pregnant mother died of iron poisoning (serum iron, 1,700 mg/dL) after deferoxamine was withheld.[165]

Chronic Iron Overload

Factors to consider for the treatment of chronic iron overload include the degree of iron overload, the expected course of transfusions, age, psychosocial background, and medical history. Patients with clinical signs of iron intoxication or total iron stores of >0.7 g/kg probably require aggressive treatment.[166] Because serum ferritin and serum iron concentrations are not specific for iron overload, biopsies of the liver or bone marrow may be necessary to confirm or estimate total body iron stores. The most frequent choice for chelation in chronic iron overload is oral deferasirox,

although there are no long-term studies on the efficacy of deferasirox or deferoxamine.[167]

Dosage Recommendations (Acute Overdose)

Intravenous Deferoxamine

Intravenous deferoxamine is the preferable route of administration for any serious iron ingestion.[141] Very little dose-response data are available to determine the appropriate deferoxamine dose for iron-poisoned patients. Consequently, the choice of a deferoxamine dose is empirical. A dose of 15 mg deferoxamine/kg/hour does not usually produce hypotension while probably chelating the most free circulating iron.[106] The exact dose required to prevent serious sequelae from massive iron ingestion has not been defined; higher infusion levels (20–35 mg deferoxamine/kg/h our) have been used anecdotally. However, these higher levels may require hemodynamic monitoring to ensure the optimization of cardiovascular parameters (e.g., pre-load, systemic vascular resistance).[168] Deferoxamine degrades quickly in alkaline (pH >10) and acidic (pH <2) solutions; at pH 4–6, deferoxamine retains 90% of the original concentration when stored at room temperature (<23°C).[169] A bolus of saline prior to deferoxamine therapy reduces the risk of acute renal failure in patients with contracted intravascular volumes during iron poisoning.[170]

Intramuscular Deferoxamine

The intravenous route is probably more effective because of the short half-life of deferoxamine (<1 hour) and the constant exposure to free circulating iron during the redistribution phase. The intramuscular deferoxamine dose is 40–90 mg/kg as a deep intramuscular injection up to a maximum of 2 g deferoxamine per injection. The maximum recommended deferoxamine daily dose is 6 g.

Deferoxamine Challenge

Previously, this procedure was administered to identify patients with free, circulating iron and the need for chelation therapy, when serum iron was unavailable or the history suggested toxic ingestion by an asymptomatic patient. The deferoxamine challenge has very limited use currently because of the reliability of the serum iron concentration and the importance of avoiding a delay in the administration of intravenous deferoxamine during serious iron poisoning. The appearance of the iron-deferoxamine complex turns the urine a reddish-orange (vin rose) color at ferrioxamine concentrations of >10 μg/mL urine.[171] The intensity of this color is dose-dependent with the color changes appearing within ~3 hours of administration.[172] Because chelation occurs optimally at a urine pH of 7–8, check the urine pH periodically. Rarely, high iron concentrations occur in the absence of colored urine, particularly when the urine pH level is <6. The deferoxamine dose is 40 mg/kg as a deep intramuscular injection (dilute 500 mg deferoxamine in 2 mL sterile water).

Duration of Treatment

Although little human data exist, the maximum recommended daily deferoxamine dose is 360 mg/kg up to a limit of 6 g deferoxamine. An infusion of 15 mg deferoxamine/kg/hour can be administered safely for 24–48 hours; most seriously poisoned patients require chelation therapy for 1–2 days. Deferoxamine infusion rates of >45 mg/kg/hour are often associated with hypotension secondary to vasodilation. Reducing the deferoxamine infusion rate to 5–6 mg/kg/hour following stabilization (typically 4–6 hours after initiation of the infusion) helps limit the total deferoxamine dose to 6 g. Empirically, deferoxamine doses of >6 g over 24 hours have been administered without complications; however, the use of *high* rates of deferoxamine infusions over several days has been associated with rapidly progressive acute respiratory distress syndrome. The decision to discontinue therapy depends on the clinical condition, the clearance of the reddish-orange color of ferrioxamine from the urine, and the return of serum iron concentrations to <100–150 μg/dL as measured by methods unaffected by deferoxamine interference.

The return of the urine to normal color after the appearance of the reddish-orange ferrioxamine complex is an indication that chelation may be discontinued after 24 hours of therapy assuming symptoms resolve. In the absence of color changes in the urine, normal serum iron concentrations help confirm the decision to stop chelation therapy. Ferrioxamine interferes with the colorimetric assay of iron; the laboratory performing these assays should be aware of the use of deferoxamine because the administration of deferoxamine may falsely decrease the serum iron concentration up to 30–50% when analyzed by colorimetric methods.[173] Deferoxamine does not interfere with the measurement of serum iron when analyzed by atomic absorption spectrometry. The exact length of therapy for iron poisoning necessary to eliminate systemic toxicity requires a better understanding of iron-induced mitochondrial toxicity and the effects of deferoxamine at these sites.[110] The deferoxamine infusion can be safely discontinued when the serum iron concentration is within the normal range and no clinical or laboratory evidence of iron toxicity (i.e., acidosis) remains.

Supplemental Care

1) Watch vital signs carefully for signs of hypovolemia.
2) Replace fluid loss aggressively.
3) Watch for signs of blood loss (guaiac-positive stool) and send type/screen and cross-match when appropriate (e.g., evidence of bleeding).
4) Follow serum creatinine, prothrombin time, and serum aminotransferases concentrations as measures of renal and hepatic function.
5) In seriously poisoned patients, invasive or noninvasive monitoring may be necessary for dynamic cardiovascular monitoring to maximize cardiac output (i.e., preload, systemic vascular resistance) while administering high-dose deferoxamine infusions.[63]

Admission Criteria

All patients requiring chelation should be hospitalized. Patients remaining asymptomatic 6 hours after ingestion may be discharged if the following conditions are met: no vomiting/diarrhea/epigastric pain/lethargy; negative upright abdomen film for iron pills; and serum iron concentrations of <350 μg/dL.[51] Significantly symptomatic cases should receive chelation, as noted above.

Chapter 16

LEAD

ELEMENTAL AND INORGANIC LEAD

HISTORY

Lead is the fifth most abundant metal in the earth's crust after iron, zinc, copper, and aluminum. Although lead is not essential to any know biological process in humans, this metal is a common constituent of the human body that results from the ubiquitous presence of lead in the environment.[1] Since the earliest recorded times, lead has been a constituent of homeopathic medicines, cosmetics,[2] building paints, and ceramic glazes. Lead-based ocher paints were part of Neanderthal artifacts recovered from the Middle Paleolithic age (~40,000 BC);[3] by the third millennium BC, Mesopotamia, predynastic Egypt, and Troy developed lead-smelting techniques. During the Neolithic age (6,200 BC), mines in Turkey contained leaded beads and slag. The Chinese Shang dynasty (1,555–1,145 BC) fabricated bronze alloys with soft metallic lead; studies suggest that aristocrats of that dynasty[4] may have ingested substantial amounts of lead while drinking rice wine stored in bronze vessels.[5]

Lead is an ancient chemical toxin.[6] Hippocrates described lead colic in 370 BC and Nicander of Colophon documented lead palsy in the 2nd century BC, both without recognizing the cause, whereas Pliny was the first writer to suspect lead toxicity as a cause of illness in Roman shipbuilders during the 1st century AD.[7] The Greek botanist–physician, Dioscorides, also described occupational lead poisoning in his book (*De Materia Medica*) during the time of Nero. The Romans discovered that the storage of wine in leaded vessels produced sweeter, more visually appealing wine and improved storage by reducing the conversion of wine to vinegar. Additionally, the grape syrup was commonly boiled down in a lead pot or lead-lined copper kettle before being added to the wine. In reality, the lead acetate in these vessels had a sweet taste and acted as a fungicide. Replication of Roman recipes suggests the wines may have contained up to 80 µg Pb/L accounting for ~50–60% of the daily Pb intake for the free Rome population.[8]

The contamination of wine by lead and the high prevalence of gout, colic, infertility, and neurological symptoms in the Roman aristocracy suggested the possibility that lead poisoning may have contributed to the downfall of the Roman Empire.[9] By the time of the fall of the Roman Empire, the estimated lead production was 40 million tons, primarily as a by-product of silver mining.[10] The use of lead pipes for water distribution was widespread in ancient Rome; analysis of lead isotopes from the harbor of Imperial Rome suggests these pipes increased the lead content by two orders of magnitude above natural lead concentrations.[11]

Examination of lake bed sentiment in Sweden indicated that the cumulative deposition of lead from anthropogenic sources in the preindustrial period (i.e., 600 BC–1800 AD) was at least as large as the cumulative lead deposition after 1800 AD (i.e., the industrial period).[12] Lead in pigments are suspected causes of illnesses suffered by Michelangelo (gout, melancholy) and the Spanish Grand Master, Francisco de Goya; wine stored in lead containers may also have contributed to

the lead exposure of Michelangelo.[13] During the 17th and 18th centuries, lead poisoning (Devonshire Colic,[14] Colic of Poitier) occurred in the English aristocracy as a result of the consumption of lead-tainted Portuguese wine transported in containers containing lead bars to enhance flavor and prevent spoilage, particularly after the Treaty of Methuen ending the War of Spanish Succession (1701–1714) increased importation of inexpensive Portuguese wine.[15]

Benjamin Franklin associated lead poisoning with a disease (dry-gripes) that affected Europe and British colonies during the early 1700s.[16] In 1723, the Massachusetts colonial legislature banned lead in heads and coils of rum stills to reduce lead-contaminated rum distribution. Franklin's subsequent discussions on lead poisoning helped Dr. George Baker discover the association of lead toxicity with Devonshire Colic (muscle weakness, weight loss, pallor) in Dr. Baker's native Devonshire. Despite the absence of evidence of motor neuropathy, chronic consumption of lead-tainted wine is a suspected cause of the deafness of Ludwig von Beethoven (1770–1827). This theory is consistent with autopsy findings of shrunken cochlear nerves and inadequate evidence for otosclerosis (his temporal bones were lost).[17] Other suspected causes of Beethoven's deafness include autoimmune disease and cochlear otosclerosis.[18] In the United States during the 20th century, consumption of lead-contaminated moonshine caused an epidemic of gout and renal disease in the southern United States.[19] Lead was administered as an abortifacient in the early 1900s with subsequent reports of fatal lead poisoning.[20]

The estimated blood lead level of preindustrial humans was 0.5 μg/dL,[21] whereas the average blood lead level in the contemporary population in the Himalayas is ~3–4 μg/dL.[22] Lead use and environmental lead pollution increased dramatically during the first part of this century, as demonstrated in sequential layers of ice in Greenland. At the beginning of the Industrial Revolution in 1780, 1 g of ice contained 10 pg Pb. Two hundred years later, the lead content in 1 g ice increased to 200 pg (i.e., 20-fold) with the largest increases occurring since 1940.[23] During the 1970s, the United States consumed 1.3 million tons of lead, releasing an estimated 100,000 tons into the air and water.[24] Beginning in the 1950s, paint manufacturers began replacing lead in white pigment with the less expensive titanium. Lead exposure in the US population decreased substantially as a result of the elimination of lead from paint in 1977 and the phaseout of leaded gasoline. Analysis of $^{207}Pb/^{206}Pb$ ratios in permanent teeth formed between 1936 and 1993 in urban African-Americans from Cleveland, Ohio, indicated that about 2/3 of the total lead uptake into their enamel was attributable to leaded gasoline.[25] In blood samples from women living in lightly populated areas of Wales, blood lead levels decreased 30% during 1972–1982, despite little change in the total amount of lead used in gasoline.[26] The changes in blood lead levels in these two studies were similar. Vehicle exhaust contributed an average of up to 24–27% of total blood lead during this time, reflecting different sources in rural and urban areas;[27] the mean blood lead level in most countries averaged ~10–20 μg/dL.[28] The last reported death from lead encephalopathy in the United States occurred in 2006 (the last preceding death was in 1990).[29]

Humans accumulate lead based on past exposure to lead in the environment; average blood lead concentrations in the US population continue to decline as lead exposure in the environment decreases. The average US blood lead level declined 37% as leaded gasoline consumption declined 55% during 1976–1980.[30] For the US population, the geometric mean for the blood lead level during 1988–1991 in Phase 1 of the NHANES III study was 2.8 μg/dL (95% CI: 2.7–3.0 μg/dL). This mean represents a 78% decline since 1976–1980.[31,32] Overall, 8.9% of children 1–5 years of age in this study had blood lead levels >10 μg/dL. Variation in the blood lead level depends on geographic area and age. In Chicago, the median blood lead levels among children declined from 30 μg/dL in 1968 to 12 μg/dL in 1988, while air lead levels decreased ~20-fold.[33] Blood lead levels continue to decline. The geometric mean blood lead level in the US population during 1991–1994 was 2.3 μg Pb/dL with 4.4% of the children aged 1–5 years having blood lead levels exceeding 10 μg/dL.[34] The geometric mean declined to 1.66 μg/dL (95% CI: 1.60–1.72 μg/dL) in 1999–2000 (NHANES III), then to 1.12 μg/dL (95% CI: 1.08–1.16 μg/dL) in 2009–2010 (NHANES IV).[35] The blood lead level in children aged 1–5 years in the National Health Nutrition and Examination Survey continued to decline in the 2010s with an estimated 97.5% BLL of 3.48 μg/dL in 2011–2014.

As blood lead levels declined, classic lead poisoning (peripheral neuropathy, kidney disease, encephalopathy) became rare and mortality from lead intoxication decreased dramatically. Within the past 40 years, epidemiological studies have provided evidence of health effects at low blood Pb levels. Research work on the clinical effects of lead now focuses on the subtle neuropsychological (reduced IQ, behavioral abnormalities), cardiovascular, reproductive, and developmental effects of chronic low-dose lead exposure. The US National Toxicology Program review of epidemiology studies raised concern about the effects of blood lead levels <10 μg/dL in several domains in children

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. (reduced academic achievement/IQ, attention-related behavior problems, reduced postnatal growth, delayed puberty) and adults (decreased glomerular filtration rate, increased blood pressure, essential tremor).[36]

Children are particularly susceptible to lead-induced impairment of neuropsychological development because of their reduced ability to excrete lead and enhanced lead absorption compared with adults. Difficulty controlling confounding variables (maternal and paternal IQ, prenatal care, educational interventions) and the relatively small effect of lead exposure compared with the effect of these confounding variables complicate the interpretation of the effect of lead on cognitive development. Because the efficacy of chelation in patients with blood lead levels <45 μg Pb/dL is unproven, treatment involves prevention and modification of the environment. In 1991, the Centers for Disease Control and Prevention (CDC) reduced the blood lead "level of concern" at which intervention is desirable from 25 to 10 μg/L. In 2012, the CDC shifted its focus to the primary prevention of lead exposure to expedite the identification of children at risk of serious lead exposure (e.g., cognitive abnormalities, behavioral development). Consequently, the CDC replaced the level of concern (i.e., >10 μg/dL) with the 97.5th percentile of the NHANES distribution of lead in US children (>5 μg/dL). The effect of low-level lead exposure is less clear in adults than children, particularly subclinical effects (e.g., inhibition of heme biosynthesis enzymes, impairment of renal tubular function, reduction of sperm formation, diminished conduction of motor nerve impulses, elevated blood pressure). The difficulty of detecting the extent of chronic lead exposure over a lifetime confounds epidemiological studies.

PHYSIOCHEMICAL PROPERTIES

Metallic lead is a relatively rare element in the natural environment. Lead occurs naturally as a mixture of the following four stable isotopes: ^{208}Pb (51–53%), ^{206}Pb (23.5–27%), ^{207}Pb (20.5–23%), and ^{204}Pb (1.35–1.5%).[37] Although lead exists in three oxidation states (0, 2+, 4+), lead exposure primarily involves the divalent inorganic salt. The excellent corrosion resistance of lead results from the formation of lead salts (carbonates, oxides, sulfates) following exposure to air or water. Most of the lead salts (e.g., sulfide, oxide) are poorly water-soluble with the exception of chlorate and nitrate. The solubility of lead chloride is intermediate between the solubility of nitrate and oxide salts. Tetravalent lead compounds occur only under extreme oxidizing conditions; consequently, inorganic tetravalent compounds do not usually exist under normal environmental conditions. Table 16.1 lists the identifying information and physical properties of lead and divalent lead salts.

EXPOSURE

The blood lead level in an individual depends on several risk factors including age, gender, menopausal status, trimester of pregnancy, smoking, and alcohol consumption.[38,39] The segment of the population with the highest risk from lead toxicity includes preschool children, pregnant women and their fetuses, and older workers (e.g., 40–59 years old) with chronic lead exposure. Despite the potentially increased release of lead from bone stores as the population ages, analysis of NHANES data and evaluation of inner-city populations over the age of 80 years indicate elevated blood lead levels as defined by >10 μg/dL were rare in this group.[40] Specific risk factors include habitation or renovation of older homes (pre-1950–1960), occupational or para-occupational exposure, smoking, and illicit wine or whiskey consumption. The overwhelming majority of serious lead exposure in adults occurs in the work environment via inhalation; lack of proper hygiene in lead-contaminated environments (e.g., eating or smoking in areas containing lead dust) increases the risk of lead toxicity.[41] In a subset of the Normative Aging Study established in 1963 to study men from Greater Boston, the highest mean bone lead concentrations occurred in protective service workers (police, firefighters, guards) and construction/extractive workers (foremen, carpenters, electricians, painters, plumbers).[42]

Other than a lead-contaminated point source (e.g., lead smelter, leaded gas fumes), the most important sources of lead exposure for young children include direct or indirect contact with lead-based paint and, to a lesser extent, house dust, contaminated soil, drinking water, formula in contaminated milk containers,[43] paint chips,[44] ceramics, and medications.[45,46] A review of the lead toxicology program in Massachusetts indicated that the most common sources of lead exposure in infants up to 12 months were the following: household renovation, direct ingestion of paint chips, infant formula preparations with lead-contaminated water, lead dust importation, and congenital exposure to an elevated maternal lead level.[43] In this study, paint chips were a more important source of elevated lead concentrations than a household renovation in the group of children aged 18–30 months. A pooled analysis of 12 epidemiological studies on children aged 6–36 months with

blood lead concentrations of 10–25 µg/dL demonstrated lead-contaminated house dust as the major source of lead exposure.[47] Major factors affecting the blood lead concentration in these children included age, race, mouthing behaviors, and site-specific factors (e.g., heavy contamination of soil by lead mining wastes[48]). The ingestion of >5 µg inorganic lead/kg of body weight in children contributes to an increasing blood lead concentration by producing a positive lead balance.

Uses

The physical properties of lead include high density, ease of fabrication, low melting point, chemical stability,

TABLE 16.2. Current and previous lead uses. (Adapted from Centers for Disease Control and Prevention).[35]

Lead Salt	Uses
Acetate	Dyeing of textiles, waterproofing, varnishes, lead driers, chrome pigments, gold-cyanide process, insecticides, anti-fouling paints, analytical reagents, hair dye
Arsenite/arsenate	Insecticide, herbicide, rodenticide
Azide	Primary detonating compound for high explosives
Bromide	Photopolymerization catalyst, inorganic filler in fire-retardant plastics, general-purpose welding flux
Carbonate	Polymerization catalyst, high-pressure lubricating grease constituent, vinyl chloride polymer coating
Chloride	Preparation of lead salts, lead chromate pigments, analytic reagents
Chromate	Pigment in industrial paints, rubber, plastics, ceramic coatings; organic analysis
Tetrafluoroborate	Salt for electroplating lead; can be mixed with stannous fluoroborate to electroplate any composition of tin and lead as an alloy
Iodide	Bronzing, printing, photography, cloud seeding
Molybdeum chromate	Analytical chemistry, pigments
Nitrate	Lead salts, mordant in dyeing and printing calico, matches, mordant for staining mother of pearl, oxidizer in the dye industry, sensitizer in photography, explosives, tanning, process engraving, lithography
Oxide (black)	Storage batteries, ceramic cements and fluxes, pottery and glazes, glass, chromium pigments, oil refining, varnishes, paints, enamels, assay of precious metal ores, manufacture of red lead, cement (with glycerol), acid-resisting compositions, match-head compositions, other lead compounds, rubber accelerator
Phosphate	Stabilizing agents in plastics
Styphnate	Primary explosive, firing Pb-based ammunition storage batteries, paints, ceramics, pigments, electrical and other vinyl compounds requiring high heat stability
Silicate	Ceramics
Tetraethyl lead	Anti-knock agent in 100 low-lead (100LL) aviation gasoline

and corrosion resistance; these desirable characteristics are useful in storage batteries, weights, solder, and pipes.[49] Occupations associated with potential lead exposure include the following: plumbers, pipefitters, construction workers, bridge reconstruction workers, steel welders and cutters, firing range instructors, shipbuilders, battery manufacturers and recyclers, printers, automobile painters, printers, glass manufacturers, lead miners and refiners, rubber product manufacturers, and plastic manufacturers. The most common worldwide uses of lead include manufacturing of storage batteries, production of leaded fuel, and formation of lead-containing alloys with the former accounting for most of the lead consumed in the United States. The US EPA banned lead arsenate and lead arsenite as insecticides in 1988. Although the US EPA banned gasoline fuel containing >0.05 g Pb/gallon for motor vehicles in 1996, other engine types can use gasoline with lead additives including farm equipment, marine craft, airplanes, and race cars.

Lead-antimony alloys insulate cables from moisture and form grids in storage batteries, whereas lead-arsenic-bismuth-tin alloys are constituents of power cables. Solders and bullets may contain lead. The chemical industry uses lead, particularly in the manufacture of sulfuric acid. The excellent sound and radiation attenuating properties of lead are favorable for use in construction and X-ray machines. Lead chromate and lead molybdate form paint pigments with excellent protective properties for bridges, pipelines, and ships. Table 16.2 lists the current and former uses of lead compounds.

Production Processes

Mined ores are the primary source of lead. Galena (PbS) is the most important lead ore; the weathering of galena produces other lead-containing minerals (cerussite, $PbCO_3$; anglesite, $PbSO_4$). Zinc and silver ores also may contain lead. Production of primary lead involves the concentration of lead in a sulfide concentrate (crushing, grinding, froth floatation, dense medium separation), followed by the removal of sulfur and the formation of lead oxide by oxidative roasting.[37] Then blast furnace reduction converts the lead oxide to lead. Secondary lead results from the recycling of lead scraps, primarily storage batteries.

Sources

The estimated daily intake of lead from the environment at the end of the 20th century was ~5–11 µg.[50] Food is usually the major source of lead intake for the general population with small contributions from

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

drinking water and air.[51] The impact of each pathway on blood lead levels depends on a variety of circumstances and behaviors. Lead toxicity in children usually results from oral exploration of a contaminated environment with certain sociological-demographic factors and housing characteristics increasing the risk of lead toxicity.[52] Sources of lead exposure in children include old lead-based house or bridge paints, take-home lead from father's workplace,[53,54,55] lead-glazed pottery, lead in dust or topsoil (e.g., near smelter dumps, burning battery casings, freeways), and traditional remedies including Hispanic, Hmong, and Indian folk medicine (e.g., pay-loo-ah, ghasard, Azarcon, Greta).[56,57,58] Table 16.3 lists potential sources of lead toxicity in children. Severe acute lead poisoning in children may occur from the ingestion of lead-containing objects (e.g., curtain weights, clothing accessories, live lead-based ammunition).[59,60] Current predictors of elevated blood lead levels in US children include air lead, residence in pre-1950 housing, African-American ethnicity, and poverty.[61]

The intentional ingestion of nonfood substances (pica) is the most important route of lead poisoning in toddlers and older preschool children, whereas the ingestion of lead-contaminated formula and exposure to lead during renovation are more important sources of lead exposure in infants.[43] Children can potentially ingest up to 20–50 mg soil/day; this amount correlates to an intake of 25 μg Pb assuming the soil contains 100 μg Pb/g.[62] Pica as a source of lead poisoning is exceedingly rare in the adult population with cases typically involving psychiatric disorders (e.g., schizophrenia, dementia)[63,64] or pregnant immigrant women.[65]

High-precision lead isotope measurements (isotope ratio, IR) help determine the sources of lead exposure.[67,68] This method identifies unique isotope ratios for each source and compares the ratio of the source to the isotope ratio in the blood. In the United States, measurements of the $^{206}Pb/^{204}Pb$ IR in natural lead sources ranged from 16.3 in the Coeur d'Alene mining district in Idaho to 22.54 in Mississippi Valley lead deposits, whereas the $^{206}Pb/^{207}Pb$ IR was 1.05 and 1.4, respectively, in these two locations.[69] Lead dust in residences is probably a composite of many sources of lead over time; lead paint chips under areas where the samples are collected may contaminate the dust sample. Two studies in the northeastern and central United States suggest that a $^{206}Pb/^{207}Pb$ IR in blood outside 1.185–1.215 indicates a geological point source for the lead.[70] The ratio is geographically specific with ratios in other areas (e.g., the western United States) varying as a result of different point sources for lead. The potential

TABLE 16.3. Potential sources of childhood lead toxicity. (Adapted from Woolf et al.).[66]

Area	Source	Examples
Environment	Antique or foreign toys, cribs, furniture	Toy soldiers, necklaces
	Contaminated foodstuffs	Homegrown vegetables, imported spices, calcium supplements, flour
	Cosmetics	Kohl, surma, ceruse,
	Crafts	Ceramic glazes, paints, stained glass material
	Exterior home material	Pewter-like fencing
	Drinking water	Leachate from leaded pipes
	Dust contamination, soil	Lead smelters, leaded gasoline sources
	Folk remedies	Pay-loo-ah, ghasard, azarcon, greta, litarigio, bali bali, coral, liga, reuda
	Herbal products	Ayurvedic medicine and supplements
	Imported material	Toys, crayons, ceramics, pewter, pots, kettles
	Methamphetamine	Lead acetate process (prior to 1970s), ephedrine or pseudoephedrine process, and lead-contaminated adulterating (cutting) agents
	Moonshine whiskey	Processes using lead containers
	Paint	Primarily houses built before the 1970s
	Plaster, putty	
Activities	Burning painted wood	Pre-1950 homes
	Hobbies	Target shooting, stained glass, glazing pottery, toy soldiers, fishing weights
	Home renovation	Primarily houses built before the 1970s
	Occupations	Auto repair, mining, smelting, demolition, battery manufacture, construction, painting, pipe fitting, plumbing, shipbuilding, welding, bridge reconstruction, firing ranges
Pregnancy (*in utero*)	Dietary supplements/herbal products	
	Hobbies	
	Lead-related jobs

TABLE 16.4. Some historical average and upper range concentrations of lead contamination in selected sources 1970s–1980s. (Adapted from Nyhan et al.).[23]

Source	Item	Estimated Lead Concentration
Food	Baby food in tin can	202 μg/L (M)
	Drink in glazed pottery mug	2,000 μg/L (UR)
	Bone meal	60–190 μg/g
Water	Drinking water	640–1,850 μg/L (UR)
Air	Smelter within 1.6 km	8–10 $\mu g/m^3$
	Smelter within 4.0 km	14–16 $\mu g/m^3$
Soil	Smelter within 1.6 km	7,600 μg/g (M)
	Urban residential	9–7,890 μg/g (M = 585 μg/g)
	Urban park	194–3,357 μg/g
House dust	New inner-city homes	2–24 $\mu g/ft^2$
	Old inner city homes	33–486 $\mu g/ft^2$ floor
	Lead smelter workers' homes	2,687 μg/g (M)
	Homes within 1.6 km from smelter	22,191 μg/g (M)
	Homes 1.7–3.2 km from smelter	2,124 μg/g (M)
	Paint chips	100,000 μg/g (UR)

Abbreviations: M = mean; UR = upper range.

sources of lead must be few in number and isotopically distinct in order for this method to identify effectively the pathway of lead exposure.[71] Table 16.4 lists lead contamination in selected sources based on data prior to the banning of leaded gasoline in the United States; data must be interpreted cautiously when extrapolating lead concentrations from various sources because of the historical reductions in lead concentrations over the later decades of the 20th and 21st centuries.

Air

The major natural sources of lead include emissions from sea spray, volcanic eruptions, and the weathering of the earth's surface. The contribution of natural lead sources to lead exposure in the general population is relatively small compared with anthropogenic sources.[72] An estimated 19,000 tons Pb/year is released from these natural sources throughout the world with volcanic eruptions accounting for about 6,400 tons Pb/year.[73] Lead concentrations in ambient air range from 0.000076 $\mu g/m^3$ in Antarctica[74] to >10 μg Pb/m^3 near smelters, with average annual urban levels <1 μg Pb/m^3. In 1925, leaded gasoline was introduced into the United States with mandatory reductions in lead content beginning in 1973 culminating in a ban on most uses by 1996. Lead has not been completely removed from aviation gasoline because damage from engine knocks may cause sudden engine failure. Prior to the restriction of leaded gasoline by the US EPA, the combustion of alkyl-leaded fuel was the major (80–90%) source of airborne lead in the United States. High lead concentrations may contaminate soils surrounding major highways as a result of the previous use of leaded gasoline. Currently, industrial processes are the major sources of lead emissions into the atmosphere with the highest lead concentrations found around smelters and battery manufacturers. In 1982, the ambient air in urban areas of Mexico contained 0.6–5.7 μg Pb/m^3 compared with <0.07 μg Pb/m^3 in US urban air after the restriction of leaded gasoline use.[75] In 1988, auto emissions accounted for only 34% of the annual amount of lead released into the air.[76] By the early 2000s, US EPA National Air Quality Monitoring Program data indicated a 94% reduction in the average air quality lead concentration since the early 1980s based on a mean atmospheric lead concentration of <0.05 $\mu g/m^3$.[77] The lead concentrations in indoor air range from 30–80% (mean ~50%) of the outdoor lead concentrations. The lead level in ambient indoor air depends primarily on the presence of lead-painted surfaces. In a study of 213 residences in the Midwestern United States during the 1990s, the mean lead concentration in indoor ambient air was 0.015 ± 0.038 $\mu g/m^3$ with a median of 0.006 $\mu g/m^3$ and a maximum value of 0.293 $\mu g/m^3$.[78] Analysis of this data indicated that the difference between the mean lead concentration in indoor ambient air from homes built before 1940 (0.046 ± 0.002 $\mu g/m^3$) was significantly different (P = 0.036) than homes built from 1960–1979 (0.013 ± 0.002 $\mu g/m^3$). However, the differences between homes built from 1940–1959 (0.022 ± 0.005 $\mu g/m^3$) or 1980–1995 (0.023 ± 0.005 $\mu g/m^3$) and pre-1940 homes were not statistically significant.[79]

Except for near-point sources (e.g., smelters,[80] battery manufacturing or disposal), airborne lead is a minor pathway of exposure in countries that limit the use of leaded fuel.[81] Lead concentrations are usually highest within 3 km of these sources; concentrations near these sites may exceed 10 μg Pb/m^3.[72] Ambient air concentrations >2 μg Pb/m^3 as a monthly average are associated with increased blood lead levels in children.[82] For each 1 μg Pb/m^3 of ambient air, the blood lead of an exposed person increases by 1–2 μg Pb/dL.[83] Global distribution of lead occurs as a result of anthropogenic sources, primarily as a result of the continued use of leaded fuel additives.

Soil

The average lead concentration in the crust of the earth is ~10–30 mg Pb/kg with the major geological sources

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

being metamorphic and igneous rocks, mostly galena (PbS). Studies of lead speciation indicate that the form of lead changes during the smelting process. Galena is the major constituent in samples obtained during ore handling, whereas lead oxide is the dominant species associated with the smelter operation.[84]

Domestic ore production and ammunition use produce most of the lead-containing solid waste. For lead contamination from anthropogenic sources, the soil is the most important repository. Soil and sediment are important sinks for lead in the environment with sources typically containing higher lead concentrations than adjacent surface waters. Both wet and dry deposition are important routes of contamination of the soil. Because lead does not dissipate, degrade, or decay in soil, lead deposited in the soil or dust represents a potential long-term source of lead exposure. Lead exposure from soil results from surface dust and the actual content of lead in soil. Background lead concentrations in soil range from 10–70 mg/kg with concentrations near point sources (e.g., highways) up to several times higher depending on proximity.[72] Local point sources of lead may increase the lead content in sediments significantly. In a study of sediment in surface waters near mines located in the old lead belt of Missouri, lead concentrations in sediment near the mines ranged from 10,550–12,400 mg/kg dry weight compared with 72–400 mg/kg in sediment from areas without lead-contaminated mine tailings.[85]

Exclusive of lead-contaminated paint sources, the lead concentration in soil largely reflects the deposition of lead from the atmosphere. The predominant species emitted from lead smelters are lead sulfur compounds.[86] Lead deposited from the air resides in the top 2–5 cm of undisturbed soil. The major chemical factors that affect the bioavailability of lead from the soil include the species of lead, the matrix attached to lead, and the size of the lead-containing particles.[87] Lead sulfide is less bioavailable compared with lead carbonate and lead oxide. Although the reduction of leaded fuel has dramatically reduced the lead concentration in air, soils within 25 m of roadways typically contain 30–2,000 ppm of lead above natural levels depending on the amount of vehicular traffic.[72] In less developed countries, cottage and conventional smelters are potential hazards for nearby residents, particularly children aged 1–2 years old.[88] In areas surrounding lead sources, the blood lead level of children correlates to soil lead concentrations, whereas the blood lead level of pregnant women does not.[89] Releases of lead from lead-based paints are usually limited to the immediate vicinity of painted surfaces; however, deterioration or removal of lead-containing paint can produce high localized lead concentrations in house dust, particularly following the use of power sanders or sandblasting. In a case series of 31 New Orleans houses, paint chips contained a median lead concentration of 35,000 μg/g with a range up to 257,000 μg/g.[90] Power sanding one of these houses (exterior paint, 130,000 μg Pb/g) resulted in blood lead concentrations in house dust from the living area and soil from the front entrance porch of 23,300 μg/g and 27,600 μg/g, respectively.

Water

Analysis of data from ocean water indicates very low lead concentrations (i.e., 0.005 μg/L) in seawater not directly affected by anthropogenic sources.[91] Lead concentrations in the ground or surface water are variable, rarely exceeding 5–10 μg/L depending on point sources, sediment contamination, and soil/water conditions (e.g., pH, temperature, humus content). The component of lead in water attributed to natural sources accounts for ~0.02 μg/L.[92] The major sources of lead in drinking water are lead pipes and leaded solder in lead service lines connecting the house to the main water lines, faucets, and fixtures, particularly in houses built before 1986. The presence of leaded water pipes may increase these concentrations substantially (i.e., 100 μg/L). Surveys of drinking-water supplies leaving treatment plants indicate lead concentrations averaging 2–3 μg/L; however, concentrations in households with corroded lead plumbing may range 10–30 μg/L, particularly in systems installed prior to 1930 or connected to main lines with lead piping. In a study of 381 water samples from 73 residences obtained during the mid-1990s throughout Maryland, the median lead concentration was 0.33 μg/L with a mean of 1.08 ± 2.01 μg/L (maximum, 13.40 μg/L).[93] Prior to the collection of the water samples, the tap was flushed for 2 minutes. First-draw water samples from a study of 2,146 private drinking water systems in Virginia exceeded 15 μg/L (US EPA standard) with brass as the likely lead source.[94]

Aquatic releases from industrial sources primarily involve leachates from steel/iron industries and lead production/processing operations with the lead primarily suspended in solids or adsorbed into the sediment. Urban runoff and atmospheric deposition are indirect lead sources. Lead concentrations typically are low in ground and surface water averaging <4 μg/L; contamination of water with lead usually occurs in the distribution system. Common areas of lead contamination in the water distribution system include 1) lead connectors (goosenecks, pigtails), 2) lead service lines or pipes, 3) lead-soldered joints in copper plumbing, 4) lead-containing water fountains and coolers, and 5)

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. lead-containing brass faucets and other fixtures. The latter accounts for up to 1/3 of the lead present in the first-draw sample. Currently, installation of residential plumbing systems involves the use of lead-free solder and copper piping; the solder and flux must contain <0.2% lead, whereas pipes, pipe fittings, and well pumps must contain <8% lead based on the 1986 Safe Drinking Water Act Amendments.

The contamination of drinking water by lead occurs during the leaching of lead from lead-laden pipes and/or lead-containing solder on copper pipes, primarily in areas with soft (low calcium, low magnesium, acidic pH) water. In April 2014, the city of Flint, Michigan, switched their drinking water source from the low corrosivity of Detroit Water and Sewage Department water (↓ chloride, ↓ chloride/sulfate mass ratio, orthophosphate corrosion inhibitor) to Flint River water (↑ chloride, ↑ chloride/sulfate mass ratio, no orthophosphate corrosion inhibitor); this change resulted in lead leaching into the drinking water from some homes with leaded water pipes (e.g., 104 μg/L, 397 μg/L, 707 μg/L).[95,96] Before the issuance of boiling water advisory in October 2014 and reduced drinking water consumption, the estimated likelihood of a child presenting with blood lead level (BLL) >5 μg/L increased by a factor of 1.91–3.5 depending on the season and neighborhood studied within Flint; however, retrospective analysis of BLL of Flint children did not support a global increase in the BLL of young children in Flint during the 18-month period of Flint River water use.[97] The geometric mean BLL of affected children decreased in blood samples during the period immediately before the switch from 1.47 ± 0.02 (n = 1,834 samples) to 1.32 ± 0.02 (n = 1,734 samples) during the 18 months of Flint River water use. Some of the increased BLL during this period may have resulted from seasonal variation in BLL (e.g., resuspension of lead-contaminated soils during the summer).[98] The city of Flint switched back to the Detroit Water District in November 2015.

Grounding of electrical systems to pipes may increase the lead content in water by increasing corrosion. Acidity increases the amount of lead in water with higher lead concentrations occurring in drinking water with pH <8.[99] Detectable lead concentrations may occur in "first draw" water from plastic or galvanized pipes despite the absence of lead-containing material. In a study of >1,000 water samples from regulated facilities throughout the United States during the 1980s, the mean lead concentration in 1-L samples of "first draw" water was 4.5 μg/L from plastic piping and 4.2 μg/L from galvanized piping without lead solder.[99] Brass faucet fixtures accounted for most of the lead content. Significant lead contamination of tap water is unusual. A follow-up study of elderly men in Boston indicated that measures of cumulative lead exposure (tibia and patella bone lead levels) correlated to first-morning tap water lead concentrations ≥50 μg/L and the daily consumption of ≥1 glass of tap water; however, there was no correlation in men to lower lead exposure.[100]

The highest lead concentrations in tap water occur in the "first-draw" water from seldom-used faucets following extended periods of disuse.[101] This "first draw" water may contain up to 10 times the lead concentration present in fully flushed water.[102] Within 3–5 hours of a 10-minute flush, the lead level in drinking water is similar to lead concentrations prior to the 10-minute flush.[103] The effectiveness of many point-of-use devices (e.g., water taps) in reducing the lead content in water depends on the location of the device in relation to the source of lead and compliance with maintenance/use requirements. Reverse osmosis and distillation units usually remove lead more effectively from water than carbon, sand, or cartridge filters.

Diet

The major source of lead exposure for the general adult population is water and food with lead intake decreasing significantly during the last part of the 20th century. The average daily dietary lead intake of a 2-year-old child decreased from 30 μg in 1980 to 5 μg in 1988.[81] The estimated daily total lead intake for all age groups (n = 176) in the NHEXAS Arizona study during the mid-1990s was 36 μg with a range of 11–107 μg.[104] The 90th percentile of lead in food analyzed in this study was 0.016 μg/g. Isolated epidemics of lead poisoning occur as a result of lead contamination in dietary sources (e.g., paprika).[105] Acidic foods (e.g., fruit/vegetable juice, salsa) can release lead from improperly fired ceramic glazes or lead-soldered cans;[106] however, the impact of the latter is decreasing as the use of lead solder decreases. Although the acidic pH of alcoholic beverages favors the leaching of lead, alcoholic beverages probably are not a significant lead source for the general population.[72] The leaching of lead from lead-containing containers is higher for some foods (e.g., corn, beans) than others with similar pH.

The quantity of lead in food decreased substantially with reductions in the use of leaded gasoline and lead-containing solder in food containers. The use of food containers with leaded solder was reduced substantially in the US markets in 1979–1989 with elimination by 1995. In the US FDA Total Diet Study (TDS) 1991–1996, analysis of lead concentrations in a market basket of 260 foods from four geographic regions of the United States detected lead below 0.03–0.05 mg/kg

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. (lower level of quantitation) in 255 foods; samples included cereal and grain products, desserts, eggs, infant and junior foods, fish, legumes, meat, milk and cheese, poultry, snacks, and vegetables.[107] Quantifiable lead concentrations occurred in canned peaches (0.032 mg/kg), canned pineapple (0.013 mg/kg), canned fruit cocktail (0.031 mg/kg), dry table wine (0.023 mg/kg), and sweet cucumber pickles (0.036 mg/kg). In a Canadian study of retail foods in five cities during 1986–1988, the median lead concentrations in food categories other than miscellaneous ranged from <0.003 mg/kg (maximum, 0.089 mg/kg) for beverages to 0.016 mg/kg (maximum, 0.37 mg/kg) for fruits and fruit juices.[108] The mean lead concentration for all categories was 0.023 mg/kg with a maximum of 0.52 mg/kg. During this 3-year period, the mean lead concentration in canned foods decreased by 60% with the increased use of lead-free containers. Rarely, chickens raised in urban gardens contaminated by lead (e.g., peeling lead paint) produce eggs containing lead concentrations in edible portions exceeding current recommended lead thresholds.[109]

Lifestyle

Common nonoccupational exposures to lead include shooting firearms, renovating, painting, lead casting, and retained bullets.[110] Potentially hazardous hobbies involving lead contamination include stained glass production, casting ammunition, assembling fishing weights and toy soldiers, painting, and furniture refinishing. Lead toxicity occurred in a family as a result of exposure to lead fumes from the extraction of gold and silver from jeweler's waste.[111] Smoking increases the risk of lead toxicity in smokers residing in lead-contaminated houses.[112] Lead content in tobacco varies from 2.5–12.2 μg/cigarette with ~2–6% inhaled by the smoker.[113] A study of filter-tip Finnish cigarettes in the 1970s detected a mean lead concentration of ~2.4 μg/g.[114] The estimated amount inhaled was ~5% with the remaining lead in side-stream smoke and ash. In 320 samples from participants in the 2009 International Tobacco Control United States Survey, the mean lead content was 0.44 ± 0.24 μg/g dry weight (range, <0.19–2.40 μg/g),[115] whereas the reference range for lead in a study of major US cigarette brands was 0.6–1.2 μg/g (dry weight).[116]

Housing

Structure Since 1978, federal US statutes restrict the manufacture of paint with lead content >0.06% (600 ppm) by weight in its final, dry solid form. The use of lead-based paint was common in older homes built before 1940, where lead content from lead carbonate and lead oxide typically ranged 5–40%. These dwellings may also contain leaded pipes that produce lead-contaminated leachate in household water. During this time interval, lead oxide was the main constituent of white pigment in paint.[117] Renovation of these homes can result in significant lead contamination.[118] The use of interior lead-based paint declined dramatically during the 1950s, but the use of exterior lead-based paint continued until the mid-1970s. A 1990s study analyzing the isotope ratios of Pb in house dust samples from an urban New Jersey environment demonstrated that outside sources of lead contribute as much Pb to the house dust wipe samples as interior lead-based paint.[119] Soil and paint in modern and well-maintained homes probably contribute little to the lead exposure of children.[120]

A temporary exacerbation of lead toxicity may occur in children following the removal of lead from old, lead-contaminated homes.[121,122] The renovation of older homes (e.g., sandblasting, sanding, heating with torches) can produce serious lead toxicity in children[123] and adults.[124] Adults performing the restoration work and the youngest children in the dwelling are at the greatest risk of developing lead toxicity. Although a typical (25–50% lead by weight) 1 cm^2 chip of paint contains ~0.5 gm Pb, most lead is not absorbed because of the lamination of the lead in the chip and the ingestion of the chip as a whole. Windows are a common source of house dust with high lead concentrations, particularly during restoration work on older homes;[125] some vinyl mini blinds contribute to the lead burden as a result of the deterioration of lead-containing material and deposition of lead-contaminated dust. In a study of 92 children with elevated blood lead concentrations in North Carolina,[126] the median lead concentration of dust on the mini blinds was 590 μg Pb/ft^2 with a range up to 73,302 μg Pb/ft^2. However, the contribution of the lead-containing mini blinds to the development of lead toxicity was not established because the study was based on a convenience sample of lead-exposed children rather than a controlled study involving a comparison group of children without lead poisoning.

Para-occupational Exposure Case series and cross-sectional studies indicate that para-occupational exposure of children may elevate blood lead levels as a result of lead-contamination of the home, cars, work shoes, and work clothes from fine-particulates transferred from severely contaminated workplaces.[127,128,129,130] However, not all studies of children in lead-contaminated environments demonstrate evidence of neurotoxicity.[131] In a study of 227 persons from 78 families of lead

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

battery recycling workers, 57% of the children aged <6 years had BLL exceeding 5 μg/dL and 16% had BLL >10 μg/dL.[132] Dust wipe and vacuum sampling detected lead concentrations exceeding 40 μg/ft^2 (US EPA lead level of concern, 3.7 μg/m^2) in 85% of vehicle dust samples and 49% of home dust samples.

Parental occupational sources for these lead exposures include the following: cottage industries (belt buckles, awards, type printing), pottery manufacturing, battery repair shops, lead or copper smelters, radiator mechanics, capacitor and resister plants, and electric cable splicing.[133] In a study of blood lead levels in families of workers from a plant manufacturing ceramic-coated capacitors from leaded glass, the mean blood lead level of family members of exposed workers was 10.2 μg/dL compared with 6.2 μg/dL in family members of unexposed workers.[129] The lead contamination of exposed workers was severe (i.e., ambient air, 61–1,700 μg Pb/m^3).

A study of construction workers with elevated blood lead levels demonstrated that these workers carried lead from construction sites on their skin; the pathway of lead contamination was workplace to worker, car, then home.[134] The highest levels occurred on the driver's and passenger's armrest with a geometric mean (GM) of 2000 μg Pb/m^2 and 1200 μg Pb/m^2, respectively. The study reported a statistically significant difference (P = 0.005) in the surface lead concentration (GM = 370 μg/m^2) in the rooms where clothing was changed compared with neighborhood controls (GM = 120 μg/m^2). Poor hygiene practices of these workers contributed to the increased lead contamination in their homes. Compared with controls, the odds ratio for workers' children with blood lead levels >10 μg Pb/dL was 6.1; however, the 95% confidence interval was large (0.9–147).

Leaded Substance Use

Drug Abuse Sniffing leaded gasoline increases blood lead levels as a result of the conversion of tetraethyl lead to inorganic lead.[135] The elimination of tetraethyl lead from gasoline has reduced significantly the hospitalizations associated with gasoline sniffing;[136] however, abuse of other lead-containing substances (e.g., lead-contaminated heroin) is a potential source of lead exposure in substance abusers.[137,138] Rare case reports associate chronic ingestion of opium containing ~3.5% lead with a blood lead level of 50 μg/dL and lead toxicity (abdominal colic, constipation, gingival discoloration, basophilic stippling).[139] Lead contamination may occur from use of lead acetate as a reagent during methamphetamine production or distribution phase from Pb-contaminated adulterating agents. A case series documented blood lead levels ranging from 49–513 μg/dL in 14 intravenous drug users using lead-contaminated methamphetamine;[140] however, a cross-sectional study of intravenous drug users presenting to an emergency department did not detect evidence of subclinical lead poisoning.[141]

Moonshine Whiskey Although lead poisoning-related deaths continue to decline dramatically in the United States, moonshine whiskey remains a source of serious lead toxicity, particularly among rural African-American men in the southeastern and midwestern United States.[142,143] Lead commonly contaminates moonshine whiskey at high concentrations as a result of the distillation of whiskey in containers (e.g., automobile radiators) with lead-soldered parts.[144] The maximum lead concentration in an analysis of 12 samples of Georgia moonshine was 5.3 mg/L; 7 of the samples contained detectable amounts of lead. Of 115 samples of suspected moonshine confiscated by local law enforcement in 1995–2001 and analyzed by the Bureau of Alcohol, Tobacco, and Firearms, 28.7% contained lead concentrations >3 mg/L (median, 0.44 mg/L; maximum, 532 mg/L).[145] In a cross-section study of emergency department patients in Atlanta, Georgia, the median blood lead level in 50 moonshine drinkers was 11.0 μg/dL (range, 1.0–107.0 μg/dL) compared with 2.5 μg/dL (range, 0.5–22.1 μg/dL) in 581 non-moonshine drinking patients.[146] Other sources of these epidemics include wine stored in leaded crystal, lead-colored glass, lead-glazed ceramic tile containers.[147]

Consumer Products Some consumer products may contain substantial amounts of lead including herbal supplements, inexpensive costume jewelry,[148] cosmetics, and folk remedies.[149,150] In a study of traditional Asian remedies sold in eastern US Asian grocery and health food stores during the early 2000s, lead was the most common heavy contaminate of these products.[151] Case reports documented the presence of lead in Chinese herbal preparations (e.g., contaminated clam shell powder producing BLL = 76 μg/dL),[152] Chinese baby powder (e.g., ~22% lead tetroxide),[153] Chinese anticonvulsants,[154] and traditional Ayurveda analgesic (3.6% lead).[155] In a study of 95 dietary supplements (i.e., primarily herbal or botanical products), the median lead concentration was 0.40 μg/g with a range of <0.02–0.49 μg/g; the highest lead concentration occurred in a sample of pseudoginseng root.[156] Analysis of Brazilian herbal medicine samples suggested that some of these products (e.g., horse chestnut, *Aesculus hippocastanum*) may contain lead concentrations exceeding guidelines for oral lead intake as measured

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

by atomic absorption spectrophotometry.[157] Lead may contaminate calcium supplements, particularly natural supplements (bonemeal, dolomite, oyster shells). In a California study of 136 calcium supplements purchased during 1996, the mean lead concentration (μg/g dry weight) for bonemeal ($n = 9$) was 0.60 ± 0.39 (range, 0.21–1.38) compared with 0.97 ± 0.49 for dolomite ($n = 5$; range, 0.39–1.56) and 0.88 ± 0.51 for oyster shells ($n = 26$; range, 0.12–2.10).[158] Refined calcium (chelated and non-chelated) also contained relatively high lead concentrations (mean = 0.73 ± 1.60; range, <0.6–10.05); $n = 37$.

Litargirio is a yellow-peach-colored antiperspirant/deodorant and a folk remedy from the Dominican Republic that contains up to 79% lead oxide.[159] Lead sulfide is a component of black eye makeup, particularly in Nigeria (tiro), India (Surma), and the Arab world (kohl, kajal).[160,161] The maximum allowable content of lead in US cosmetics is 0.6% w/v.[51]

Occasionally, case reports document lead contamination in traditional herbal medicine following consumption of ayurvedic medicines for diabetes,[162] fertility (deshi dewa),[163] psoriasis,[164] and malaise (mineral tonics).[165] In a review of published cases concerning 76 patients with lead encephalopathy, 87% of the cases were associated with Middle Eastern traditional medicines (surma or kohl, saoott or cebagin, bint al dahab, santrinj, bokhoor), 7% with Ayurvedic medicines, and 7% with other traditional medicines from Latin America (azarcon, greta) and China (ba-baw san, po ying tan).[166] Two lead-containing Mexican remedies (azarcon, lead tetraoxide; greta, lead oxide) were folk remedies for the treatment of colic (empacho).[167] Other names for these remedies include liga, alarcon, coral, Maria Luisa, and rueda.

Hobbies

General Hobbies associated with potential lead exposure include pottery glazing, stained glass construction or repair, lead soldering, car or boat repainting, fishing or hunting with lead sinkers or shot, target shooting, reloading lead bullets, and remodeling older homes. Lead-containing products include casting fishing weights or toy soldiers (molten lead), pottery making (frits, leaded glazes), paintings (lead paint), glass blowing (coloring agents), and screen or platinum printing material.[168]

Pottery Rare case reports attribute lead poisoning to the use of lead-contaminated ceramics[169,170] including cocktail glasses glazed with lead sulfide.[171] Lead is a common component of earthenware glazes, particularly low-fired glazes. Some lead compounds (e.g., carbonate, monosilicate, oxide) are highly soluble. The addition of various oxides to lead-bearing glazes increases the solubility, even in glazes formulated to yield small amounts of lead. Frits are glassy materials that fuse various glaze components, imparting a smooth, glossy finish to the fired earthenware. The use of frits reduces the solubility of lead glazes, but their use does not guarantee a glaze of low lead solubility.[170] The use of an airbrush to apply fritted lead glazes produced lead poisoning in a potter.[172] Concentrations of lead oxides in ceramic glazes range up to 25–30%; the ingestion of ceramic glazes by mentally impaired residents of a nursing home resulted in serious, acute lead toxicity.[173] Both heat and the storage of acidic food increase the leaching of lead from earthenware;[174,175] however, the clinical relevance of the use of lead-containing ceramics to the total lead burden remains unclear because of variability and complexity in determining the amount of lead absorbed from lead-containing ceramics.[176]

Retained Lead

Wounds Lead intoxication from retained bullets is rare compared with the incidence of gunshot wounds as a result of the encapsulation of the bullets in soft tissue. In a convenience sample of 451 patients presenting to an urban emergency department with retained projectiles (typically, copper-clad lead bullets), the prevalence of whole blood lead levels >20 μg/dL at 3 months and 6 months was 11.8% and 2.6%, respectively.[177] Although ~60,000–75,000 nonfatal firearm-related injuries occur each year in the United States, there are only ~100 case reports of lead toxicity from retained bullets, primarily as a result of retained lead bullets near or in joints.[178] These injuries usually occurred before the mid-1990 when steel shot replaced most lead shot. Risk factors for the development of lead intoxication in these cases include bullet fragmentation within the joint space,[179] embedding of the fragments in fractures (thorax, long bones) with cyst formation surrounding the lead,[180] bullet composition, total lead load, and contact with cerebrospinal, synovial, or pleural fluid. The retention of large numbers of lead pellets from shotgun wounds can produce substantially elevated blood lead concentrations and lead toxicity as a result of the larger surface area of many small pellets.[181,182] Bullets lodged in joints or in other relatively acidic environments degrade more easily than environments with neutral pH, increasing lead absorption.[183,184] Although retained lead bullets represent a potential risk of lead intoxication, neither the exact risk of intoxication nor the length of the latency period can be predicted accurately because existing data is based on case reports.[185] Lead toxicity from retained lead bullets may occur within

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

a few days to many years after the bullet enters the wound in patients with substantial risk factors.[186,187] Case reports indicate that lead bullets may remain in nonarticular tissues for 50 years without the development of lead toxicity.[188] Fatal lead toxicity from retained bullet fragments is extremely rare; typically, these lead fragments lodge near bone and toxicity may occur many years after the gunshot wound.[188] A variety of factors may precipitate lead toxicity in these patients including metabolic stress (infection, substance abuse, thyrotoxicosis, sepsis, shock, multiple fragments, recent trauma or fracture, long duration of retention) and pregnancy. Rapid bone growth may precipitate lead toxicity in patients with retained bullets long after the wound.

Analysis of lead fragments removed from patients with lead toxicity secondary to retained lead bullets suggests that lead hydroxide carbonate ($C_2H_2O_8Pb_3$, CAS RN: 1319-46-6) is the main form of lead on the surface of these fragments.[189] Pseudocysts may form from bullet fragments outside of synovial cavities as a result of redistribution of lead from the bullet fragments; these pseudocysts contain large amounts of soluble lead, friable lead dioxide, and fine, insoluble, black, radiopaque material lining the cyst.[190]

The amount of lead in air rifle pellets has changed over the years; the popular mushroom-shaped *Diablo* pellets contain soft lead, whereas the newer *Prometheus* pellets contain steel and nylon.[191] Ball bearings and *Prometheus* pellets are often ferromagnetic, resulting in strong deflections in magnetic fields that limit the use of MR imaging.[192]

Ingestion The ingestion of lead foreign bodies poses little risk of lead poisoning when the foreign body passes through the GI tract. Occasional case reports document the development of lead-induced encephalopathy from retained lead (i.e., fishing weight) in the stomach[193] or mild lead poisoning from a lead shot pellet retained in the ascending colon or appendix.[194,195,196]

ENVIRONMENTAL FATE

Air

Inorganic lead exists primarily as particulates in the atmosphere with median particle size in lead released from smelters of ~1.5 μm; high-temperature combustion processes produce relatively small particles.[37] Although the wide distribution of lead from point sources occurs via the atmosphere, ~80% of the lead discharged to air typically deposits near the source (i.e., <10 km).[197,198] The remaining 20% is dispersed widely to remote locations up to several thousand kilometers away. The actual distance lead travels depends on particle size with most particles >2 μm depositing close to the source. An estimated 20–60% of the lead particles from auto exhaust (i.e., primarily lead halides) fall into the soil within 25 m of the road. The average residence time of inorganic lead in the atmosphere is ~10 days.[199]

Soil

Chemical and biotic processes in soil transform most forms of lead released from anthropogenic sources into adsorbable lead salts (i.e., PbClBr, $PbCO_3$, $PbCrO_4$, $Pb(OH)_2$, PbS, $PbSO_4$).[87] Most of the lead halides present in automobile exhaust are converted to lead carbonates or lead sulfates within 24 hours.[200] Some transformation of inorganic lead to tetramethyl lead may occur in the soil, but the significance and source (i.e., abiotic transformation, biomethylation) are unclear. Lead complexes typically precipitate in soil, particularly in soil containing high amounts of organic matter and pH 6–8; subsequently, most lead is bound in the upper 5 cm of soil.[201] At pH 6–8, lead complexes with insoluble organic compounds. These processes substantially limit the mobility of lead in soil. Except under very acidic soil conditions, the leaching of lead into groundwater is very slow. The presence of lead carbonate in the soil and soil pH 8–10 minimizes the penetration of lead into groundwater.[202]

Lead persists in soil. The soil around houses built after 1978 does not usually contain elevated lead concentrations, whereas the soil near a house built before 1950 may contain substantial lead concentrations.[203] Although lead is an element that is not subject to degradation, transformation of inorganic species and/or particle size may occur in soil. In the soil, the bioavailability of lead depends on several factors including mineral content, temperature, pH, the presence of organic material, and the subsequent speciation of lead. These factors cause adsorption of lead at the mineral interfaces, formation of lead complexes with organic matter, and precipitation of poorly soluble lead salts. The processes that reduce lead mobility in the soil also reduce lead uptake by plants. The bioavailable lead in a vegetable plant depends on cation exchange capacity, pH, soil moisture, and the concentration of organic matter or other soil amendments.[37] In a pilot study of plants grown in an urban setting, lead concentrations in the edible portion of the plant did not correlate to soil lead concentrations.[204] Despite high lead concentration in the soil (27–4,580 mg/kg), only 1 (i.e., cucumber, 81 μg

Downloaded from https://onlinelibrary.wiley.com/doi/ by University Of Cincinnati, Wiley Online Library on [28/07/2026]. Pb/g) of 52 fruiting vegetables contained detectable lead concentrations (>10 μg/g); however, after washing, 12 of 31 samples of the leafy vegetables had detectable lead concentrations in the edible portions with a range of 11–60 μg/g. Plants and animals may bioconcentrate lead from aquatic or terrestrial food chains, but these organisms do not biomagnify lead.[37,205]

Water

Following the deposition of lead in water, rapid partition into sediment occurs. Lead exists in water either as soluble lead or undissolved particles in suspension or on surface coatings. In contaminated aquatic systems, most lead is bound to sediment with little lead dissolved in water.[72] The tendency of lead to complex with common anions to produce compounds of low solubility significantly limits the ability of lead to contaminate natural water. The amount of lead in the solution depends on pH and dissolved salt content. At pH >5.4, the maximum solubility of lead is ~30 μg/L in hard water compared with ~500 μg/L in soft water. Precipitation of lead sulfate limits lead concentrations in soft water (pH <5.4), whereas lead carbonates reduce the solubility of lead in hard water (pH >5.4). Typically, benthic organisms and algae contain the highest lead concentrations in aquatic environments, whereas carnivorous fish (i.e., upper trophic level predators) contain much lower lead concentrations.

DOSE EFFECT

Blood Lead Levels >25 μg/dL

The effect of confounding factors complicates the association of specific blood lead levels with neurological abnormalities including age, gender, diet, disease, parental IQ/educational level and home environment,[206] socioeconomic status, and co-exposure to neurotoxins, particularly determining the magnitude of the effect of lead. The developing brain of a young child is more susceptible to the neurotoxic effects of lead than the mature brain of an adult, resulting in a reduction in neuropsychological function (IQ, sustained attention)[207,208] and behavioral abnormalities.[209] Table 16.5 summarizes observed approximate threshold blood lead levels associated with specific adverse health effects.[210] Substantial variability in response to a specific blood lead level may occur between children and adults. Examination of 55 chronically lead-intoxicated (mean = 48 μg/dL, range 9.2–119.1 μg/dL) Andean children revealed a relatively normal neurological examination in most children.[211]

Neurological impairment may occur following exposure to blood lead levels <25 μg/dL including decreased intelligence, behavioral and learning disorders, and reduced neuropsychiatric testing scores (e.g., visuomotor function, perceptual integration, verbal abstraction).[212] Observed deficits on neuropsychological testing based on standardized norms included the following: reduced tendon reflexes, finger tapping,

TABLE 16.5. Observed lower thresholds of blood lead levels associated with specific health effects. Subclinical effects may occur at lower blood levels than noted. The table does not indicate when the effect will probably occur. (Based on Centers for Disease Control, CDC).[210]

BLL (μg/dL)	Children	Adults
>10–15	↑ Zinc protoporphyrin	
>15–25	↓ Vitamin D	↑ Erythrocyte protoporphyrin (women)
>25–30		Elevated erythrocyte protoporphyrin levels; zinc protoporphyrin[a]
>30–40	↓ Peripheral nerve conduction	↑ Urinary tubular enzymes, proteins
>40	↓ Hemoglobin synthesis	↓ Peripheral nerve conduction (subclinical), ↑ blood pressure, chronic nephropathy, ↓ fertility
>50	Peripheral neuropathy	↓ Hemoglobin production, impaired neuropsychiatric testing scores, ↓ testicular function, gastrointestinal distress (abdominal pain, nausea, diarrhea, constipation, anorexia)
>60	Colic	Female reproductive effects, central nervous system symptoms (sleep disturbances, headaches, mood changes, impaired memory/concentrations)
>70	Colic, gastrointestinal distress	Clinical peripheral neuropathy
>80	Encephalopathy, chronic nephropathy (e.g., aminoaciduria)	Anemia
>100		Encephalopathy

Abbreviations: BLL = Blood Lead Level

[a] May occur at 10–15 μg/dL in women.

impaired visual pursuit, math calculation skills, and visuomotor integration.[213] The lack of consistent normative data for the specific population tested complicates the interpretation of abnormalities on neuropsychological testing. Abnormalities in gross motor movements were rare.

Blood Lead Levels <10 μg/dL

Although the ancient Greeks and Romans recognized the toxicity associated with high lead levels, recognition of the adverse health effects associated with low-level Pb exposure did not occur until the second half of the 20th century. The US Centers for Disease Control and Prevention lowered the recommended blood lead level limit for children from 30 μg/dL to 25 μg/dL in 1985. In 1986, the World Health Organization reduced the upper acceptable limit for blood lead to 20 μg/dL based on studies that indicated that lead exposure *in utero* was associated with preterm delivery, decreased birth weight, and increased stillbirths. In 1991, the CDC revised the recommended blood lead limit from 25 to 10 μg/dL as a result of studies that suggested impaired cognitive and behavioral development at blood lead levels of 10–15 μg/dL. Concern persists that chronic exposure to blood lead levels <10 μg/dL causes adverse neurological, developmental, reproductive, renal, and blood pressure effects. In 2012, the CDC shifted focus to the primary prevention of lead exposure to expedite the identification of children at risk of serious lead exposure (e.g., cognitive abnormalities, behavioral development); the CDC replaced the lead level of concern (i.e., >10 μg/dL) with the 97.5th percentile of the NHANES distribution of lead in US children (>5 μg/dL). The medical literature contains many thousands of studies on the effects of lead levels in humans. The 2012 US National Toxicology Program Review of Epidemiology studies identified several effects concerning the effects of chronic blood lead levels <10 μg/dL including reduced academic achievement/IQ, attention-related behavior problems, reduced postnatal growth, and delayed puberty in children, as well as decreased glomerular filtration rate, increased blood pressure, and essential tremor in adults.[36]

Table 16.6 summarizes the conclusions of the US NTP regarding the effects of chronic exposure to blood lead levels <5 and <10 μg/dL. The duration of lead exposure and the lead concentration to probably cause these effects are not well defined. Measuring a single blood lead reflects an equilibrium between current and past exposure (half-life of lead in blood ≈1 month), whereas bone lead represents long-term lead stores (half-life Pb bone ≈10–30 years).

TABLE 16.6. Summary of National Toxicology Program conclusions on the health effects of low-level lead exposure. (National Toxicology Program).[36]

Life Stage (BLL μg/dL)	NTP Conclusion	Principal Health Effects	Bone Lead Evidence
Children <5	Sufficient	↓ Academic achievement, IQ, specific cognitive measures; ↑ attention deficits/behavioral problems.	Tibia/dentin Pb associated with behavioral/attention problems, cognition.
	Limited	Delayed puberty/↓ renal function in ≥12 years of age.	Single available study does not support association with postnatal growth.
<10	Sufficient	Delayed puberty, ↓ postnatal growth, ↓ hearing, ↓ IQ.	No data.
	Limited	↑ Hypersensitivity/allergy by skin prick test, ↑ IgE[a].	No data.
	Inadequate	Asthma, eczema, non-allergy immune function, cardiovascular effects, ↓ renal function <12 years of age.	No data.
Adults <5	Sufficient	↓ Glomerular filtration rate, ↓ fetal growth for maternal blood <5 μg/dL.	Single available study supports ↑ bone Pb/↓ renal function.
	Limited	↑ Essential tremor.	No data.
<10	Sufficient	↑ blood pressure, ↑ risk of hypertension, ↑ incidence essential tremor.	↑ Bone Pb more consistently associated with cardiovascular effects than blood Pb.
	Limited	Psychologic effects, ↓ cognitive function, ↓ hearing, ↑ incidence ALS, ↑ cardiovascular mortality, ↑ incidence of spontaneous abortion/preterm birth for maternal blood Pb <10 μg/dL.	↑ Bone Pb more consistently associated with ↓ cognition than blood Pb.
	Inadequate	Immune function, stillbirth, endocrine effects, birth defects, fertility/time to pregnancy,[b] sperm parameters[b].	No data.

Abbreviations: ALS = amyotrophic lateral sclerosis; BLL = Blood Lead Level; IgE = immunoglobulin E; IQ = intelligence quotient; Pb = lead.
[a] Not necessarily related to disease; [b] Reproductive and developmental effects may be associated with Pb >10 μg/dL.

TOXICOKINETICS

Absorption

Gastrointestinal Tract

The absorption of metals in humans depends on several factors including chemical species, environmental matrix that surrounds the metal, particle size, contents of the gastrointestinal tract, diet, age, nutritional status, and characteristics of the media containing the lead.[214] Gastric acid solubilizes lead salts, whereas alkalinization and calcium reduce solubilization. Serious elevations in blood lead concentrations may occur following the ingestion of large amounts of small lead pellets because the large total surface area promotes lead dissolution.[215] The ingestion of lead accounts for the vast majority of the lead body burden. Lead absorption occurs in the small bowel by active and passive transport. A recently fed adult absorbs ~5–10% of an ingested lead dose, primarily in the duodenum by saturable mechanisms as suggested by the curvilinear relationship between blood lead and lead in drinking water.[216,217] Tracer studies suggest that lead absorption increases substantially (40–50%) in a fasting individual.[218] In a study of 23 adults ingesting ^{203}Pb during the fasting state, the whole-body counter indicated the retention of ~60% of the ingested dose.[219] The retention rate after eating a balanced meal and ingesting the lead tracer was ~4% of the dose, probably as a result of the lead complexion of calcium and phosphate salts in the meal.

Lead bioavailability is substantially less in lead-contaminated soil than in solutions of water-soluble lead salts commonly used in experimental studies with similar differences in the fasted and fed states. An *in vivo* study of volunteers ingesting 250 μg Pb/70 kg body weight from soil collected in the Bunker Hill Mining & Metallurgical Complex demonstrated average lead absorption of 26 and 2.5% in the fasted and fed states, respectively, based on isotopic analyses.[220] The particle size of the lead in the soil from the Superfund site was <250 μm. In small, nonfasting children, gastrointestinal absorption of water-soluble lead is higher than that of nonfasting adults, approaching 40%.[221] Decreased iron, protein, calcium, and zinc concentrations increase lead absorption.[222,223] In a prospective study of Nigerian children 12–18 months old followed by 18 months, the addition of calcium supplementation (400 mg elemental calcium daily) to 2,500 IU vitamin A did not alter the blood lead concentration as determined by a multiple linear regression model.[224] During this study, the mean blood lead level decreased from 11.1 ± 7.8 to 8.1 ± 6.3 μg/dL.

Lungs

The bioavailability of lead is greater following inhalation than ingestion. The amount of lead absorbed from ambient air depends on a variety of factors including the ambient lead concentration, duration of exposure, respiratory rate, and physical characteristics of the lead species (i.e., particle size, solubility, chemical form).[225] The average estimated rate of deposition of particulate airborne lead in an adult is ~30–50%.[37,226] In an experimental study of volunteers inhaling inorganic lead aerosol through a standard respiratory mouthpiece for 5 minutes, ~25% of inhaled lead chloride or lead hydroxide was deposited in the respiratory tract. The mass median aerodynamic diameters (MMAD) of the two lead salts were 0.26 μm and 0.24 μm, respectively.[227] In a study of three volunteers inhaling $^{203}PbCl_2$, the lungs retained ~40% of the dose, whereas ~60% was exhaled.[228] Once deposited, lead absorption depends primarily on particle size and solubility. The absorption of submicron particles (<1 μm) of lead is almost complete when these particles reach the alveoli. Significant differences occur in the size distribution of lead aerosols as a result of variation in the production process and chemical form.[229] Approximately 14% of an inhaled dose of 0.05 μm mean-diameter particles of lead sesquioxide cross the alveolar epithelium.[230] In an industrial spray painting operation that used lead salts as drying agents in oil-based paints, the maximum airborne lead concentration was 2–3 mg/m^3; however, only 2% of the particles were in the respirable range (10 μm).[231] Ciliary action (i.e., mucociliary transport) removes particles >2.5 μm impacting the ciliated portions of the airway either by swallowing or expectoration. The gastrointestinal tract absorbs <10% of the amount of lead swallowed compared with ~95% absorption of submicron particles in the gas exchange areas of the lung.[232]

Skin

Although data are limited, available evidence indicates that inorganic lead does not pass easily through the skin with an absorption rate of <1% of the dose. Studies of human skin indicate the dermal absorption of lead acetate is poor based on *in vitro* studies.[233] Following skin application of ^{203}Pb-labeled lead acetate in cosmetic preparations (1.2 mg Pb/mL) to eight volunteers for 12 hours, the estimated lead absorption from the solution was ≤0.3% based on whole-body counts and tracer concentrations in urine and blood.[234] The estimated lead absorption from similar solutions during normal use of cosmetics was 0.06%. *In vitro* and *in vivo* studies of lead oxide suggest that some dermal

See the Terms and Conditions (https://onlinelibrary.wiley.com/terms-and-conditions) on Wiley Online Library for rules of use; OA articles are governed by the applicable Creative Commons License

absorption of lead oxide can occur, but the clinical relevance of this route of exposure compared with pulmonary absorptions remains unclear.[235,236] A case report associated the subdermal injection of lead-based red vinyl paint in the hand of a ship painter with lead toxicity.[237] Although ~90% of the injected paint was removed during surgery 24 hours after the incident, the patient developed headaches, nausea, dizziness, abdominal discomfort, weakness, insomnia, tremor, and hyperreflexia. The blood lead level 19 days after the incident was 82 μg/dL; subsequently, the blood lead level increased to 94 μg/dL 1 week later prior to chelation.

Distribution

The distribution of absorbed lead is similar regardless of the route of exposure.[238] Kinetic studies of volunteers on metabolic wards using enriched $^{204}PbNO_4$ indicate lead distributes into three compartments as outlined in Figure 16.1. The blood and soft tissue represent the active pool and bones the storage pool. Following acute ingestion of lead, steady-state concentrations in the tissue occur after several days. In the blood, 95–99% of the lead exists in the red blood cells (RBCs). Most intracellular lead binds to δ-aminolevulinic acid dehydratase (i.e., ~80%), primarily on zinc-binding sites on this molecule; lesser amounts of lead are bound to other intracellular proteins (e.g., pyrimidine-5-nucleotidase).[239] Genetic polymorphism in the enzyme δ-aminolevulinic acid dehydratase (ALAD) affects the toxicokinetics of lead as a result of the associated anemia and reduction in red cell mass. When not excreted (bile, urine), plasma lead redistributes to soft tissue or bone. Hence, blood lead levels may not reflect the total body burden.

Animal studies suggest that lead distributes from the blood initially to soft tissues and then to repositories in the bone.[37] About 2–5% of the total body lead burden distributes in soft tissue (kidney, liver, pancreas, spleen, lungs, thyroid, brain) with a half-life of ~1–2 months based on stable isotope tracer studies in healthy volunteers.[240] Although data are limited, lead probably does not accumulate in the soft tissues of adults including the brain with age.[241,242] In a postmortem study of adults without documented lead exposure, calcified tissues (bones, aorta) contained the highest lead concentrations, whereas nonglandular tissues (adipose, fascial and dermal collagen) and muscular tissues (heart, bladder, muscle) contained the lowest lead concentrations on a wet weight basis.[243] In postmortem examination of 32 long-term, lead-exposed smelter workers, the major soft tissue organs containing were, in decreasing order, liver > kidney > lungs > brain.[244]

Bones are the major depository for lead in the body containing ~90–95% of the total body lead burden in the adult skeleton, primarily in dense bone (i.e., cortical bone).[245] The body burden of lead (i.e., ~70%) in the skeleton of children is somewhat smaller than that of adults. Lead deposits in the bones increase steadily during life; these deposits exist as insoluble lead phosphate that does not produce toxicity unless the chemical form of lead changes.[246] In a study of 14 retired lead workers followed for 18 years, the half-life of lead in finger bone based on an *in vivo* X-ray fluorescence method followed a tri-exponential model with group half-times of 34 days (95% CI: 29–41 days), 1.2 years (95% CI: 0.9–1.8), and

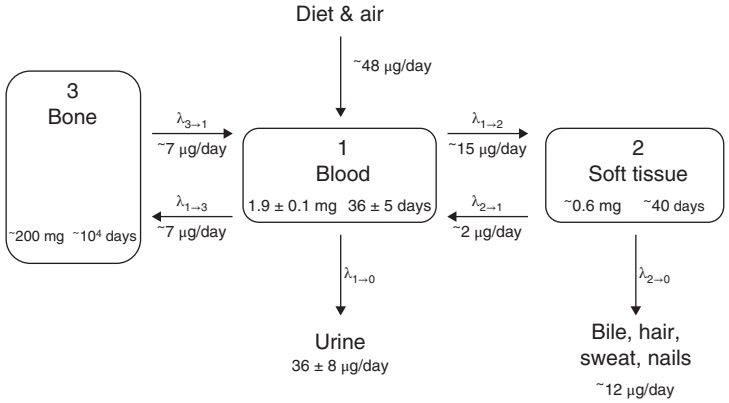

FIGURE 16.1. Three-compartment model of lead distribution based on tracer and balance data. The figure displays the lead distribution in three compartments with the estimated lead content and mean life of each pool along with rates of lead movement between pools (λ) based on mean intake of 48 μg Pb/day by five volunteers. Pool 0 represents the excretion of lead from the body including urinary and fecal elimination. Loss of lead from pool 2 (soft tissue) includes lead elimination in integumentary structures (hair, nails, sweat) and secretions from the alimentary tract (bile, stomach, pancreas, saliva). (Rabinowitz et al.).[240]

13 years (95% CI: 10–18 years).[247] The turnover of lead in bone is slow; the high body burdens in bone from prior occupational lead exposures contribute significant amounts of lead to the blood lead level in lead workers, primarily from the surface layers of the bones.[232] The calculated turnover rates for compact bone in the tibia and skull average ~2%/year in healthy adults compared with ~8% for the spine.[248] These rates vary with age; higher turnover rates occur at the beginning and toward the end of life. Bone and blood lead stores exist in equilibration. Up to 70% of steady-state blood lead concentrations may derive from the bones of adults without occupational lead exposure. In a study of five adults with low blood lead levels (<6 μg/dL) and no occupational lead exposure, stable lead isotope studies indicated that bone lead stores contributed ~40–70% of the blood lead.[249]

Elimination

Urine

The kidney filters absorb lead unchanged, although at high concentrations some active tubular transport occurs. Following lead absorption, urinary lead concentrations increase within several hours with steady-state concentrations occurring within several days. The urinary excretion rate depends on the glomerular filtration rate and renal plasma flow. The elimination of lead through the kidney is slow because relatively small amounts of lead appear in the plasma compared with erythrocytes. Most ingested lead appears in the feces. The kidney accounts for 75% of daily lead loss; integumentary (nails, sweat, hair) and alimentary losses account for the remainder. Humans maintain a positive lead balance with a total body burden of ~165 mg Pb in subjects without occupational exposure.[241]

Whole Blood/Plasma

The half-life of lead in blood follows a three-compartment model with a fast phase, an intermediate phase (soft tissues, trabecular bone), and a slow pool (cortical bone). The average half-lives of these three compartments are ~30 days, 1 year, and 13 years, respectively.[247,250] The half-life of lead in whole blood varies with age, body lead burden, lead concentration, hematocrit, and the presence of more than one biokinetic compartment. Retrospective analysis of venous blood lead data suggests the lead elimination rate from the body is slow. In a study of 573 children without chelation therapy, the time required for the whole blood lead concentration to decrease from 25–29 to <10 μg/dL was ~24 months compared with 9 months for children with an initial blood lead concentration of 10–14 μg/dL.[251]

The relationship between plasma and whole blood lead concentrations is curvilinear (i.e., concave downward). Analysis of case series of lead poisoning suggests that saturation of lead binding sites in the erythrocytes occurs with increasing blood lead levels, particularly at lead concentrations >40–70 μg/dL.[252] Additionally, anemia associated with chronic lead toxicity further reduces the volume of erythrocytes and lead binding sites. In a study of plasma and whole blood lead concentrations in five adults exposed to lead for 1–144 months and followed for 21–316 months, the average plasma elimination half-life was ~1 month (range, 23–69 days).[253] The whole blood elimination half-life could not be calculated within the duration of the study, but the value was much slower than the plasma elimination half-life.

Maternal–Fetal Kinetics

Blood
